Springer Handbooks

Springer Handbooks maintain the highest standards of references in key areas of the physical and applied sciences for practitioners in industry and academia, as well as graduate students.
Designed to be useful and readable desk reference books, but also prepared in various electronic formats, these titles allow fast yet comprehensive review and easy retrieval of essential reliable key information. Springer Handbooks cover methods, general principles, functional relationships and fundamental data and review established applications.
All Springer Handbooks are edited and prepared with great care by editors committed to harmonizing the content. All chapters are written by international experts in their field.
Indexed by SCOPUS. The books of the series are submitted for indexing to Web of Science.

Foreword by Chihiro Hamaguchi

The first semiconductor device, named "point-contact transistor," was demonstrated on the 17th of December 1947 by John Bardeen, Walter Brattain, and William Shockley at Bell Laboratories. About a month later (January 1948), Shockley invented the "junction transistor." The first demonstration of a radio receiver made with point-contact transistors was performed in December 1947. The design of solid-state devices for electrical amplification was organized at Bell Laboratories under the guidance of Shockley, who was also interested in a new device to control surface electrons with a metal gate. A FET-like transistor had already been patented in the USA by Julius Edgar Lilienfeld in January 1930; the idea was not realized because of the high density of surface states in silicon. The difficulty was resolved by using an oxide surface layer processed in high-temperature vapor atmosphere, as proposed by C. Frosch in 1954; the deposition of a metal gate on the oxide layer was achieved by J. Attala and D. Kahng at Bell Laboratories in 1959. First, PNP and NPN junction transistors were commercialized and used to design solid-state circuits; however, the Si-MOSFET, invented afterwards, revealed its superiority over the junction transistor, in view of designing and manufacturing digital circuits.

So many people were involved in the early development of integrated circuits (ICs); among them, Jack Kilby of Texas Instruments (hybrid integrated circuit, 1958) and Robert Noyce at Fairchild Semiconductor (monolithic integrated circuit, 1959) played a very important role in the opening of IC technologies. The advancement of IC technology is well explained by Moore's law: "the number of transistors in a chip of integrated circuits doubles every two years." Moore's expectation expresses quite well the history of ICs from 1970 till 2020. This advancement has been supported by many new technologies, materials, processes, circuit-design strategies, and others. Starting from the simple planar technology, structures are now more complex and three dimensional. The technological revolution in the field of the semiconductor devices radically changed many aspects of the social organization (communications, economy, transportation, and all the primary necessities of everyday life), so that in the present time, human beings find it difficult to survive without ICs.

Semiconductor-device operations are based on fundamental electrical and optical properties of the materials, as anyone can easily agree about just by leafing through this *Springer Handbook of Semiconductor Devices*. The knowledge of energy band structures is essential for understanding any device operation. In other words, energy band calculations provide knowledge on electronic and optical properties of semiconductors. Many semiconductor properties are well understood on the basis of the effective masses of electrons in the conduction band and holes in the valence bands, in addition to the (direct or indirect) band gap. Pioneer data from cyclotron resonance experiments in Ge and Si were interpreted by the theory based on $k \cdot p$ perturbation method by G. Dresselhaus, C. F. Kip, and C. Kittel in 1955, and revealed the many-valley structure of the conduction band and the spin-orbit splitting of the valence bands in these elemental semiconductors. The energy band calculation in the full Brillouin zone for 14 semiconductors of the diamond and zinc-blende structures was reported for the first time by M. L. Cohen and T. K. Bergstresser in 1966 by means of the pseudopotential method. More advanced theoretical approaches have been reported afterwards, and some of them are dealt with in this handbook.

This *Springer Handbook of Semiconductor Devices* provides a quite useful framework suitable to guide the interested reader across a massive amount of information, and achieves an almost complete review of the basic and advanced knowledge of semiconductor devices. The editors planned to cover the present status and future development of semiconductor devices, including physics, structures, processing, designing, and simulation. Part I is concerned with the technological aspects of semiconductor devices, and deals with the manufacturing of semiconductor memory devices together with the technology of processing, measuring parameters, advanced lithography, and dielectric materials. In addition, FinFETs and advanced technologies for future materials and devices are discussed. Part II deals with basic semiconductor devices and applications, including Si-based devices such as MOS devices, MOSFETs, capacitors, and CCDs. Part II also deals with the topics of sensors, semiconductor lasers, and solar cells. Part III deals with new-generation devices and architectures, such as resonant-tunneling devices, bioelectronics, spin-based devices, quantum-computing devices, and other innovative structures. Part IV is devoted to device modeling and process simulation, where both classical device-simulation tools and more advanced methods are described in detail.

Even though many kinds of semiconductor devices are still designed and produced, and new and advanced devices are expected to appear in the future, this handbook can be considered a milestone reference, since it covers a large spectrum of devices and surveys their structures and properties in depth. The editors selected the topics cleverly, and the contributors are specialized and outstanding scientists from all over the world. Therefore, on the basis of my experience in this field, I consider this *Springer Handbook of Semiconductor Devices* the most important guide book for researchers, in industries and academic institutes, as well as graduate students. I congratulate the editors and all the authors for bringing such an excellent handbook to publication.

Professor Emeritus at Osaka University
IEEE Life Fellow
March 2021

Chihiro Hamaguci, Ph. D.

Foreword by Herman Maes

I was born in the year 1947, the blessed year so to speak of the revolutionary invention of the point-contact transistor by Shockley, Bardeen, and Brattain. Perhaps this explains my fascination to this day for semiconductors, the physics, the devices, and the technology, in that order. I had the pleasure to admire this first "transistor" at the Bell Labs in Murray Hill, New Jersey. I moreover have had the privilege to meet John Bardeen and attend a few of his classes during my postdoctoral research stay at University of Illinois Champaign-Urbana in 1974–1975. I even had a brief, accidental encounter with William Shockley in 1974. I graduated as an electronic engineer at the Katholieke Universiteit Leuven, Belgium, in 1971 at a time when the semiconductor industry had in fact only just come out of the starting blocks. Intel just launched its Intel 4004, the first processor-on-chip consisting of 2,300 transistors. We were still within the first phase of the semiconductor saga, a few years after Gordon Moore had reported his findings on the evolution in size of the first integrated circuits (IC) and launched his predictions, later known as Moore's Law. Only on the basis of a few data points, Moore concluded and predicted that the number of transistors in ICs on a chip would double every year with innovations in lithography as the main driving force to enable transistor scaling. How more visionary could a man be? And exactly these kinds of bold statements have been so typical and have, as we experienced, in fact been driving the development of this fascinating semiconductor technology field over the past nearly 65 years. This is commonly referred to as self-fulfilling prophecy.

During our engineering training in the late 1960s, a somewhat older professor, close to retirement, actually strongly doubted whether those semiconductors would eventually break through and therefore still spent a lot of attention to the usefulness, properties, and application of vacuum tubes. Fortunately for us, there was this other, young, dynamic, visionary professor, Roger Van Overstraeten (the founder of imec in 1984), who had obtained his

Ph.D. from Stanford University and who had returned a few years earlier to our university. He was so enthusiastic and inspiring about the latest developments and opportunities of semiconductor science and technology that he could convince many of us to fully engage ourselves in that direction. My fascination was aroused and from then gradually turned into passion and hunger for knowledge. So, we started to look for suited books. In these early years, appropriate textbooks were still scarce. The books that were being produced mostly focused on specific technological and solid-state physics issues. I personally remember a few of these while in college, the SEEQ series on the bipolar transistor, Andy Grove's *Physics and Technology of Semiconductor Devices*, and of course Simon Sze's standard work *Physics of Semiconductor Devices*, which saw its first edition in 1969. Over the past 50 years, numerous new handbooks have become available, many of them covering in detail specific disciplines or aspects of the strongly expanding field of semiconductor devices. However, at this early stage there was a need of books providing a broad-scope and balanced mixture of state-of-the-art, prospect, insight and context of all inherent aspects of semiconductor technology, devices and applications, offering high level treatments with more than mere encyclopedic knowledge, with attention to interdisciplinary aspects and to the mutual support of the various disciplines: such books, in fact, remained rather scarce.

After about 45 years in the twentieth century and 20 years in this twenty-first century, the industrialized world has been marked by extremely rapid technological (r)evolutions. We witnessed the incredible and far-reaching developments of the semiconductor industry with growing amazement and disbelief, even to those who were involved in the process from the first rank. This was largely due to the extremely successful scaling endeavors by research and industry. The Intel 4004 processor that we referred to earlier was realized in the 10 μm technology node, today we have reached the 5 nm node (a feature size scaling by 2,000), allowing fabrication of chips with over 50 billion transistors! Semiconductor technology today is a very mature, established industrial discipline. The entire semiconductor market is close to 500B$ and expected to further grow year after year, with even a doubling in 10 years' time. This industrial progress went hand in hand with (and was also steered by) profound societal changes in its most diverse aspects and led us into the Information Age. Semiconductor devices, ICs, and products played an undeniably prominent role in these tremendous transitions. They are now used in every corner of our "digital" society and are taking an increasingly crucial and essential role in almost all economic sectors, information technology, multimedia, communication, automation, robotics, transport, medical and health sector, games, education, environment, energy, cryptography, smart buildings, and smart cities.

But we are today on the verge of a new disruptive landslide. The transition from the Information Age to the Digital Age is taking place, with expected revolutions in the interfaces for speech recognition, augmented reality, virtual reality, and artificial intelligence, just to name a few. Our businesses and the economy will have to realize that this transition will not come gradually, in small steps. After all, a characteristic of a revolution is that the change comes abruptly and is accompanied by breaking with the past. And if we had thought to have reached the pinnacle of technologically possible developments, we realize that many even more far-reaching technological breakthroughs will be needed in the future.

The semiconductor industry is facing a new era in which device scaling and cost reduction will no longer continue to proceed on the path followed for the past few decades. Further advanced nodes, even when feasible, may no longer bring the desired cost benefit. Moreover, R&D investments in new lithography solutions and devices below 5 nm nodes are rising substantially. Therefore, the insatiable and ever-increasing demand in the digital era forces the industry to come up with ever more innovative and sophisticated technology solutions to bridge the gap and improve cost/performance while at the same time adding more functionality through integration. The so-called More-than-Moore devices (including

MEMS and sensors, CMOS Image Sensors, power devices, THz devices) represent this new functional diversification of technologies, combining performance, integration, and cost not merely limited to CMOS scaling. Their role is expected to become more and more predominant. Semiconductor device and technology engineers and scientists will therefore have to continue the quest for ingeniously new electronic devices and functionalities. We are in fact on the cusp of big changes.

More than ever, semiconductor researchers, scientists, and engineers will have to maintain the widest possible view of these rapidly evolving fields. They need to be constantly and continuously curious, interested, amazed, fascinated, and triggered by the evolution and the developments in their own fields but also in the domains adjacent but often complementary to their own specialization. They therefore need to acquire thorough yet easy-to-digest, appropriate, timely, and reliable knowledge on the state of the art but also on the newest developments and trends in these domains. And above all, they count on obtaining this information from specialists and experts in these fields.

A handbook is a book capable of being conveniently carried as a type of ready reference work, providing information, facts, insights, and instructions on a particular field, subject, or technique, designed to be easily consulted and providing useful, quick, but solid and reliable answers in a certain area. It covers and offers scientific basics, fundamentals, methods of research, general principles, functional links, and review of established or potential applications. Moreover, even in rapidly expanding fields, the information and content need to be sufficiently timeless.

Springer Handbooks respond to such needs fully and successfully. They strive to provide and maintain the highest standards of references in well-selected fields and key areas of physical and applied sciences and technology. They are intended for practitioners in academia and industry, as well as graduate students. They are allowing fast yet comprehensive review and easy retrieval of reliable key information.

It is Springer Handbooks' tradition to come up *at the right time* with new, well-considered initiatives for launching appropriate reference books. Recent examples have been the handbooks on nanotechnology, robotics, mechanical engineering, and automation.

Today certainly is the right time to launch this Springer Handbook on semiconductor devices, considering the transition to the even more challenging post-scaling era.

Conceiving and realizing such a handbook is a daring, challenging, and ambitious endeavor. It is a major undertaking and requires vision, significant organizational skills, and commitment. One also needs to have a network of experts who look up to the editor.

This Springer Handbook on semiconductor devices you have in hand fully meets the strict requirements and high-level standards of the Springer Handbook series. It provides comprehensive coverage of numerous technological and fabrication aspects of advanced semiconductor devices, focusing not only on advanced "traditional" structures but also on ingeniously new and often futuristic, beyond CMOS, and More-than-Moore concepts for many applications. Rightly so, strong attention was paid to the indispensable advanced modeling and simulation methods for predictive and supporting purposes, as well as an outlook toward near or far future needs. This handbook is not the first one covering semiconductor technology and device disciplines, and it will undoubtedly not be the last one. But the differentiator, the USP of this handbook according to me, is this mixture of broad scope, thoroughness of treatment with still sufficient accessibility, the wide range of concepts for many applications, and the foresight. And, worth noting, all chapters have been written by international experts, innovators, and leaders in their field. The reasoned interpretations of developments in each area are commendable and often unique. The editors did a wonderful and tremendous job in not only selecting the 45 rightful and relevant topics but also in inviting the right specialists to treat these topics and share their expertise and experience with the knowledge-hungry reader.

This has resulted in an extensive, voluminous yet digestible standard work that deserves to be on the shelf of graduate students of nanoelectronics, and researchers in academia and industry who are active or intend to be active in this field and who are looking for in-depth, up-to-date information. Finally, also practicing scientists and engineers who want to expand their know-how in adjacent fields will strongly benefit from this book.

I would like to congratulate the editors and all the authors for their excellent contributions, one by one, bringing this ambitious and formidable challenge to a successful conclusion.

Professor Emeritus Katholieke Universiteit Leuven, Belgium Herman E. Maes, Ph.D.
Former Senior VP imec, Leuven, Belgium
March 2021

Preface

No other class of materials than semiconductors, since the early identification of their electrical, optical, and thermal properties at the beginning of the nineteenth century, has been so deeply investigated and used to design all kinds of devices. The first theoretical models about the physics of semiconductors, based on quantum-mechanical grounds, fueled the design of solid-state diodes and transistors; these, in turn, have opened new horizons to electronics, computer science, and sensors, and have greatly impacted the global market with annual revenues of the order of 500 billion US dollars in the present days.

In turn, semiconductor companies pushed ahead the search of new semiconductor materials and structures suited for specific applications, and urged academia and the industry's R&D toward the elaboration of more and more powerful simulation tools to inquire about the effects of miniaturization, interfaces, and doping on device performance and reliability, or to benchmark specific semiconductor properties before investing resources in expensive innovations of the production lines.

All the above justify the effort of putting together, in this *Springer Handbook of Semiconductor Devices*, many cross-disciplinary competences about present-day and near-future semiconductor devices, namely modern concepts in solid-state physics, material science, growth and process technology, device design, and advanced simulation strategies.

When we speak about semiconductor devices, what we consider "future" is very often already "present time" somewhere in the world. Thus, this handbook not only includes the most recent progress in research and technology of conventional semiconductor devices and sensors but enlarges its view to include some specific topics related to new materials and designs, presently at the frontier between science and technology, nonetheless suitable to be employed in the next-generation semiconductor-technology challenges.

The handbook is organized in four parts: 1. Technological Aspects; 2. Basic Devices and Applications; 3. New-Generation Devices and Architectures; 4 Modeling. Almost 100 leading scientists from both academia and industry were invited to contribute to the 45 chapters of the handbook, which has been conceived for professionals and practitioners, material scientists, physicists, and electrical engineers working at universities, industrial R&D, and production. Each chapter is self-contained and refers to related topics treated in other chapters when necessary, so that the reader interested in a specific subject can easily identify a personal path through the massive contents of the handbook.

We are very grateful to all the authors who joined this ambitious enterprise, to the referees who generously contributed to improve the quality of the final outcome, to Springer's editors who patiently followed our work step by step, and, last but not least, to Prof. Chihiro Hamaguchi (Osaka University) and Prof. Herman Maes (KU Leuven and imec) for providing forewords based on their long-term experience in the field of semiconductor science and technology.

May 2021 M.R., R.B., S.R.

Contents

Part I Technological Aspects 1

1 CMOS Manufacturing Processes 3
Aaron Douglas Lilak and Patrick H. Keys

2 Semiconductor Memory Technologies 37
Paolo Fantini, Giorgio Servalli, and Paolo Tessariol

3 BCD Process Technologies 67
Giuseppe Croce, Antonio Andreini, Paola Galbiati, and Claudio Diazzi

4 Measuring Techniques for the Semiconductor's Parameters 117
Alessandra Alberti, Filippo Giannazzo, Francesco La Via, Salvatore Lombardo, Antonio M. Mio, Giuseppe Nicotra, Stefania M. S. Privitera, Riccardo Reitano, Fabrizio Roccaforte, Corrado Spinella, and Emanuele Rimini

5 Interconnect Processing: Integration, Dielectrics, Metals 169
Shyng-Tsong Chen, Nicholas A. Lanzillo, Son Van Nguyen, Takeshi Nogami, and Andrew H. Simon

6 Wet Chemical Processes for BEOL Technology 219
Cornelius Brown Peethala, James J. Kelly, Donald F. Canaperi, Mahadevaiyer Krishnan, and Takeshi Nogami

7 From FinFET to Nanosheets and Beyond 259
Nadine Collaert

8 Advanced Lithography 279
Alberto Roncaglia

9 Advanced Technologies for Future Materials and Devices 309
Francis Balestra

Part II Basic Devices and Applications 329

10 MOS Capacitors, MOS Transistors, and Charge-Transfer Devices 331
Massimo Rudan, Susanna Reggiani, and Giorgio Baccarani

11 Electrostatic Doping and Devices 371
Raymond J. E. Hueting and Gaurav Gupta

12 Planar MOSFETs and Their Application to IC Design 391
Salim El Ghouli and Denis Rideau

13 Silicon Power Devices 423
Noriyuki Iwamuro

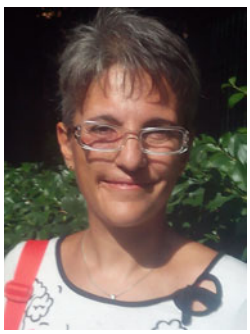
About the Editors

Massimo Rudan received a degree in electrical engineering in 1973 and a degree in physics in 1976, both from the University of Bologna, Italy. His research interests are in the field of physics of carrier transport and numerical analysis of semiconductor devices and solid-state sensors. In 1986, he became a visiting scientist, on a one-year assignment, at the IBM Thomas J. Watson Research Center at Yorktown Heights, NY, studying the discretization techniques for the Boltzmann transport equation. In 1990 he became Full Professor of Electronics, and in 2021 Professor Emeritus, at the University of Bologna. An IEEE Life Fellow, and a recipient of the 1998 Körber Foundation Award, Massimo Rudan has coordinated several research projects funded by the European Commission, international companies and foundations, the National Council of Research, and the National Ministry of University and Research.

Rossella Brunetti received her master's degree cum laude in physics in 1981 and her Ph.D. degree in physics from the University of Modena, Italy, in 1987. Since 2002, Rossella Brunetti is Associate Professor of Condensed Matter Physics in the Department of Physics, Informatics and Mathematics at the same university. Her research activity has mainly been focused on charge transport, in both semi-classical and quantum conditions, in semiconductor structures and devices. Rossella Brunetti is experienced in a variety of numerical techniques (mainly the Monte Carlo, Molecular Dynamics, and Hydrodynamic Methods) which have been applied to validate theoretical models against experiments and to predict new effects. In the past few years, Rossella Brunetti focused her research on transport properties of chalcogenide materials in view of their applications in the field of emerging memory devices.



Susanna Reggiani received her Ph.D. degree in electrical engineering from the University of Bologna in 2001. Since 2001, she is with the Department of Electronics and the Advanced Research Center for Electronic Systems (ARCES) at the same university. Her scientific activity has been devoted to the physics, modeling, and characterization of electron devices, with special emphasis on transport models in semiconductors. She has been involved in projects dealing with TCAD analysis of power MOSFETs, modeling and characterization of hot-carrier stress degradation and reliability of wide-bandgap semiconductors, and modeling of package influences on high-voltage ICs. In 2020, she became full professor in the School of Engineering at the University of Bologna.

Abstract

In this chapter, we will discuss the common fabrication processes and methods utilized in the fabrication of CMOS devices. This discussion will include doping techniques such as ion implantation and diffusion along with a discussion of etch, deposition, and lithography techniques used to pattern and fabricate devices at the nanometer scale. This chapter will conclude with a survey of foreseeable changes which are emerging in regard to semiconductor manufacturing processes.

have densities measured in the billions/cm^2 and emerge from multi-billion dollar facilities that look more like hospitals than factories. This chapter will discuss the manufacturing processes used to create these devices at such scale and quantity.

This discussion will begin with an introduction to doping and activation techniques including ion implant and diffusion. As semiconductor assemblies are built in a layer-by-layer manner by adding and subtracting materials and dopants, the tools used for deposition, etch, and lithography will be described. Finally, a discussion of foreseeable process-related trends will conclude this chapter.

1.2 CMOS FinFET Process

The fabrication of transistors is more an art than it is a science; however, these fabrication processes do tend to follow a similar series of operations. While there are embodiments and numerous variations of these steps and operations and resultant geometries; a (much) simplified block process flow for fabrication of a FinFET transistor through front-end fabrication is shown in Fig. 1.1. The operations and flow variations required to implement these processing steps and those required to add electrical interconnections in the back-end fabrication are described within this chapter.

1.3 Ion Implantation

Ion implantation is a means of material modification used in semiconductor fabrication. This material modification may be done for purposes of introducing doping, creating regions of damage, removal of material or cleaning of a surface, modification of etch properties of a material, or for purposes of intermixing a material surface in order to modify a subsequent deposition process. Ion implantation is utilized in both front-end and back-end processes. Ion implantation tools are broadly categorized as either beam line or plasma immersion tools.

1.3.1 Beam Line Ion Implant

Beam line ion implantation tools used in modern CMOS fabrication can trace an origin to the ion implantation device patented by William Shockley in [31] . In his patent "Forming Semiconductive Devices by Ionic Bombardment," Shockley first illustrates how atoms of one material may be ionized from a gas phase, accelerated to a known energy with an applied voltage, and then implanted into a semiconductor wafer.

In Shockley's original patent, a gas containing a dopant specie, for example, boron trifluoride, is allowed to flow into the assembly through tubing indicated as (22) in Fig. 1.2. Atoms of this gas are ionized and accelerated through use of an applied voltage between a cathode (32) and an anode (31). A wafer (25) is placed on the holder assembly (26) and conductive base (48, 49). By manipulating the flow rate of gas and arc used to ionize the particles, a beam current may be adjusted. This current may be measured as it exits the conductive base in the implanter and is a measure of the number of implanted charges and hence related to the number of implanted impurity ions. By adjusting the voltage applied between the cathode and anode, the energy of each implanted ion may be manipulated in order to change the range and distribution of the implanted ions. The ions may be introduced at a tilt or rotation by manipulating the orientation of the wafer holder assembly.

Modern ion implantation tools like in Fig. 1.3 have evolved from this basic configuration of Shockley, but share the same fundamental concepts. Mass selection is accomplished through passing the ion beam through a magnetic field and series of apertures. Additional magnets and computerized control enable the shaping of the ion beam, and the beam can be rastered across the wafer. Single-wafer tools have evolved into batch process tools which mount wafers on a rotating assembly and can process

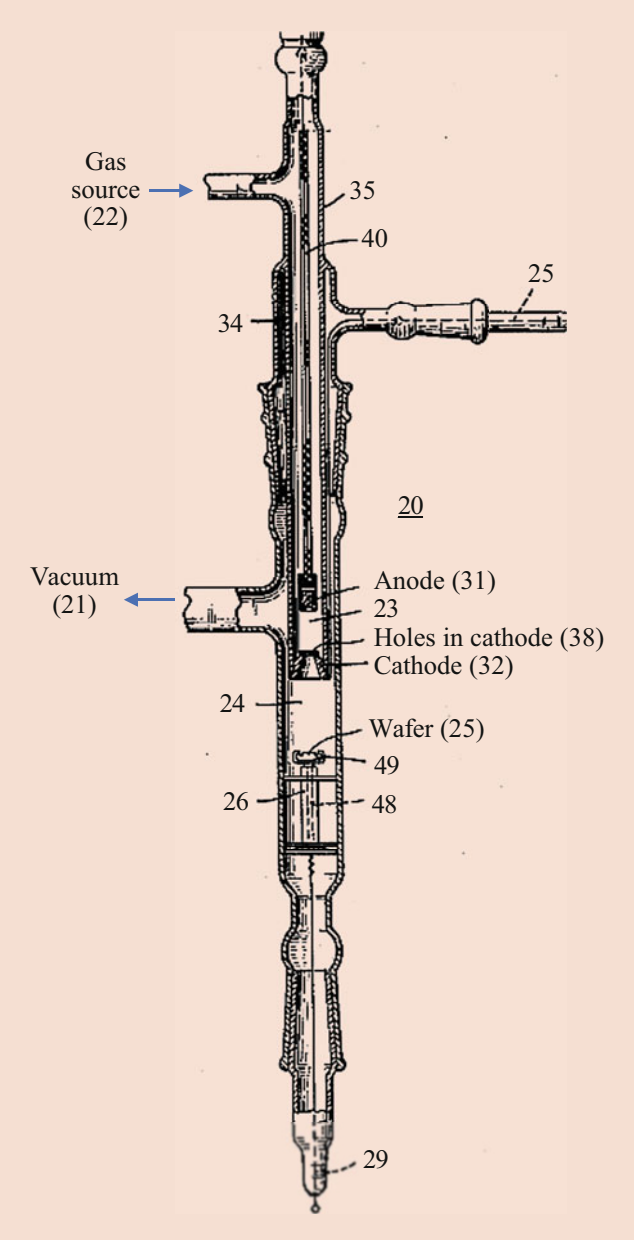

Fig. 1.2 The ion implanter assembly proposed in Shockley's original patent for an ionic bombardment apparatus. Most of the functional elements of this crude device are in place in modern ion implanters

multiple wafers simultaneously. Wafer temperature can now be adjusted during the implant process, and specialized tools have been developed for high-current, high-voltage, and other applications.

While ion implantation was initially largely integrated in CMOS processes for the purposes of introducing doping, it has since evolved as a means of material modification. Particularly in the BEOL metallization and contact processes, beam line implant continues to find new applications. A representative list of implant species from the periodic table is shown in Fig. 1.4.

1.3.2 Ion Stopping

An implanted ion interacts with both the electrons and atoms in a target material and loses kinetic energy at a rate of dE/dx in a process referred to as stopping. Nuclear stopping involves interactions with the atoms of the target material, and electronic stopping involves interactions with the electrons of the target material, and the total stopping is represented by the sum of the two components. Several derived and empirical relationships have been proposed to express these nuclear and electronic stopping components. These stopping powers may be simulated with the aid of a computer program such as SRIM as shown for silicon in Fig. 1.5.

1.3.3 Amorphization and Channeling

For a single-crystal semiconductor material, the stopping power of the crystal to the implanted ion can vary significantly as the orientation of the beam relative to the crystal surface is changed. Ion implanters enable this orientation adjustment through tilt of either the ion beam or surface of the wafer relative to the ion beam and through rotation of the wafer relative to the ion beam. Ions which experience a relatively lower stopping power are referred to as being channeled. Channeling is common for low-dose implants such as V_t adjust or well implants or for implants of lower-mass species such as boron.

Plots such as that of Fig. 1.6 indicate a very significant implant beam orientation dependence to the resultant implant profile. A fluctuation of less than a degree in tilt or rotation or slight fluctuation in wafer orientation can result in a significant difference in a channeled tail. This effect can result in a fabrication process with very high sensitivity to implant beam orientation or with significant process fluctuation. One approach to alleviate this sensitivity is to intentionally implant highly channeled implants such as boron wells (P-well) in an off-channel orientation such as 7 degrees tilt or 7 degrees tilt/22 degrees rotation for a (100) orientated silicon crystal where possible. This effect is shown in Monte Carlo simulation in Fig. 1.7.

Amorphization refers to the process of accumulating damage within an ordered crystalline or polycrystalline material until the atomic positioning within the crystal becomes randomized. A randomized crystal will not experience channeling on ions. Ion implantation is a common means used for amorphizing semiconductor crystals due to ability to adjust the depth of amorphization through the use of ion energy, the ability to determine the area of amorphization through the use of lithography to pattern implant blocking layers, and the ability to adjust the amount of implant damage through the use of implant dose (see Fig. 1.8).

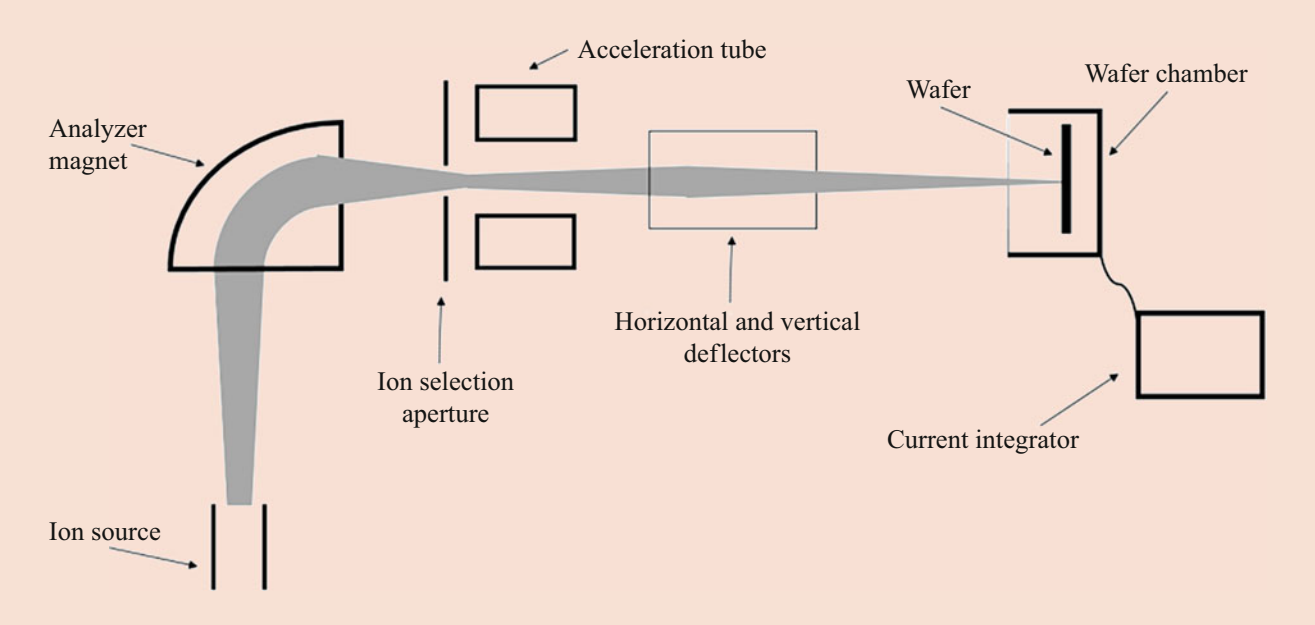

Fig. 1.3 A schematic of a modern ion implanter

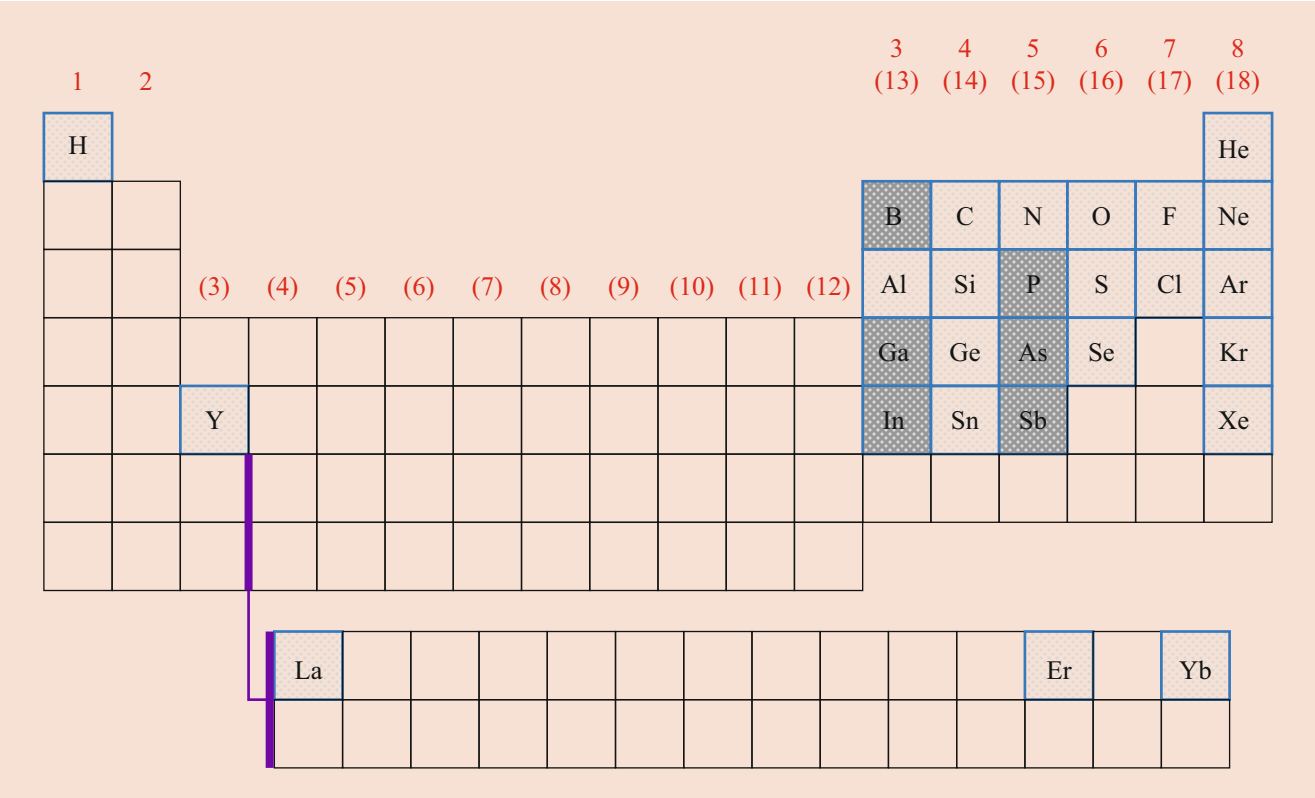

Fig. 1.4 Periodic table showing a partial list of beam line implant species regularly available for CMOS processing. The darker shaded atoms comprise a historical list of the silicon dopant species and the lighter shaded atoms reflect those which are commonly used for material modification purposes. This list continues to expand

Fig. 1.5 SRIM simulation of stopping components for a silicon implant into a silicon substrate

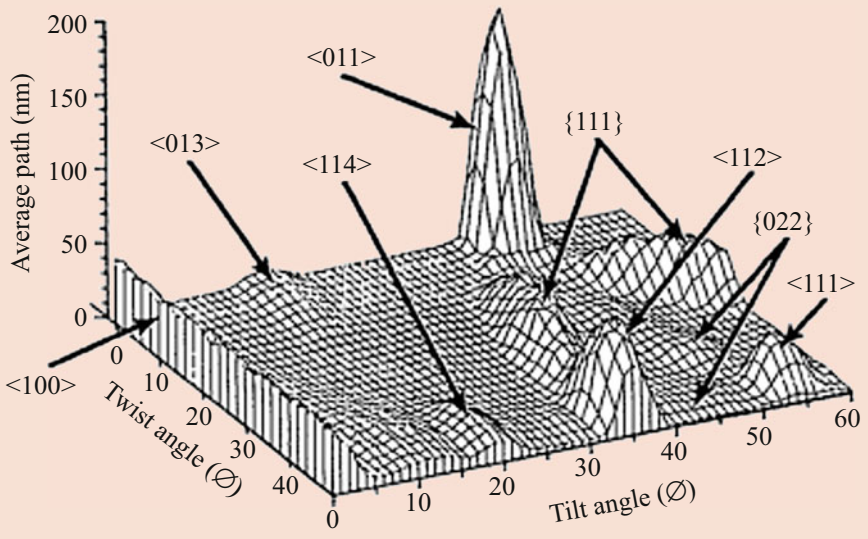

Fig. 1.6 Monte Carlo simulation results of 5 keV B-11 ions implanted into (100) oriented silicon as a function of tilt and twist of the wafer. Regions of this plot reflecting a low average path indicate implant into a randomized crystal orientation, while those which experience longer implant average path lengths reflect crystal orientations which present a highly ordered atomic cross section to the ion implant beam

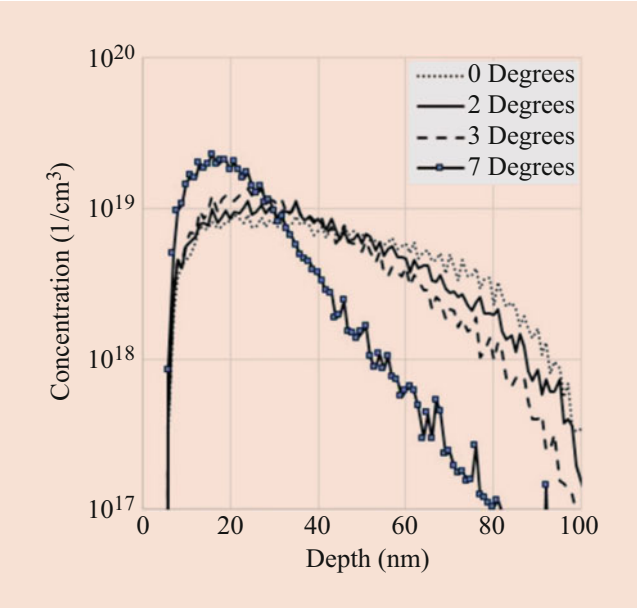

Fig. 1.7 Monte Carlo simulation of 3 keV boron implant at 5e13/cm^2 dose implanted into a (100) orientated silicon wafer. A slight variation in tilt angle toward (110) results in a substantial reduction in channeling tail of the implant

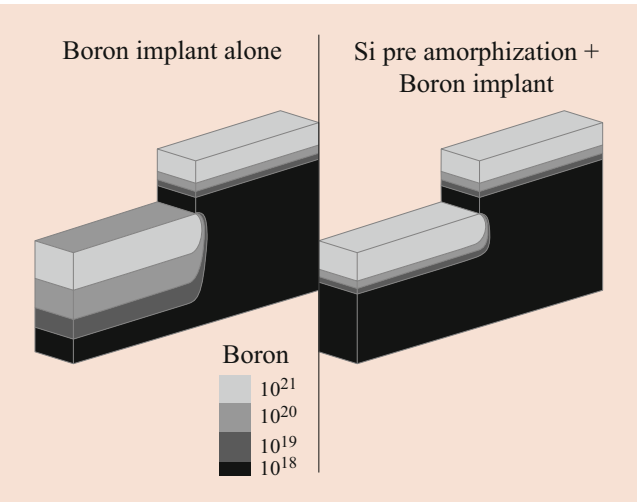

Fig. 1.8 Simulation showing the impact of a pre-amorphizing implant upon a subsequent non-amorphizing boron implant. In both cases, the boron implant is identical. In addition to a much more abrupt vertical implant profile, the lateral profile is also several nm more abrupt for the process which includes a pre-amorphizing implant

Amorphization may be accomplished by the same implants which are used to induce doping. This process is referred to as self-amorphization. For a group IV semiconductor crystal such as Si or Ge, self-amorphization commonly occurs with higher mass implanted species such as In, Sb, As, or P. Self-amorphization with lighter atoms such as B may be achieved through the use of cluster species such as BF2. In a region which is self-amorphized, the damaged location and ion positioning will largely overlap. It is common in a self-amorphized material to see a strong dependence between the implanted dose and measured projected range of the implant with the lightest dose self-amorphizing implants experiencing a longer projected range due to channeling which occurs before the self-amorphization process is completed.

Amorphization may also be accomplished through the use of a separate non-doping or co-implant specie. For a group IV semiconductor, amorphization without introducing doping is commonly achieved through the use of an implant specie from group IV such as Si, Ge, or Sn or through the use of an implant of a noble gas specie such as Ar, Kr, or Xe or through the use of species such as F or cluster implant species which do not contain a dopant atom. In a separately amorphized or pre-amorphized region, the damage and ion profiles need not overlap.

In addition to amorphization, another means of minimizing channeling is through the use of an amorphous capping layer placed above a crystalline semiconductor region. In this case, the amorphous capping layer serves to randomize the ion trajectories before they reach the semiconductor.

Amorphization and implant damage are important effects in that they significantly impact the channeled tail of an implanted ion distribution. This can manifest as a shallower vertical or more abrupt lateral junction. For this reason, CMOS processes which involve tip extension implants, source/drain implants, or source/drain contact implants may involve an implant of a non-doping specie performed prior to the implant of a doping specie. This implant may or may not be (separately) amorphizing and serves to confine the implanted doping laterally which may lead to improved device short channel effects, reduced device V_t, and higher channel mobility.

1.3.4 Impact of Implant Process Knobs upon Resultant Distributions of Implanted Ions and Implant Damage

The electrical behavior and characteristics of a transistor are heavily impacted by the placement and concentration of dopant atoms. Integration and optimization of a transistor fabrication process requires a thorough understanding of the positioning of both damage and ion, as well as an understanding of how processes downstream from the implant operation are impacted by the results of a prior implant operation. Such understanding is normally gained through the use of TCAD tools and the models upon which these tools are based. The principal outputs of these simulations are the ion profile and the crystal damage profile. These quantities may then be utilized in TCAD models to create profiles of excess damage which may drive dopant diffusion, grow and nucleate extended defects such as {311}'s and end-of-range

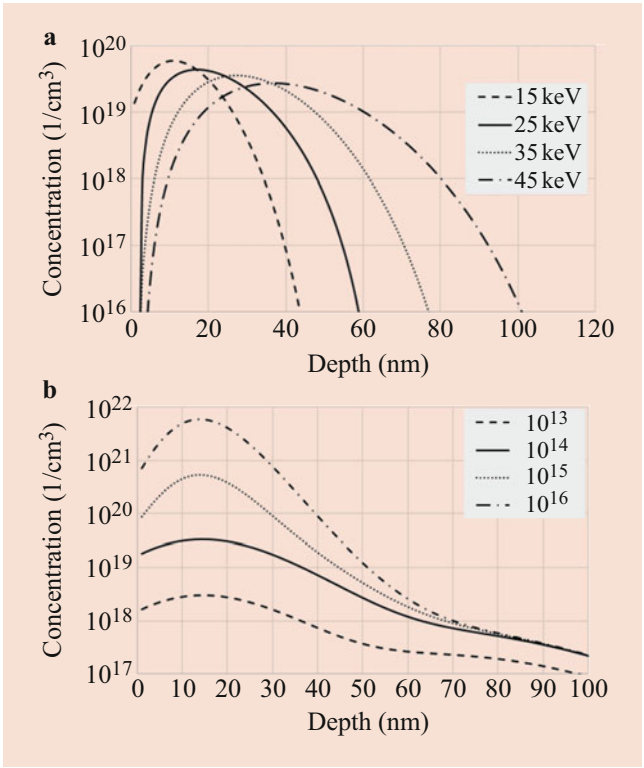

Fig. 1.9 (**a**) Simulation of arsenic implant at 15/25/35/45 keV at fixed 1e14/cm^2 dose into a randomized (100) Si crystal. As energy of the implant is increased, the resultant profile is deeper and broader. (**b**) simulation of 10 keV phosphorus implant into an undamaged (100) Si crystal. As the dose is increased, the fraction of channeled ions is decreased which results in a profile shape change

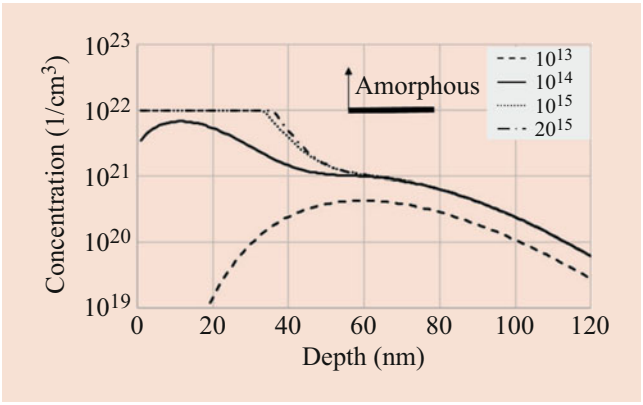

Fig. 1.10 Simulated cascade damage resultant from a 10 keV phosphorus implant into (100) Si at doses of 1e13 to 2e15/cm^2. The 1e15 and 2e15/cm^2 implants will result in an amorphous layer being formed in the structure. As implant dose is increased, the peak cascade damage also increases until amorphization is reached. Increasing dose further will lead to an increase in the depth of amorphization

(EOR) loops, lead to dopant deactivation or clustering, and initiate recrystallization of an amorphized layer. Therefore, it is critical to understand the impact of implant parameters upon these quantities.

The two most fundamental implant parameters are dosage/dose and implant energy. The implant dose is commonly measured in units of 1/cm^2 and represents the number of ions which are implanted per unit area as measured perpendicular to the ion beam. The measurement of implant dose perpendicular to the ion beam results in an effective dose reduction at wafer surface for an implant in which the wafer is tilted at time of implant and not orientated perpendicular to the ion beam.

Implant profiles for arsenic and phosphorus are shown in Fig. 1.9. As energy of the implant is increased, the resultant profile is deeper and broader. As the dose is increased, the fraction of channeled ions is decreased which results in a profile shape change. Both of these effects can be modeled with either Monte Carlo implant simulations or with continuum models which utilize shape functions (as shown in these figures).

The implant damage can also be modeled with TCAD tools, as demonstrated in Fig. 1.10. As would be expected, increasing the implant dose will lead to an increase in implant damage until amorphization is reached. In many TCAD implant models, amorphization is represented as a threshold function in which a region is amorphized if the damage exceeds a value. This damage is a measure of the quantity of vacancies which have been introduced to the crystal lattice due to collisions and recoil events and the interstitials which are created as the recoiled atoms come to rest. Computationally efficient models such as those of Hobler have been proposed to describe these effects and are commonly used in TCAD tools to describe implant damage. A measure of the vacancies injected from an implanted ion can also be determined through a Monte Carlo implant simulator such as MARLOWE or SRIM.

Until recently, most ion implants used in CMOS processes were performed at room temperature. Modern implant tools, however, now have the ability to perform the implant into either a heated or cooled substrate. An implant into a heated substrate will tend to dynamically heal implant damage during the implant, and heated implants have found applications for situations where amorphization must be avoided such as high-dose well implants for a bulk FinFET process. Conversely, cryogenic (or chilled) implants have found applications where abrupt amorphizations are desired such as for pre-amorphization implants done at contact formation.

For high-volume manufacturing, it is common to operate the implanter at the highest reasonable beam current (and hence the lowest time on the tool to achieve the desired dose); however, ion implanters can operate at different beam current levels, and this is a knob which is also used for process optimization at times. It has been shown experimentally that

implant-induced defects and their thermal dissolution can be modulated by the implanter beam current.

1.3.5 Consideration for Implant into Nonplanar Surfaces

A beam line ion implantation tool is a "line-of-sight" tool. During CMOS fabrication, it is common for there to be a height variation in the top surface to be implanted. As implants are tilted and rotated, this elevation change in top surface can lead to regions of the semiconductor wafer being blocked or partially blocked from the implant beam by another higher elevation feature located lateral to that exposed location within the line-of-sight of the implant beam as shown in Fig. 1.11. In modern CMOS fabrication, especially for FinFET processes, this effect often determines the tilt/rotation process window bounds for an implant process. To overcome this limitation, tilted and rotated implants are commonly performed in pairs at the same tilt (offset by 180 degrees of rotation) or in quadruples (offset by 90 degrees of rotation) depending upon the application. This shadowing effect also manifests as a nonuniformity in implant profiles which is introduced with irregular patterns.

Height variation in an implanted surface may also lead to proximal doping effects. The most familiar of these effects is a well-proximity V_t effect in which the threshold voltage of a device is dependent upon the distance from the well boundary. These effects are manifested as a lateral variation in implanted dose which is due to implanted ions scattering from a location higher in elevation on the wafer and being re-implanted elsewhere as shown in Figs. 1.12 and 1.13. This ion scattering can originate from either a topographical feature of the assembly (for instance, a fin or gate structure) or the blocking and resist layers used to mask off regions of a wafer for which implant is not intended.

1.3.6 Plasma Implant

A second category of ion implant tools used in CMOS fabrication are those which place a target wafer within a plasma source or sheath. These tools are referred to broadly as plasma immersion ion implantation (PIII) tools. Once placed within a plasma, the wafer is subjected to a DC bias or a pulsed voltage which serves to form an electric field between the target and the plasma and to draw out the charged particles which are implanted into the target. The plasma composition may be varied and both p-type and n-type implant options have been developed.

A main advantage of this technique results from alleviating the line-of-sight restriction present with a beam line ion

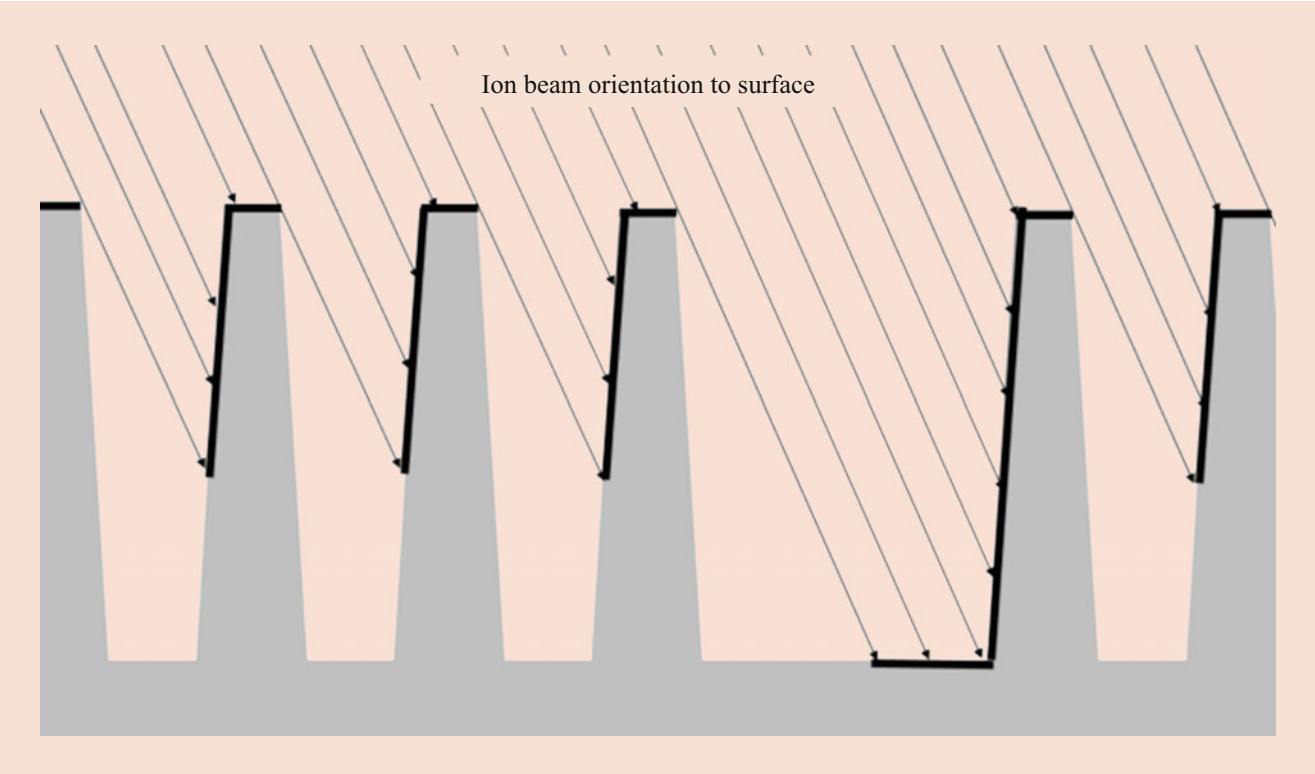

Fig. 1.11 A representation of shadowing which occurs with a tilted ion implant and a surface with height variation. Areas of the surface which are exposed to the implant beam have a dark top interface. This effect leads to a nonuniform doping profile across the array of fins or the grating pattern

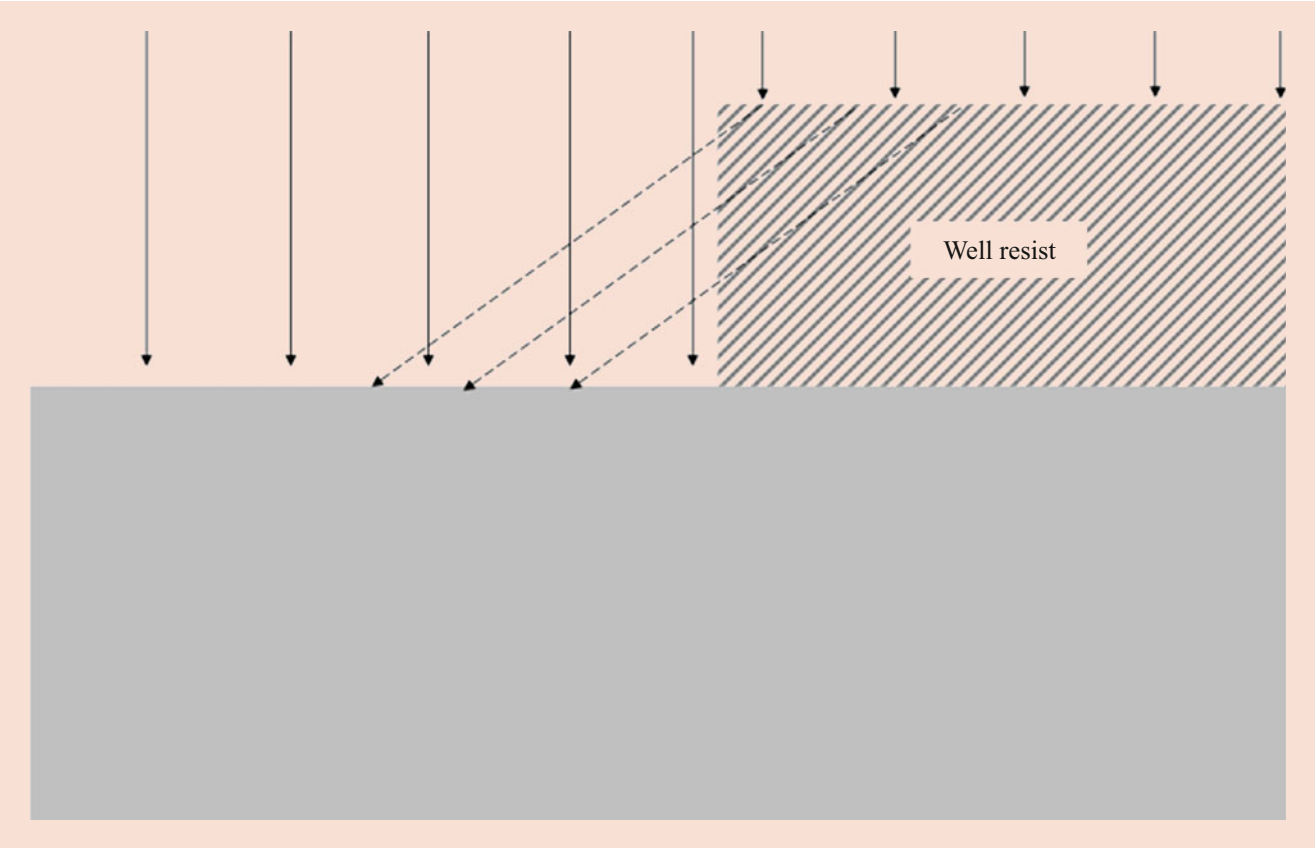

Fig. 1.12 Well proximity doping effect. Ions from the incoming ion beam (solid lines) are scattered (dashed lines) at a higher elevation within the well resist and are re-implanted at a lower elevation proximal on the wafer. The net dose of implanted ions becomes a function of distance to the well boundary and devices which are formed within the region where these scattering events occur may experience a layout-dependent performance variation

implant tool as the target wafer is immersed within the plasma sheath directly. In theory, this enables conformal dosing to be achieved on nonplanar target surfaces. In practice, some degree of non-conformality is present even with a plasma source ion implant. A second advantage of this technique is that it enables very high throughput or high doses to be achieved (to ~e18/cm^2). At these high doses, percent level concentrations of impurities may be introduced to a target. For this reason, many common applications of a plasma-source ion implant in CMOS manufacturing entail near-surface material transformation of a target from one material or phase to another.

Plasma implant does have several key disadvantages that have traditionally limited the applicability of the technique to niche applications. Chief among these limitations is that the implanted species consist of every specie present in the plasma. For instance, a plasma implant intended to introduce boron doping from a BF_3 plasma source may implant a soup of all permutations of B and F molecular and atomic species to the substrate. In addition to charged species in the plasma, neutral species are commonly injected into the plasma to improve conformity and may also be implanted through a recoil effect. These species will differ in mass which may yield an implant distribution profile with a longer tail than would a beam line implant, which presents a severe drawback if an abrupt implant profile is desired. In addition to implanting desired doping or impurity species, it is often necessary to implant high doses of unintended species as well when a plasma implant is used.

1.3.7 Implant Sputtering and Backscattering

In addition to damaging the crystalline structure of the target material, implanted ions may also eject material from the surface of the target or themselves be ejected or reflected. These processes, diagramed in Fig. 1.14, are referred to as implant sputtering and backscattering. Sputtering may be used advantageously in certain CMOS and memory processes such as non-selective surface clean operations, and backscattering is generally an unavoidable consequence of high-angle implant operations or implant operations into structures with topographical variation. In general, this sputtering process is most significant for higher mass implanted species with incidence at high angles relative to the localized surface implanted at high doses (>~ e15/cm^2). The efficacy

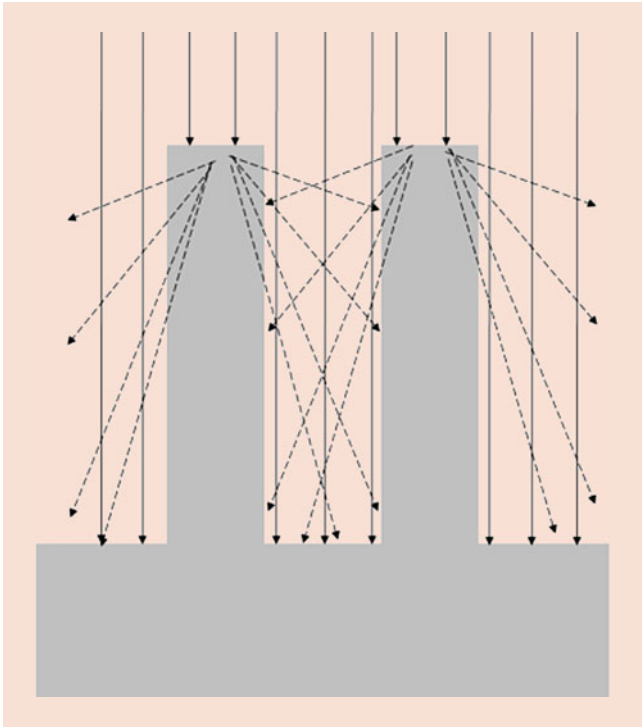

Fig. 1.13 Proximal doping resultant from normal incidence implant into a fin or grating structure. Even in instances where the sidewalls of the fin or grating structure are parallel to the original ion beam (solid lines), they are still implanted due to scattering events (dashed lines) which occur in adjacent fins or grating structures

of the sputtering process is specified by the sputtering yield which is a value representing the mean quantity of target atoms ejected for each incident implanted ion. The calculated sputtering yield from SRIM software is demonstrated in Fig. 1.15. For cases where the target material is not composed of a single atomic specie, the sputtering yield of each atomic component of the target may be determined, and in general, these quantities will differ. A common manifestation of sputtering for CMOS FinFET processes is that sharp corners are eroded and rounded with high-dose n-type implants (such would be present with a NMOS source/drain or contact implant). In addition to certain CMOS processes, the sputtering process also forms a basis for several analytical techniques such as SIMS (secondary ion mass spectrometry) profiling.

1.3.8 Implant Ion Beam Mixing

In certain CMOS processes, it is necessary to implant through a capping layer, a superlattice structure, or a stack of materials. This is particularly applicable to implants used for workfunction modulation in the gate stack of materials and implants used in contact processes. In these situations, the implant beam can recoil and mix the stacked or lattice layers together and blur the boundaries that once existed between the distinct regions or materials and introduce unintentional impurities or doping into the layers beneath. Figure 1.16 shows these events can be predicted with the aid of TCAD simulation tools or simulators such as SRIM.

1.4 Thermal Annealing

The process of annealing is used to influence the properties of the materials within semiconductor devices. It is commonly performed to control the location and electrical activation of dopants, setting the p-n junction locations. Alternatively, it can stabilize a material that has just been deposited or damaged from a previous process step like ion implantation or etching.

As shown in Table 1.1, different materials can withstand different temperatures and times. Silicon devices can be annealed in the range of 500 °C for hours to 800 °C for minutes and up to 1200 °C in the millisecond timeframe. Semiconductor materials with higher melting points such as SiC can sustain higher thermal budgets. Conversely, semiconductors with lower melting temperatures like Ge need to be annealed at a reduced thermal budget. Similarly, once the metals used for source, drain, or gate contacts are introduced into the semiconductor devices, annealing temperatures must be kept moderate, usually below 400 °C so as not to diffuse the metals or deactivate the dopants in neighboring semiconductor regions.

There is a strong correlation between cohesive energy of elements and their melting temperature, Fig. 1.17. Similarly, the self-diffusivity of materials has also been correlated to their cohesive energy. This can be used as a guide to understand the relative temperature ranges that different materials can tolerate.

1.4.1 Annealing Methods

Furnace annealing is a batch process in which multiple wafers are loaded into a heated quartz tube at atmospheric pressure with a flowing gas such as nitrogen, N_2, or forming gas, 5% H_2 in N_2, and maintained at the desired temperature for hours. Vertical tube furnaces have become more popular than the earlier favored horizontal tube furnaces. Examples of these are diagramed in Fig. 1.18, showing the differences.

Rapid Thermal Annealing

Rapid thermal annealing (RTA) uses an array of heat lamps to increase the temperature of the exposed wafers, enabling

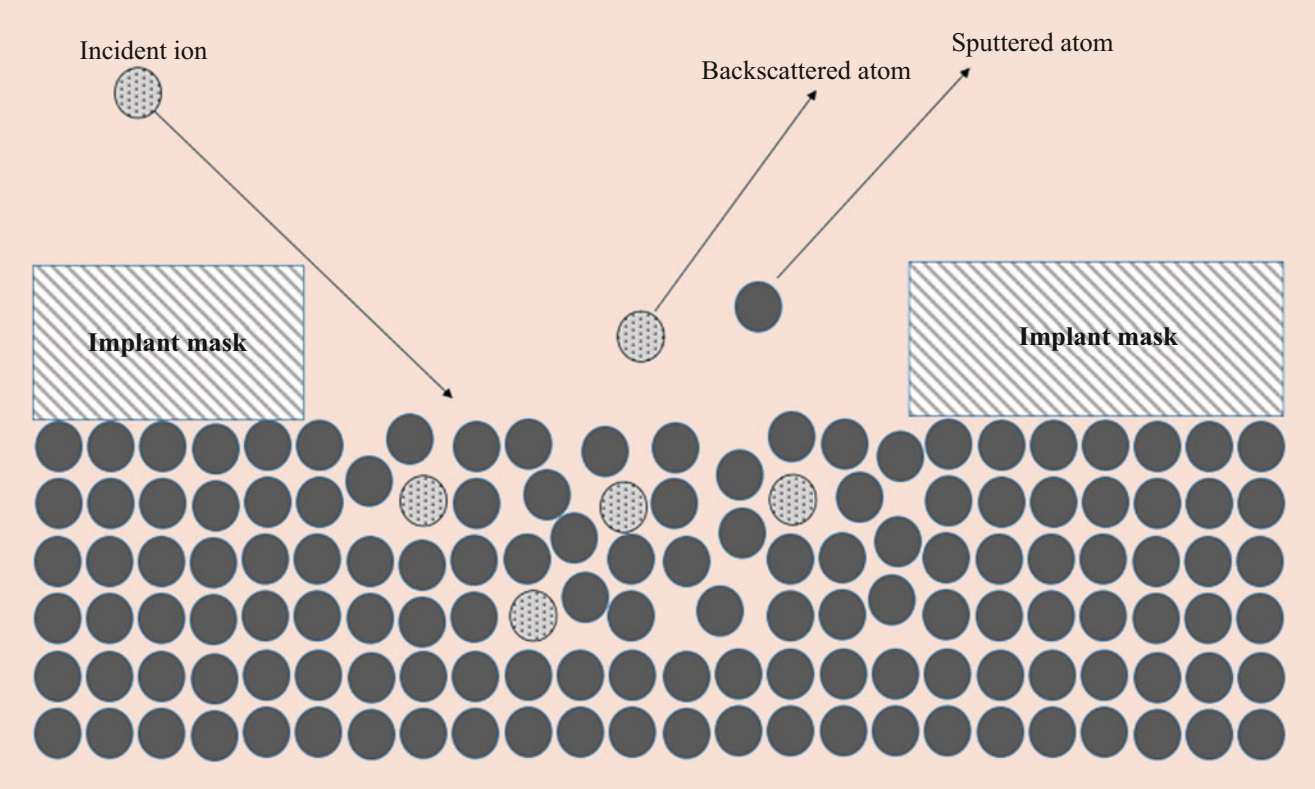

Fig. 1.14 The sputtering and backscattering process. An incident ion is implanted into a substrate and may induce lattice disorder, cause atoms of the surface to be ejected through a sputtering event, or be scattered themselves and ejected from the substrate in a backscattering event

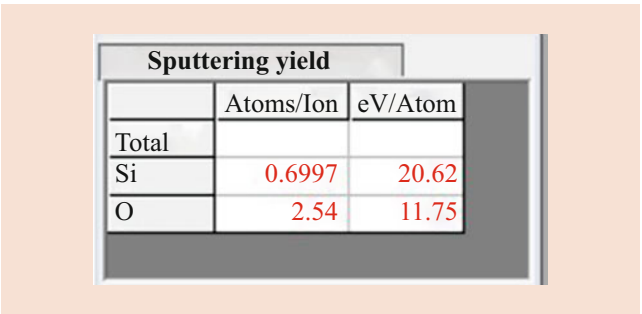

Sputtering yield

	Atoms/Ion	eV/Atom
Total		
Si	0.6997	20.62
O	2.54	11.75

Fig. 1.15 Sputtering yield extraction from a Si implant into SiO_2 performed with SRIM. In this simulation, the incident ion was Si directed at a horizontal initial surface with a beam tilt of 45 degrees relative to the surface. For each implanted Si ion, on average ~0.7 Si substrate atoms and 2.54 O atoms are sputtered

faster ramp-up and cooling than furnace annealing. This method can bring the anneal time down to the range of seconds as opposed to hours [1]. The short dwell time at maximum temperature for the RTA process makes it ideal for minimizing the diffusion of implanted dopants, forming shallow channel to source/drain junctions, maintaining high dopant activation, oxidizing ultrathin gate dielectrics, and making contacts through silicide reactions with metals. Advanced methods use "spike anneals," wherein high temperature ramp rates are used for both heating and cooling, while also minimizing the dwell time at peak temperature. The extreme case of this is commonly referred to as "flash annealing" in which case a high-arc discharge lamp is used to expose the surface of the wafer to a millisecond flash of light resulting in thermal absorption and heating. The wafer itself acts as a heat sink, leading to rapid cooling of the surface after the flash exposure. Configuration like the one shown in Fig. 1.19 utilize two sets of lamps to provide RTA heating of the wafer backside and high temperature flash on the top surface of the wafer.

Laser Heating

Laser heating has also been used to anneal semiconductor materials. In this application, a laser is rastered across the surface of a wafer resulting in localized heating that can be as short as nanoseconds. The thermal profile can be compressed to high temperatures for ultrashort durations as shown in Fig. 1.20 to reduce thermal diffusion budget.

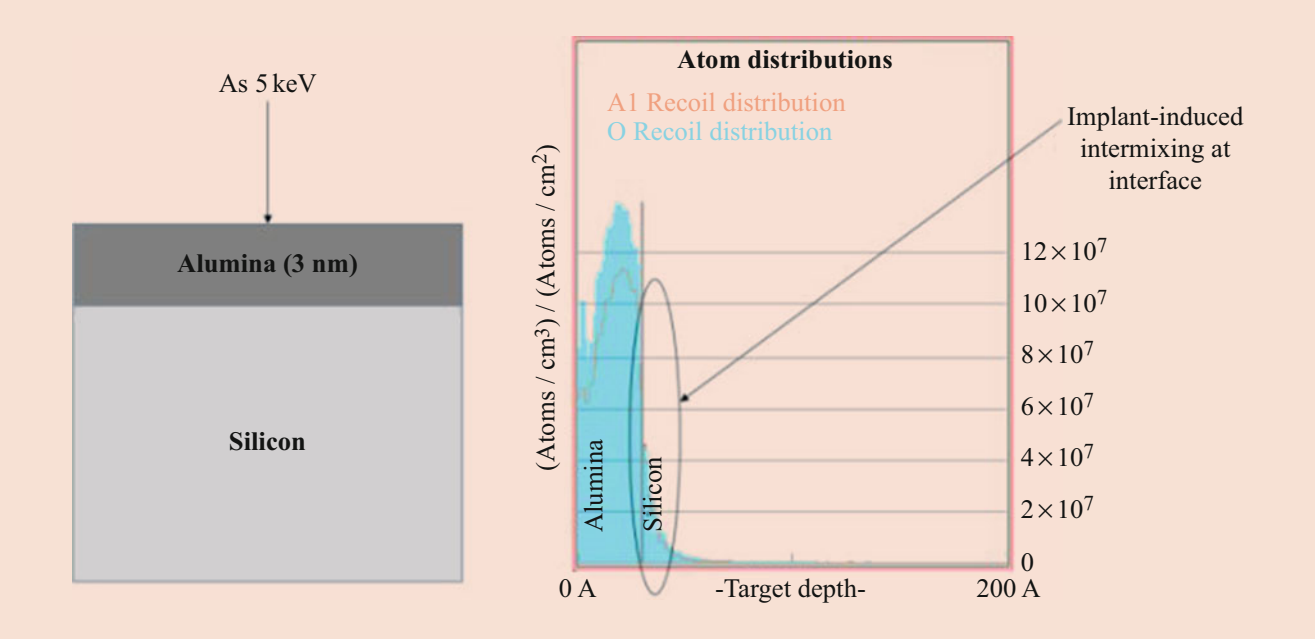

Fig. 1.16 An example of ion beam mixing which distorts the interface between a capping layer and the underlying materials. In this hypothetical example, aluminum and oxygen atoms are recoiled several nm into the underlying silicon material

Table 1.1 Material melting temperatures and cohesive energies

Material	Melting temperature (°C)	Cohesive energy (eV/atom)
SiC	>2730 (decomposes)	–
GaN	>2500	–
Si_3N_4	>1800 (decomposes)	–
SiO_2	>1600	–
Si	1415	4.63
SiGe	Varies between Ge and Si based on Ge%	–
Ge	937	3.85
GaAs	1238	–
InP	1062	–
W	3422	8.90
Ti	1668	4.85
Ni	1452	4.44
Cu	1083	3.49
Al	659	3.39

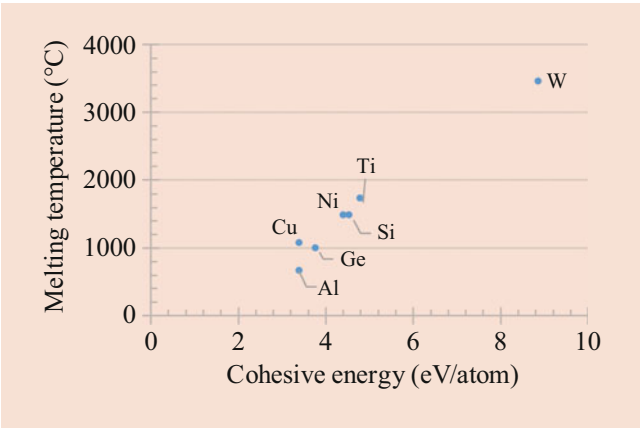

Fig. 1.17 The relationship between melting point of a material and the cohesive energy showing that materials with higher cohesive energy generally have higher melting points

1.4.2 Diffusion

The introduction of dopants must be done in a controlled manner to reliably set the electronic properties of different regions. During annealing, dopants can redistribute and diffuse into neighboring areas. Figure 1.21 shows a conventional P-N junction formed in-diffusion of P-type dopants from a surface.

Diffusion of dopants occurring at low dopant and point defect concentrations (<1 atomic percent) can assume dilute approximations. In this regime, Fick's laws of diffusion are valid and can be useful for describing dopant motion. Fick's first law relates the flux, J, of particles passing through a unit area per unit time to the concentration gradient, dC/dx, in proportion to the diffusion coefficient, D.

$$J = -D\, dC/dx \quad \text{(in 1 dimension, } x\text{)} \tag{1.1}$$

Combining the continuity equation $dJ/dx = -dC/dt$ with Fick's first law gives Fick's second law.

$$dC/dt = D\, d_2C/dx_2 \tag{1.2}$$

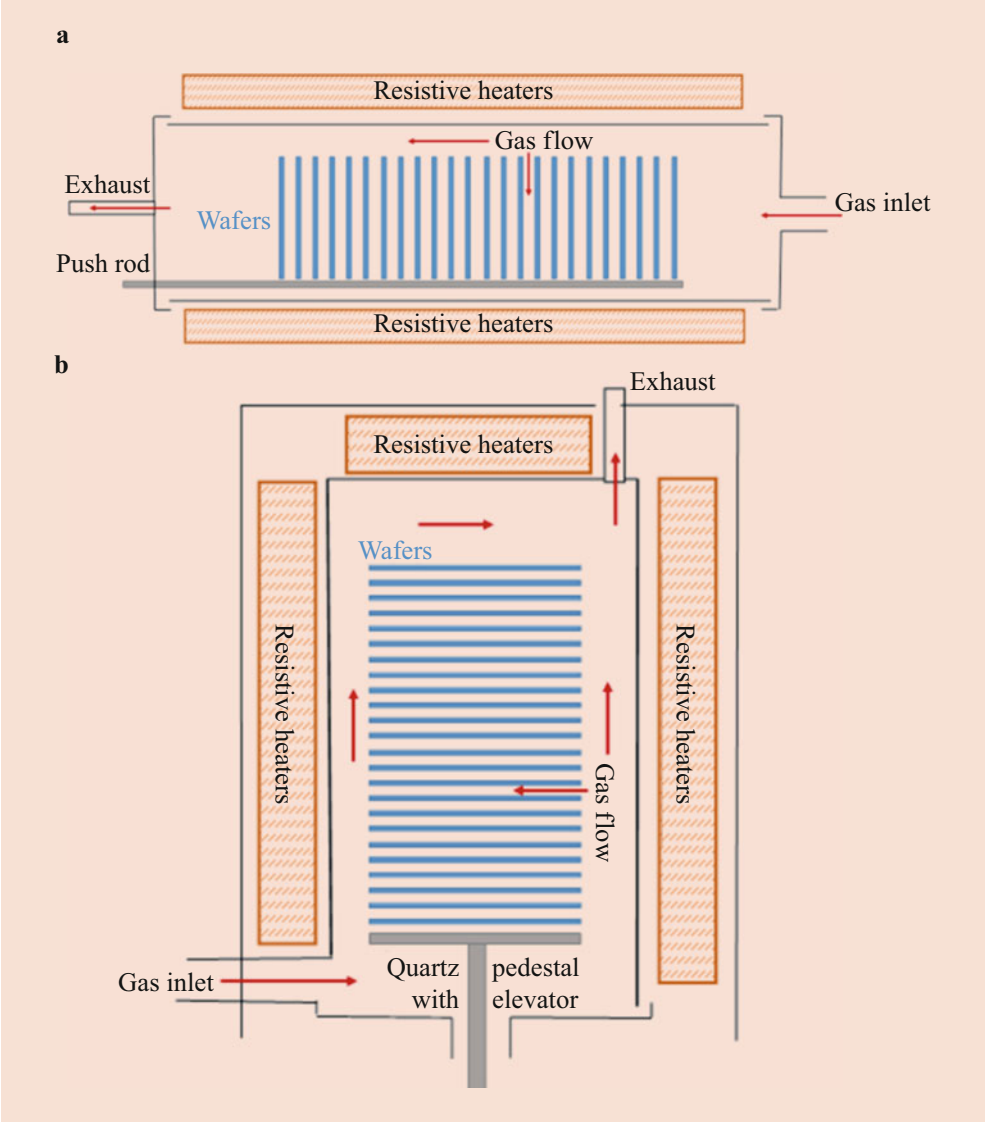

Fig. 1.18 Schematic of a horizontal (**a**) and vertical furnace (**b**) showing key functional elements

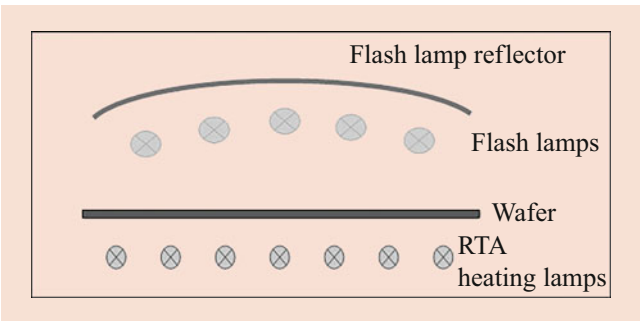

Fig. 1.19 Schematic of a flash chamber showing an array of lamps and reflector positioned about a wafer

The diffusion coefficient follows an Arrhenius dependence with an exponential prefactor, D_0, and an activation energy, E_a, for the thermally activated process.

$$D = D_0 \exp\ (-E_a/kT) \tag{1.3}$$

The presence of nonequilibrium concentrations of point defects can further be included to proportionally enhance the diffusion over the equilibrium, C^*, levels such as for the case of vacancies:

$$\mathrm{d}C/\mathrm{d}t = D_\mathrm{v}\ C_\mathrm{v}^*\ \mathrm{grad}\left(C_\mathrm{v}/C_\mathrm{v}^*\right) \tag{1.4}$$

As a simple analytic approximation for the case of junction formation by indiffusion, the junction depth, X_j, is estimated by the square root of the diffusivity, D, at a given temperature multiplied by the duration of the anneal, t.

$$X_\mathrm{j} = \mathrm{Sqrt}\,(Dt) \tag{1.5}$$

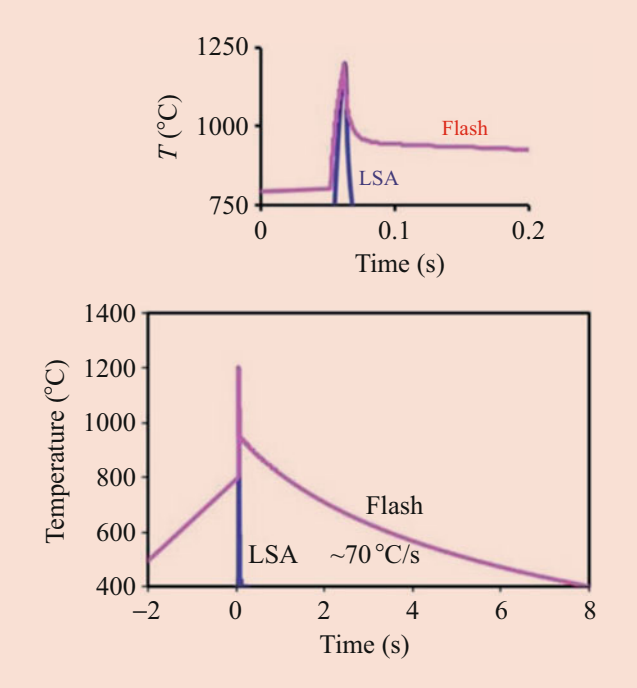

Fig. 1.20 Comparison of typical flash and laser anneal (LSA) time-temperature profiles showing the much faster transients involved in a laser anneal process

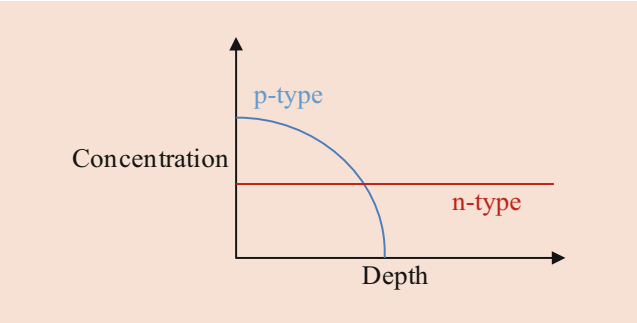

Fig. 1.21 An electrical junction is formed at the position where the active p-type doping concentration equals the active n-type doping concentration

Several dopants and impurities have been experimentally quantified for semiconductor materials such as silicon.

Grain Boundary and Interfacial Diffusion

The existence of grain boundaries in polycrystalline materials can provide a pathway for faster diffusion than their single crystalline counterparts as shown in Fig. 1.22. The density of grain boundaries, segregation, and the cohesiveness of the grain boundaries ultimately determine how much faster polycrystalline diffusion is. For metals, the diffusivity in grain boundaries can be orders of magnitude higher than bulk lattice diffusivities. Fisher proposed a model for GB diffusion that assigns an effective width to the highly diffusive grain

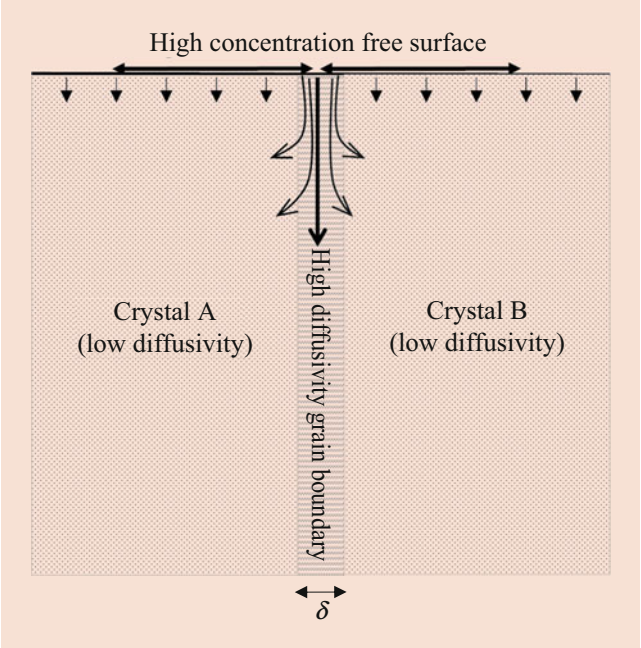

Fig. 1.22 Schematic showing enhanced diffusivity which may occur along a grain boundary

boundaries and extracted a value on the order of two atomic layers (about 5 angstroms). This type of diffusion can be important for semiconductor devices as electromigration is directly influenced by the diffusivity of atoms in interconnect lines.

1.4.3 Dopant Activation/Clustering/Deactivation

Dopant impurities in semiconductors such as boron, phosphorus, arsenic, and antimony in silicon can provide excess electrical carriers (electrons or holes), shifting the Fermi level of the material to be more n-type or p-type. To do so, these dopants typically reside on substitutional sites within the crystal lattice. However, when present in high concentrations, the dopants can begin to exceed soluble limits and form clusters or precipitate [6, 7, 26]. The critical concentration for equilibrium electrical solubility is a temperature-dependent property. Annealing at high temperatures increases the critical concentration allowing dopants to be captured in their metastable soluble state by quenching via a rapid cooling step. The quenching rate need to be fast enough, usually exceeding their diffusivity rate, so that dopants are kinetically limited from coming out of solution. However, further annealing at moderate temperatures can allow the dopants to deactivate as the system moves toward its lower temperature equilibrium state.

1.4.4 Semiconductor Recrystallization

Semiconductor materials that are in an amorphous state either from deposition or ion implantation can be recrystallized into polycrystalline or single crystal during thermal treatment. Solid-phase epitaxial recrystallization (SPER) is the heterogeneous recrystallization of an amorphous region in contact with an underlying single crystal material of similar type. The rate at which the amorphous region regrows and the crystalline quality of the regrown region has been shown to depend strongly on the surface orientation normal to the regrowth front, temperature, and doping/impurities within the amorphous layer [18–20].

1.4.5 Simulators

Computer software is now commonly used to simulate dopant diffusion through the solution of partial differential equations using finite element methods [22, 23]. These programs can be more generalized than the above analytical solutions allowing for a multitude of geometry effects and producing spatially varying diffusion contours. The diffusion models developed within them can include extensively more physics such as the interaction of dopants with point defects under intrinsic and extrinsic conditions along with varying temperature profiles and have become commonplace within the semiconductor industry [25, 28].

1.4.6 Oxidation

Annealing in a gas ambient can lead to the growth of new materials on the surface. For example, silicon exposed to an oxygen-rich ambient will form a silicon dioxide layer on the surface through the following chemical reaction:

$$\text{Si (solid)} + \text{O}_2 \text{ (gas)} \rightarrow \text{SiO}_2 \text{ (solid)} \qquad (1.6)$$

As the reaction proceeds, the rate of oxidation will slow down due to the diffusion of oxygen reactant through the formed SiO_2 layer to the silicon surface where the reaction can continue to form new oxide. Due to the difference in density of SiO_2 and the silicon that it replaces, there is a volumetric expansion of about 2.2× resulting in an intrinsic stress. The rate of oxidation was initially modeled by equating the flux of reactants for three primary mechanisms, resulting in a linear parabolic dependence of oxide thickness per time [4, 12]. Later models were added to improve the growth kinetics for low thicknesses typically under 200 angstroms [13]. Additional modifications can be made to account for changes in growth rate with dopant concentration and surface orientation [3].

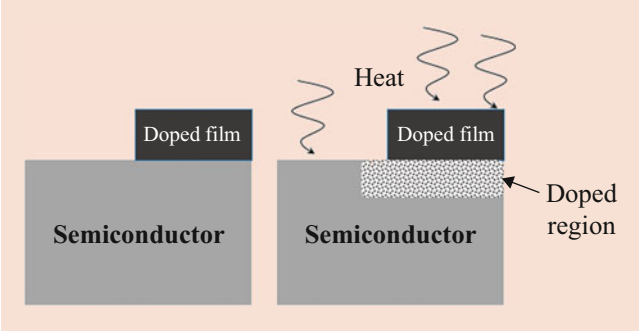

Fig. 1.23 An example of solid source doping. A doped film is deposited on a region of semiconductor, and the assembly is then subjected to thermal anneal. This anneal drives dopant species from the film to the semiconductor

1.4.7 Solid Source Diffusion

In addition to implanting dopant species or growing a doped epitaxial layer, another means that has historically been utilized to dope a semiconductor crystal is through the use of a solid source diffusion as in Fig. 1.23. In this technique, a material with a high concentration of doping atoms is deposited upon regions of the semiconductor which are desired to be doped. The wafer is then thermally annealed to diffuse dopant species from the deposited material into the semiconductor. Common material utilized for the doping source include borosilicate glass (BSG), phosphosilicate glass (PSG), and doped oxides. It was disclosed that this technique was utilized by Intel to dope under the fins as a punch through stopper doped layer.

1.5 Deposition

Materials deposition is an important step in the semiconductor device fabrication process. New layers can be deposited to epitaxially align with the exposed crystalline surface. Due to the dependence on exposed crystalline surfaces, epitaxial deposition can be a selective process that only grows in desired regions through balanced control of the absorption and desorption rates of the depositing atoms. Alternatively, non-epitaxial deposition of polycrystalline and amorphous layers can result in the conformal deposition across the entire exposed surface as shown in Fig. 1.24.

1.5.1 Deposition Methods

Physical vapor deposition (PVD) or sputter deposition is a physical process in which a target material is sputtered from a source onto a nearby wafer. The deposited material can be of very high purity and does not require a chemical reaction

for the deposition to take place. Typically, the target is an electrically grounded metal cathode in a vacuum chamber. Argon gas is introduced into the chamber, gets positively ionized, and is accelerated toward the cathode target. Though ion impacts with the target, metal atoms are displaced such that they deposit onto the surface of a nearby wafer.

In chemical vapor deposition (CVD) depositing atoms are delivered by gases flowing over the wafer surface in a heated chamber. When the transport gases are brought in contact with the wafer, chemical reaction occurs on the surface resulting in deposition of new material. The species contained in the gases can lead to deposition of thin semiconductor layers like silicon with controlled amounts of dopant or insulators like SiO_2.

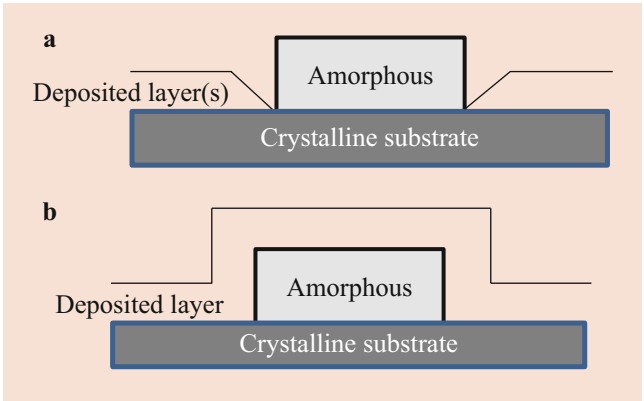

Fig. 1.24 Figure showing the resultant geometries created by a selective deposition seeded from a crystalline substrate (**a**) and a conformal deposition (**b**)

CVD is a heterogeneous reaction with three main steps: (1) chemical arrival, (2) surface reaction, (3) removal of by-products. More specifically, these steps can be broken down into their individual influences as shown in the heterogeneous model in Fig. 1.25.

The rate of deposition is controlled by the rate of arrival of reactants, the surface reaction rate, and the rate of removal of by-products. For typical CVD processes, it is desired to have the rate of arrival of the reactants be the rate-limiting step for epitaxial growth, resulting in the best crystal quality and process control. Plotting the deposition rate exponentially over temperature for a particular chemistry and reactor geometry will often make two distinct regimes observable as shown in Fig. 1.26. The kinetic regime occurs at lower temperatures when the surface reaction is the rate-limiting process. The mass transport controlled regime occurs at higher temperatures and is limited by the diffusion or rate of arrival of reactants.

The morphology of the deposited layer is controlled by the rate of arrival relative to the surface diffusion rate, with a faster arrival rate leading to more polycrystalline morphologies.

The quality of the epitaxial layer resulting from CVD deposition is highly dependent upon the cleanliness and crystal quality of the surface prior to epitaxial growth, the lattice mismatch between the crystal surface and the depositing film, the arrival rate relative to the surface diffusion rate, and the

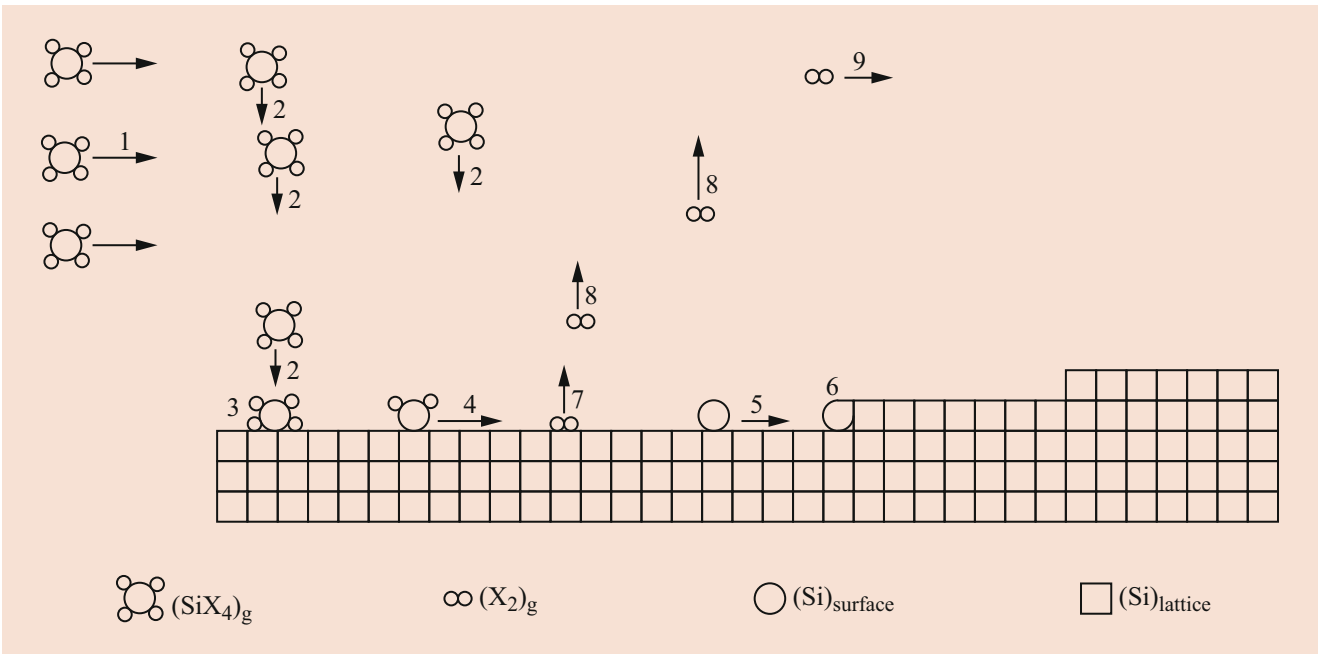

Fig. 1.25 Heterogeneous reaction model illustrating arrival (1, bulk transport of reactants; 2, diffusion of reactants to surface; 3, reactant absorption), surface reaction (4, chemical reaction; 5, surface diffusion; 6, incorporation into crystal), and by-product removal (7, by-product desorption; 8, by-product gas transport; 9, by-product bulk transport evacuation)

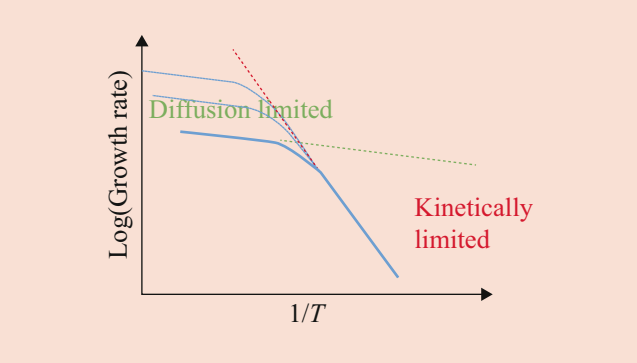

Fig. 1.26 Growth rate vs. reciprocal of temperature for a typical deposition process

nature of the lattice incorporation. Due to the differences in surface diffusivity and lattice incorporation for different surface crystal orientations, the growth rate and quality for different orientation can vary. Typically (111) surfaces will have slower deposition rates than (110) and (100) resulting in faceting for nonplanar surfaces and possible stacking fault formations.

Atomic Layer Deposition

A thin film deposition method that allows for conformal layers that are angstrom to nanometers in thickness is atomic layer deposition (ALD). This process is similar to CVD but relies on an alternating set of self-limiting chemical reactions on the surface of the wafer. For each step, the wafer is exposed to gas precursors until the surface reaction for a single atomic layer is carried out to completion. A second set of self-limiting precursors are then exposed to the new surface in order to build a new atomic layer on the first. The set of alternating chemical reaction exposures is called a cycle. Through the repeated sequence of these cycles, a thin film can be atomically deposited layer by layer. This method has proven to be very useful for the formation of high dielectric constant (Hi-K) gate insulators.

Molecular Beam Epitaxy.

Molecular Beam Epitaxy (MBE) is an atomic deposition process performed under ultrahigh vacuum (UHV) in a chamber like the one shown in Fig. 1.27. MBE can result in exceptionally high-quality epitaxial layers [2]. Ultrahigh purity sources of the depositing elements are heated in Knudsen effusion cells or electron beam evaporators directly across from a target deposition wafer. The targets are heated until they begin to sublime, releasing a low concentration of atoms for deposition. The released atoms will condense on the neighboring wafer surface. The temperature of the source will control the rate of material impinging on the substrate surface. The temperature of the substrate affects the rate of hopping or desorption occurring during the epitaxy process. Reflection high-energy electron diffraction (RHEED) is used

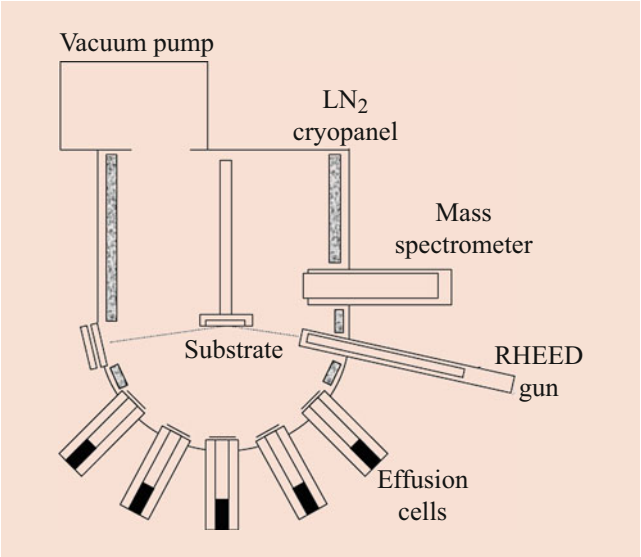

Fig. 1.27 Schematic of an MBE reactor

for in situ monitoring of the crystal quality and thickness of growth. Although MBE can deliver high-quality epitaxy, the throughput is too slow for high-volume manufacturing except in specialized cases. The sub-nanometer control and epitaxial quality afforded by MBE allow for band gap engineering and generation of delta-doped layers suitable for precise device dimensions.

1.6 Etch

Materials can be removed during the fabrication of semiconductor devices through the chemical process of etching. In this step, the materials are introduced to chemicals such as halides (F, Cl, Br, Xe) or acids to form a reaction at the exposed surfaces resulting in the controllable loss of material. Portions of the device can be covered with etch resistant materials to protect from the etchant, resulting in different device geometries. The primary methods of etching can be categorized into two approaches: (1) wet etching based on liquids and (2) dry etching based on gas or vapor phase chemistries.

1.6.1 Wet Etch

The mechanisms for wet chemical etching involve three essential steps: the reactants are transported by diffusion to the reacting surface, chemical reactions occur at the surface, and the by-products from the surface are removed by diffusion and evacuation. The etch rate, which is the amount of film removed by etching per unit time, is influenced by the concentration of the etchant in the solution, the agitation of

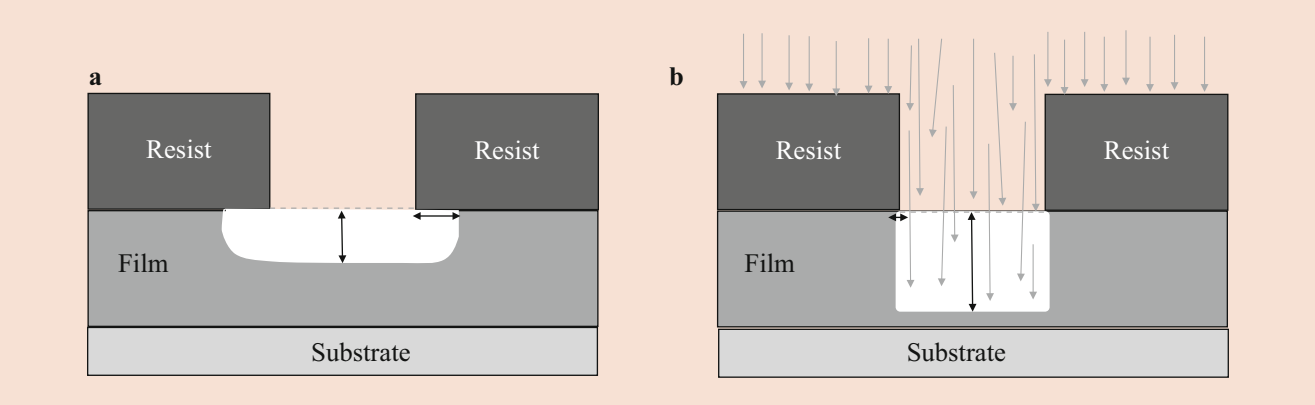

Fig. 1.28 Resultant etch profiles from an isotropic wet etch (**a**) and an anisotropic dry etch (**b**). The wet etch may undercut a masked feature and the dry etch acts in a vertical or line-of-sight fashion

the liquid, and the temperature of the etchant solution. Wet etching often results in isotropic removal (i.e., having the same lateral and vertical etch rates) of the etchable materials producing undercutting of masking material as shown in Fig. 1.28a. This can lead to a loss of resolution in the etched pattern. However, due to the reliance on chemical reaction, high selectivity between the etch rates of different materials can be achieved.

1.6.2 Dry Etch

Dry etch methods include plasma etching, reactive-ion etching (RIE), sputter etching, magnetically enhanced RIE (MERIE), reactive-ion-beam etching, and high-density plasma (HDP) etching. These dry etch methods have been developed to achieve high-fidelity transfer of mask patterns by producing highly anisotropic etch rates in which the lateral etch rate is almost zero relative to the vertical etch rate (Fig. 1.28b). This is done by applying a directional bias to the etchants often through the generation of plasma in a gas at low pressure. Positive ions bombard the surface at high speed giving more directionality to the etch process. Due to the physical nature (sputtering and bombardment) associated with dry etching, it can yield anisotropic profiles, but it is also associated with lower etch selectivity and severe bombardment-induced damage.

1.6.3 Chemical Mechanical Polish or Chemical Mechanical Planarization

Chemical mechanical polishing/planarization (CMP) is a process which has relatively recently been applied to semiconductor manufacturing. The introduction of this process somewhat coincides with the introduction of copper interconnects and the associated difficulty in etch removal of copper.

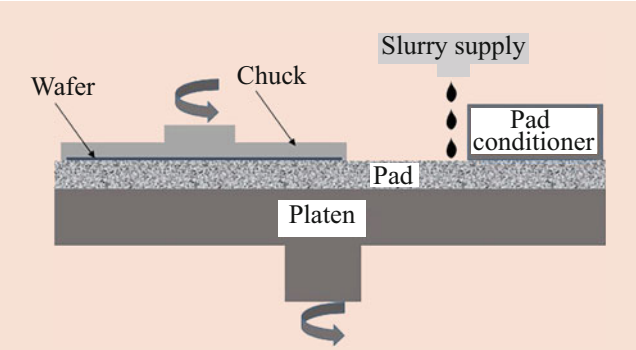

Fig. 1.29 A functional schematic of a CMP tool. A wafer is loaded onto the chuck in an inverted state. The chuck and/or platen may rotate as a slurry mixture is deposited upon the pad

Unlike other etch processes, CMP uses both chemical and abrasive methods to remove material as shown in Fig. 1.29. A slurry is utilized which can contain particulate to serve as abrasives and chemicals such as dilute HF. This slurry is deposited on a pad composed of a porous material which is mounted on a platen which may rotate. The wafer is mounted on a chuck which may then rotate in contact with the slurry and/or pad.

Since introduction, the CMP process has been incorporated into numerous front-end and especially back-end processes. The process is heavily reliant upon the slurry and pad characteristics, and these consumable items can represent a very significant cost to the manufacturing process. The CMP process is capable of angstrom-level control and can be end pointed through various techniques.

1.6.4 Etch Selectivity

In practice, it is difficult to find etch chemistries that can target a specific material and have non-zero etch rates in

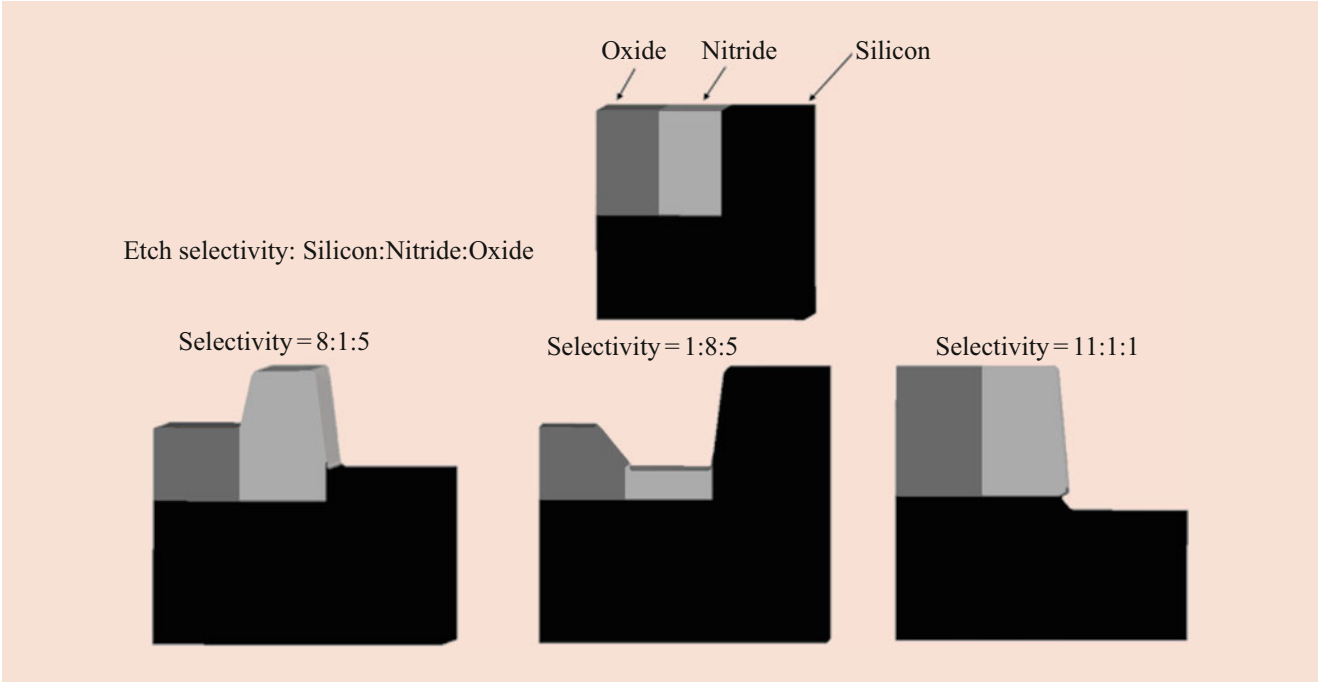

Fig. 1.30 An illustration of etch selectivity from a wet etchant. The selectivity is specified for silicon, nitride, and oxide materials and each material will etch a different amount during the same operation

all other materials. It is equally as difficult to find etch chemistries that etch all materials at the same non-zero rate. For this reason, etch processes are commonly classified by their etch selectivities to the different materials in the assembly, resulting in differences as shown in Fig. 1.30. This metric is fundamentally a measure of the ratio of etched material in one material to another.

It is also important to understand that semiconductor processes involve materials that may all informally be classified as the same material, but in actuality have far different properties. For instance, a thermal oxide will have different etch properties from a deposited oxide, and there may be a dozen of different recipes for deposited "oxides" which may all differ in etch rate and/or chemical composition. Experimentation is the key to determining an accurate sense of how an etch process will behave.

1.6.5 Atomic Layer Etch

Atomic layer etching (ALE) is a relatively new technique for etch operations in semiconductor processing. This technique has exhibited extremely high selectivities for certain applications with precise angstrom-level controllability. ALE relies upon alternating self-limiting reactions performed in a cyclical manner. Etches can be specified by the number of cycles. The process is becoming heavily utilized in R&D areas of semiconductor process development, and it is foreseeable that it will see some commercial adoption in the future.

1.6.6 The Coloring Problem

Semiconductor features are becoming so small that, in many cases, very high etch selectivities are required. Ideally, it would be possible to target etches that would remove a layer with infinite selectivity to all other materials present; however, this is not the case. Technology developers, instead, rely upon materials which have highly selective etches to all other common materials. Unfortunately, the list of these materials is quite short which limits the ability of technology designers to implement new features or requires them to utilize additional expensive patterning operations to protect some region of the semiconductor die from etchants. This problem is commonly referred to as a coloring problem.

1.7 Lithography

Lithography is the process by which patterning is introduced to semiconductor assemblies. When one refers to the process node, it is a reference that historically has some correlation to the smallest feature which can be lithographically imaged. While lithographic challenges in future technology nodes associated with the light source are perhaps the most documented and discussed, challenges exist in regard to resist chemistry, resist processing, mask formation, and optics as well. Therefore, it is vital to discuss these concepts in conjunction with each other and take a holistic approach to lithography technology.

1.7.1 Fundamental Lithographic Process

The fundamental goal of lithography for semiconductor processing is to pattern a region on a semiconductor assembly in a repeatable and prescribed manner (Fig. 1.31). In its most basic form, a semiconductor lithographic process entails the exposure of a light-sensitive chemical, commonly referred to as photoresist or simply resist, which is placed atop a semiconductor assembly. This exposure is performed through a patterned photomask which enables the transmittal of light in some regions and prevents it from others. In this manner, the pattern of the photomask is transferred to the resist on the semiconductor assembly like in Figs. 1.31 and 1.32.

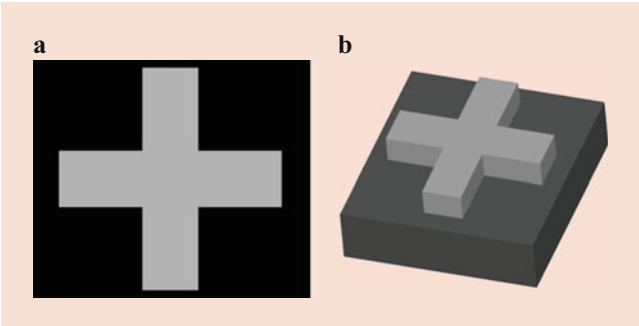

Fig. 1.31 (**a**) top down view of lithographic mask, (**b**) 3D view of patterned feature using a lithographic process with the same mask

1.7.2 Lithographic Constraints Due to Light Source

While this text is not going to go into great depth to explain the physics underlying light at the nanometer scale, a basic understanding of the role of the light source may be obtained by considering the Rayleigh criterion. Where R is the resolution provided by the light source, $k1$ is a parameter related to processing factors such as defects associated with the resist and the use of resolution enhancement techniques, λ is the wavelength of the light source, and NA is the numerical aperture of the projection lens.

$$R = \frac{k1 * \lambda}{\text{NA}} \tag{1.7}$$

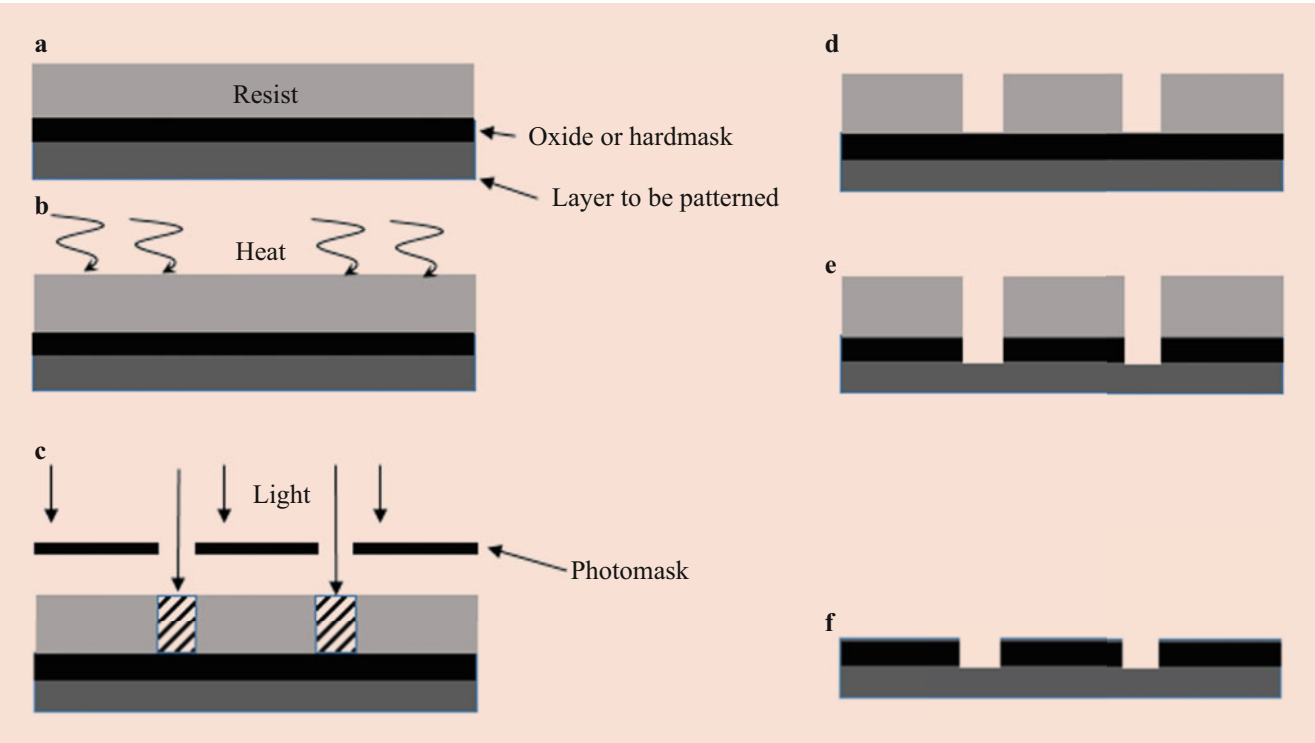

Fig. 1.32 Usage of photoresist in a lithographic process. (**a**) Photoresist is deposited on an assembly with typically a spin-on process. (**b**) The deposited resist is thermally baked to reduce defect-causing solvents from within it and to improve adhesion to the substrate. (**c**) The resist is exposed through a photomask to light; (**d**) the resist is subjected to an additional bake step and developed to remove either the exposed or unexposed resist; (**e**) the underlying structure may be processed (etch, implant, deposit, etc.); (**f**) the resist is stripped

This single equation explains both the industry focus on reducing the wavelength of the incident light and focus on providing high-quality optics for lithography operations.

1.7.3 The Role of the Stepper/Scanner and Impact to Feature Resolution

A stepper is a tool used in the lithographic processing of semiconductor wafers which provides the light to expose the photoresist on the wafer through a photomask. Stepper is an acronym for step-and-repeat camera which further indicates that it processes only part of the wafer at a given time, versus the entire wafer as was done in the early years of semiconductor manufacturing. Scanners are advanced versions of steppers that move the mask and wafer in opposing directions and can utilize smaller lenses. These are typically some of the most expensive tools in a fab.

The light source provided by the illumination system in the stepper has a characteristic wavelength determined by how the light was generated. Over the past roughly 30 years, the industry has moved from 436 nm g-line, to 365 nm i-line, to 248 nm krypton fluoride (KrF) laser, to 193 nm argon fluoride (ArF) laser as light sources have been unable to resolve increasingly small details required by advancing process nodes. By examining Rayleigh's criterion, and noticing that resolution is directly proportional to the wavelength of the light source, the reasoning behind this progression becomes apparent. Indeed, in 2018, we now find ourselves at the cusp of the next transition which is expected to be to a 13.5 nm EUV light source.

The numerical aperture of the projection lens is also an important part of Rayleigh's criterion and is representative of the ability of a lens to collect light. Namely, the resolution is inversely proportional to the numerical aperture and a lens with a higher numerical aperture will be able to resolve smaller features.

1.7.4 The Role of Resist in Lithographic Process

As previously explained, resist is a light-sensitive polymer which is used for photolithographic imaging. A resist can be classified as either negative or positive tone which reflects respectively whether the exposed or unexposed areas of the resist are polymerized and become more difficult to remove. In addition to tone, resists are characterized by the critical dimension they can image, the light wavelength and dosage required for exposure, and parameters related to how it spins on and adheres to the substrate. Resists which are suitable for one wavelength of light or one application may not be suitable for a different wavelength or application. For instance, finding low dose resists is one of main limiters to adoption of EUV.

1.7.5 Lithographic Enhancement Techniques

Phase Shift Mask

Phase shift masks (PSM) are photomasks that are designed to locally introduce a shift in the phase of the light which is transmitted through them. In a standard or binary mask, chrome or other opaque absorber materials are utilized to change only the intensity of the light which is transmitted through a transparent material of constant thickness. As features become smaller and closer in pitch, the diffractive effects of light transmitted through a binary mask increasingly prevent the resolution of small features. A phase shift mask operates differently by changing both the intensity of the transmitted light, like a binary mask, and also the phase of the transmitted light in localized regions where enhanced resolution is required.

To understand this physically, one must consider the phase angle of transmitted light. Light which is transmitted through quartz regions of differing thicknesses will emerge with different phase angles. Phase shift masks which rely upon this effect are commonly referred to as alternating phase shift masks (altPSM). Likewise, light which is transmitted through different materials or a stack of different materials may also undergo a phase shift relative to light which is transmitted through a single transparent material of the same thickness. Phase shift masks which rely upon this effect are commonly referred to as attenuated phase shift masks (attPSM) as shown in Fig. 1.33.

Optical Proximity Correction (OPC) and Inverse Lithography

OPC is a lithographic correction technique which compensates for diffraction effects and also for process-related effects which produce final patterned shapes which differ from those which appear on the mask as shown in Fig. 1.34. In-

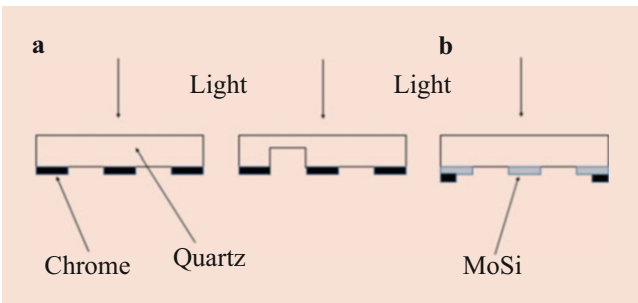

Fig. 1.33 Three types of photomasks. (**a**) A conventional or binary mask which relies upon light intensity only to pattern images. (middle) An alternating phase shift mask which changes the thickness of material through which light is transmitted to introduce a phase shift in the transmitted light. (**b**) An attenuated phase shift mask which utilizes a semitransparent material such as MoSi to induce a phase shift in the transmitted light

Fig. 1.34 A simple example of OPC correction. A rectangular shape is desired; however, an ellipsoidal shape is produced due to diffraction and processing effects. These effects can be partially compensated through the use of alternative shapes on the initial mask

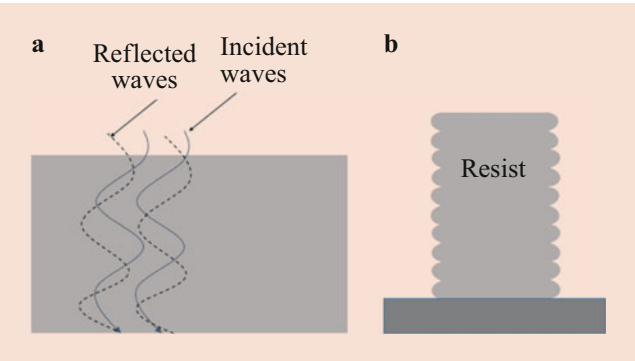

Fig. 1.35 (**a**) An example of reflected light created by exposure of photoresist without an antireflective coating (ARC) used. The ARC layer serves to absorb the light after it penetrates the resist and prevent or minimize the formation of reflected waves. (**b**) An example profile of a standing wave profile formed into the sidewall of an exposed resist feature

verse lithography (ILT) is the field associated with providing mask representations necessary to create desired features or solving the OPC problem in inverse. These fields are heavily reliant upon automated software tools such as those provided from EDA vendors. OPC correction and ILT are very time and computationally demanding and are being increasingly performed on more lithographic layers at each process node.

Antireflective Coatings

Antireflective coatings (ARCs) or bottom antireflective coatings (BARCs) are materials which are deposited in conjunction with a photoresist to minimize the reflection of light back into the unexposed resist. This serves to enhance the resolution of the lithography technique and minimizes the formation of standing wave patterns which may form from exposure to phase shifted light reflected from beneath the resist layer, demonstrated in Fig. 1.35.

1.7.6 Multiple Patterning Approaches

Single patterning 193 nm immersion lithography enables the formation of features to roughly 40 nm half-pitch. In order to enable continued scaling of device features in the absence of a viable EUV lithography solution for sub-30 nm process nodes, alternative means of forming sub-resolution features have been devised. Common techniques to accomplish this are pitch division, spacer-based approaches, and implant-based pitch division methods.

Pitch Division Methods

The most basic form of pitch division is to divide a desired pattern to be imaged, which contains sub-resolution features, into individual masks such that there are no features on any individual mask which are closer than the resolution limit of the lithography tool as shown in Fig. 1.36. This approach was the first one taken to image sub-resolution features for CMOS processing. Two similar approaches have been developed based upon this idea: litho-etch-litho-etch (LELE) and litho-freeze-litho-etch (LFLE) [5]. Both of these approaches add additional operations to achieve sub-resolution features. In particular, the lithography patterning is repeated in both processes and presents a challenge in terms of alignment or registration of these operations. These alignment challenges and increased count of processing operations are significant limiters to adoption of these techniques.

Litho-Etch-Litho-Etch (LELE) Pitch Division

LELE processes entail two litho operations and two etch operations to image a single layer. A common LELE process will begin with the deposition of two hardmask layers which are individually patterned to assemble the composite pattern. A process flow for this technique is shown in Fig. 1.37.

Litho-Freeze-Litho-Etch (LFLE) Pitch Division

LFLE is very similar to the LELE process in that it utilizes two lithographic operations, but it eliminates one etch process and requires only a single hardmask layer to be deposited. This operational count reduction is the chief advantage of this technique versus a LELE process. A LFLE process does require a specialized thermal or chemical freeze treatment to prevent shrinkage of the first patterned layer during the processing. A process diagram of this technique is shown in Fig. 1.38.

Triple Patterning and beyond

A logical extension to the LELE and LFLE approaches is to add additional lithography/freeze/etch operations. Triple patterning is a broad classification which encompasses

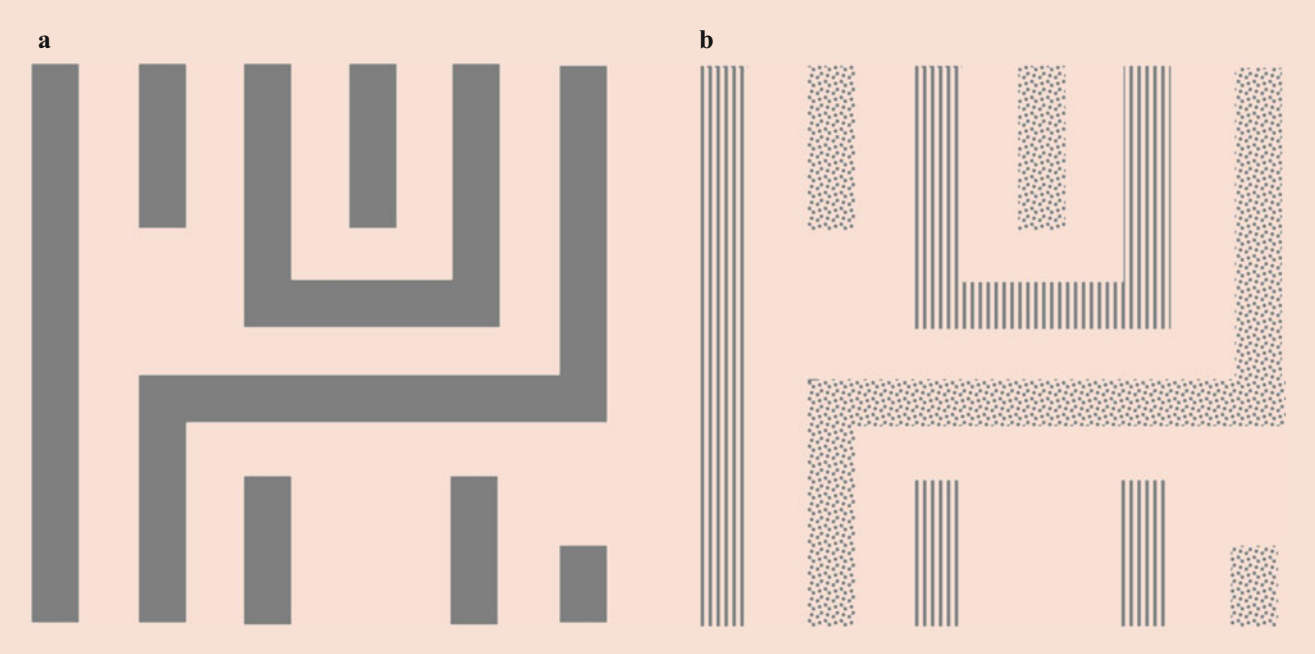

Fig. 1.36 Example of mask decomposition for a double patterning approach. The features of the pattern (**a**) are located closer than can be resolved with the lithography tool and the mask is decomposed into two separate masks (**b**)

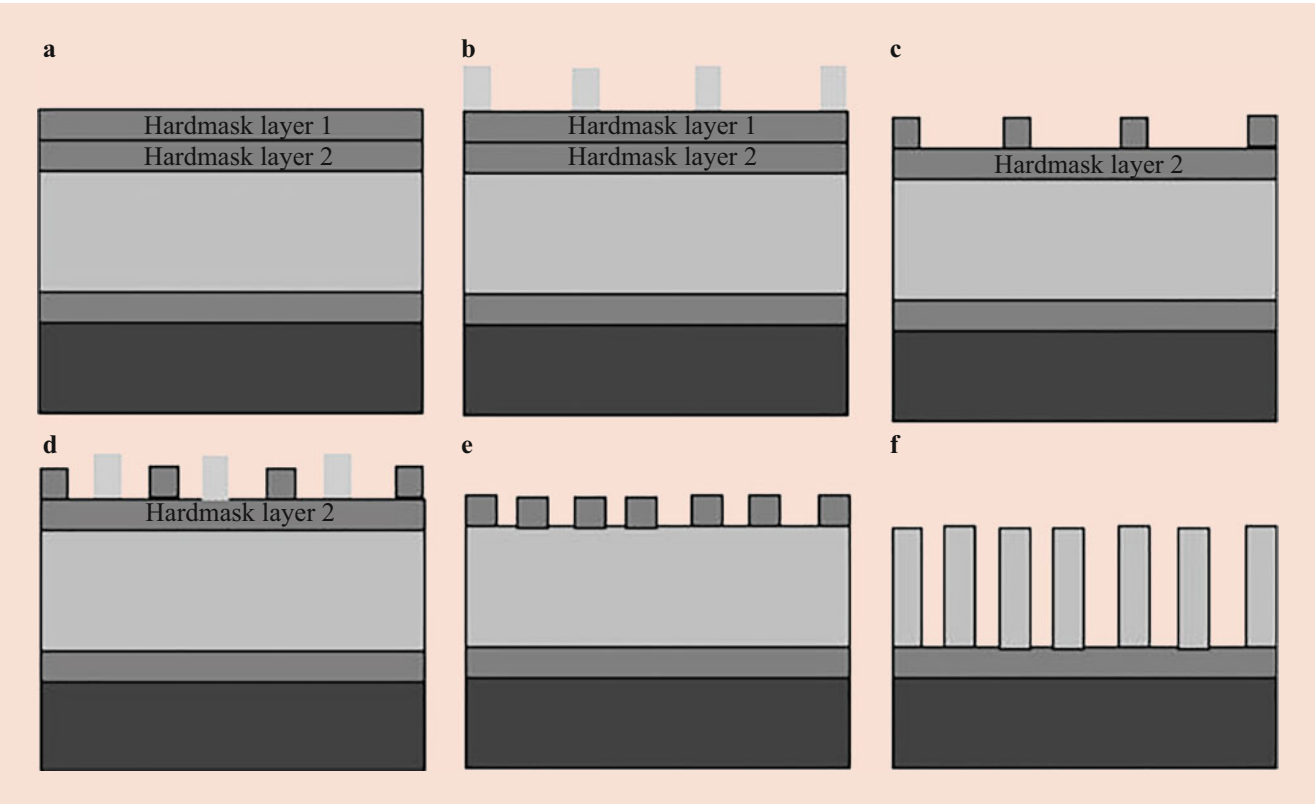

Fig. 1.37 Operational flow for a LELE patterning process. (**a**) Two hardmask layers are deposited atop the layer to be patterned. (**b**) A first pattern is lithographically printed. (**c**) The first lithographic pattern is used to pattern the first hardmask layer. (**d**) A second pattern is lithographically printed. (**e**) The second hardmask layer is patterned with the composite pattern from the first and second lithographic operations. (**f**) The layer is patterned

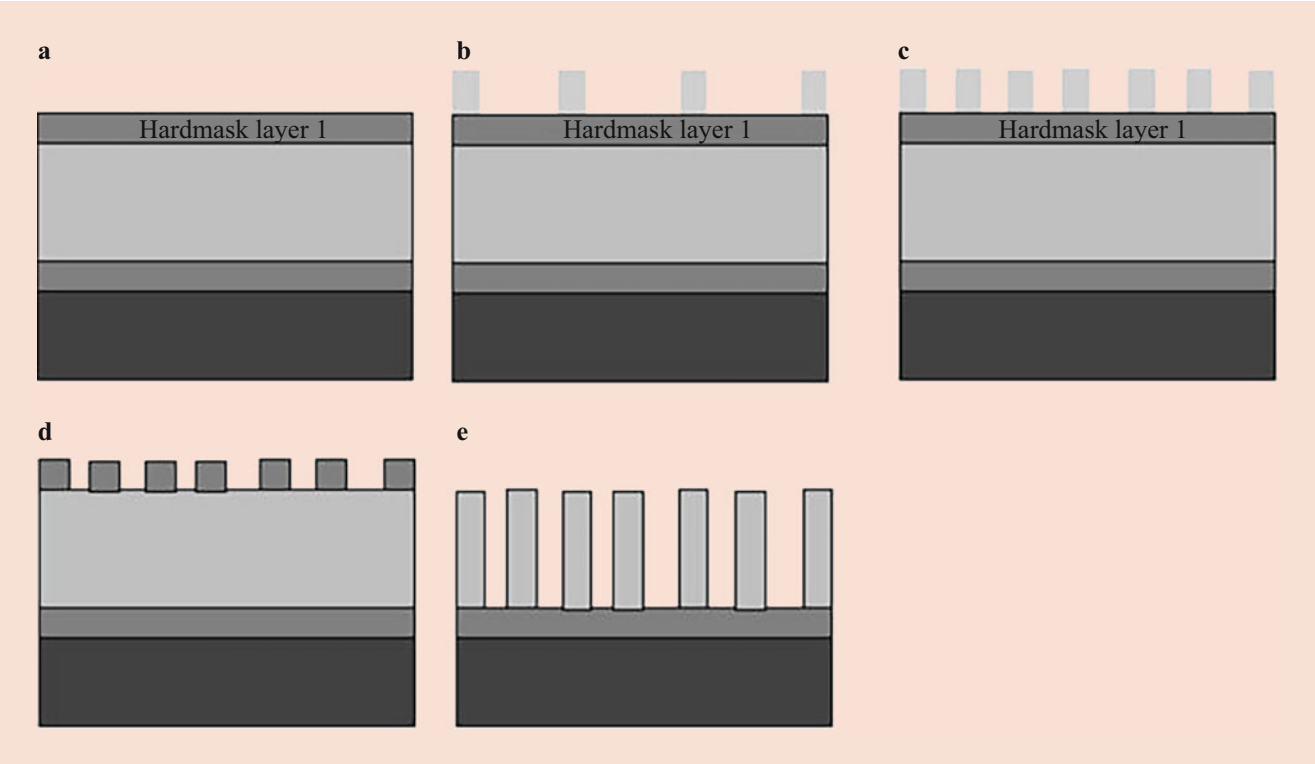

Fig. 1.38 An example LFLE process flow. (**a**) A hardmask layer is deposited atop a layer to be patterned; (**b**) a first lithographic set of patterns are printed; (**c**) the first resist features are frozen, a second resist is deposited, and a second set of lithographic patterns are printed; (**d**) the hardmask layer is etched with the lithographic patterns of both the first and second lithographic patterns; (**e**) the layer is etched

techniques utilizing three lithographic operations for imaging of a single layer. Techniques such as litho-etch-litho-etch-litho-etch (LELELE) have been proposed as EUV alternatives for sub-10 nm process nodes. As these processes are scaled to additional lithographic operations, the alignment problems become increasingly more severe, the process count increases, throughput decreases, and the challenges placed upon EDA software tools for mask decomposition become increasingly complex.

Spacer-Based Pitch Division

Deposition and etch processes have process control which is tighter than the resolution limit of 193 nm lithography. In a spacer-based pitch division process, an initial feature is imaged with a mask called a mandrel. Deposition and etch processes are then utilized to create spacers about this original feature which may then be utilized as masking layers to a subsequent etch process. This technique and variations are variously referred to as self-aligned double patterning (SADP), sidewall image transfer (SIT), pitch halving, or spacer patterning. Spacer-defined pitch division methods have a key advantage versus other pitch division approaches in that the divided pitch features are self-aligned to the mandrel features and are not prone to lithographic misregistration. A process flow for this technique is shown in Fig. 1.39.

The SADP process has been successfully utilized to form features at sub-20 nm half-pitch. The process of Fig. 1.39 is typically used with a trim mask to define the spacer features to be printed. Significantly, however, this SADP process entails far more operations than does a single exposure lithographic process which results in reduced throughput and increased processing cost. The burden of this process has been shifted from a lithography constraint to etch and deposition constraints, and etches of high selectivity are required. In addition to these processing constraints, it also becomes very difficult to form features which are bidirectional with SADP and layouts may require unidirectional features. Finally, SADP requires spacer features to be minimal size, whereas that constraint does not exist for other pitch division approaches.

Self-aligned quad patterning (SAQP) approaches have been derived from the SADP process. In these processes, a second spacer region is formed on a backbone of first spacer features. SAQP processes have been proposed as a means to achieve features at the 7 nm half-pitch process node. In practice, the line spacings of these spacer-defined patterning approaches are reliant upon the process control and variability of the spacer deposition and etch, and a degree of variability is introduced with each cycle of operations.

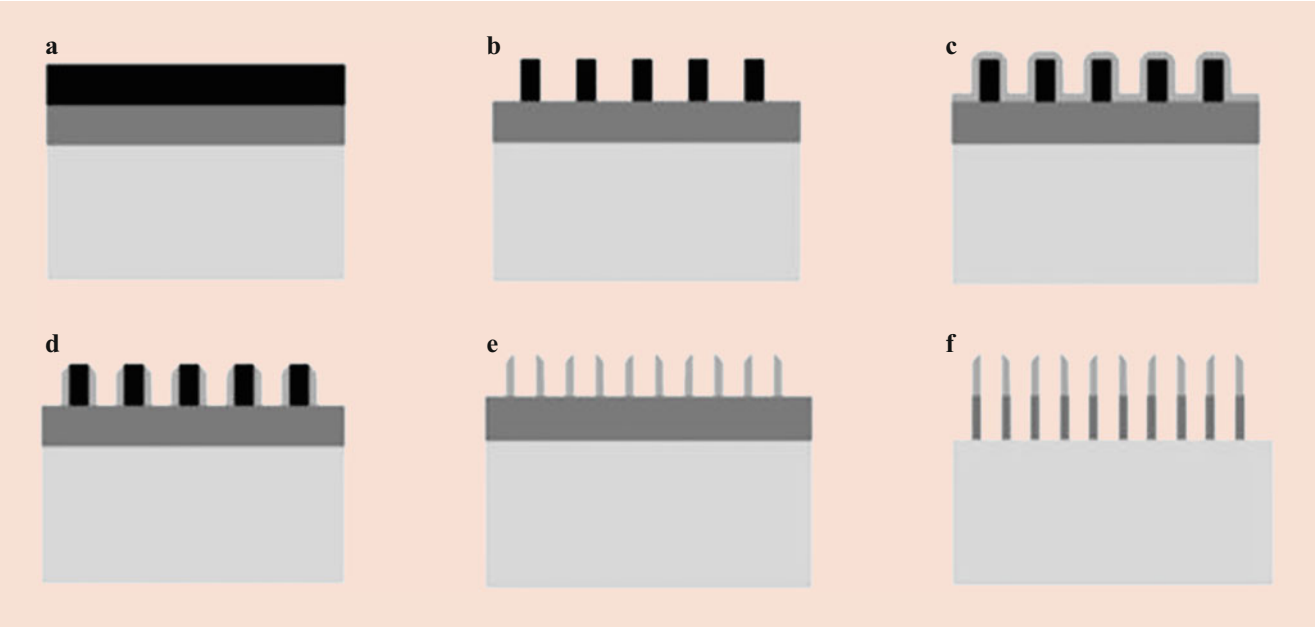

Fig. 1.39 An example of a SADP process. (**a**) Resist and lithography layers are deposited upon an assembly; (**b**) a mandrel mask is used to form a first patterned layer; (**c**) a conformal or isotropic deposition is utilized to deposit a layer about the surface containing the mandrel feature; (**d**) a dry etch is used to form spacer features on the sidewall of the mandrel feature; (**e**) the mandrel feature is removed with an etch which is highly selective to the spacer material; (**f**) a second dry etch is performed which utilizes the spacer features as a masking layer. By completing this process, the pitch between adjacent features can be effectively halved

Implant-Based Pitch Division

Another technique for pitch division uses a self-aligned tilted ion implant (TII) process to pattern and modulate the etch properties of an etch-block layer. This etch rate modulation may be driven by either a damage-based mechanism or an impurity-enhanced etch rate mechanism. Specifically, an argon implant has been demonstrated to modulate the etch properties of a silicon dioxide layer and is self-aligned through an ion beam shadowing process off of a mandrel feature which is controlled by the tilt of the ion beam relative to the wafer surface. An exemplar process flow of this technique is shown in Fig. 1.40.

The principal advantages of an implant-based pitch division process versus other multi-patterning approaches are the reduction in operational count and associated improved throughput. In practice, this technique has several challenges and has not seen widespread adoption. The most significant challenge associated with this technique is related to the implant profile which is neither laterally abrupt (due to lateral ion scatter) nor vertical (due to the ion beam tilt). The tilted ion implant also scatters at the corners of the masking layer to implant the entirety of the area between the patterns to some extent and will erode the corner of the masking layer at higher doses through a sputter process. Another concern with this technique is the etch selectivity of the masking layer is not binary to impurity concentration and typically not sufficiently high relative to the unimplanted region. This results in implant-defined mask features which are non-vertical and often possessing nonlinear sidewalls. These effects are shown in Fig. 1.41.

1.7.7 Post-optical Lithographic Techniques

A variety of techniques have been proposed as replacement for optical lithography utilizing 193 nm light sources. These include EUV, nanoimprint lithography, and direct self-assembly approaches. Each of these techniques have their merits; however, they all also currently have challenges associated with their adoption.

Extreme Ultraviolet Lithography (EUV)

EUV lithography is considered a key enabler for future device scaling and appears to be at the cusp of limited adoption for the sub-10 nm process nodes. This technology has been under development since the 1980s (at the time referred to as X-ray lithography), but adoption has been deferred in the face of numerous tool cost, uptime, mask, and resist problems. In addition, engineers have continuously pushed out the limits of 193 nm lithography using some of the resolution enhancement techniques previously mentioned. When EUV is adopted, it is likely to only be utilized for a few select tight-pitch layers such as those for local interconnect, with the remainder of the lithographic operations being performed on legacy tools.

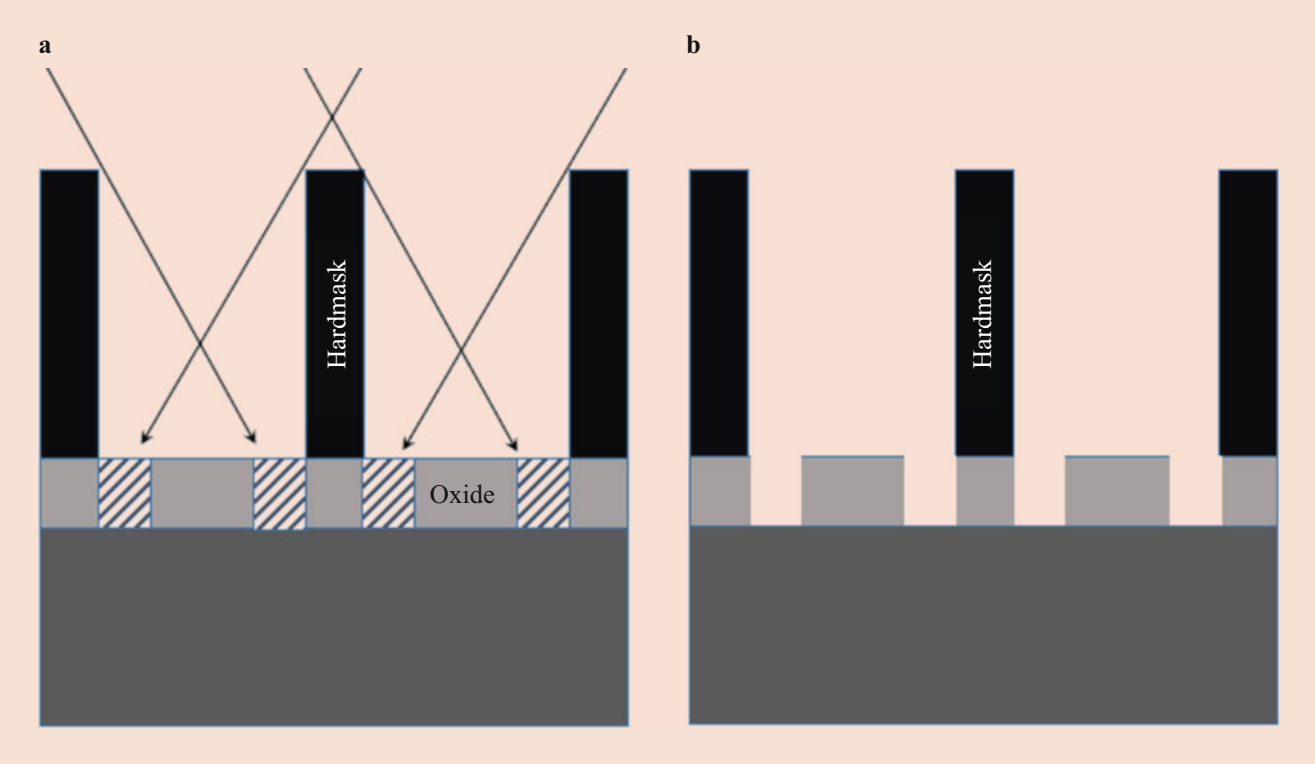

Fig. 1.40 Ion implant-based pitch division approach. (**a**) A hardmask or implant blocking layer is patterned at a loose pitch. These patterned features serve to enable shadowing of subsequent tilted implant operations. Two tilted ion implant operations are then performed at 180 degrees rotation to each other. (**b**) These implants are used to modulate the etch rate of an implanted layer which lead to preferential removal of the implanted region of that layer

Nanoimprint Lithography

Nanoimprint lithography (NIL) is a means of using a physical mold to imprint features into a resist layer or other polymer as shown in Fig. 1.42. This technique has been applied to NAND flash processing by Toshiba and has been proposed as an alternative to EUV for sub-10 nm technology nodes. NIL processes, in comparison to SADP/SAQP or pitch division approaches, utilize relatively simple equipment and are very cost efficient as they avoid the use of optical lithography tools. Variations to the NIL process pertain to whether the resist is cured with heat or with UV light and in regard to whether the contact operation displaces a resist layer or deposits a resist pattern. Tools have been developed for NIL which utilize either a wafer-scale imprint or a method which imprints a small area, moves to a new area, and repeats.

NIL technology does introduce a new set of integration issues related to the implant process. Specifically, adhesion between the template and resist is an issue. Adhesion can be minimized with the use of an anti-adhesion coating such as perfluorodecyltrichlorosilane (FDTS). In addition, the mechanical force to cause the imprint can lead to template wear; NIL is subject to gas bubble-related and density-related defects, and registration of the template to the target is an issue.

Direct Self-Assembly as Alternative Lithography

Almost every semiconductor company has investigated the directed self-assembly of a block copolymer (BCP) system as a means of nanolithography. The most common material system currently utilized is based upon the polystyrene-block-polymethylmethacrylate (PS-b-PMMA) system. DSA is not a stand-alone lithography solution; rather, it allows features patterned with an existing lithography solution to be self-aligned and/or pitch-divided.

DSA research focuses heavily on the ideas of chemoepitaxy and graphoepitaxy. In chemoepitaxy, brushes or molecules are grafted, or covalently bonded, to existing features on the target. These existing features would commonly be fabricated with a typical lithography/deposition/etch process. Graphoepitaxy then relies upon confinement created by the patterned features to self-assemble the block copolymer in a prescribed manner. This self-assembly is dictated by the phase diagram of the BCP system, the confinement, and the Flory-Huggins chi parameter. By altering the geometry, the ratio of the components in the BCP, or the chi value, it is possible to generate spheres, cylinders, gyroidal, or lamellae features in the self-assembled BCP. Selective chemical etches exist for the BCP components and

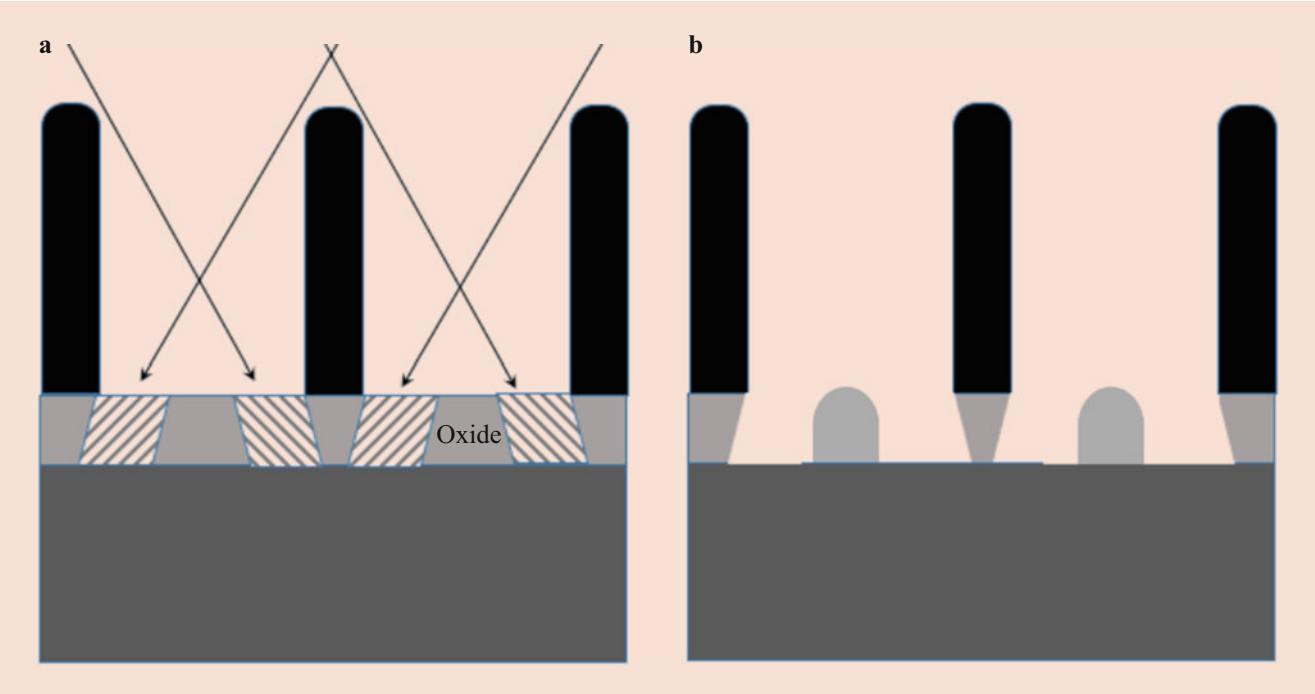

Fig. 1.41 Realistic implant and etch selectivity concerns are challenges to the integration of implant-based pitch division approaches. Ion implant as shown on the left does not result in vertical profiles. The corners of the masking features are rounded through a sputtering process and implant lateral straggle and implant scatter from the corners of the shadowing features into the nominally masked central region lead to rounded features being formed as shown on the right

various process flows have been proposed to utilize these behaviors for the formation of nanoscale features.

DSA does have numerous integration challenges. One main concern is in regard to finding a BCP system with sufficiently high chi value. Self-assembled geometries are also highly sensitive to defects or geometry fluctuations which can produce, in some cases, geometries and patterns that fluctuate dramatically both laterally and in the thickness dimension.

Electron Beam Lithography

Electron beam lithography is occasionally touted as a replacement for optical lithography. This process scans a focused electron beam onto a photoresist covered surface to pattern features. The chief advantage of e-beam lithography is that sub-10 nm resolution is possible. Indeed, e-beam lithography is used to pattern the masks used in other forms of optical lithography. However, this comes at a severe cost in throughput. A modern stepper or scanner can process hundreds of wafers per hour, while an e-beam tool would require many hours to expose a single wafer which makes these systems impractical for high-volume manufacturing (HVM) use. Attempts to productize these systems for HVM manufacturing have been undertaken in the past with very limited success.

1.8 Metalization and Contact Formation

Fabricated transistors require metal contacts and metal routing to form CMOS or VLSI circuitry. A modern CPU may contain more than 60 miles of metal wires within a package that is roughly the size of your thumbnail. This metal wiring distributes power, clock, and signal to form the VLSI circuitry through which CPUs and logic devices are formed. Metal routing in a traditional CMOS process utilizes a tiered metal system which begins with contact made to the transistor itself and terminates with contacts provided to the outside world through the package.

1.8.1 Silicide Contact to Transistor

A good contact to a transistor should provide a low barrier height to charge transport and be composed of a low resistivity metal. The contact should also be formed in a manner which does not deleteriously impact the already formed devices. These contacts may differ from NMOS to PMOS transistors as different metals may provide more optimal barrier heights; however, this comes at the cost of additional lithographic and other process operations.

Metal silicides are commonly utilized for contact to the source and drain regions of a silicon transistor. Silicide has

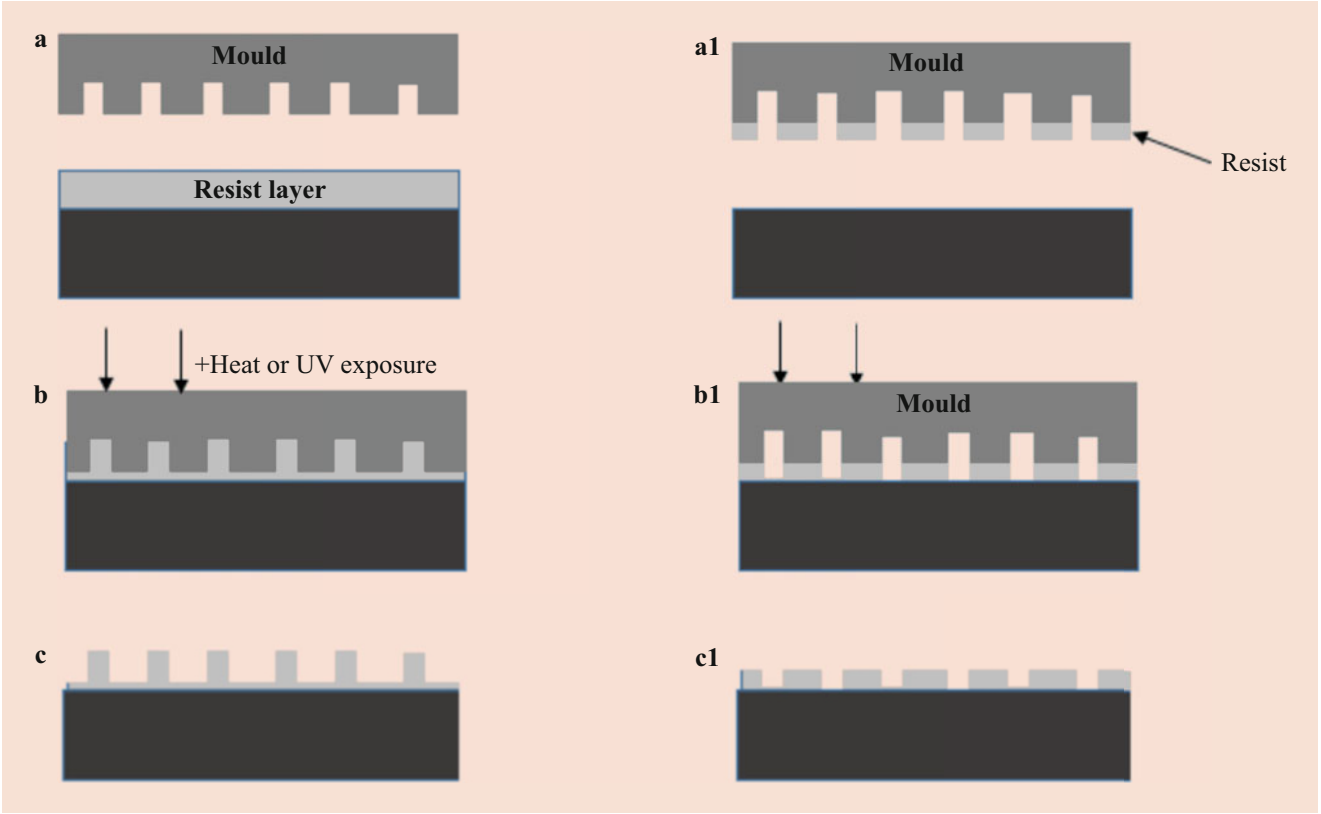

Fig. 1.42 Different NIL process flows. At the left are shown the steps in a UV or thermal NIL process. (**a**) A resist is deposited on a target wafer and planarized and a mold is prepared. (**b**) The mold is imprinted into the resist, and heat or UV light is applied to the assembly; (**c**) the mold is removed leaving the patterned resist. At the right is shown a nanocontact NIL process which is similar; (**a1**) resist is placed upon the features of a mold; (**b1**) the mold is contacted to the target; (**c1**) the mold is removed leaving the patterned features

also historically been utilized for contact to a polysilicon gate or for complete silicidation of a polysilicon gate (FUSI). A silicide is simply a compound formed by a metal and silicon atoms. Similarly, for a germanium-based transistor, a germanide could be formed. The process to form a silicide or germanide is as simple as depositing metal upon an exposed semiconductor surface and annealing the assembly, like it is shown in Fig. 1.43. The electrical barrier between the silicide and semiconductor may be further lowered by providing a high level of active doping adjacent to the silicide/semiconductor interface. This doping may be introduced by forming a contact to a highly doped and activated epitaxial layer or by implanting and activating dopant atoms about this interface. The area of the contact between the silicide and the semiconductor may also be increased to reduce the contact resistivity.

The silicide process does, however, have several technological impacts. Firstly, the contact resistance between the silicide and the semiconductor is not negligible and increasingly is becoming one of the major bottlenecks to CPU performance and power consumption. The resistance of the contact is, in part, determined by the phase of the silicide with different phases being more optimal. For instance, nickel deposited on silicon may form several different phases of silicide depending upon how it was annealed and factors concerning the metal deposition such as NiSi, Ni_2Si, and $NiSi_2$. Silicides formed with these contacts may differ in resistivity by a factor of nearly 2.5. A second concern is in regard to semiconductor voids which form in proximity to the silicided region. This concern is especially prevalent for silicide phases which are silicon rich. A third concern is the thermal processing required to form the desired silicide phase that must have a minimal impact upon the already formed device features, in particular, the gate stack and gate dielectric thickness. Finally, the silicide needs to be thermally stable to back-end metallization and packaging thermal processes.

1.8.2 Interconnect Stack

A complex CMOS process will utilize numerous layers of metal (Fig. 1.44). The first couple layers closest to the transistor are used for forming interconnect between transistors and are referred to as local interconnect. The upper layers are referred to as global interconnect and used for routing across the die. Vias are metal interconnects which connect metal from one level to another.

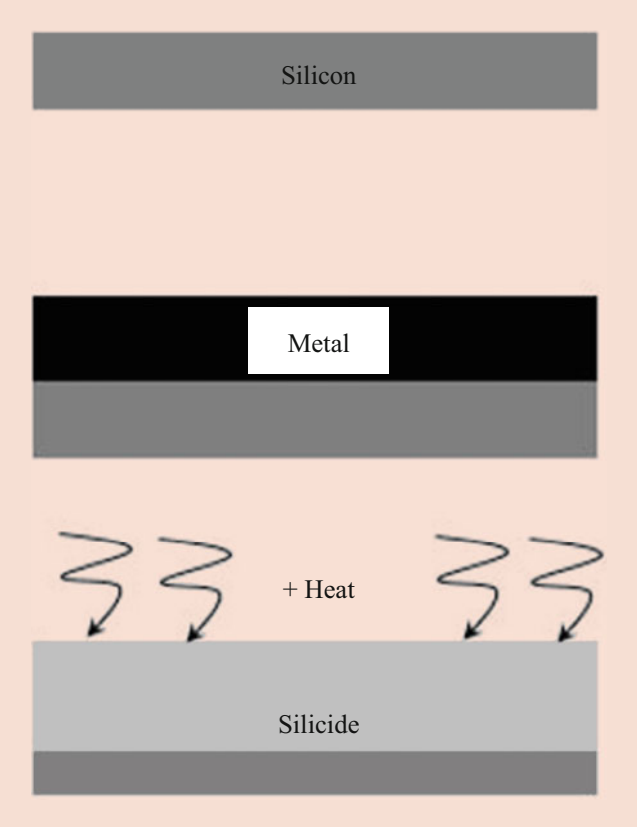

Fig. 1.43 A sample silicide process. A metal is deposited upon a silicon surface which is then thermally annealed to form the silicide

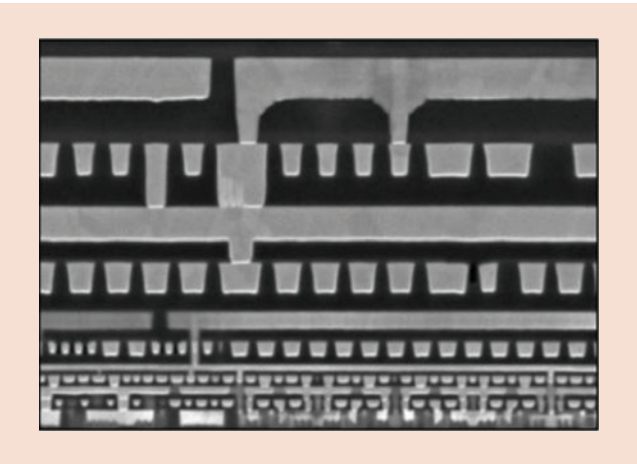

Fig. 1.44 Interconnect stack from 14 nm Intel process

Of critical concern are the local interconnects which are thinnest and spaced closest together. As devices continue to scale, the pitch and CD of these local interconnects also continue to scale. Historically, these metal layers were formed of aluminum. At the 180 nm process node, IBM transitioned from aluminum to copper interconnect as copper has lower resistivity and improved electromigration tolerance. The industry followed shortly thereafter.

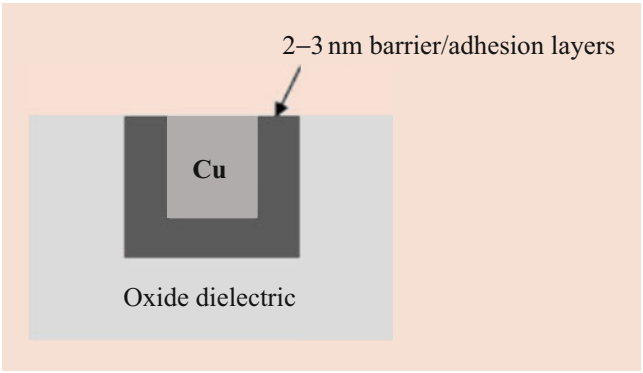

Fig. 1.45 Copper interconnect layers require barrier and adhesion layers of 2–3-nm thickness. As metal lines scale, an increasing fraction of the metal line volume is consumed by the barrier and adhesion layers

This transition to copper interconnect presented several challenges as copper has a high diffusivity in dielectric layers which necessitate the use of barrier and adhesion layers for copper metallization and dedicated toolsets to prevent contamination. In order to prevent the diffusion of copper into dielectrics, liners such as TiN at thicknesses of 2–3 nm have been implemented (Fig. 1.45). With the scaling of metal CD to sub-10 nm values, this liner requirement allows copper width of only 4–6 nm. Because of this barrier requirement, in large part, Intel has recently announced that cobalt interconnect will be utilized for some local interconnect layers in their 10 nm process.

1.8.3 Damascene Metal Processes

With the introduction of copper interconnects and continued scaling of metal line pitch, damascene metal processes have become typical as shown in Fig. 1.46. In a damascene process, the dielectric layer is patterned and etched, and then the liner and metal layers are deposited. The metal deposition is commonly done through an electroplating operation which deposits and excess of metal. The structure is then subjected to a chemical mechanical polish/planarization (CMP) operation to planarize and remove the excess metal. A dual damascene process is similar except both the metal lines, and vias are filled during the metal deposition step.

1.8.4 CMOS Process Technology Development through Nontraditional Techniques

Recent CMOS technology nodes have delivered performance and density gains not just through traditional scaling but also

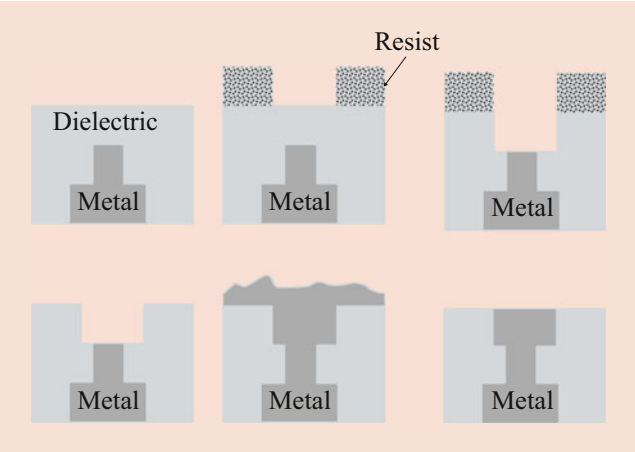

Fig. 1.46 An example of a damascene metal process. Instead of directly patterning the metal layer, the dielectric is patterned and filled, and then the resulting structure is subjected to a CMP operation. This figure does not show a liner layer; however, if a liner is required, it would be deposited prior to the metal layer

through the use of nontraditional techniques such as substrate engineering, hybrid semiconductor integration, stress engineering, different architecture, and gate stack engineering. It is expected that future process nodes will continue this trend, especially in the areas of architecture where numerous papers have been presented detailing gate-all-around architecture and vertical integration. It is important to understand the process-related implications of these techniques and understand how these ideas are being integrated into future technology nodes.

1.8.5 Substrate Engineering and Hybrid CMOS Integration

The integration of multiple semiconductor channel materials is a current major research area. By introducing different semiconductor crystals for the NMOS and PMOS regions of the die, the devices can potentially be optimized beyond what could be attained if they were both formed of the same crystal. Material properties such as carrier mobility, stress response, and band gap can be exploited to yield devices with both high electron and hole mobilities or devices which are more suitable for power/high voltage applications on die with other devices which are more suitable for low-power CMOS logic. The two major techniques for hybrid integration are epitaxially templated regrowth and wafer bonding.

Epitaxially Templated Regrowth Technique

Epitaxy has historically been a technique to introduce a dissimilar semiconductor grown from a seed of an original semiconductor. Epitaxially templated regrowth (ERG) or aspect ratio trapping (ART) is a technique which utilizes

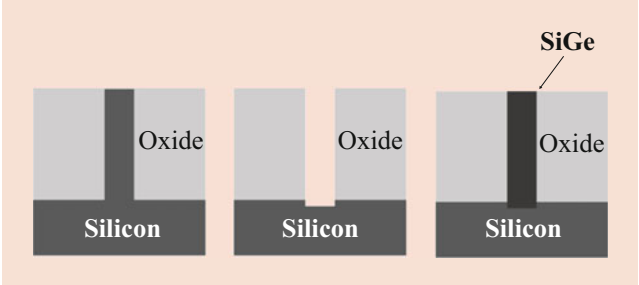

Fig. 1.47 An example of the ART/ERG technique of heterogeneous integration of multiple semiconductor systems on a single CMOS wafer. A fin, or other structure, is selectively etched to form a mold within a dielectric layer. An epitaxial layer is then formed from the seed left in the semiconductor layer with a second semiconductor that is lattice matched or nearly lattice matched to the seed material

epitaxy to form a new semiconductor region within a mold formed of a different material or insulator. This technique can be utilized to fabricate new device features at the same pitch and approximately the same aspect ratio as the material used to form the mold. As current CMOS technology is largely Si-based, these processes are of great interest as they provide a means to introduce already patterned III-V or Ge/SiGe single-crystal regions to an existing die patterned with silicon features.

An example process of an ERG/ART process is shown in Fig. 1.47 fabricated upon a silicon substrate. This process first entails the formation of silicon fin features which are surrounded by a dielectric material such as silicon dioxide. The fins are then selectively etched leaving the oxide behind to act as a mold and a silicon seed region remaining at bottom of the mold. The structure is then subjected to epitaxial process which grows a new fin within the mold comprising a different semiconductor crystal.

The ART/ERG process does have several drawbacks, however. Chief among these is the presence of crystal defects which may be nucleated at the interface between the epitaxial and substrate material. These defects are particularly problematic as they will continue in the epitaxial material until they are terminated at an interface. These defects are caused by lattice mismatch and strain energy introduced between the two semiconductor materials and become more severe as the lattice parameters become more dissimilar. For this reason, careful consideration is given to semiconductor materials for both the substrate and epitaxial layer, and the use of grading layers or seed layers prior to the deposition of the main epitaxial region is common.

Some defects from ART/ERG are unavoidable, however. By introducing taller fins formed within a deeper mold, the defects which run perpendicular to the fin length direction can normally be terminated and removed; however, the defects which run in the length direction of the fin cannot be trapped or terminated. If a device is then fabricated of a fin

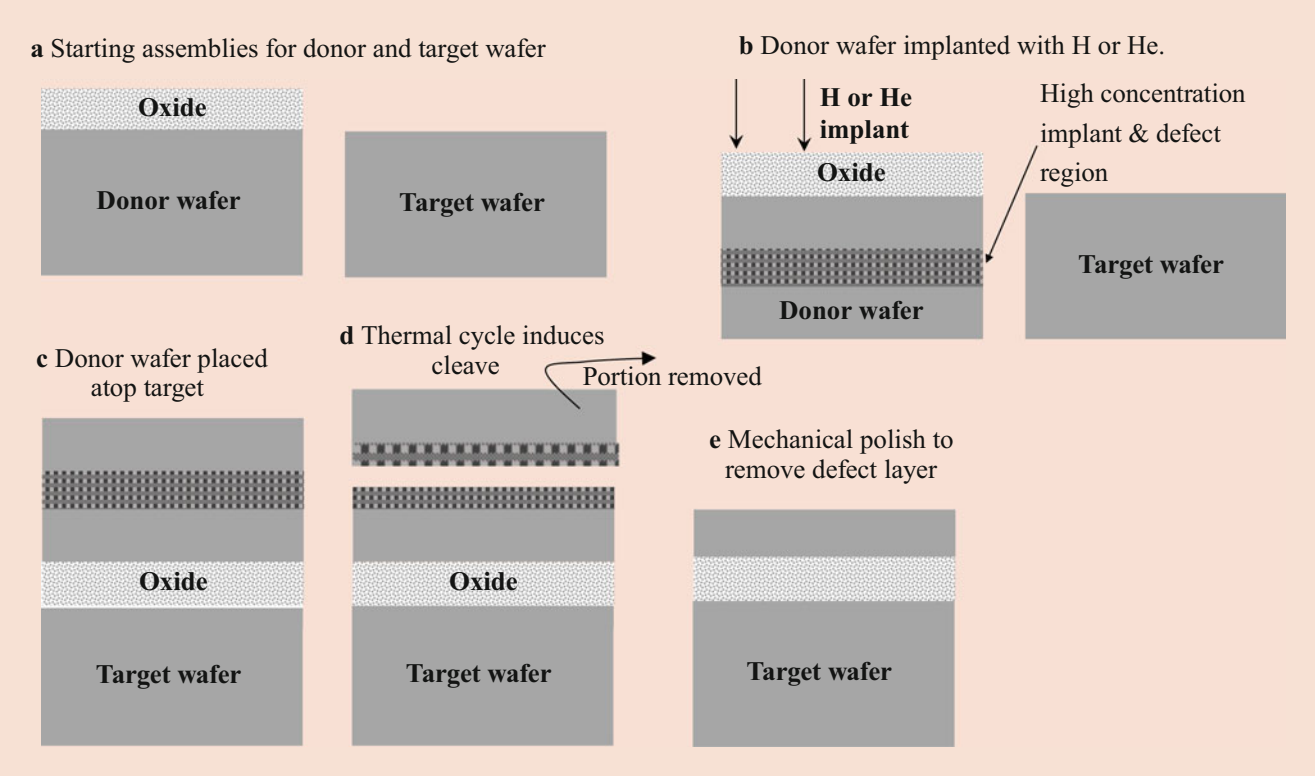

Fig. 1.48 An example of a layer transfer process using oxide bonding. There are several variants of this technique including various semiconductors, bonding layers, etch stops, and anneal sequences. This technique can result in the transfer of a relatively defect-free crystalline layer of a second semiconductor material atop a first semiconductor material

with such a defect running across a p-n junction or near the channel region of a device, an electrical leakage path will ensue which will degrade performance of the device and potentially render it unusable.

Wafer Bonding Technique

Wafer bonding is a technique used to introduce a blanket second semiconductor region atop a first semiconductor region. Unlike ART/ERG, these material systems do not have constraints on lattice parameters, and the second semiconductor layer may be introduced relatively free of crystal defects. However, this process results in the introduction of a second vertical layer or strata of semiconductor crystal. The semiconductor layers are separated by a dielectric layer which is used to bond them together and can also serve as electrical isolation between devices fabricated on the upper device strata from the lower device strata. As this technique involves the introduction of a vertical stack of semiconductors, it is of great interest to research areas involved with the vertical stacking of devices such as the complementary FET (CFET) process from IMEC.

There are several different methods of wafer bonding. In a common implementation, a donor wafer is processed with an oxide (or other bonding layer) deposition and a high-dose (5e16/cm^2–2e17/cm^2) H or He ion implant to form a region of percent level H/He atomic impurity concentration. The donor wafer is then placed oxide side down upon a second wafer and subjected to a series of anneal steps which serve to bond the oxide (or other bonding layer) to the second wafer and also to condense the H/He impurities into a narrow band of bubbles which then expand in volume and shear off a region of the donor wafer at a depth prescribed by the energy of the ion implant process. The transferred layer may then be polished to remove any defects associated with the implant process, and in some instances an epi etch-stop layer may be introduced into the donor material to facilitate this etch. The donor wafer may also be polished and reused many times for this process. This process is shown in Fig. 1.48. This process may be repeated multiple times to form many device strata.

Semiconductor-on-Insulator Formation

Variants of the previously mentioned layer transfer process have been commercially used to produce semiconductor-on-insulator (SOI) substrates. An alternative process uses direct ion implantation of oxygen into a silicon substrate and is referred to as separation by ion implantation of oxygen or SIMOX as shown in Fig. 1.49. This process demands very high doses of oxygen implanted at high energies and a significant anneal step. Variations of this process have been proposed for localized oxidation on a CMOS wafer.

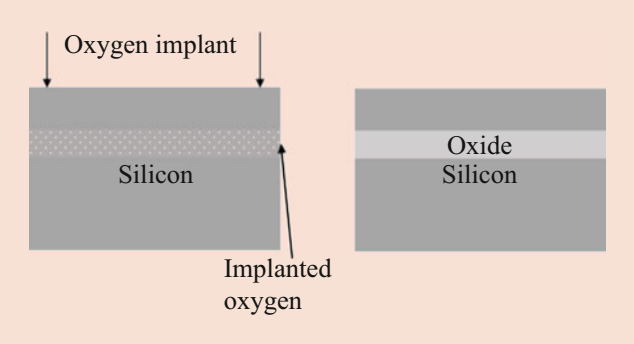

Fig. 1.49 An example of a SIMOX process. Oxygen is implanted at high doses and high energies into a silicon substrate to form a buried oxygen-rich layer. The structure is then annealed to form a buried oxide layer

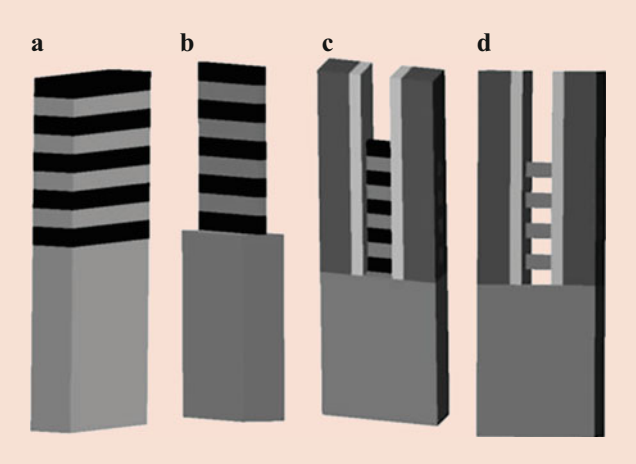

Fig. 1.50 A common process for the formation of a GAA transistor. (**a**) A series of alternating epitaxial layers are deposited upon a wafer with materials with high etch selectivity to each other (Si and SiGe are common); (**b**) fins are formed from this stack of epitaxial layers and a device is fabricated as would be done for a replacement gate process; (**c**) the sacrificial gate material is removed exposing the channel; (**d**) the sacrificial material is removed from the channel with a wet etch exposing the entire periphery of the nanowires. This step is done while the nanowires are stabilized by the source/drain and gate spacer. From this state, the processing is completed as normal with gate dielectric deposition and gate stack formation

Transistor Architecture Advances

The introduction of the FinFET or trigate device by Intel in 2011, with their 22 nm technology node process, was the first instance of a 3D transistor technology developed for high-volume manufacturing. Various industrial and research papers have indicated that the next architectural change is likely to be a transition to a gate-all-around (GAA) transistor. In addition, there have been several recent research papers looking at the vertical integration of transistors themselves. The two main approaches proposed for this are monolithic stacking and complementary FET (CFET) processes.

Gate-All-Around Transistor Structure Formation

The most common proposed process in literature for formation of a GAA transistor structure utilizes a series of epitaxially deposited layers on a blanket structure and a gate-last process. A fin is fabricated from this lattice structure, and the gate region is exposed with the source/drain region stabilized or a spacer in place as a stabilizer. A selective etch process is then utilized to remove one set of layers from the lattice structure in the gate region. From this structure, the gate dielectric can be deposited around the entire periphery of the individual wires, and a gate stack can be deposited atop that. This process is shown in Fig. 1.50.

Vertical Integration of Multi-Strata CMOS

Recently there has been a significant amount of research into means of placing transistors in a vertically stacked arrangement as a means to provide a new scaling vector. The two main approaches are a sequential monolithic stack such as used by LETI with their CoolCube™ architecture and the CFET approach from IMEC. Each of these approaches offer advantages and disadvantages.

The sequential monolithic stacked architectures such as CoolCube™ offer, perhaps, the simplest means to achieve 3D scaling. However, a sequential process comes at the cost of repeating virtually every operation in the front-end of the process which may minimize the cost savings. The density scaling provided by this approach, also, appears to be partially offset by the area required for inter-strata local interconnects. One of the main concerns with this approach is that the thermal processes of the second strata would deleteriously impact the electrical properties of the already formed devices and the development of a low-temperature process for the devices of the second device strata is a key enabler.

The CFET approach from IMEC utilizes a fin-over-fin monolithic approach with buried power rails. The proposed process for fabrication of this device places heavy emphasis on fill depositions and etch-back processes. This approach resolves several of the challenges associated with the CoolCube™ including challenges associated with local interconnects and enables a higher temperature process for the devices on the second device strata.

1.8.6 Stress Engineering

With the 90 nm process node, Intel was the first to utilize strain as a performance enhancer for a high-volume manufacturing CMOS process. In this process Intel utilized strain from a lattice mismatched epitaxial source/drain on the PMOS device (Fig. 1.51) and from a stressed cap layer on

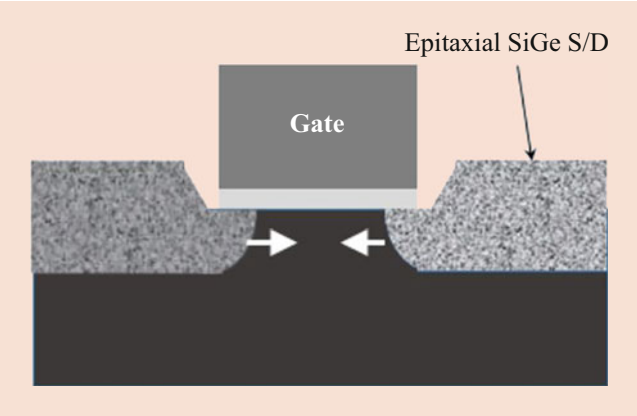

Fig. 1.51 An example of an epitaxial stressor inserted as a source/drain material for a PMOS transistor. The SiGe region has a larger lattice constant than the silicon region it is seeded from, and this serves to introduce a beneficial compressive stress within the PMOS channel

the NMOS device. Since this time, numerous other methods of introducing strain have been investigated including stress from dopants, dielectrics, and metals. It is likely that all future technology nodes utilizing silicon or other column IV semiconductors will utilize strain in some fashion, and it is important that these effects be considered when designing a process technology.

When considering stress in a transistor, the nuances of a process become of upmost importance. For instance, the same metal or film may be deposited with one of many different recipes, all of which will have a different stress associated with them. Stress effects may also diminish over distance from a free surface or geometry change; this can give a position-dependent stress response.

1.9 Summary

This chapter has introduced, at a very simplistic level, the fundamental processing operations utilized in the fabrication of CMOS integrated circuits and a brief introduction to foreseeable future trends in this field. Through these processes, it is possible to create nanometer-scale transistors and assemblies with the high degree of repeatability necessary for high-volume manufacturing.

Abstract

The aim of this chapter of the *Handbook of Semiconductor Devices* is to provide an overview on semiconductor-based memory technologies. A preliminary introduction will contextualize the topic considering the actual scenario of the memory ecosystem. Then, the chapter will describe the main volatile memory technologies, in terms of fundamental operating principles and memory array organization. In the following, the principles, the applications, and the roadmap of the main nonvolatile memory technology will be presented. A subsequent section will illustrate the phase-change memory (PCM) technology as example of emerging memory technology among various flavors that will be cited. The chapter will close with a forward looking considering the potential opportunities of emerging memory technologies in the field on in-memory computing and neuromorphic applications.

the information and data that man has created and that, thanks to the amazing retention time of some writing and imaging generation techniques, arrived up to us progressively increased. Coming closer to nowadays, the miniaturization of the digital computers that started ~40–50 years ago marked a dramatic exponential increase of data production and storing that does not show any hint to slow down. On the contrary, it is predicted to explode in the next years, asking more and more support to the semiconductor memory technology (see Fig. 2.1). Already actually, there are more than 2.5 exabytes of data created each day, and this trend is accelerating with the pervasion of the Internet of Things (IoT). We also would like to recall that the term Google is born from a misspelling of Googol, coined in mathematics to represent an incredibly high number 10^100, roughly corresponding to the total number of particles in our universe. This scenario depicts a context where semiconductor memories are occupying a more and more important role in the semiconductor technologies.

The aim of this chapter of the *Handbook of Semiconductor Devices* is to illustrate the actual scenario of semiconductor memory technologies; the chapter is organized as follows:

- The first section will provide a general introduction to sketch the classes of memory technologies in terms of volatile, nonvolatile, and emerging memories, their fundamental features, and applications.
- The second section will be a dig into the volatile memory technologies;
- the third section will be dedicated to explain the principles, the applications, and roadmap of the actual nonvolatile memory technology.
- The fourth section will deepen the phase-change memory (PCM) technology among the various flavors of emerging technologies, illustrating the device physics and architecture together with the main issues of PCM technology to challenge conventional nonvolatile memory solutions.
- The last section will be dedicated to the potential opportunities of the memory technologies in the field on in-memory computing and neuromorphic applications.

2.2 Semiconductor Memories Taxonomy

Semiconductor memory has always been an indispensable component and backbone of modern electronic systems. All familiar computing platforms ranging from handheld devices to large supercomputers use storage systems for storing data temporarily or permanently. Figure 2.2 reports in a tree structure the various typologies of semiconductor memories that can store data in the form of binary information (bits). It shows that a storage unit is distinguished into two main categories:

1. Volatile memory: it loses its data, when the power is switched off.
2. Nonvolatile memory: it is a permanent storage and does not lose any data when the power is switched off.

Two types of volatile memories, both invented more than 50 years ago, are listed: DRAM and SRAM. The class of nonvolatile memories is more expanded, including EPROM, EEPROM, flash, and ROM. In this variety, the present chapter will describe in detail the flash memories, as significant nonvolatile memory technology that serves today an actual computer system together with DRAM and SRAM.

They have been in fact circled in the scheme of Fig. 2.2 as objects of the description of their working principle and applications in the following of the chapter.

Since the functionality and performance of today's computing systems are more and more dependent on the characteristics of the memory subsystem, another memory taxonomy with respect to this usage can be illustrated. In this context, the solid-state memory system that currently serves

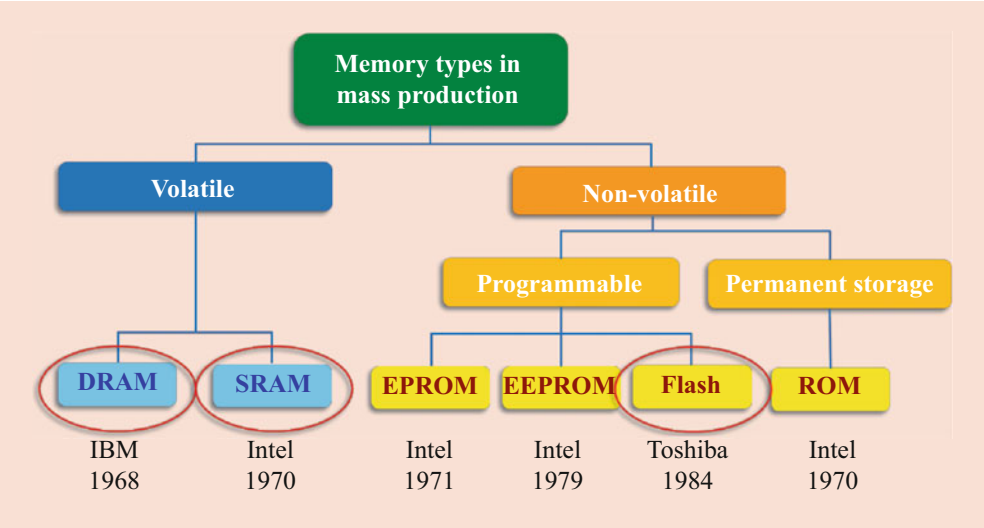

Fig. 2.2 Types of semiconductor memories that reached the mass production. The circled types of memory are the main memories that serve today an actual computer system and that will be described in the present chapter

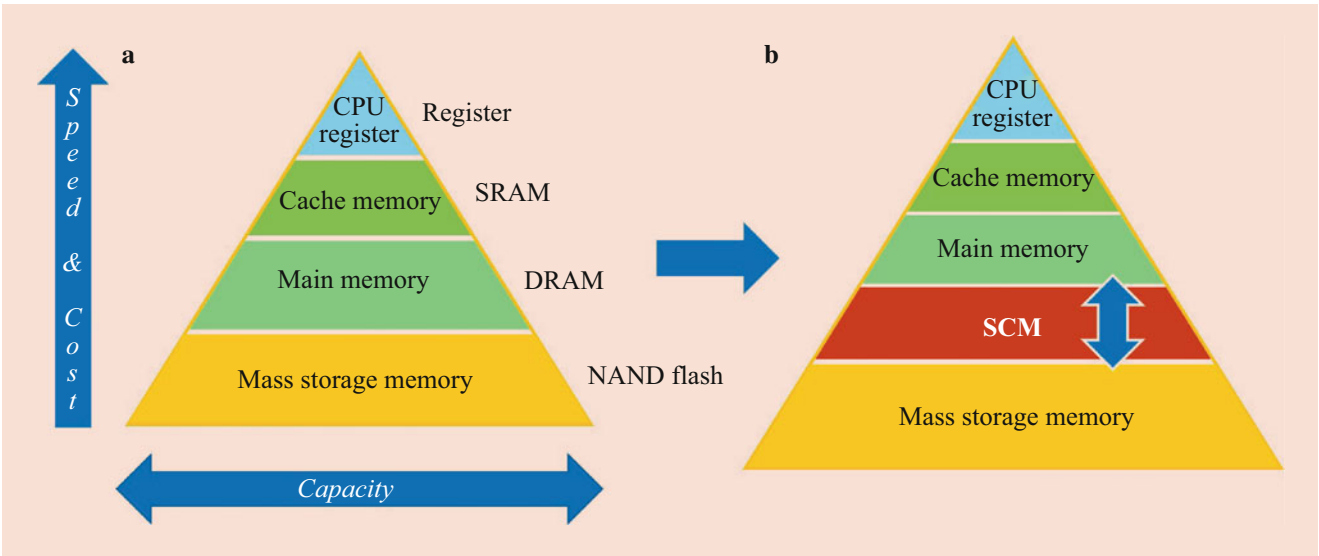

Fig. 2.3 (**a**) Memory hierarchy organized according capacity, cost, and speed parameters. (**b**) The same hierarchic scheme with the addition, between the gap in capacity, cost, and speed of DRAM and flash of the storage class memory (SCM) as new memory system. SCM represents the ideal realm for the emerging memory technology as it will be discussed in the chapter

the CPU is organized according a hierarchy based on these three parameters, the response time, the capacity, and the cost as reported in Fig. 2.3, exploiting the shape of a segmented pyramid, where the extension of the portions of the pyramid are related with the memory capacity and the vertical position has to deal with the memory speed and cost that typically move together.

The parameter that defines the speed of memory is the latency, defined as the time taken to transfer a block of data either from main memory or caches. The latency is thus the time the CPU waits to obtain the data. The types of memory that in Fig. 2.3 are at the basis and the vertex of the pyramid show, respectively, complementary features: at the basis, there is the NAND memory technology that is slow but nonvolatile and cheap and serves as the main solid-state storage memory. Close to the vertex of the pyramid, there are SRAM and DRAM that are fast, answering to the CPU with very low latency time, thus serving as the main working memory, but volatile. Since neither DRAM nor NAND is ideal for the needs of the system, the concept of "universal" memory was introduced in the early 2000s, combining the best of DRAM with the best of NAND features. This concept alludes to a potential new memory that could possibly replace several of the existing nonvolatile memory technologies such as NAND flash and even replace some current volatile memory technologies such as DRAM

Table 2.1 Taxonomy of NAND and DRAM as a function of their attributes

Attributes	NAND	DRAM
Nonvolatile	Yes	No
Scaling to	1× nm	1× nm
Power	~flash	High
Write bandwidth	10+ MB/s	100+ MB/s
Read latency	15–50 us	20–80 ns
Endurance	10^4–10^5	Unlimited

with a nonvolatile but equally high-performance memory, opening up new memory and chip design concepts. Indeed, nowadays this dream has been abandoned with the awareness that both the memory systems and the market are not in favor to give away to any performance of DRAM and NAND and the bundle in a single memory device of all the advantages of DRAM and NAND, simultaneously, is not realistic. In addition, physiology indicates that the human memory shows, from neurological basis, as a heterogeneous entity with complementary features, including the short-time memory (like DRAM, short both for latency and retention) and the long-time memory (like NAND, long both for latency and retention): this supports the idea that a heterogeneous memory ecosystem is the right direction to efficiently serve a modern computer system.

However, the gap in performance between DRAM and NAND spans several orders of magnitude on many key technology parameters illustrated in Table 2.1: the scalability, the programming power, the write bandwidth, the time latency, and the endurance over the programming cycling.

In particular, a part the volatility that has been recalled, there are two value propositions that are both, someway related with the velocity: the bandwidth and the latency. However, they indicate, specifically, different aspects of memory performance related with the concept of velocity. Nevertheless in synoptic Table 2.1, bandwidth is reported for write and latency for read, and they can be referred to as both write and read operation. But while latency refers to the transfer time needed to read or write a block of data, the bandwidth represents the amount of data that can be read or written within a unit of time (in other words, it measures the throughput of memory). An acute paper written by D. Patterson in 2004 [2] explains very well as bandwidth was more significantly helped by the technology scaling according with Moore's law, enabling more devices per unit of area that can operate in parallel. At variance, latency that is the fundamental measure of the speed of memory is more difficult to be improved. And this led to a chronic imbalance between bandwidth and latency with the technology scaling. D. Patterson reports in his paper this illuminating exergue by an Anonymous: "There is an old network saying: Bandwidth problems can be cured with money. Latency problems are harder because the speed of light is fixed—you can't bribe God." This has been true for temporary memory devices closer to the CPU, at the vertex of the pyramid of Fig. 2.3, like the cache and the DRAM that directly serve processors for computing operations. But it has been also more dramatically true for permanent memory of which, for many years, the hard disk drive (HDD) was the embodiment. In fact, the mechanical movement of the head in a specific sector of the HD platter necessary for any read or write operation was inherently slow, thus the HDD performance did not improve so much when, at variance, the performances of the CPU strongly improved over the technology roadmap. Hence, few years later, at IEDM 2009, Al Fazio by Intel [3] underlined the need to improve the latency of permanent memories to better serve the computing systems, where most memory accesses are nonsequential. The introduction of NAND technology to build solid-state disks (SSDs) that replaced the HDD represented a significant step forward in this direction. But there is room to do more. In fact, coming back to Table 2.1 and looking at the application requirements, the so large gap between DRAM and NAND (several orders of magnitude!) required, in the last years, the definition of a new type of memory. Such a new memory system is referred to as storage class memory (SCM) [4]. The goal for a SCM is to complement the existing memory hierarchy and operate at a performance and cost between that of NAND flash and DRAM as sketched in Fig. 2.3b. It represents a big opportunity for *any* emerging memory with properties in between DRAM and NAND, both in terms of latency (access time <10 ms) and cost (cost <1$/GB). Being so wide the SCM gap, two spaces exist for a SCM to enter in the market: a storage-type SCM, which operates as a faster, higher endurance NAND flash, whose primary driver is the cost, and a memory-type SCM, which is similar to DRAM with the added nonvolatility benefit, whose primary focus is on write speed and read latency. Close to the end of the chapter the phase-change memory will be presented also in terms of its potential ability to cover SCM applications.

2.3 Volatile Memory

In 1945, John von Neumann wrote a paper, titled *The First Draft of a Report on the EDVAC* [5], with a detailed description of a "very high speed automatic digital computing system." This paper is recognized as the foundation of modern computer architecture, in which the data and the program codes are both stored in the computer's memory in the same address space. The von Neumann architecture was widely used since the late 1940s and is still the standard architecture for most computers. The use of memory in digital computers to store both sequences of instructions and data was a breakthrough to which von Neumann made major contributions. Figure 2.4 reports the von Neumann computer architecture scheme.

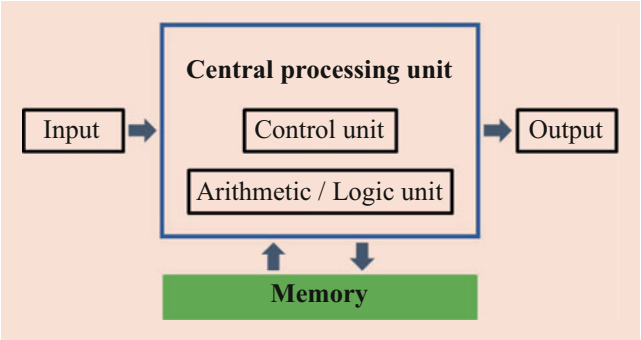

Fig. 2.4 Scheme of von Neumann architecture for a computing system with memory

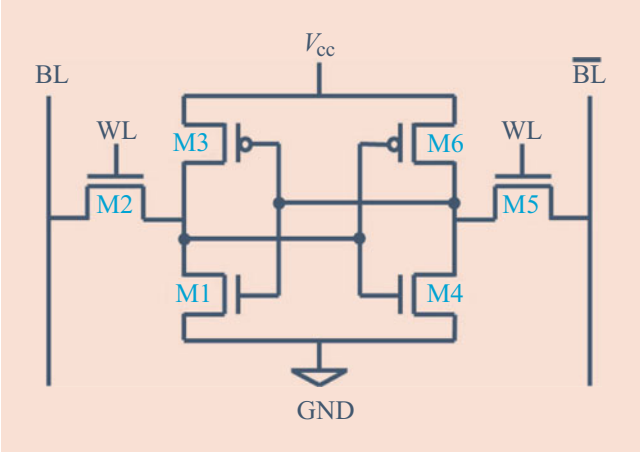

Fig. 2.5 6T SRAM cell schematic

In all modern computers and in most of high-performance electronic systems, the role of memory is played by two kind of devices: SRAM (static random access memory) and DRAM (dynamic random access memory). Both are volatile memory, which means that they retain data only if power is supplied to the devices.

SRAM is a type of semiconductor memory that uses bistable latching circuitry to store each bit of data in a single cell which is composed by several CMOS transistors. SRAM devices provide the fastest access to data and are typically used for computer cache memory and as part of the random access memory digital-to-analog converter on a video card. Once data are written in a SRAM cell, retention is guaranteed as long as power is supplied, without need for a periodic refresh of the information.

DRAM is a type of semiconductor memory that stores each bit of data in a cell composed by a capacitor and a transistor (the so-called 1T1C cell). Binary information is stored as positive or negative charge in the capacitor, and the transistor is used to access the capacitor. A DRAM cell will lose its information in a fraction of a second because of leakage, so a periodic refresh operation is needed to retain the data while the system is active. A DRAM cell is much smaller than SRAM and allows to reach very high densities at a much cheaper cost: this is the reason why DRAM is used as main memory instead of SRAM, despite the added complexity and power needed by refresh management.

2.4 SRAM Cell and Basic Operating Principles

The integrated bipolar SRAM was invented by Robert H. Norman at Fairchild Semiconductor in 1963 [6], becoming an alternative to magnetic-core memory. It was followed by the development of MOSFET SRAM, requiring six MOS transistors for each bit of data, invented by John Schmidt at Fairchild in 1964. Commercial use of SRAM began in 1965, when IBM introduced the SP95 memory chip for its System/360 Model 95, the first family of computer designed to cover a complete range of applications. Since early development, CMOS technology has been recognized as superior for SRAM application with respect to bipolar since it reduces power and allows to reduce cell size.

The SRAM memory cell works thanks to cross-coupled connection of inverters: SRAM uses bistable latching circuitry to store each bit. The basic SRAM cell is built with six transistors, with two back-to-back connected inverters: the output of each inverter is connected to the input of the other one forming a latch. Access to the cell occurs through a wordline and through two bitlines which use complementary voltage signals.

The working principle of a SRAM cell is briefly explained referring to Fig. 2.5.

When the wordline (WL) is at 0 V, the access transistors M2 and M5 are in off state, and the data is held in the latch. To write the cell, WL is raised to V_{cc} while the data (V_{cc} or 0 V) is applied to the bitline (BL) and the complementary data is applied to the complementary bitline BLB: in this way the latch is forced to move in the direction of the applied voltages, and the charges in the latch are overwritten with the new values. To have a good write capability, a high pull-up ratio is needed, that is, a high ratio between the current driven by transistor M2 with respect to the current of transistor M3 (and equivalently of M5 respect to M3).

To read the cell, the WL is raised again to V_{cc} and the charge of the latch can flow through the bitlines to reach the sense circuit, which is a simple differential amplifier. The stability of read requires a high cell ratio, meaning a high ratio between the current driven by transistor M1 with respect to the current of transistor M2 (and equivalently of M4 respect to M5): in this way the cell is less exposed to disturb issues during read.

Alternative SRAM cells with eight or ten transistors are used to allow multiple access to the same SRAM cell simultaneously, providing a memory with higher data bandwidth, at the cost of layout size, lower speed, and higher power consumption.

SRAM cell are built with the same MOSFET devices of logic processors and is the only memory architecture whose speed is comparable to the one of logic ports. For this reason, despite having a large cell area, SRAM is still today the main type of semiconductor memory, used as cache integrated into processor chips (Chap. ► 12).

2.5 SRAM Scaling

Because of the complexity of 6T circuit and the need to connect each cell to an array with common wordlines and bitlines, the area of a single SRAM cell is quite large with respect to the minimum lithographic feature λ that can be printed, as reported in Fig. 2.6

In the first generations of CMOS technologies, SRAM cell is scaled following general technology rules, using devices with dimensions balanced to optimize performances. In the most recent generations of microprocessors, which use several levels of cache to improve performances and parallel processing, SRAM arrays occupy a large fraction of the area of the whole chip: for this reason, cell SRAM scaling is a primary technology parameter, and the size of high-density 6T SRAM cell is often used as the key metric for pure logic technology density.

To allow length scaling with a proper control of short-channel effects, the conventional CMOS transistors based on SiO_2 oxide have been progressively replaced by devices with stress engineered junctions and then by high K metal gate transistor from 45 nm on. Scaling involves not only dimensions but also voltages: V_{cc} reduction is a key element to allow device scaling and to reduce the power consumption at chip level, and this is again a critical factor for cell stability.

SRAM cell uses devices with minimum width and length and for this reason is more exposed to process-induced variations in device size, threshold voltage variability due to dopant fluctuations, and mismatch issues: all these problems reduce the cell working window, its stability, and finally its yield.

The scaling of SRAM arrays involves not only the scaling of the transistors of each cell, but also the improvement of the layout of the 6T cell to make it scalable-friendly. The traditional layout of a SRAM cell as in Fig. 2.6 was realized in a way to optimize some array characteristics, sharing horizontal routing for the wordlines, and vertical routing for the bitlines, power, and ground, but the shape of all the lines is complex.

From 65 nm on, the layout of SRAM cell has been modified to what is called “thin cell” or “wide cell,” shown

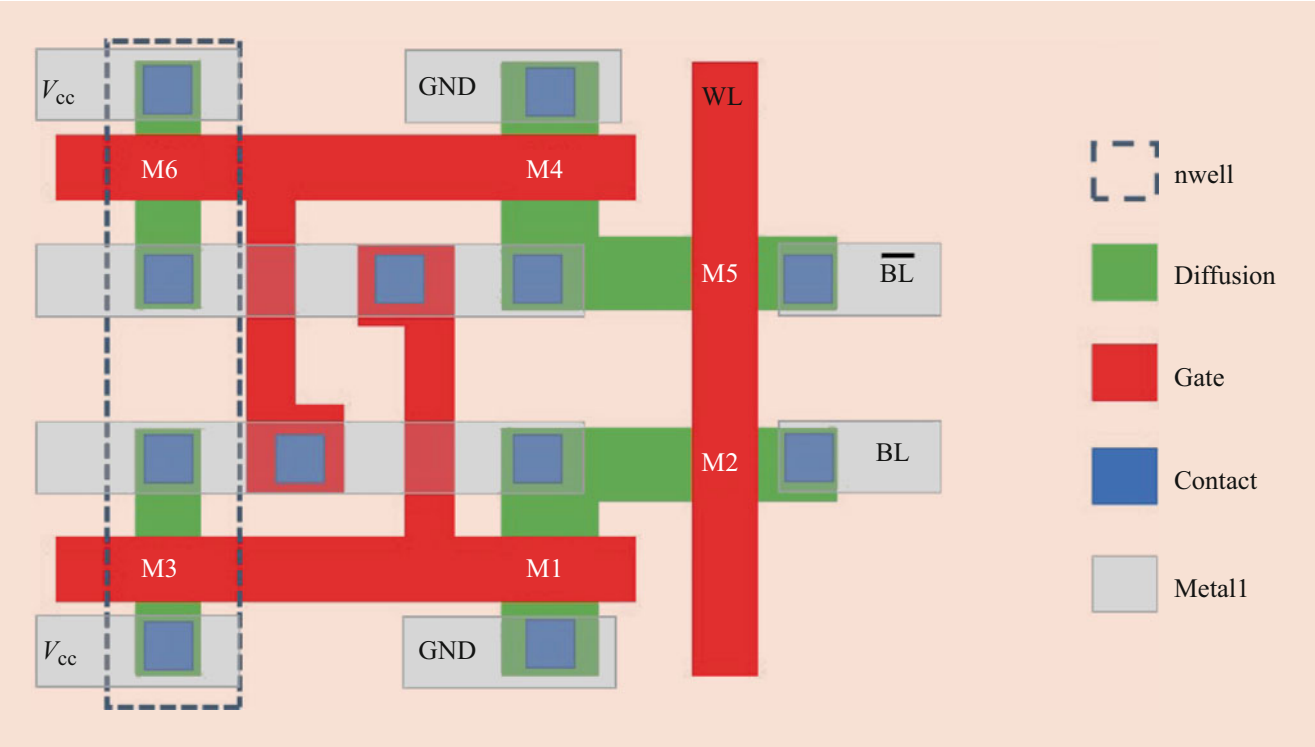

Fig. 2.6 Example of 6T SRAM cell layout; connections above metal1 are not shown

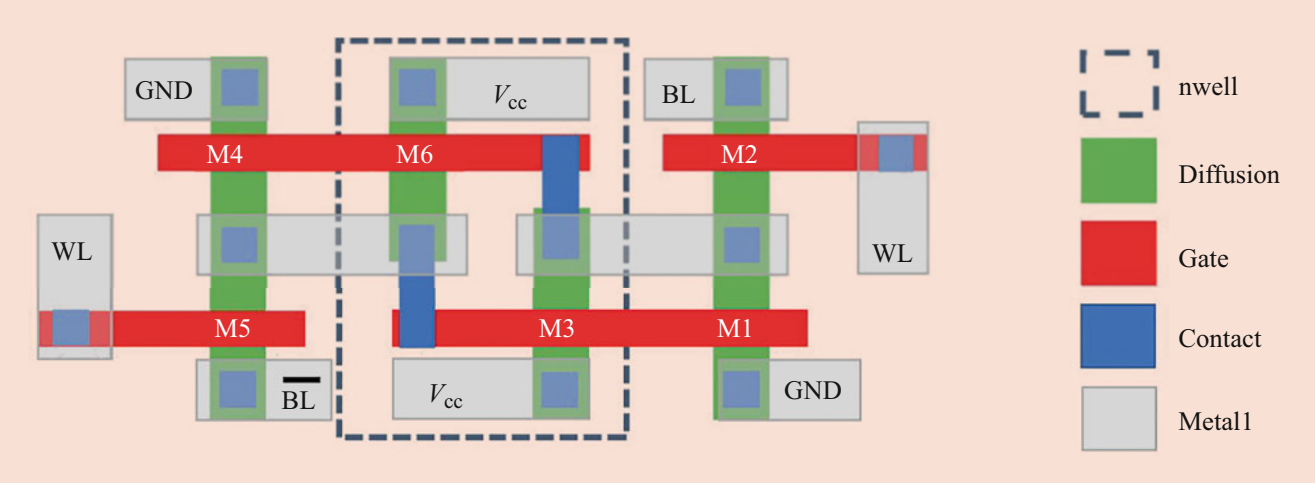

Fig. 2.7 Example of the "thin" 6T SRAM cell layout; connections above metal1 are not shown

in Fig. 2.7, where bending of diffusions and gate lines are avoided, transistors are all oriented in one direction, and bitline capacitances are minimized: this modification helps not only to improve the cell performances in terms of transistor matching and low capacitance but also to simplify lithography and patterning steps, allowing to scale the area of the cell thanks to the scaling of the active devices and to the tightening of the spacings and of the process tolerances.

The introduction of patterning-friendly layout at all levels, including the very tight contact and metal interconnections, allowed to extend the use of 193 nm lithography and 193 nm immersion lithography well beyond the optical resolution limits, thanks to self-aligned multiple patterning solutions. Scaling of 6T SRAM cells over various technology nodes are schematically shown in Fig. 2.8, as from [7–11]. Self-aligned quadruple patterning solution is used for 10 nm state-of-the-art technology. EUV lithography is expected to be introduced at 7 nm node.

From 22 nm technology on, planar MOSFETs are replaced by FinFET (Fig. 2.9), invented in 1988 in Hitachi's labs [12]. Differently from planar devices, FinFETs have several advantages for scaled and low-voltage applications: short-channel effects and subthreshold current are much better controlled thanks to the fact that the gate surrounds the channel; better gate control allows to use devices with very low threshold, which is fundamental to reduce voltages, and enables low channel doping, which further improves performances and uniformity among devices.

At the same time, FinFET devices limit the flexibility in the design of SRAM cells, since the width of each transistor in the SRAM can be only an integer multiple of the width of a single fin; this constraint, together with the reduction of the supply voltage, is critical with respect to the working window of the cell and has been addressed with a dedicated management of voltages in the SRAM array [13].

Table 2.2 6T SRAM cell scaling for Intel processors technologies

Date	Technology node (nm)	SRAM cell size (μm^2)	V_{cc} (V)
1993	500	44	3.30
1995	350	21	2.50
1997	250	10.6	1.80
1999	180	5.59	1.60
2001	130	2.09	1.40
2003	90	1	1.20
2005	65	0.57	1.20
2007	45	0.346	1.00
2009	32	0.148	0.75
2011	22	0.092	0.75
2014	14	0.0499	0.70
2019	10	0.0312	0.70

Thanks to all these solutions, SRAM cell area has been continuously scaled in the last 25 years, following up to 2009 the fast pace dictated by Moore's law (number of transistors per unit area doubles every 2 years); from 2009, the scaling is continuing with a lower speed. Table 2.2 shows the scaling path for SRAM 6T used in Intel processors from 1993 onward [14].

Alternative SRAM cell architectures have been developed to reduce cell area with respect to 6T standard: for example, a 4T 2R SRAM cell can be built, substituting p-channel transistors M3 and M6 of Fig. 2.5 with two highly resistive resistors.

4T 2R SRAM cells have been widely used in standalone SRAM market in the past, but this architecture has been abandoned in the most recent technologies because of added technology complexity (need to integrate extra layers for polysilicon resistors in high-performance logic technology) and because of worse performance at low-voltage operation (increase off current flowing in the resistors and poor mem-

ory cell stability because of low static noise margin below 1.8 V) [15].

2.6 DRAM Cell, Array, and Basic Operating Principles

DRAM was invented at IBM by Robert Dennard in 1966 [16]: while he was working on field-effect transistors, he had the idea to store binary data in a capacitor, as positive or negative charges, with a very fast programming and reading speed. But Dennard had to face the problem of leakage out of the capacitor, so that the information could be lost in few milliseconds. For this reason, he proposed and developed a solution where a single MOSFET device could read the charge and put it back thousands of times per second, in the so-called "refresh" operation. This single access transistor would then be responsible for each bit of information, thus reducing the size of the whole cell dramatically with respect to SRAM cells just developed. The constant refreshing of the charge on each capacitor is why Dennard's chip is referred to as "dynamic" RAM. The ultimate effect of Dennard's invention was that a single chip can hold a billion or more RAM cells in modern computers.

In 1970, the newly formed Intel company publicly released its first DRAM, the famous 1103 1 Kbit chip, which by 1972 was the best-selling semiconductor memory chip in the world, definitely defeating magnetic-core type memory which was bigger, costlier, and more power-consuming.

Today DRAM is still based on the original concept, but the evolution of the technology in 50 years has been dramatic, as we can see in Table 2.3, that compares some of the most relevant characteristics of a 1973 4 K DRAM to 2015 8 Gb DRAM chips.

A DRAM 1T-1C memory cell is formed with one transistor and one capacitor (Fig. 2.10a). The capacitor, with capacitance C, holds binary information in the form of stored charge Q, while the transistor, called access transistor, operates as a switch between the capacitor and the digitline that connects the cell to the sensing circuitry. One of the terminals of the capacitor is called plate, and it is a common node biased at $V_{cc}/2$. The other terminal can be biased to V_{cc} or to 0 through the access transistor, storing a positive or negative charge $Q = \pm V_{cc}/2{*}C$ corresponding to logic state 1 or logic state 0.

A DRAM device is composed by an array of 1T-1C cells (Fig. 2.10b), organized in wordlines (rows) and digitlines (columns). Each digitline consists of a multitude of DRAM cells and is highly capacitive because of the quantity of cells connected and because of the proximity to other features: digitline capacitance is a key parameter for DRAM design. The gate terminal of the access transistor is connected to a wordline, common to a multitude of cells and physically orthogonal to the digitlines.

Reading a DRAM is a differential operation, involving pairs of digitlines (see Fig. 2.11). To read data from a DRAM array, first all the digitlines are equilibrated to $V_{cc}/2$ with the wordlines off. Then a single wordline is raised to a voltage called V_{ccp}, which is higher than V_{cc} plus the threshold voltage of the access transistor. At this moment, all the capacitors connected to the selected wordline begin to discharge, each of one sharing its own charge to its digitline, whose voltage consequently increases in case of stored 1 or decreases in case of stored 0, generating a small signal (typically less than 200 mV). The value of this signal is a function of the cell capacitance C, of the stored charge Q, and of the digitline capacitance C_{digit}:

$$V_{signal} = \frac{Q}{C + C_{digit}} = V_{cc} \cdot C / \left(C + C_{digit}\right)$$

The small signal of each cell is sensed with an amplifier connected to each digitline, which compares the signal with a reference voltage coming from a paired digitline which has no selected wordline. This sensing circuit amplifies the small signal to a digital V_{cc} or 0 V value.

During the read operation, the charge on each selected cell is lost: it's a destructive read. Since the selected wordlines remain at high voltage during the reading process, the amplified signal is written back from the sensing circuit into the cell capacitors, restoring the charge on the selected capacitors. When the reading operation is completed, the wordline is turned off, trapping the fresh charge in the cell.

Write operation in a DRAM is similar to the sensing and restoring steps which happen in read, except that a separate circuitry determines the data that will be placed into the cells: the voltage of each digitline is forced to V_{cc} or 0 V by the write drivers and then a wordline is turned on to V_{ccp} to charge or discharge the capacitor of each cell.

As already underlined, the DRAM capacitor loses its charge is a short time, because of leakage current of the access transistor. To keep the information, a periodic refresh

Table 2.3 Comparison of early DRAM features to recent devices

	MOSTEK1973	Micron2015
Density	4 Kbit	8 Gbit
V_{cc}	12 V	1.2 V
Minimum lithography feature	8 μm	17 nm
Cell area	1280 um^2	2555 nm^2

operation is needed on each single cell every few ms, typically between 64 ms and 32 ms in the recent devices. The refresh operation works like a read operation, which restores the full charge on each single capacitor.

2.7 DRAM Technology Evolution

The evolution of DRAM technology followed Moore's law from the early 1970s up to 2015, scaling the array features from 8um down to 20 nm in 45 years. Cell area scaling was executed in parallel with cost reduction, power reduction (mainly through operating voltage scaling), density increase, and performance increase, introducing huge technology and design innovations on the same basic device concept developed by Dennard.

We can observe a reduction of scaling rate in the last 5 years (see Fig. 2.12), because of the increasing challenges in cell area reduction, but DRAM unique features are hard to be replaced in a short term by other technologies, in particular considering its fast switching speed (~10 ns), its small switching energy (~2 fJ/cell), its unlimited cycling endurance, and its small cell area with simple 1T-1C structure.

DRAM technology scaling involves all the key elements of array: capacitor, access transistor, WL and DL resistances and capacitances, and CMOS circuitry performances.

Also the integration of these devices into an efficient array is an impressive accomplishment of DRAM technology: beside lithographic and patterning evolution, which is tracked by the minimum feature λ, the layout of DRAM cell improved from $20\lambda^2$ in the early 1990s to $6\lambda^2$ today, as shown in Fig. 2.13, with the possibility to move to $4\lambda^2$ area [17].

This improvement in the cell form factor has been realized moving the integration from a conventional planar approach derived from CMOS technology to a dedicated 3D approach which leverages on the integration in the vertical direction, using the space below the silicon surface and the one above it.

In the next paragraphs, we will focus on the dramatic evolution of the key devices of the cell: the capacitor and the access transistor.

2.8 DRAM Capacitor Scaling

At a first approximation, digitline capacitance is constant with scaling, since the reduction of the distances between adjacent digitlines is compensated by the reduction of digitline lengths. Since the signal of the cell is related directly to the ratio between the charge stored in the capacitor and the digitline capacitance, also the capacitance of the single DRAM must be kept approximately constant to have a good signal. It means that the capacitance per cell area needs to be increased, node by node, working on all the directions: increasing the dielectric constant of the capacitor, reducing the dielectric thickness, and increasing the effective area of the capacitor, all with the constraints of dielectric leakage control to have a tolerable refresh rate.

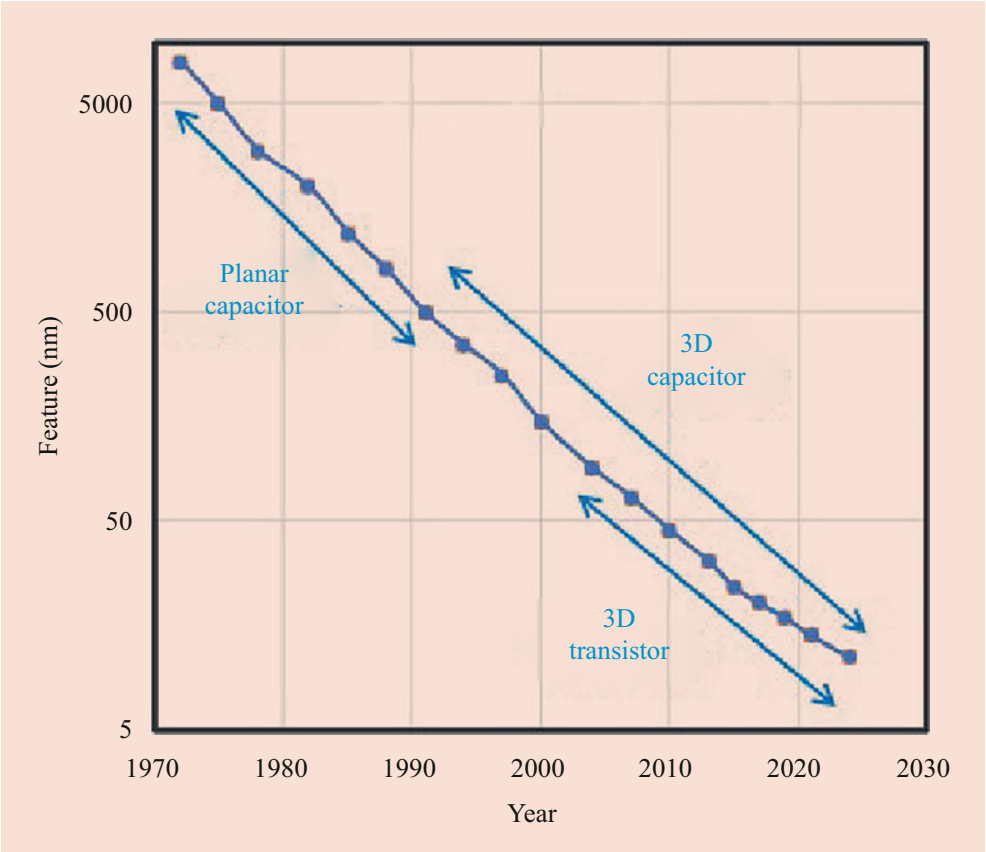

Fig. 2.12 Scaling of DRAM technology expressed in terms of minimum feature λ. (Source: Various publications & IRTS)

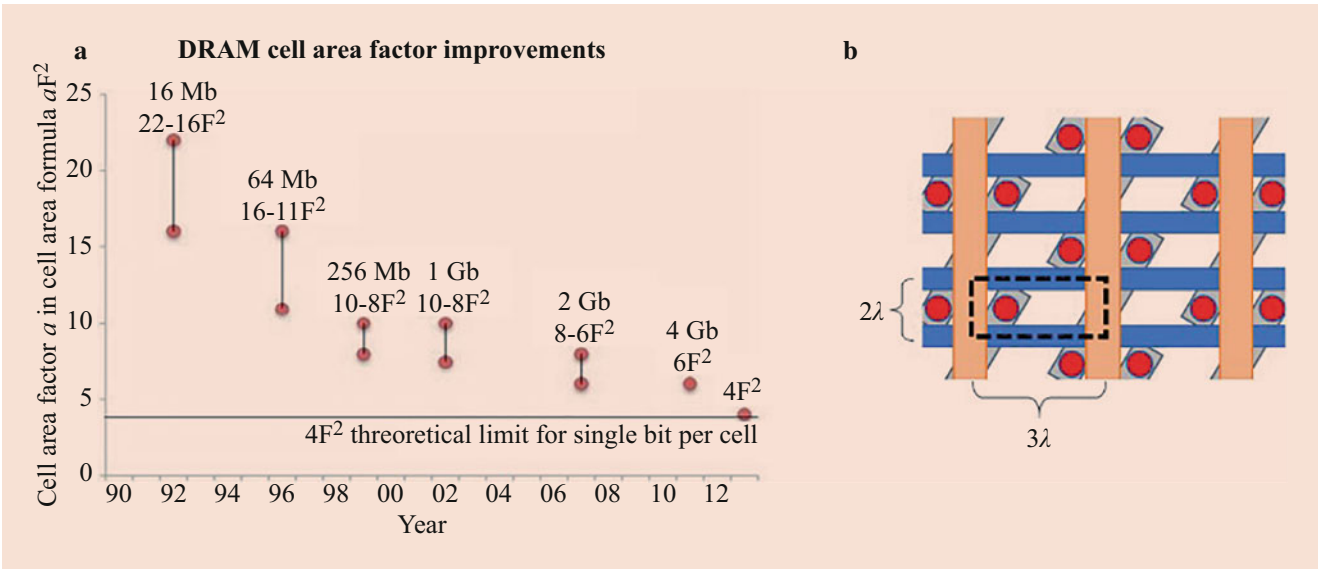

Fig. 2.13 (**a**) Scaling of DRAM technology expressed in terms of minimum feature λ and (**b**) compact layout of a state-of-the-art $6\lambda^2$ DRAM cell

The first DRAM cell was built with a pure planar process, with a SIS (semiconductor-insulator-semiconductor) capacitor built with SiO_2 dielectric between a polysilicon gate and highly doped substrate, placed beside the access transistor.

To increase the effective area of the capacitor, the shape of the cell changed from planar to a progressive increase of aspect ratios, to distribute the cell capacitor area along the vertical direction instead of the horizontal one. So, the capac-

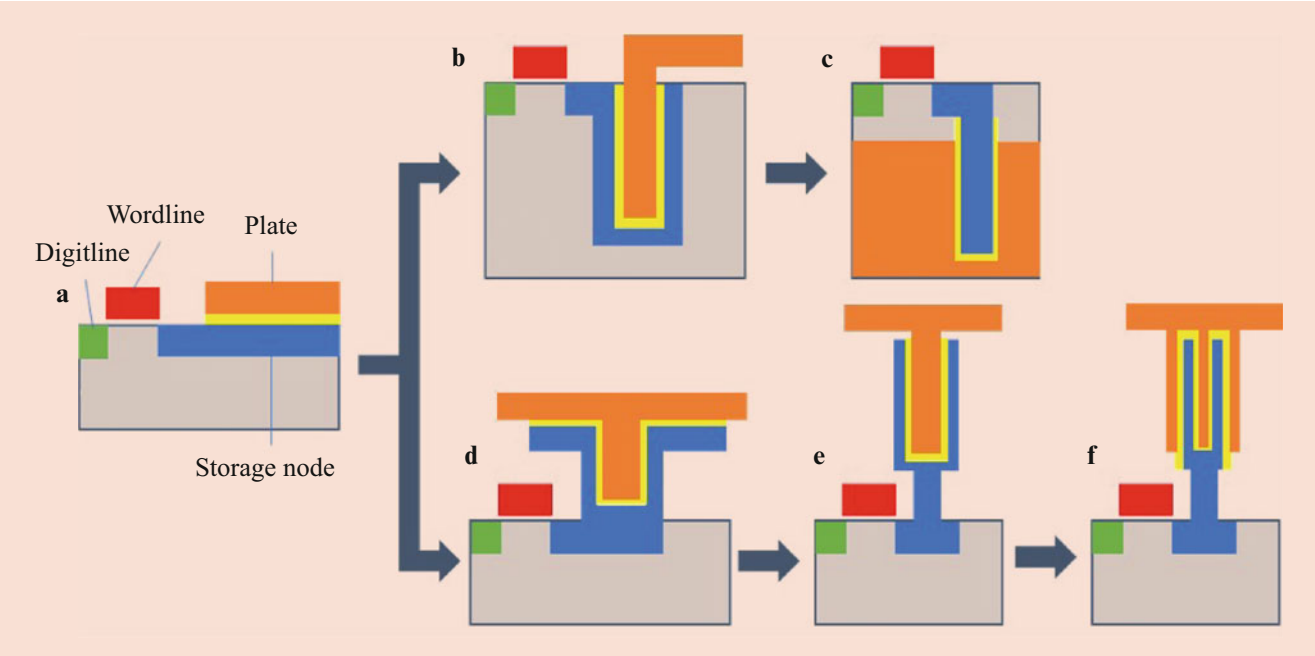

Fig. 2.14 Evolution of DRAM cell capacitor, from planar device (**a**) to 3D integrated device in the substrate like trench capacitor (**b**) and substrate-plate capacitor (**c**) or over the access device like stack capacitor (**d**), container cylindrical capacitor (**e**), and container dual-sided cylindrical capacitors (**f**)

itor, once integrated directly over silicon surface, then moved below the substrate or on top of it, as shown in Fig. 2.14. More examples of capacitor solutions for high-density DRAM can be found in literature, in references [18, 19].

The state of the art of the DRAM technology today is a cell with a tall cylindrical capacitor, called container, stacked over the silicon surface like in Fig. 2.14e. In the last 15 years, the diameter of the container decreased from 150 nm to 20 nm, and the aspect ratio of the container, that is, the ratio of its height to its diameter, grew from 10 to 35, challenging not only lithography but all the process technologies and process controls: etch, cleaning, thin metal, and dielectric film depositions [20]. To increase the capacitance of each cell without increasing too much the aspect ratio of the container, most advanced array uses dual-sided capacitors, like in Fig. 2.14f.

Starting from SiO_2 SIS, the technology evolved using MIM (metal-insulator-metal) and introducing insulators with increased dielectric constant: $Hf2O_3$, Al_2O_3, and ZrO_2. The dielectric in the capacitor is today composed by a thin ZAZ (ZrO_2-Al_2O_3-ZrO_2) dielectric between TiN electrodes [21], whose dielectric constant is more than 10 times higher than the one of SiO_2 and that guarantee a limited leakage. Metal and dielectric films are deposited in the container using atomic layer deposition technologies to obtain very uniform characteristics in structures with such high aspect ratios.

2.9 DRAM Access Transistor Scaling

DRAM access transistor needs to have a low off current to reduce charge dissipation from the cell; it needs to drive at least 1uA on current to charge the capacitor in few ns (current requirement does not change with technology node, since cell capacitance does not scale) and needs to be integrated in the cell available in an effective way, considering the array organization.

Up to ~100 nm technology node, the access transistors were built as planar devices, with improvement in the engineering of the junction to reduce short-channel effects. In the following nodes, the reduction of the length of the transistors was not achievable with a limited Ioff, so the device has been progressively recessed into the Si substrate, as in Fig. 2.15, creating a U-shaped channel whose length is higher than the physical size of the gate and introducing the so-called RAD (recessed access device) technology [22]. Then, to improve channel control and wordline resistance, metal gate substituted conventional polysilicon gate.

Today the state of the art of DRAM technology in a 6F2 cell is based on a BRAD access transistor (buried-recessed access device), where the whole metal gate is recessed below the silicon surface and is completely isolated from the surface, to give space to the contacts for the digitlines and for the cell capacitors. Wordlines are in contact with the surface

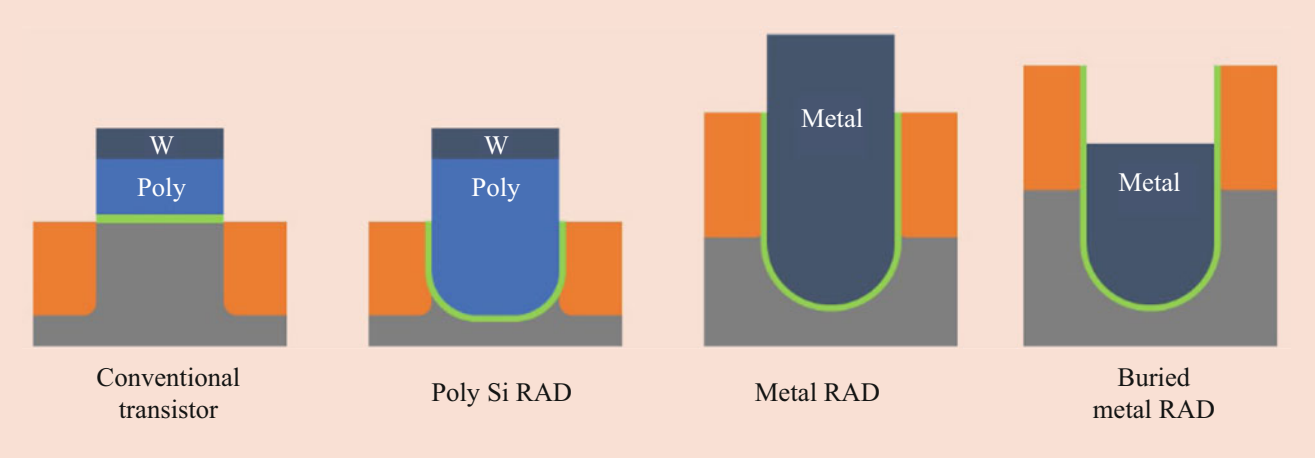

Fig. 2.15 Access transistor scaling; in the buried metal, RAD gate is completely recessed and the surface of the wafer is used for cell contacts

of the silicon and with the standard periphery just at the edge of the array.

2.10 DRAM Product Evolution

In parallel with technology evolution, also DRAM product design evolved to increase memory density, improve performances, and reduce power.

The first-generation DRAM worked in asynchronous mode, but in 1992 the first SDRAM device (synchronous DRAM) was presented, which has the advantage of accepting sequences of commands in a pipeline before the completion of running commands and the possibility of using contemporaneously many different memory blocks of the same chip. All DRAM today are SDRAM.

At single cell level, the performances of DRAM technology did not improve much in the last years: the latency is approximately constant, in the range of few tens of nanoseconds, limited by array resistances and DRAM capacitor. The most relevant improvement in DRAM chip performances has been obtained increasing the bandwidth, with wide data paths and internal pipelining.

From 2000, the new concept of DDR SDRAM (double data rate SDRAM) became a standard in the market: with the same clock frequency, the bandwidth of a DDR memory is doubled with respect to a std. SDRAM because data are transferred both on the rising and the falling edges of the clock signal, thanks to a strict control of the internal timings of the device.

From the introduction of DDR devices, the evolution of the following DRAM generations has been in terms of clock frequency and operating voltage, reaching a transfer rate of ~20 GB/s in DDR4 (Table 2.4).

Other architectural solutions to increase performances are the increase of I/O count and the 3D die stacking with TSV (through silicon vias) interconnects [23] and/or interposers: HBM (high bandwidth memory) [24] and HBC (hybrid memory cube) [25] are two solutions in the market, providing improved bandwidth for graphical and network applications (see Fig. 2.16).

2.11 Nonvolatile Memory: The Flash Memories

In 1967 D. Khang and S.M. Sze at Bell Laboratories proposed the concept of floating gate MOS transistor [26] that paved the way for one of the most successful solid-state integrated electronic device based on charge storage: the flash memory. Capitalizing this concept, Intel developed in 1971 a 2048-bit user-erasable EPROM memory (erasable programmable read-only memory) that could be reused multiple times by erasing the pattern with ultraviolet light [27]. Generations of UV EPROMs with multimillion bits of storage from Intel and others found wide application for storing and modifying program codes as firmware in microprocessor-based system designs.

Few years later, Eli Harari, working at Hughes Microelectronics from 1976 to 1978, demonstrated that a thin oxide floating gate could be an electrically erasable PROM (EEPROM), thus eliminating the need for external UV erasure [28]. George Perlegos employed the thin oxide technique for Intel's first EEPROM in 1978. A couple of years later, in 1980, Fujio Masuoka at Toshiba modified the EEPROM architecture to increase the speed of programming, appropriately naming it "flash" [29]. Professor Fujio Masuoka's ideas allowed overcoming the electrical and architectural limita-

Table 2.4 DRAM generations

DDR SDRAM standard	Internal rate (MHz)	Bus clock (MHz)	Data rate (MT/s)	Transfer rate (GB/s)	Voltage (V)
SDRAM	100–166	100–166	100–166	0.8–1.3	3.3
DDR	133–200	133–200	266–400	2.1–3.2	2.5
DDR2	133–200	266–400	533–800	4.2–6.4	1.8

DDR4	133–200	1066–1600	2133–3200	17–21.3	1.2

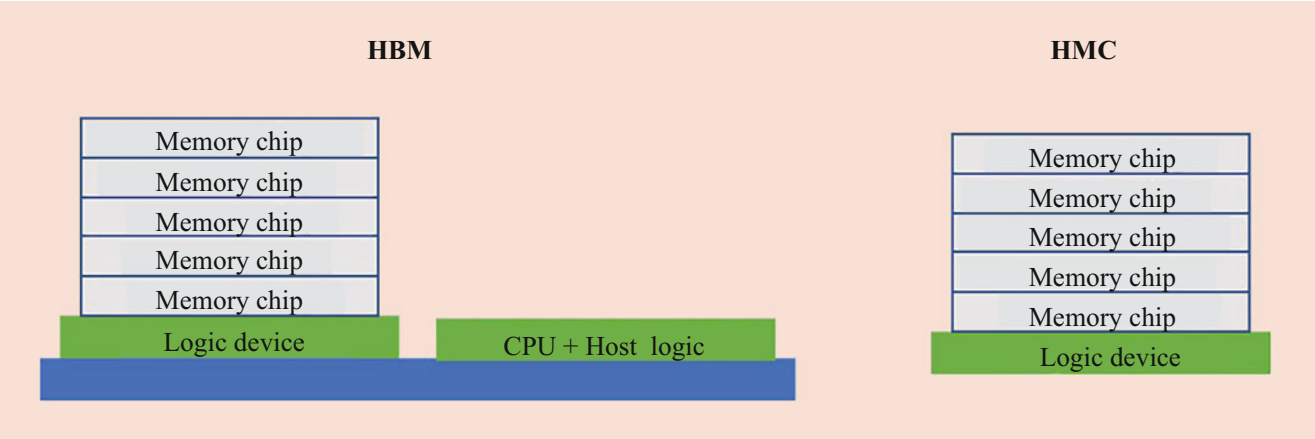

Fig. 2.16 HBM and HMC with stacked DRAM memory chips

tions of the early implementations of the charge storage-based memories such as EPROM or EEPROM by means of a simple memory cell transistor (1T = 1 cell) with particular array arrangements in order to allow parallel operations over a large group of cells and achieve higher array efficiency. Masuoka's research group presented the cell matrix architecture called NOR flash in 1984 [30] and then, in 1987, a second cell matrix architecture called NAND flash [31] that several years later would have been the fundamental technology block for USB flash memory stick and solid-state disks (SSD). Toshiba introduced its commercial flash products in 1987 followed by Intel in 1988. From then on, flash memory has found widespread use in such personal device applications as mobile phones, cameras, and GPS navigation systems.

Other matrix and architectural variations have been proposed (see Table 2.5); however, the original NOR and NAND flash remained the dominant solutions, and today NAND flash is the industrial standard for widely used solid-state storage systems, for instance, in SSDs and SD cards.

In the last 30 years, driven by the CMOS scaling roadmap, flash memory devices experienced a spectacular scaling, and nowadays, thanks to the transition from planar to the 3D integration, a single monolithic chip of NAND flash could reach logical density above 500 Gb/cm^2 [32] with a total memory density of 1 Tb = 128 GB [33].

Even if the technological challenges necessary for further density increase are huge, this scaling path is expected to continue since the global market for flash is growing with impressive CAGR (compounded average growth rate), boosted by the hunger of memories in more and more pervasive technologies such as smartphones, cloud computing, and IoT.

2.12 Floating Gate MOSFET Devices

A flash cell is basically a MOS transistor with the addition of a floating conductive electrode sandwiched between the channel and the gate node. Being the added element to the simpler MOSFET structure a conductive layer completely surrounded by dielectrics, it is coherently called floating gate (FG).

The device physics describing the FG MOS transistor can be therefore obtained from the conventional MOS transistor equations by replacing the MOS gate voltage with the FG voltage and transforming the device parameters, such as threshold voltage V_T and the conductivity factor β to values measured with respect to the control gate. In such a device, the gate node, above the FG, allows controlling the electrical behavior of the "transistor," but through the capacitive coupling with the FG node [34].

The gate of the FG MOS device is thus named control gate (CG), while the FG acts as storing electrode in the cell structure, being electrically isolated. In fact, the charge injected and stored in the FG modulates the "apparent" threshold voltage (i.e., the V_T seen from the CG) of the cell transistor. Figure 2.17 sketches the equivalent electrical model of the floating gate (FG) MOSFET device that can be useful for describing its operating principle. Being C_{FG}, C_S,

Table 2.5 Flash memory array architectures: in bold the market dominant solutions

Array architectures								
Cells in series		Cells in parallel

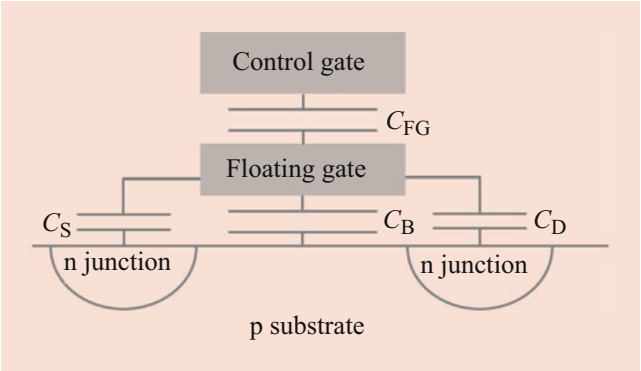

Fig. 2.17 Capacitive model of FG MOSFET

C_D, and C_B the capacitances between the FG and the control gate, source, drain, and substrate regions, respectively, the potential of the FG due to capacitive coupling can be written as:

$$V_{FG} = \frac{C_{FG}}{C_{TOT}} \cdot V_{CG} + \frac{C_S}{C_{TOT}} \cdot V_S + \frac{C_D}{C_{TOT}} \cdot V_D + \frac{C_B}{C_{TOT}} \cdot V_B + \frac{Q_{FG}}{C_{TOT}} \tag{2.1}$$

where:

$$C_{TOT} = C_{FG} + C_S + C_D + C_B \tag{2.2}$$

The capacitive ratio C_{FG}/C_{TOT} is often called α_G and represents the coupling factor between the control gate and the floating gate. α_S, α_D, and α_B are, consequently, the other coupling ratios.

Assuming both source and body at 0 V, Eq. 2.1 can be simplified as:

$$V_{FG} = \alpha_G \cdot V_{CG} + \alpha_D \cdot V_D + \frac{Q_{FG}}{C_{TOT}} \tag{2.3}$$

Then, defining V_T^{FG} as the potential that must be applied to FG to reach the inversion of the surface population (MOS threshold definition), the potential to be applied to the control gate to realize this condition, V_T^{CG}, can be found by using Eq. 2.3 that leads to:

$$V_T^{CG} = \frac{1}{\alpha_G} \cdot V_T^{FG} - \frac{Q_{FG}}{C_{FG}} \tag{2.4}$$

Since V_T^{FG}, α_G, and C_{FG} are in a good approximation constant, for a given technology, depending only from constructional parameters, then Eq. 2.4 ties the dependence of FG MOS threshold with the amount of charge stored in the floating gate.

2.13 Flash Memory MOSFET Devices

The description of the floating gate MOS device leads straightforwardly to the FG memory cell or flash memory. We just saw that under certain conditions, the threshold voltage V_T of a MOS transistor depends linearly from the amount of charge stored in the gate capacitor system. For an n-channel enrichment MOSFET, the general form of this dependence, from Eq. 2.4, can be written as:

$$V_T^{CG} = A - \frac{Q_{FG}}{C_{FG}} \tag{2.5}$$

where A is a constant depending on constructional parameters of the transistor and C_{FG} is the capacitance of gate system [34]. Thus, negative charge increases the threshold, while positive charge in the FG decreases it. The digitalization of this dependence in two or more discrete threshold states is the base of flash memories.

General convention assigns logical state 1 at non-charged state (erased cell) and logical state 0 at the charged state (programmed cell), as in Fig. 2.18.

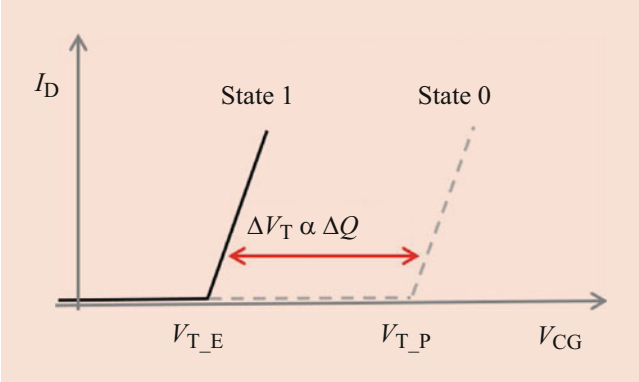

Fig. 2.18 Shift of ideal MOS I_D-V_G transcharacteristic due to negative charge injection in the gate/substrate capacitor system

Standard flash cells can displace the threshold over several volts; however, the size of the working window is limited by fundamental phenomena, mainly by the maximum electric field that can be sustained by the dielectric layers.

Considering the intrinsic variability of the threshold voltages over a large collection of cells, the minimum separation between logical states (also known as read window budget, RWB) is dictated by the width of the statistical distributions of the thresholds of the erased and programmed cells. The precise control of the placement of the V_T of the cell for both state 0 and state 1 is achieved thanks to engineered program and erase algorithms [35]. These programming algorithms tighten the width of threshold distributions and enable the placement of additional V_T distributions in between the erased and the programmed cell, thus offering the opportunity to store more than one logical bit in one physical cell.

In Fig. 2.19, an ideal representation of the threshold distributions over a large cell collection (block of cells) for single bit technology (SLC = single-level cell) and 2-bits technology (MLC = multilevel cell) is reported.

The actual state of the art of multibit technology features up to 4 bits per cells in the most advanced NAND flash products [36, 37], which means that 16 different distributions are placed in the V_T accessible range.

The overall separation of logical states represented by the RWB quantity measures the reliability of the data storage and becomes more and more critical with the increase of the number of distributions (number of bits per cell), considering the already mentioned constraint to not enlarge over a certain limit the total program to erase window (max threshold displacement).

In current flash memory technologies, especially NAND flash, in which the reading operation is naturally performed in parallel over a large cell collection, the decoding of logical states relies on error correction code (ECC) techniques to overcome RWB and reliability limitations [38].

For NAND flash, the large dimension of the page, which is the portion of array read in parallel, allows to use many bits of ECC without significative penalties. Instead, random read access and single bit granularity in NOR flash are preventing the use of many ECC bits due to an unacceptable degradation of random read performances.

2.14 Charge Storage Solutions

In flash memories, the "memory effect," thus the digitalization of threshold states, is achieved by adding a net amount of electrical charge in the floating gate. In addition, the capability to retain this stored charge for a long time (years at max operative temperature) even when the gate bias is not present, makes this memory device nonvolatile.

Indeed, the floating gate technology is not the unique solution to achieve a charge storage element above the channel of a MOS transistor. Two solutions are widely adopted as industrial standards to store charge above the channel able to modulate the threshold of the transistor:

1. Adding a conductive electrode in between control gate and channel, creating the FG technology extensively described in the previous paragraph. To enhance charge retention and the device performance, the insulation structure between floating and control gates is often made by stacking multiple dielectric layers, alternating silicon oxide (O) and silicon nitride (N), giving rise to the ONO dielectric.
2. Embedding materials and interfaces, inherently dielectrics, able to trap charges, into the gate oxide of the MOS transistor. A common solution for this is the use of silicon nitride-based films: for this reason, this kind of devices is often called SONOS (silicon-oxide-nitride-oxide-silicon) or MONOS (where M stands for metal) [39].

Figure 2.20a, b show the ideal cross sections of a generic SONOS and generic FG devices (n-MOS based) with the typical stack and industry standard materials.

From the physical point of view, the capability to retain a net charge is related to the electronic bands structure of the stack built by metals, dielectrics, and semiconductor materials.

In FG cell, the conduction band offset between the conductive polysilicon electrode and the surrounding silicon oxide-based materials is 3.1 eV at room temperature, approximately. This is the energy barrier preventing that free electrons, stored in the FG, are emitted in the conduction band of surrounding material and thus lost toward substrate or control gate.

The charge trap-based cell, like the SONOS cell, has more complex retention mechanism: it relies into the potential

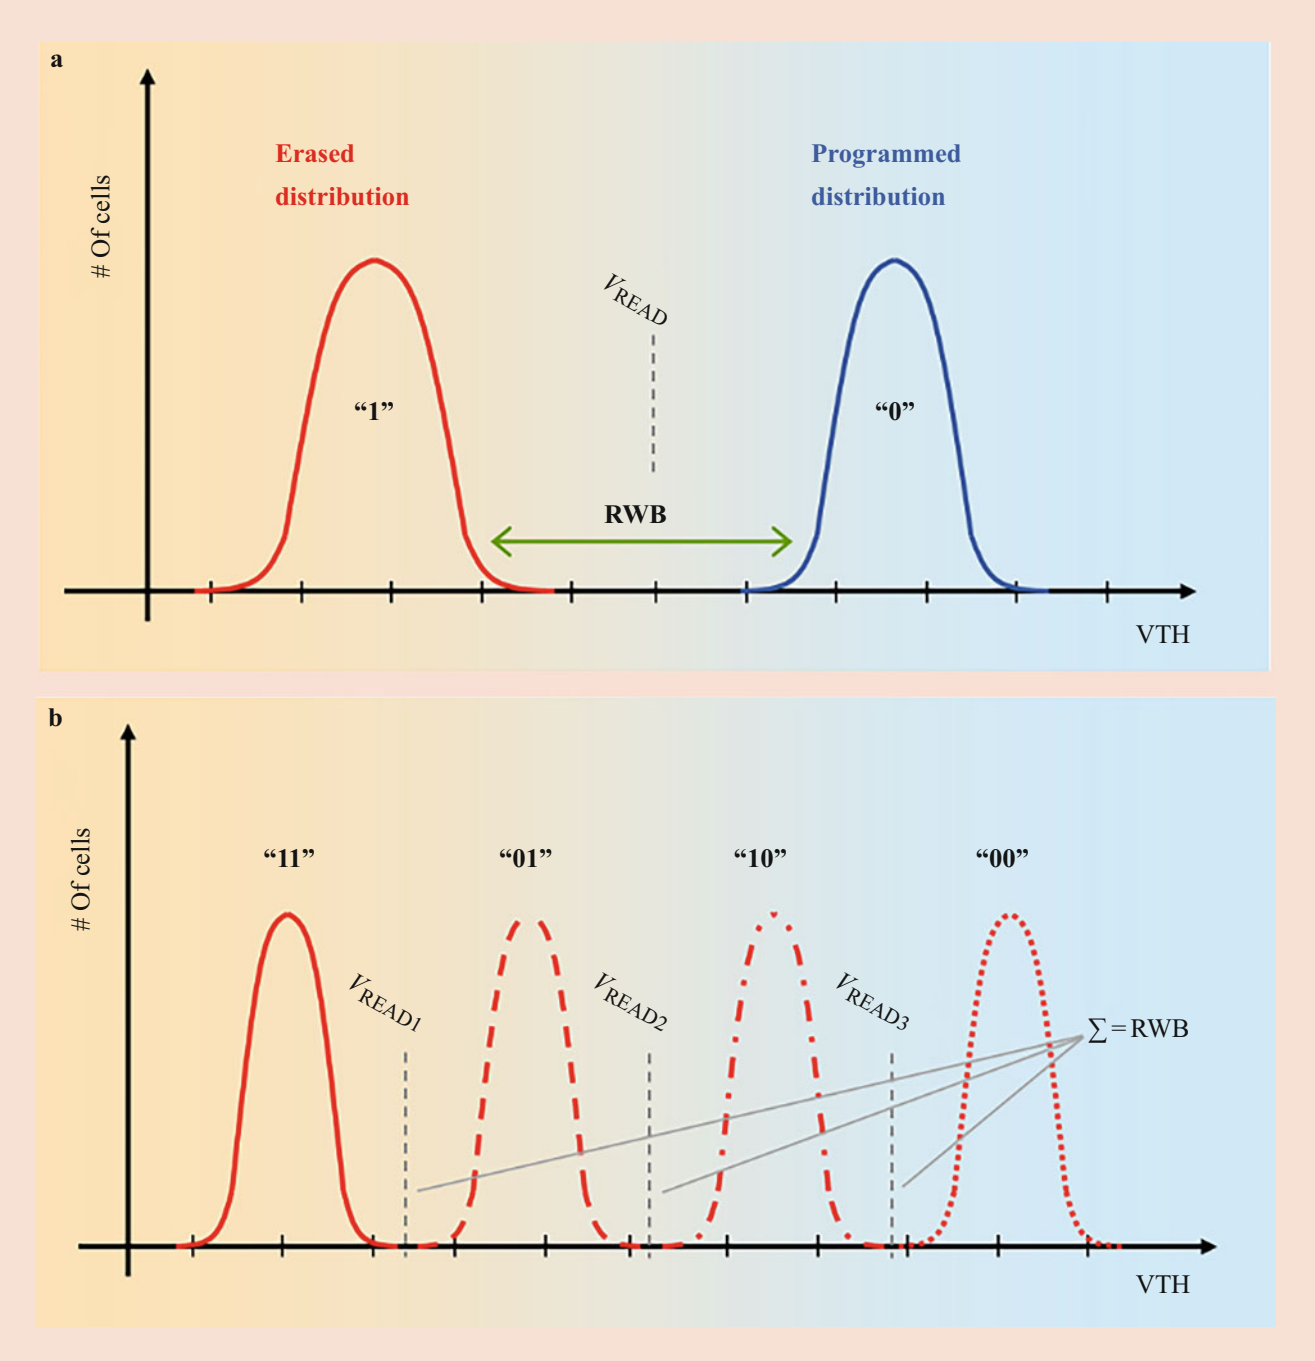

Fig. 2.19 (**a**) Ideal threshold voltage distributions for SLC and (**b**) MLC technologies

wells where the charge is stored in localized states into the trapping material, generally defects of crystalline lattice. This potential well can be ideally described as the depth of the energetic level of the trap in the forbidden gap of the dielectric trapping material. For commonly used silicon nitride-based material, this depth lies in the $1 \div 2$ eV energy range. However, the emission of a trapped charge toward external electrodes is a multistep phenomenon (Poole-Frenkel and band to band emissions), whose activation energy can differ from the energetic depth of trap level.

2.15 Charge Injection/Extraction Mechanisms: Programming/Erase Operations

Once we have in place the charge storage system inside the gate to substrate capacitor (either charge trap or FG systems), then the problem is to change the charge in a tightly controlled way, that is, let the charge flow through a dielectric: it could be a single layer or a composite stack

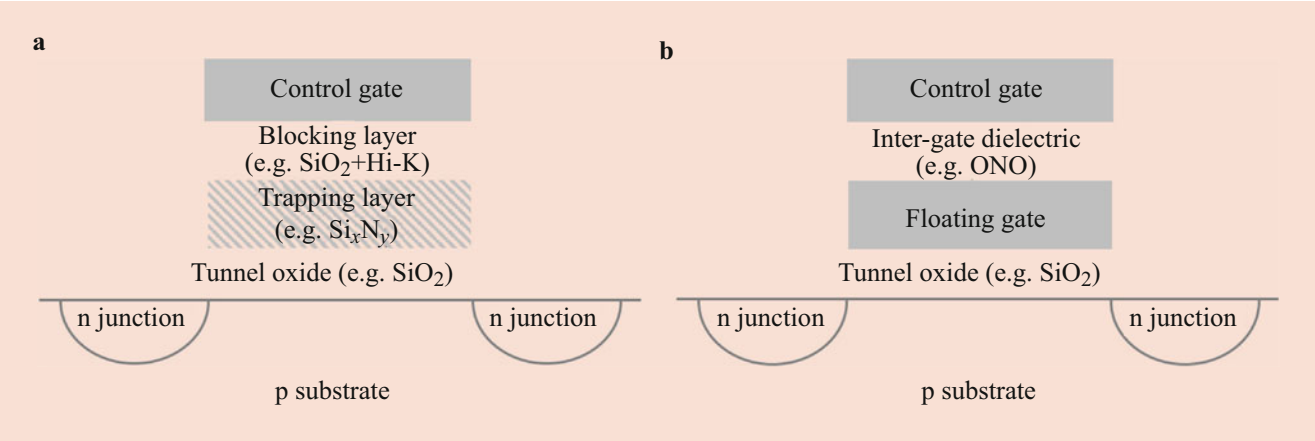

Fig. 2.20 Ideal cross sections of (**a**) a generic SONOS and (**b**) a generic FG device (n-MOS based)

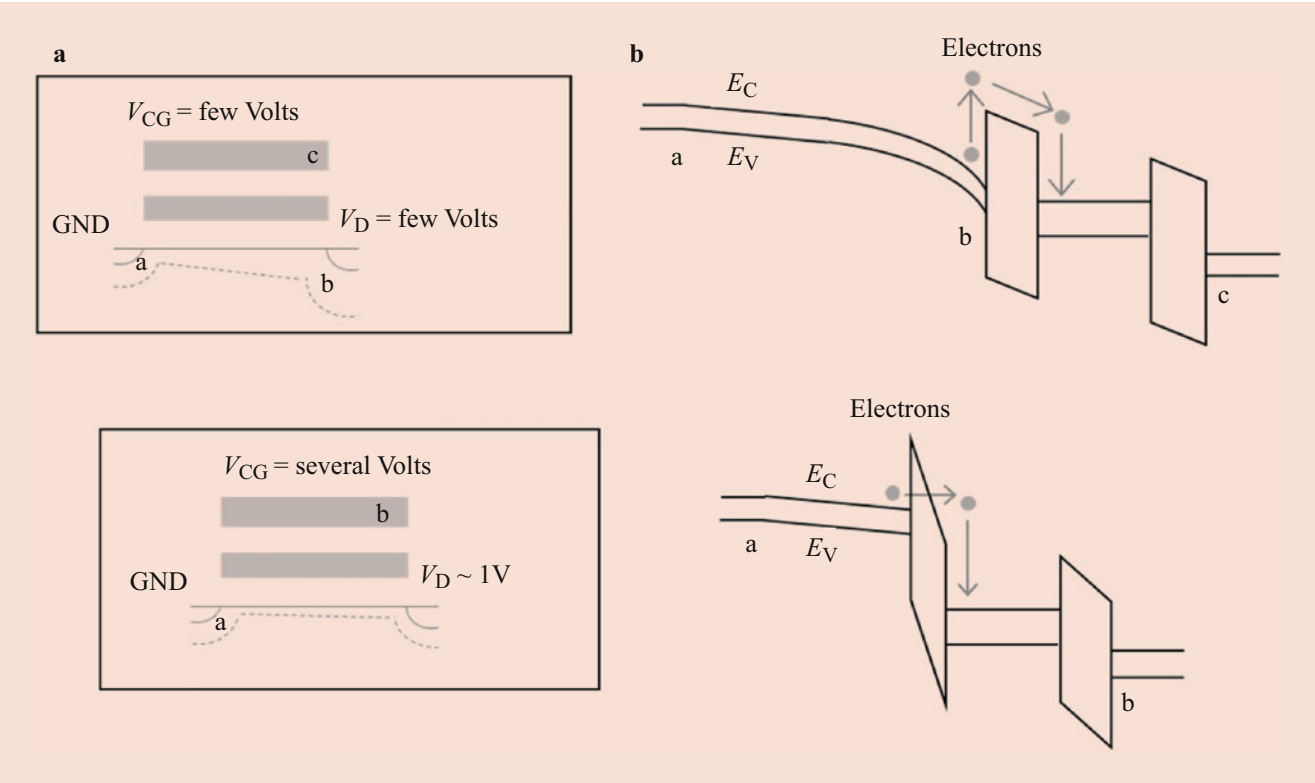

Fig. 2.21 (**a**) Biasing scheme and schematic energy band diagram related with the electron injection processes: by hot-carrier and by (**b**) Fowler-Nordheim tunneling

when the so-called band engineered (BE-tunnel) solutions are required [40].

Generally flash memories use two alternative mechanisms to make this charge transfer possible:

1. Hot-carrier emission and injection: they could be electrons or holes.
2. Quantum tunneling across a triangular energy barrier, also known as Fowler-Nordheim tunneling: it could be either for electrons injection or electrons extraction (flash memory cell is probably the most common man-made object relying on quantum mechanical effect: a real triumph of modern physics).

Figure 2.21 shows schematically the band energy diagram of a generic FG n-channel MOSFET system promoting an electron injection in the FG by using hot-carrier or Fowler-Nordheim tunneling.

Both mechanisms are strongly modulated by geometrical and constructional parameters of the device, such as doping, material features, thicknesses, and cell shape. It is important to notice that high energy carriers generated in both mechanisms are also source of spurious effects potentially leading to device degradation and limiting the total number of program and erase cycles that a flash memory device can experience in its lifetime.

NOR flash relies on hot-carrier injection for programming phase, while tunneling is used for erasing. NAND flash uses tunneling either for programming and erasing phases.

2.16 NOR Flash Array, Operations, and Reliability Aspects

NOR flash memory cells (generally FG MOS transistors) are connected as in Fig. 2.22 to form a memory array.

In this structure, every cell shares its source and drain contact (bitline – BL) with another cell whose control gates are connected to a different terminal (called wordline – WL). The NOR array can provide random access both for read and write operation.

Read operation is executed sensing the I_{DS} of cell (bitline current) and comparing it with a reference current. From a logic perspective, the array resembles a NOR gate where the inputs are the wordlines of cells connected in parallel to the BL. With this configuration, when one of the WL is brought high, the corresponding cell acts to pull the output BL low, analogously to the logical operation of a NOR gate.

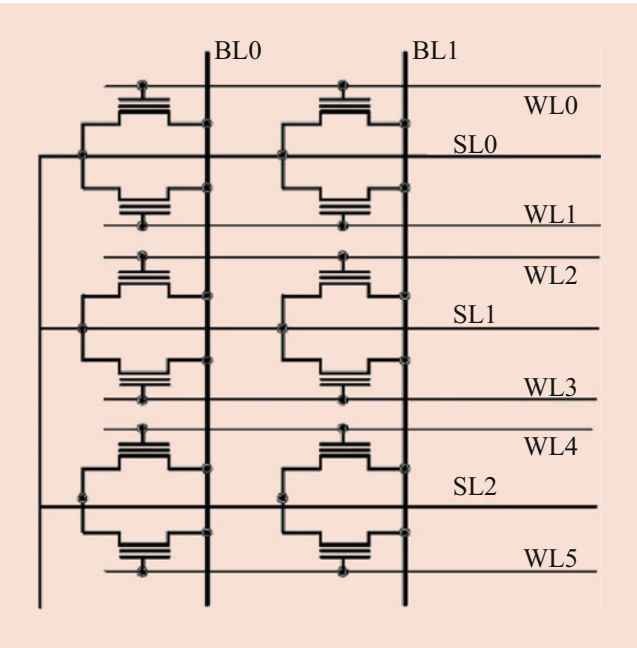

Fig. 2.22 NOR flash array section of 12 cells: 2 bitlines and 6 wordlines

In NOR flash cell, the programming or writing operation is performed by using hot electrons injection: these hot-carriers are generated by a high drain to source voltage (~5 V) and the increased probability for "lucky" electrons injection in the floating gate is granted by a vertical electrical field generated by an appropriate gate to source voltage. This mechanism is quite inefficient because of the large amount of I_{DS} required to generate a high enough number of "lucky" electrons. To avoid excessive power consumption, the maximum program parallelism is low: only few cells can be programmed at the same time.

The erase operation employs the Fowler-Nordheim (FN) tunnel effect by applying a high electric field across the cell stack (gate to source in the early version of the NOR cell, then gate to body in the more recent versions where triple well architecture is available). This high electric field bends the energy band structure enhancing the probability of electrons to tunnel through the oxide, thus extracting them from the FG. Being FN current very low, the erase operation can be performed in parallel over large sections of memory array (block erase) overcoming the intrinsic slowness of erase operation.

Figure 2.23 shows the TEM cross sections of industry standard NOR cells along with two orthogonal directions: (a) parallel to the WL; (b) parallel to the BL.

In particular, Fig. 2.23a shows two cells with shared control gates, but separate floating gates; while Fig. 2.23b shows two cells with shared bitline and drain contact but separate control and floating gates.

For NOR flash products, the data retention must guarantee up to 10 years at 65–85 °C and the dominant wear out mechanism for charge loss and gain occurs through electrons trapping in the tunnel oxide of the cell. This results in leakage through the insulator and the dielectric damage primarily induced by the ERASE/WRITE operations of a cell. Therefore, the maximum number of program and erase (P/E) operations is limited: typically, up to ~100 K cycles of program and erase.

2.16.1 NOR Flash Applications and Roadmap

NOR flash memory is used as primary storage for firmware such as the BIOS for PCs or set top box systems, because of the supported execute in place (XIP) capability granted by the random access for read and write operations.

In the early stage of mobile phones and digital cameras era, NOR flash has been used also as primary mass memory device in removable media (compact flash, MMC); however, the limitation of scalability and the high process cost due to

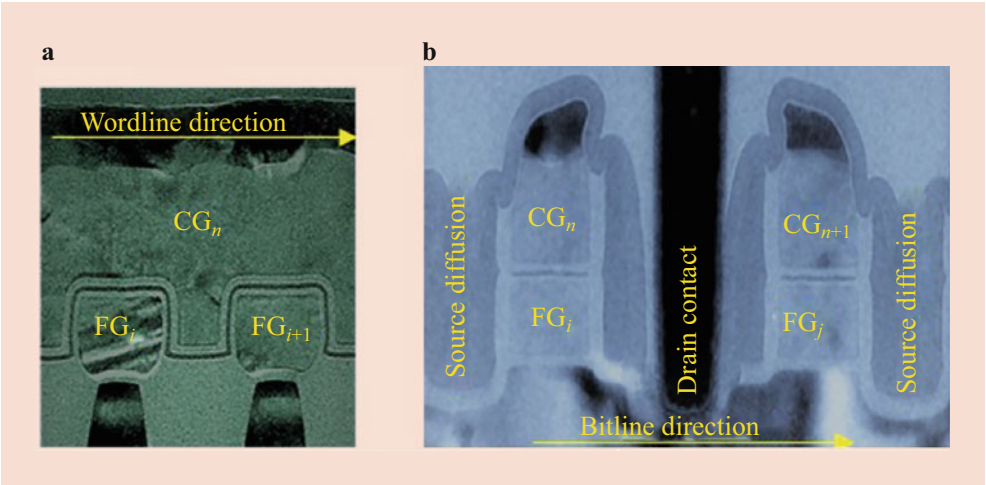

Fig. 2.23 NOR cell TEM sections: along WL direction (**a**) and BL direction (**b**)

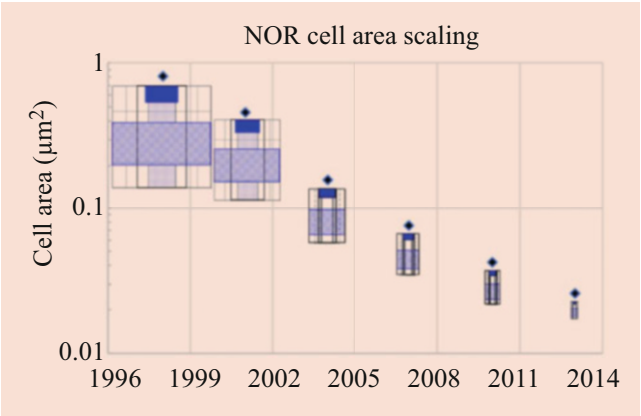

Fig. 2.24 Cell area reduction over 20-year roadmap of NOR flash cell

the need to integrate a drain contact (BL contact) every two cells prevented the diffusion of NOR flash in favor of NAND flash, which offers significative advantages in density and cost per bit as it will be illustrated in the following.

The technology effort for NOR cell scaling and thus for density increase is shown in Fig. 2.24; it practically ended after the first decade of 2000 with the introduction of the 45 nm node cell and 2 bits per cell (MLC) technology, but the market for NOR flash devices is in any case still growing driven by industrial, IoT, and automotive applications.

2.17 NAND Flash Array, Operations, and Reliability Aspects

In the quest for cheaper solid-state mass memory solutions, NAND flash became the solution of choice among all the invented array architectures and for all the high-volume memory manufacturers, thanks to the fact that NAND flash has the highest array efficiency and it can consequently reach density of memory not achievable with other flash architecture or by any other nonvolatile solid-state technologies.

In the array of NAND flash, the cells, which can be floating gate or charge trap-based MOS, are connected in series to form elements called strings as in Fig. 2.25. The number of cells tied in a single string varies according with the technology: e.g., up to 128 cells as for ultimate planar technologies. The string is then connected to the common source and to a single bitline (BL) by selector devices. The drain selector (DSL) connects the string to the bitline, while the source selector (SSL) connects the string to the common source. The selectors are generally MOS transistors or additional cells, not used to store data, integrated in the string with a similar technology process used for the cell formation.

Putting a large number of cells in series helps in diluting the overhead to array efficiency due to the presence of selector devices, but it must deal with electrical drawbacks, such as increased disturbs and higher series resistance, in particular for 3D NAND where the cell substrate is polycrystalline silicon.

In planar NAND technologies, the cell area approaches the ideal $4\lambda^2$, where λ is the minimum half pitch definable by lithography by means of advanced multiple patterning technologies. The transition to 3D architectures gives the possibility to move beyond this limit by stacking more cells on the same footprint and then to effectively decouple the density increase roadmap from the lithography node and patterning capability. In simple words, the transition to 3D architecture occurred arranging in vertical the NAND string and then moving out of the plane the integration Scheme [41]. 3D NAND architectures featuring this vertical channel and horizontal WLs are today the industry standard, and their simplified basic scheme is sketched in Fig. 2.26 [42–44].

NAND array is organized in pages, blocks, and planes. The page is the collection of cells sharing the same wordline

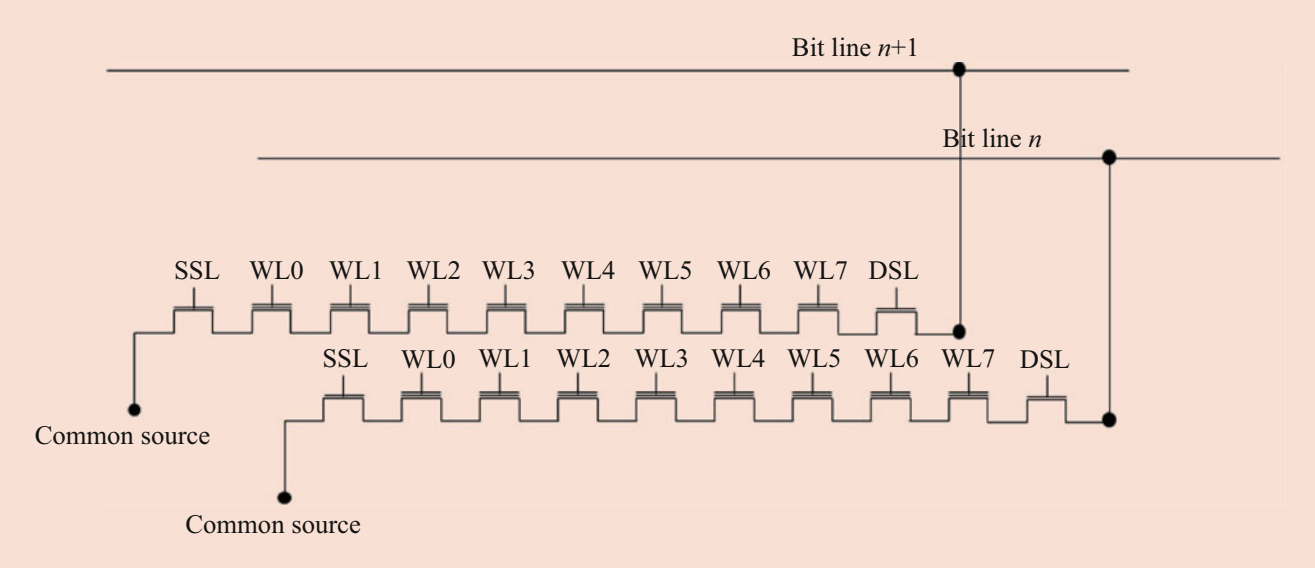

Fig. 2.25 Planar NAND array schematic showing two strings (BLn and BLn + 1) with 8 WLs

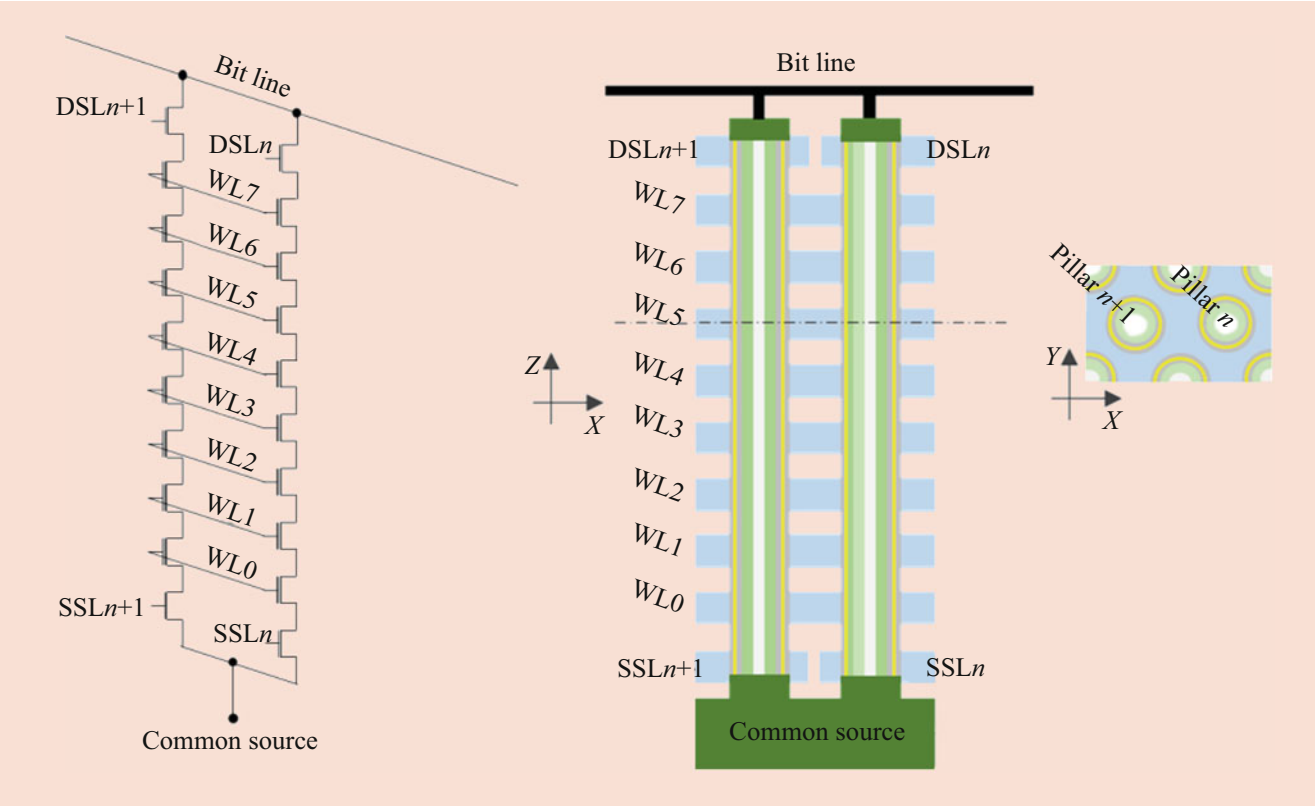

Fig. 2.26 3D NAND array schematic and pictorial sections showing two strings/pillars (vertical channel) and eight horizontal WLs

(WL) across a number of bitlines, spanning a dimension from 2 KB to 16 KB. The page defines the array section which can be read and programmed in parallel. For parallel reading, a large bank of sense amplifiers (called page buffer) is connected to the bitline system. Sense amplifier is a complex circuit mixing analog and digital parts.

During the read operation, by turning on both DSL and SSL, the current can flow through the string to the BL. Sense amplifier senses such a current, discriminating the threshold state of addressed cell identified by its WL (page index), and it digitalizes the information by storing it in one or, in case of multibit technology, more register latches which form

the data cache. The remaining cells belonging to the same string are turned on, regardless their threshold state, with a sufficiently high gate bias called pass voltage. Once the data from the page are stored in the data cache, then the output is obtained by serializing the page into data path to I/Os (typically by bytes).

The products of page size by the number of cells in NAND string define an array section called block. It is a collection of pages, and for a planar NAND, it has a physical density up to 16 Mb, while in 3D NAND it is generally bigger, from 32 to 64 Mb, thanks to an additional level of decoding due to drain selector. Block is the smallest array section that can be erased.

NAND flash uses the tunneling effect (see Fig. 2.21) for both program and erase operation. To program a cell, its WL is brought to a high voltage (more than 20 V) while its channel is kept low by turning on the DSL and keeping the BL to ~0 V. For the other cells sharing the same WL but located in different strings, the programming operation is inhibited by putting their channels in floating condition: in this way, the floating channel is coupled with WL potential, thus limiting the electric field across tunnel oxide and preventing tunneling current.

As said before, the tunneling mechanism requires a very low current, and then it is ideal for the high parallelism required by NAND page operations.

However, the propagation into the array of high voltage necessary for effective tunneling is creating electrical constraints, power dissipation, and reliability concerns. The typical page programming time is a function of the number of bits per cell, and it can span between 200 μs (SLC) and 2 ms (QLC). The overall energy necessary to program a bit is again function of number of bits per cell, array architecture, and technology parameters: for a MLC planar technology, it could be around 1000 pJ/bit [45].

While for planar NAND, the cell structure is similar to what described in the general section (Fig. 2.20a, b), for industry standard 3D NAND, the cell has a cylindrical geometry being formed by the intersection of WL plane wrapping all around the polycrystalline silicon pillar acting as substrate (see Fig. 2.27).

2.18 NAND Flash Roadmap

NAND flash devices are today the cheapest solution for solid-state mass memory systems. They are widely used for solid-state drive and memory cards such as microSDs. Until 2013, all the commercial NAND flash have been made using planar architecture in which roadmap is dictated by the scaling of planar transistors: definition of active areas, definition of gate, and interconnections. Scaled planar NAND flash devices use immersion lithography and double patterning techniques such as SADP (self-aligned double patterning)

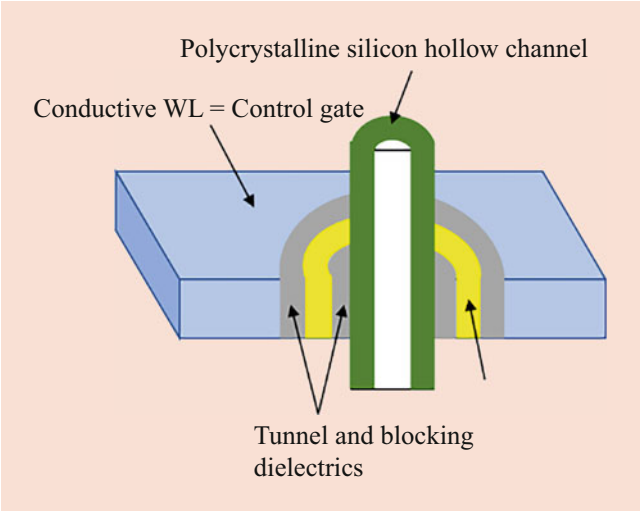

Fig. 2.27 Ideal semicircular cross section of the 3D NAND pillar and gate all around cell

to reach cell dimension well below 20 nm [46]. From 2013 the transition to 3D NAND flash architecture boosted the density to a new level. First industrial 3D NAND flash was fabricated by Samsung and featured 24 layers [47], but soon the transition to 32, 48, 64, and 96 layers happened [48–50]. Now, the race is going on and 128-layer technology has been announced by major industry players [51] while 176-layer outlook seems the next step [52]. TLC (triple-level cell) is the standard for 3D NAND; however, we have already seen makers able to deliver QLC devices at 64 layers [53]. Currently the highest density for a monolithic 3D NAND flash is 1 Tb, but this limit is expected to be outperformed soon [54].

2.19 Emerging Memories: An Insight on Phase-Change Memories

The previous two parts of the chapter have been dedicated to the main volatile and nonvolatile memory technologies nowadays present in a computer system. This section of the chapter will describe the phase-change memory (PCM) technology, classified as an emerging nonvolatile memory technology (see Fig. 2.28 reporting a map of emerging memories). Most of emerging memories are non-charge based, at variance with respect to the DRAM and flash concepts, previously discussed. In particular, ferroelectric memory (Fe-RAM) is based on the physical movement of atoms in response to an external field, which happens to be extremely fast, settling in about 1 ns. It is a random access memory similar, in construction, to DRAM but using a ferroelectric layer instead of a dielectric layer to achieve nonvolatility [55]. Floating-body RAM is one transistor memory cell used as a storage element, by modulating the threshold of the transistor

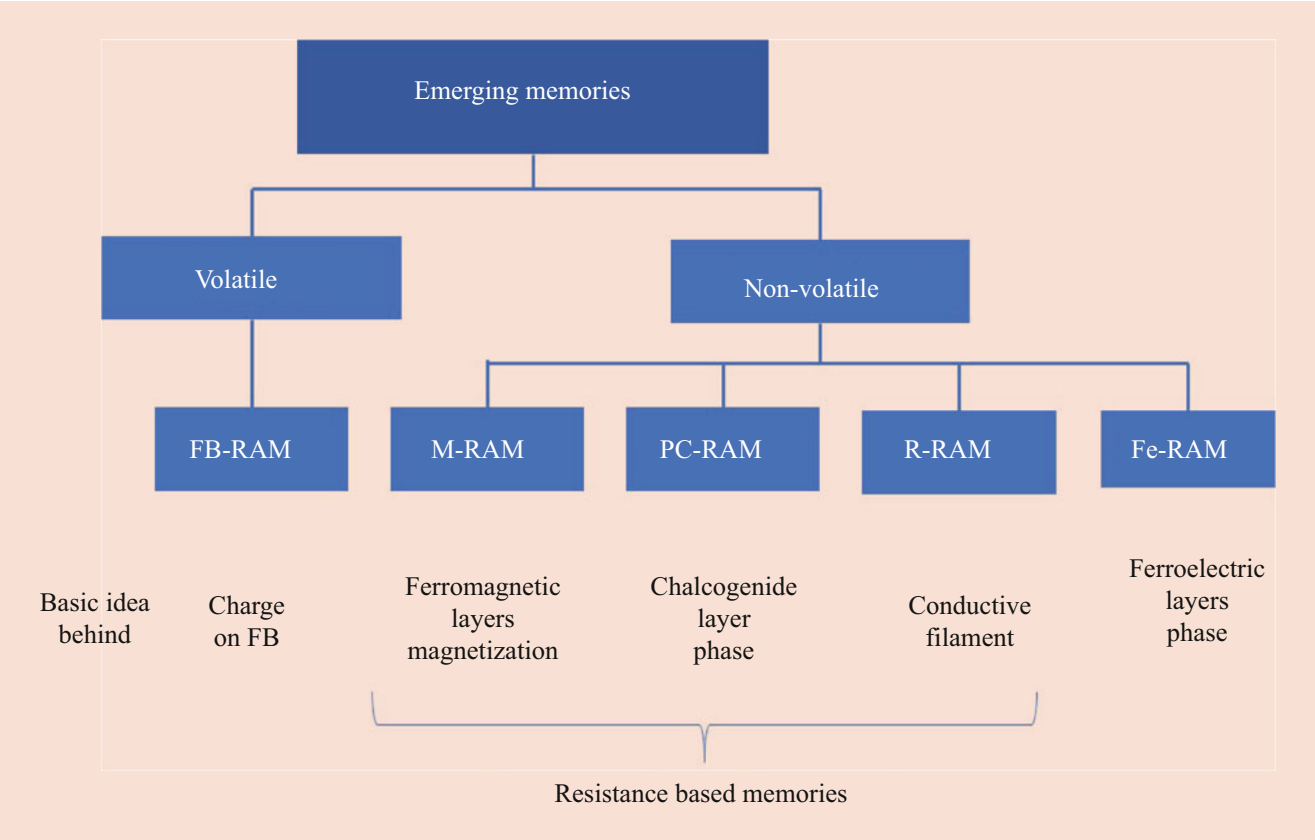

Fig. 2.28 Main proposals of emerging memories that can potentially complement the features of the DRAM and NAND previously described

via hole accumulation or depletion in the floating body region [56]. It was also proposed as potential candidate to replace the DRAM or even the 6T SRAM. The other proposed emerging memory concepts address the development of two-terminal devices that differentiate each other on the basis of the switching mechanism that controls the toggle between a high resistance state (HRS) and the low resistance state (LRS). The transition between the two states can be triggered by an electrical stimulus (i.e., voltage or current pulse). STT-MRAM relies on the parallel configuration (defining LRS) and anti-parallel configuration (HRS) of two ferromagnetic layers separated by a thin tunneling dielectric layer [57]; RRAM relies on the formation (LRS) and rupture (HRS) of conductive filaments within insulating layers sandwiched between two electrodes [58] (Chap ▶ 29).

PCM is the object of the present section. The physics at the basis of this technology and how the new physics might apply to build more efficient memory device will be described; at the same time, the opportunities and challenges to complement the previously described existing memories will be addressed.

The working principle of the PCM technology lies on the peculiar property of some chalcogenide alloys to reversibly toggle between the amorphous and the crystalline phase, thus the name phase change. The structural phase change also produces pronounced contrasts in the physical properties between the two phases. The optical contrast between the amorphous and crystalline phase makes these chalcogenide materials suitable for technological applications in the field of optical media and memories. The amorphous and crystalline phases also present a strong electric contrast: being the disordered amorphous network insulating, while the crystalline phase is conductive (Chap. ▶ 40). The abrupt resistivity change between the two phases (~3 orders of magnitude!) can be employed as the basis of electrically programmable and readable data storage. Hereto, the idea at the basis of the phase-change memory (PCM) is to *electrically* induce the phase transition of a chalcogenide-based thin film and to measure the device resistance as logic state of the cell. Since both states are stable, no energy is required to keep data stored, and PCM results in an inherently nonvolatile memory (NVM) technology. The best chalcogenide alloys for PCM applications belong to the class of GeSbTe compounds which follow a pseudo-binary composition (between GeTe and Sb_2Te_3, also including the GeTe and Sb_2Te_3 corners). Among them, the $Ge_2Sb_2Te_5$ (usually referred as GST) is the mostly used since it provides a good compromise between the speed of transformation from the disordered to the crystalline structure and the stability of the amorphous phase able to meet retention product requirements like 10 years at 85 °C.

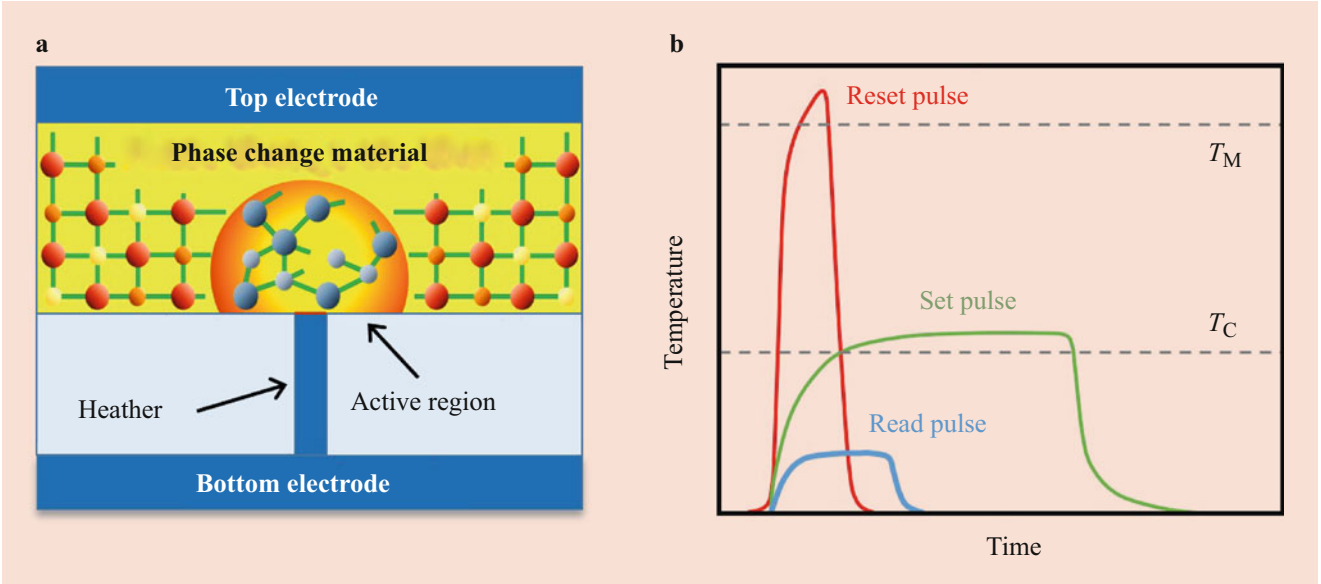

Fig. 2.29 (**a**) Sketch of the prototypical mushroom-like PCM cell where the current crowding through the small heater-phase-change material contact gives rise to the active area of the cell with mushroom boundary. (**b**) Temperature-time scheme of the pulses used to program the PCM cell in the reset and set states and to readout the state of the cell. Electrical pulses change the temperature in the active region of the cell, accordingly

The PCM cell architecture is essentially a resistor constituted by a thin film of chalcogenide material with a low-field resistance that changes by orders of magnitudes, depending on the phase state of the chalcogenide alloy in a possibly thinner layer than the total film thickness that is called active region of the cell. A prototypical architectural example of a PCM device is shown in Fig. 2.29a: it's called mushroom-type because of the shape of the active region coupled with the heater.

The switching between the two states of the active region is temperature activated. The glassy state of the material in the active region can crystallize when it reaches a critical temperature (T_c) and crystal nucleation and growth can occur (set operation). To bring the chalcogenide alloy back to the amorphous state (reset operation), the temperature must be increased above the melting point of hundreds of °C and then very quickly quenched down to prevent any ability of the glass to crystallize, leaving the cell in the amorphous state (Fig. 2.29b). The very small heater/phase-change contact area that characterizes this kind of PCM architecture is the key feature to develop a sufficient Joule heating effect to locally reach both the critical temperatures, T_c and T_M, thanks to the current crowding.

Figure 2.30 illustrates the electrical characteristics of the PCM cell. Depending on the chalcogenide material phase, the memory device features one of the two electrical characteristics depicted in Fig. 2.30a. The crystalline phase behaves as a resistor with a slope mainly dominated by the heater resistance itself. The amorphous phase shows an S-shaped negative differential resistance (SNDR) that starts from a high resistive off-state and collapses, with a decreased bias on the cell, into a high conductive on-state through the so-called threshold switching effect [59]. Figure 2.30b shows a typical programming curve of a PCM cell where the x-axis reports the programming current intensity of squared pulses of 100 ns duration and the *y*-axis the measured resistance as a function of the programming stimulus.

Both types of state transitions are shown in the figure. For the reset to set transition, the cell was always prepared in the reset state (correspondingly to $R \approx 1.5$ MΩ) prior to the application of the programming pulse. In this case, the programmed resistance steeply decreases for programming currents greater than 100 μA, due to the crystallization of amorphous chalcogenide film in the active region. The figure also shows the opposite (set-to-reset) transition, where the cell is prepared in the low-resistance crystalline state ($R \approx 3$ kΩ). Here, the cell resistance remains unchanged for moderately small programming currents and then abruptly increases for current values greater than 500 μA. This current value marks the chalcogenide melting temperature within the active region. In fact, rapid cooling of the melted chalcogenide along the falling edge of the program pulse results in a final amorphous phase, increasing the cell resistance. Note that the falling edge is a critical parameter in the set-to-reset transition: if the falling edge is not fast enough, the melted glass may re-crystallize leading to a final state with lower resistance. As already noticed, since both the crystalline and the amorphous state are stable, the two phases could be used to store binary information in a nonvolatile memory device, where the bit "1" corresponds to the conductive state and

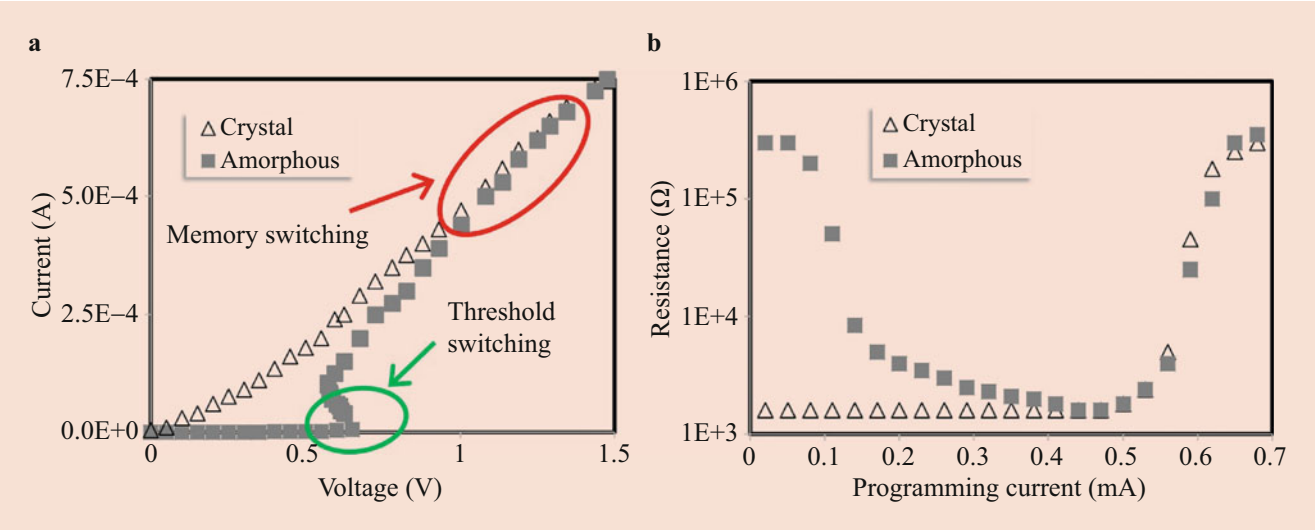

Fig. 2.30 (**a**) Current-voltage characteristics of the PCM cell with the chalcogenide alloy in the crystalline and amorphous phase and in (**b**) the R-I "U-shaped" programming curve of a PCM cell together with the R-I programming curve starting from the set state

the bit "0" to the insulating one. This electrically induced structural and electronic change has been thus named memory switching. It is worth noting that the threshold switching effect is required to get the memory switching mechanism but not vice versa. In fact, an amorphous chalcogenide has to be driven in a highly conductive electrical state through threshold switching to get the transition temperatures without enormous electrical fields [59, 60].

The minimization of the reset programming current, in addition to the power consumption control, addresses many performance implications enabling the PCM technology: the thermal cross-talk between adjacent cells, the need of a selector device able to drive high current in the programming on-state and to inhibit the current flow in the off-state, the *IR* drop management with large memory arrays, and the cell endurance with programming cycling. Several PCM architectures have been proposed to minimize the reset current.

Schematically, the various PCM cell architectures reported in literature can be classified into two main categories with their specific advantages and weakness, according to the taxonomy and philosophy:

- Built-in heater architecture where a dedicated element, hence named "heater," generates the heating necessary for the phase transition inside the PCM cell.
- Self-heating architecture that relies on the Joule heating generated inside the chalcogenide itself to increase the temperature and promote the phase transition.

The above presented mushroom-type PCM cell is the prototype of the first class that has been realized following different process embodiments and seize features [61–64]. In ref. [64], the synopsis of the process integration of one of them, the so-called "wall structure," that demonstrated its manufacturability at the 45 nm technology node as a 1 Gb PCM product operating at 1.8 V and exploiting a reset current as low as 200 μA can be found. At variance, an example of self-heating based cell in its extremely scaled version where the PCM cell constitutes the conformal connection between carbon nanotube electrodes with few nanometers diameter size is reported in ref. [65]. This is an academic work that demonstrated both the phase transition on the nanometer scaled device and the reset current scalability as low as 5 μA.

In addition to architectural approaches, mostly related to the programming current minimization, a lot of efforts have been devoted to other areas of improvement of the PCM to sublimate its performances, mainly by means of these three vectors:

- The thermal engineering in which guidelines can be found in ref. [66].
- Phase-change material optimization about which some refs can be found in [67–69].
- The minimization of the drift issue enabling the management of multilevel PCM as addressed in ref. [70].

It is worth to mention that, in 2009, PCM technology demonstrated the maturity to enter into the market through a 1Gb PCM product fabricated at the 45 nm technology node [71]. At that time, the feature set and main market focus for this product were the replacement of NOR flash memory in cellular phones. The product specifications were superior to NOR flash and ~10 millions of these devices were used in phones: it is believed that still today this represents the largest volume of bits ever shipped of a non-charge based solid-state memory device.

However, the choice of targeting the NOR cellular market may not have been the best choice. With the advent of smartphones, the cellular phone architecture started to rapidly move from a NOR-based "execute in place" architecture to a NAND+DRAM-based "store and download" architecture. This transition was driven by the rapid increase in storage required by the smart phone which was enabled by the rapid increase in density supplied by NAND. The NOR flash market in cellular phones dramatically decreased over the past 12 years and thus the PCM opportunity in this segment. Ultimately the cost of the technology was too high for the value delivered, and, while the technology was successful in manufacturability, endurance, and performance, the density was not high enough (meaning the cost structure not low enough) to be consistent with the feature set. The technology was not capable of delivering an "overwhelming compelling value" adequate to get the systems to make the changes required for its option. Definitively, this is the challenge for any emerging memory: since current system hardware and software architectures are heavily entrenched with many years of evolved development built into them in order to exploit the capabilities and mitigate the deficiencies of the existing DRAM and NAND memories, any emerging memory, such as PCM, must offer an "overwhelming compelling value" over conventional memories to motivate the entire ecosystem to adopt it and to eventually achieve success in the market. As mentioned in the semiconductor memories taxonomy at the beginning of this chapter, the storage class memory (SCM) applications represent the target of emerging memories. While from the side of performances like speed, power-consumption, and endurance, the PCM technology is demonstrating to be a top contender in the arena of SCM, the cost structure needs to be torn down. The 3D structure integration can reduce the cost of PCM devices. A cross-point stacked solution combining a PCM with an ovonic threshold switching as selector has been proposed in 2009 [72]. An emerging memory called 3D XPoint™ technology, without any details released by producers [73], but on which TechInsights reported that storage and selector elements are chalcogenide-based glasses [74], is entering to the market with a 128 Gb product at 20 nm lithographic node, showing the possibility for a new SCM.

2.20 In-Memory Computing and Neuromorphic Applications

The incipit of the volatile memory section of the present chapter recalled the von Neumann architecture introduced and used since the late 1940s and still the architectural principle for most computers (Chap. ▶ 32). In this architecture, there is a strict separation between the computation unit and memory. Thus, all data is stored in memory and then transported to the calculation engine back and forth. Data and instructions for the processing unit use the same data bus, leading to the so-called von Neumann bottleneck. Definitively, shuttling around all this data carries with it a significant power and performance price. Just think that in highly data-centric computing, most of the energy is consumed not in computation but in transferring data to and from the memory [75]. So, although the astounding progress through Moore's scaling law made possible demonstrations of truly remarkable tasks of artificial intelligence (AI), these results are achieved at the expense of an energy consumption that is orders of magnitude higher than the one of the human brain. Thus, radically new approaches, in some way emulating the human mind, are essential for creating a more efficient next-generation information technology.

Let's again have a look to biology: we already recalled as the human memory shows as a heterogeneous entity with complementary features, thus addressing the storage class memory as an opportunity, more favorable than the research of a universal memory. And in comparison to the separation of memory and logic of the von Neumann paradigm, biology figures out a better way: doing the compute in memory.

So a new frontier for memory technologies and systems lies in the development of a new computational memory paradigm where certain computational tasks are performed in the memory itself by exploiting the physical attributes and state dynamics of the memory devices. Conventional computation done in the CPU logic unit executes advanced operations through a sequence of elementary Boolean logic operations among bits. It has been quite recently demonstrated as emerging memories belonging to the class of memristive devices can emulate logic gates capable to carry out these functions [76].

Again, digital computers address the solution of problems such as linear systems by using a large number of computing steps by using the Boolean algebra, calling for possible most efficient ways to solve these kinds of algebraic problems. In this scenario, the nonvolatile memory (NVM) crossbar arrays represent a natural framework where, by construction, the matrix-vector multiplication (MVM) can be performed. Some ideas for the solution of algebraic problems with cross-point resistive arrays starting from the ability to execute MVM computations have been recently demonstrated [77, 78]. Figure 2.31 sketches a cross-point circuit for solving a linear system and mapping the elements of matrix A at the basis of the matrix formula: $Ax = b$, where b is a known vector (in this example the input currents) and x is the unknown vector [79].

In addition, an amazing feature of the human brain lies in its cognitive functions that are possible thanks to the learning and memory processes of a nervous systems. In neuroscience, the basis of the brain learning is found to be related to the process that modulates the connection strength of the

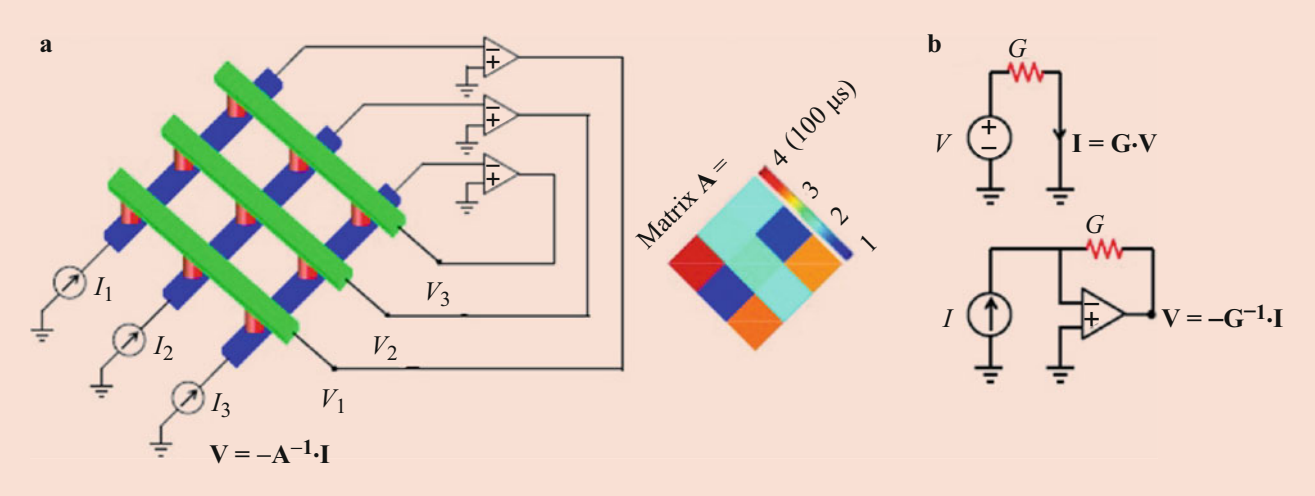

Fig. 2.31 (**a**) Cross-point circuit for solving a linear system or inverting a positive matrix. RRAM elements (red cylinders) are located at the cross-point positions between rows (blue bars) and columns (green bars). Conductance values mapping the elements of matrix *A* are also reported in figure a. (**b**) Circuits to calculate a scalar product $I = G{\cdot}V$ by Ohm's law and to calculate a scalar division $V = -I/G$ by a transimpedance amplifier

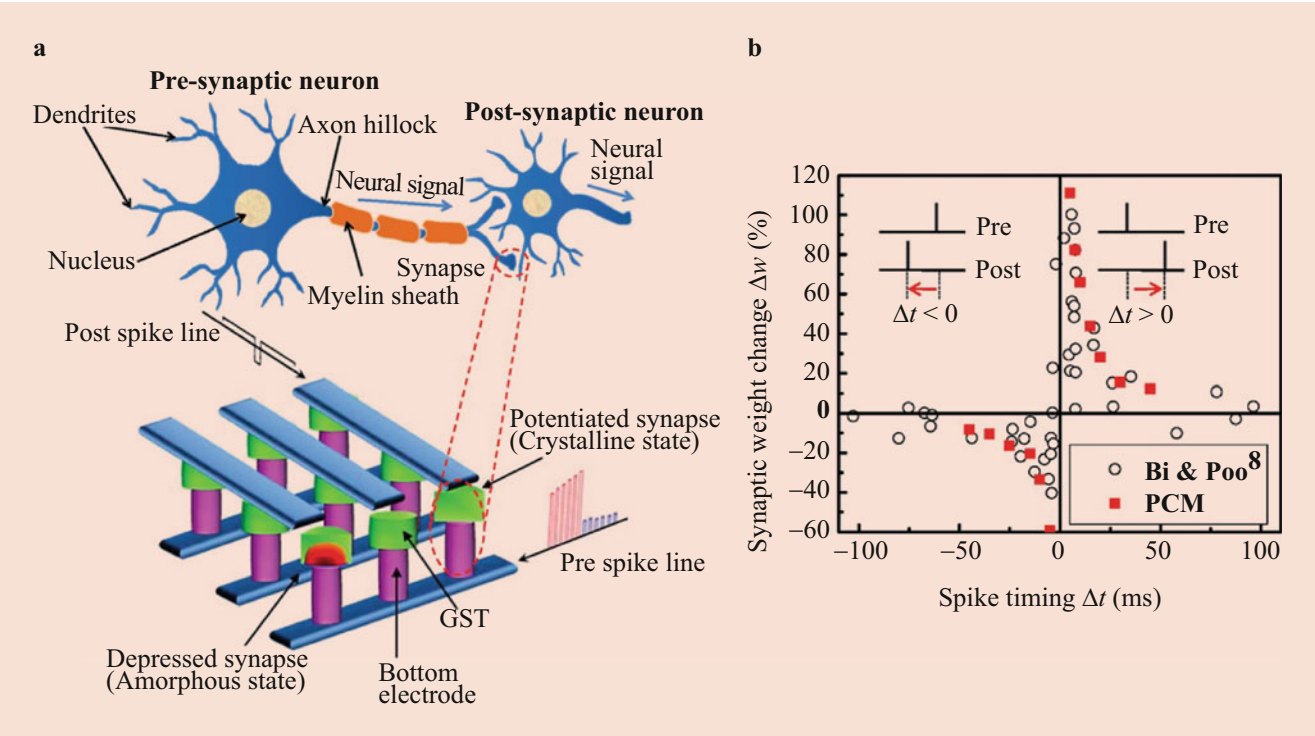

Fig. 2.32 (**a**) Schematic structure of biological pre-, post-, and synaptic connection. Bioinspired interconnection scheme of PCM synapses lies between post-spike and pre-spike electrodes; (**b**) synaptic weight change as a function of the relative timing of pre- and post-spikes implemented through PCM cells [80]. The good comparison with biological data demonstrates the ability to mimic the STDP behavior with PCM-based artificial synapses

synapse linking two neurons (referred to as synaptic weight). In particular, the spike-time-dependent plasticity (STDP) is a form of synaptic plasticity that updates the synaptic weight on the relative timing between pre-synaptic and post-synaptic spikes (see Fig. 2.9a). As it is shown in Fig. 2.32a, if pre-synaptic spike fires before the post-synaptic spike, long-term potentiation (LTP) will occur. Long-term depression (LTD) occurs when firing order is reversed.

Definitively, an electronic analog of a biological synapse needs the ability to exhibit STDP in order to mimic the synapse functionality. It has been shown that many emerging memory devices can really reproduce the synapse plasticity, fitting the biological behavior of synapses. An example of this is shown in Fig. 2.32b, where STDP is carried out by a PCM cell [80, 81]. In this context, IBM is strongly working employing phase-change memories that offer multiple advantages such as scalability, reliability, endurance, and multiple programming resistance levels giving them a suitable candidate for implementing large-scale synaptic systems.

In summary, dense crossbar arrays of emerging memory devices represent an opportunity to emulate the non-von Neumann human brain computing paradigm with high degree of connectivity (any given neurons having as many as 10,000 inputs from other neurons) through adaptive elements (synapses). This structure enables the massive parallelism and energy-efficient operation found in the human brain [82]. Nonvolatile memory (NVM) crossbar arrays to few nanometer dimensions are a promising path to build computing systems able to overcome the so-called "von Neumann bottleneck," performing the computation in the memory elements while they remain in place, thus avoiding the redundant load-and-store operations as the human brain suggests.

Abstract

This chapter provides an overview of BCD (Bipolar CMOS DMOS) process technologies which are devoted to realize smart power ICs for different applications in the automotive, industrial, computer peripherals, and personal electronics domains.

After an initial overview of the possible isolation schemes and their reflection on the BCD platform differentiation, a description of the BCD technology architecture, compared to more standard CMOS processes, is presented.

Focus is then given on the technology enablers which are driving the innovation in order to meet the evolution of the applications.

The increase of digital processing capability and the need for embedded nonvolatile memories enabled by the minimum lithography reduction and by new emerging memory technologies are first discussed.

Then the requirements for more efficient and robust high voltage and high current power stages and the demands coming from analog functions are described showing power component architectures and innovations in the metal and dielectric layers which need to withstand very high currents and thermomechanical stresses.

The section on new technology enablers ends up with the presentation of passive modules to address specific analog and high voltage applications.

Finally, the future trends and challenges for BCD technology development are summarized.

3.1 Introduction

The name BCD has been created in the mid-1980s to classify that family of mixed processes which allow to integrate into a single-chip bipolar, CMOS (complementary MOS), and DMOS (double diffused MOS) transistors to realize power IC class called smart power ICs (Fig. 3.1) [1].

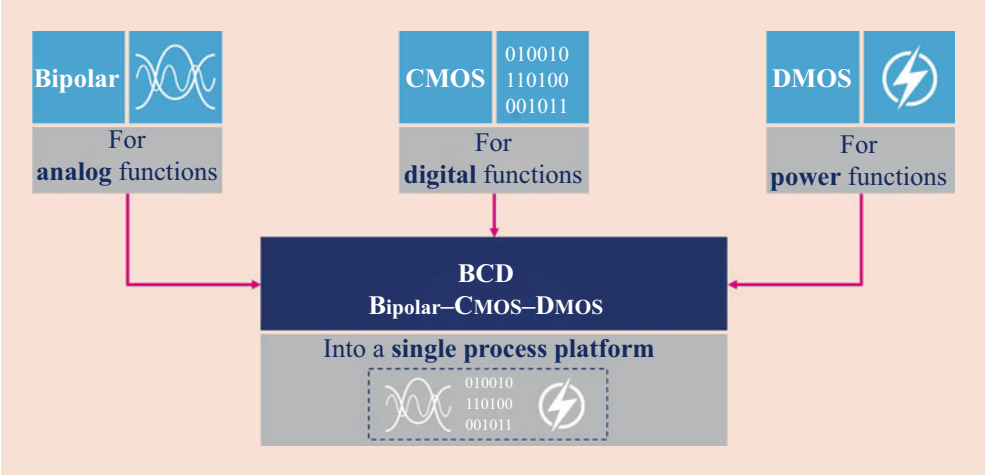

Fig. 3.1 Merging in one single BCD technology of bipolar, CMOS, and DMOS transistors

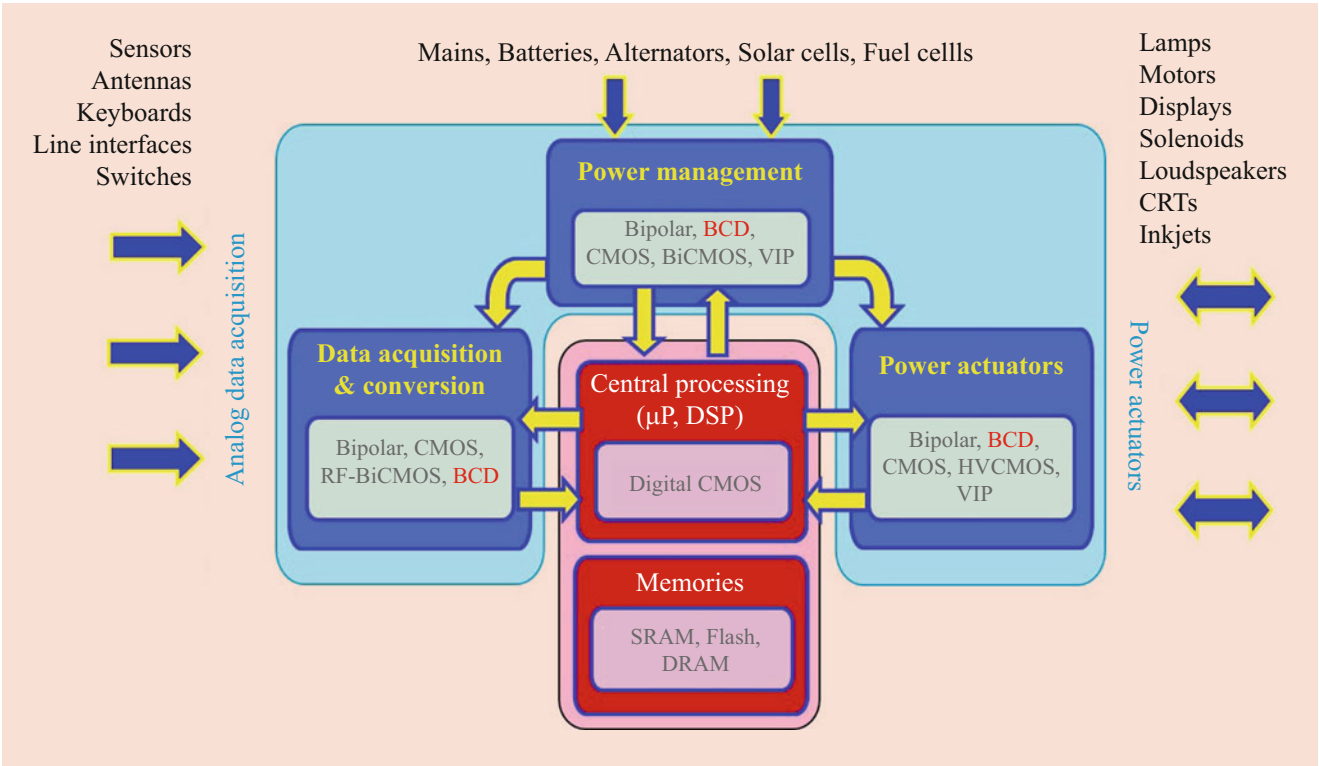

Fig. 3.2 Generic electronic system description highlighting the different functions addressed by BCD technology power ICs

This kind of technologies increased drastically the complexity of control circuits that could be integrated and led to a new way of approaching system integration, enabling:

- Higher energy efficiency solutions.
- Improved system reliability.
- Reduced electromagnetic interference.
- Smaller footprint of the final application.

Thanks to the BCD process technology features, the usage of this platform for power IC realization has been growing during the years since it has been possible to integrate in a cost-effective way many different functions in the same chip.

Today it is possible to state that any electronic system in any application field is requiring one or more power ICs realized in a specific BCD process technology to address (Fig. 3.2) some specific actions such as the following:

- Data acquisition securing, for example, system battery voltage accurate measurement, current and motion sensors output signals conditioning, or interface specific communication bus (LIN, CAN, FlexRay in the automotive application).

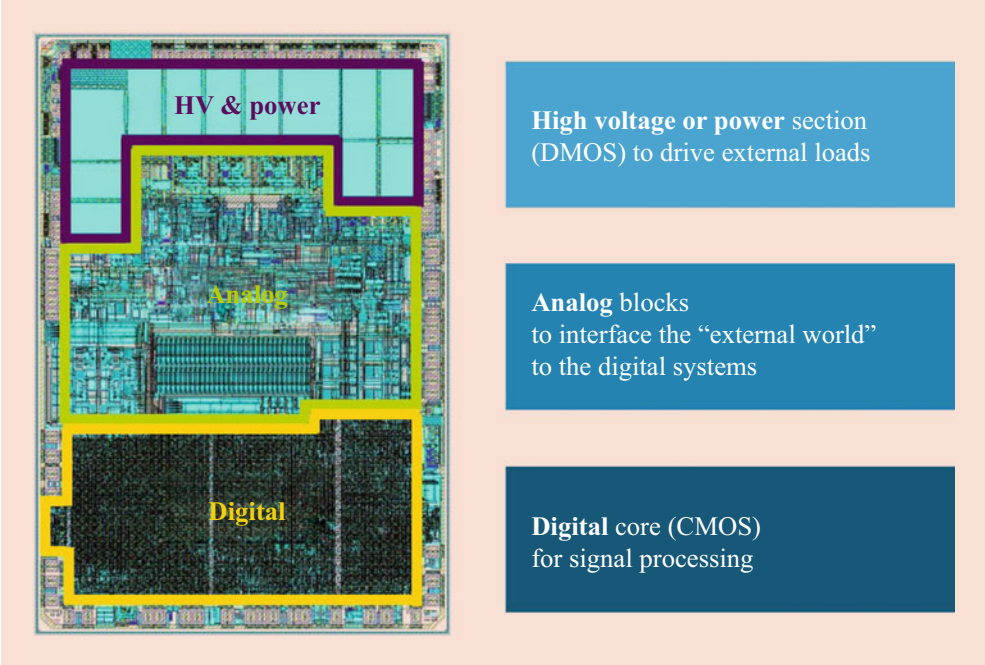

Fig. 3.3 Typical BCD power ICs embedding digital core, analog stages, and power section

- Power management securing the supply voltage and current to specific complex ASIC (application-specific integrated circuit – microcontrollers, memories) realized in advanced technology node.
- Actuation to drive many different loads such as electrical motors, gasoline car injectors, audio loudspeakers, or external large power discrete devices when loads are requiring higher power level.

In Fig. 3.3 a typical BCD power IC product is reported highlighting the three main integrated blocks for digital processing, analog signal conditioning, and power stages.

Given the very wide spectrum of application addressed with many different specific requirements, the integrated functions on BCD power ICs are driven by the overall electronic system cost and performance requirements. For this reason, the evolution of BCD technology roadmap during the years is following multiple paths (Fig. 3.4) to enable the right level of function integration on a single chip securing the application performance requirements with the minimum system cost level.

In the following paragraphs, the main enablers driving BCD technology evolution will be addressed.

This chapter describes the evolution of smart power technologies for automotive, industrial, and consumer applications that is going both in the direction of microlithography reduction; of improved power device performances, increasing voltage and current capabilities; and of additional tailored modules and analog features (Fig. 3.5).

Advanced technology nodes down to 40 nm with embedded nonvolatile memory solutions are today announced enabling added intelligence for monitoring and control.

Voltage capability is provided up to 2000 V and even on-die galvanic isolation up to 10 kV can be realized.

High current (tens A), severe energy dissipation requirements, extended life, and temperature range can be satisfied thanks to the availability of novel metallization schemes and packaging solutions.

3.2 BCD Technology Platform Differentiation from Isolation Scheme

In BCD technology, multiple devices are integrated in the same chip to realize the different functions. Electrical isolation among the different active and passive elementary components plays a key role in the final product performance. This is particularly true given the very demanding application constraints such as high junction temperature, high current switching power devices, and accurate analog stages.

Different solutions are adopted to achieve the appropriate isolation performance (see Fig. 3.6).

- Junction Isolation (JI)

  Today it is the most common solution given the lower integration cost. Isolation among devices is obtained through reverse biased P-N junctions (Fig. 3.7). Larger silicon area is required to withstand the voltage between adjacent high-doped deep n layers: reduced lateral diffusions and introduction of specific P-type bottom layers are required to mitigate the extra size. Since parasitic stray substrate bipolars are triggered during product operations, area consuming active protections are needed to mitigate cross talk among different devices.

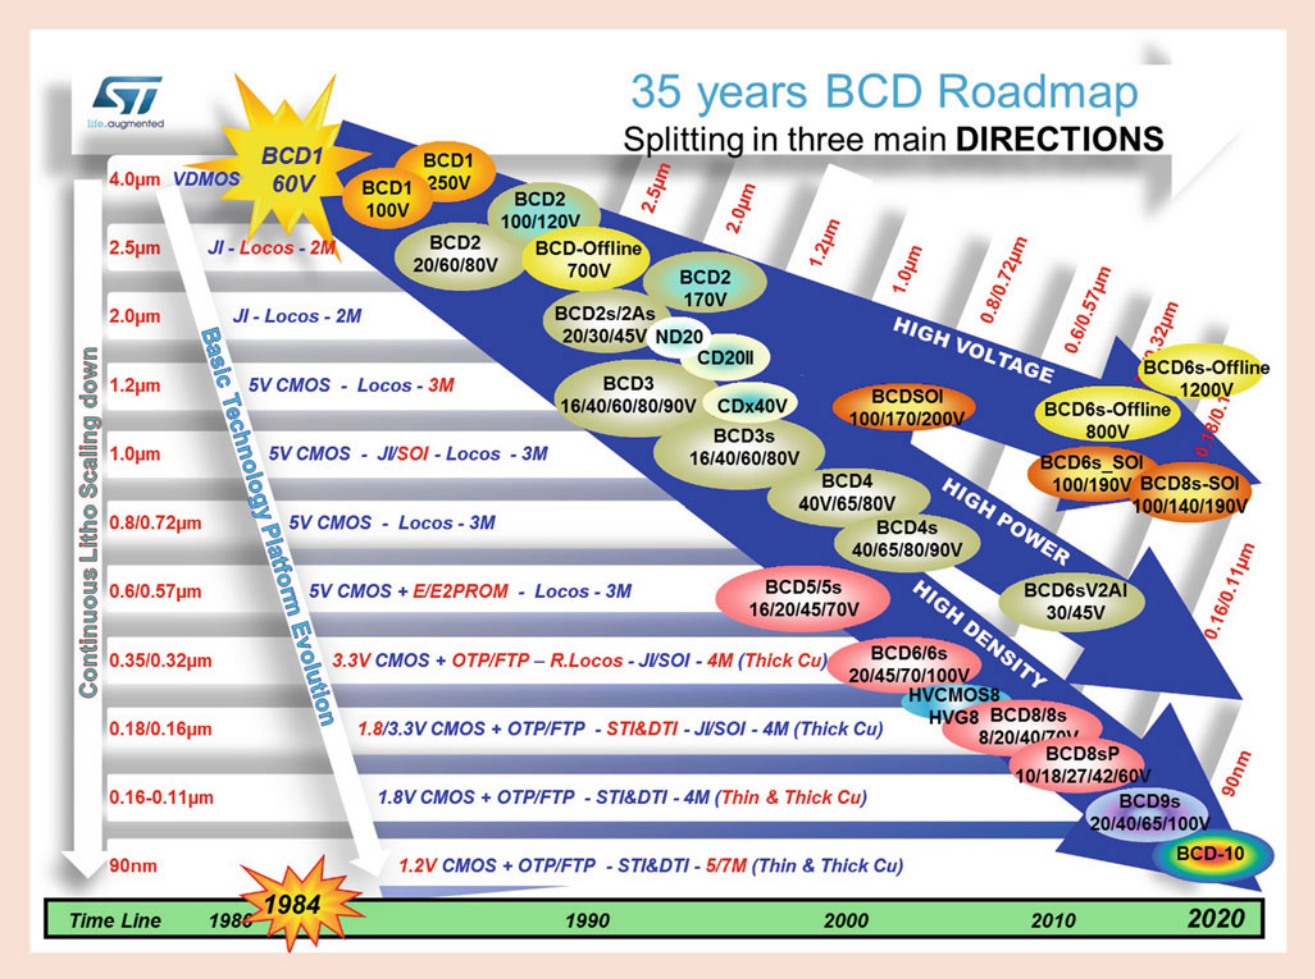

Fig. 3.4 ST BCD technology roadmap

- Deep Trench Isolation (DTI)

  Two adjacent devices are laterally isolated by a thick oxide in a deep trench in silicon (Fig. 3.8). This solution leads to a meaningful isolation area reduction (Fig. 3.9) increasing with higher rating voltage.

  The lateral contribution to intrinsic PNP parasitic bipolar (see Fig. 3.10) is inhibited by the deep trench limiting the amount of current injected in the substrate during the power operations. At the same time, deep trench is also limiting the lateral NPN bipolar gain reducing the electrons equivalent diffusion length in the substrate (see Fig. 3.11). Overall this is leading to a meaningful area gain and improved latch-up immunity.

  Together with the oxide isolation layer, many solutions have been presented introducing a highly conductive film (highly doped boron polysilicon or tungsten plugs) to secure a good ground connection to the substrate [2–4].

  The main drawback of this solution is the increased cost coming from the integration of different layers and process steps.

- Full Dielectric Isolation (Silicon on Insulator, SOI)

  This is the most effective solution to eradicate any parasitic effect among different devices securing an area effective electrical isolation (Fig. 3.12). Starting from silicon-on-insulator substrate, N-type silicon regions are separated laterally by oxide filled trench. To minimize cross talk among adjacent pockets in some implementation, a grounded silicon region is placed between two trenches. Increased thermal resistance and high starting material cost are limiting the adoption of this solution to a reduced number of applications usually requiring larger voltage (above 150 V) or demanding performance such as large negative voltage management, high power efficiency, or high junction temperature.

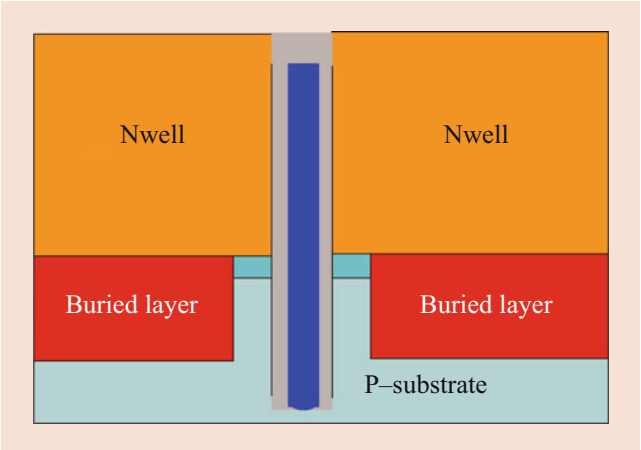

Fig. 3.8 Deep trench isolation architecture schematic cross section. Two adjacent N-type regions separated by a deep trench filled with a dielectric. In some implementation, a conductive layer may be added (blue region)

3.3 BCD Technology Architecture

The typical BCD technology architecture is shown in Fig. 3.13 in one of the latest implementation.

The most advanced BCD nodes are conceived following a process scheme as depicted in Fig. 3.14, which is realized adding some basic bricks to a typical CMOS flow:

- Buried layers and epitaxial growth.
- Scheme of isolation among components.
- Dedicated wells and implants for high voltage and power components.
- Steps for embedding of nonvolatile memories, both conventional and emerging types.
- Specific schemes of power metal levels.

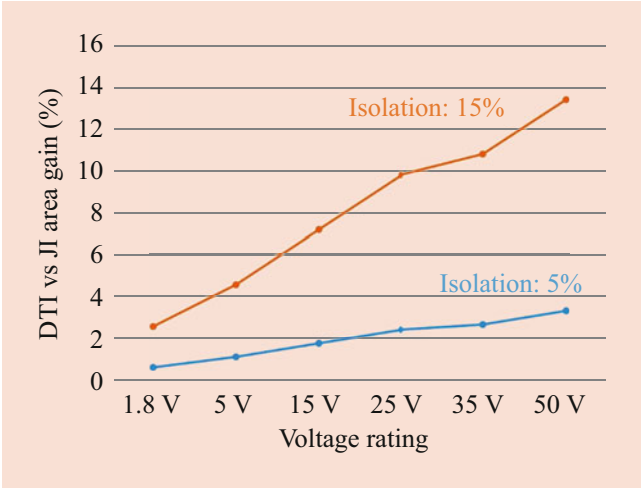

Fig. 3.9 Deep trench isolation area gain vs junction isolation for different rating voltage. Different curves refer to different amount of isolation in the circuitry. (Reference: ST proprietary BCD technology)

3.3.1 Buried Layers and Epitaxial Growth

Heavily doped N-type buried layers are historically introduced in BCD technology.

The original purpose of these layers has been to provide a low resistive path to collect the drain current of vertical power DMOS transistors bringing it to the die surface through heavily N-doped sinker diffusions.

The other N-buried layer functions are to reduce parasitic current injection into the substrate, to secure high voltage vertical isolation and to act as collector region in NPN bipolar transistors (Fig. 3.11). In this way the CMOS logic blocks are protected from collecting parasitic current injected in the substrate by the switching of power transistors, and therefore they are immune from disturbances coming from the power sections of the smart power IC.

In present BCD technology integrating lateral power DMOS transistor architecture, the drain current collecting function described above is no more required.

P-type buried layers can be added in the flow to enhance lateral isolation between components, as part of a junction isolation scheme.

Following buried layer implantations, lightly doped epitaxial layer is grown in order to build then all active and passive devices.

Its thickness and resistivity are key parameters to define the voltage capability: thin and low resistivity layers are commonly used for low voltage (<60 V) applications, while thicker and higher resistivity layers are adopted for higher voltage.

Different flavors of epi doping can be found in the microelectronic industry:

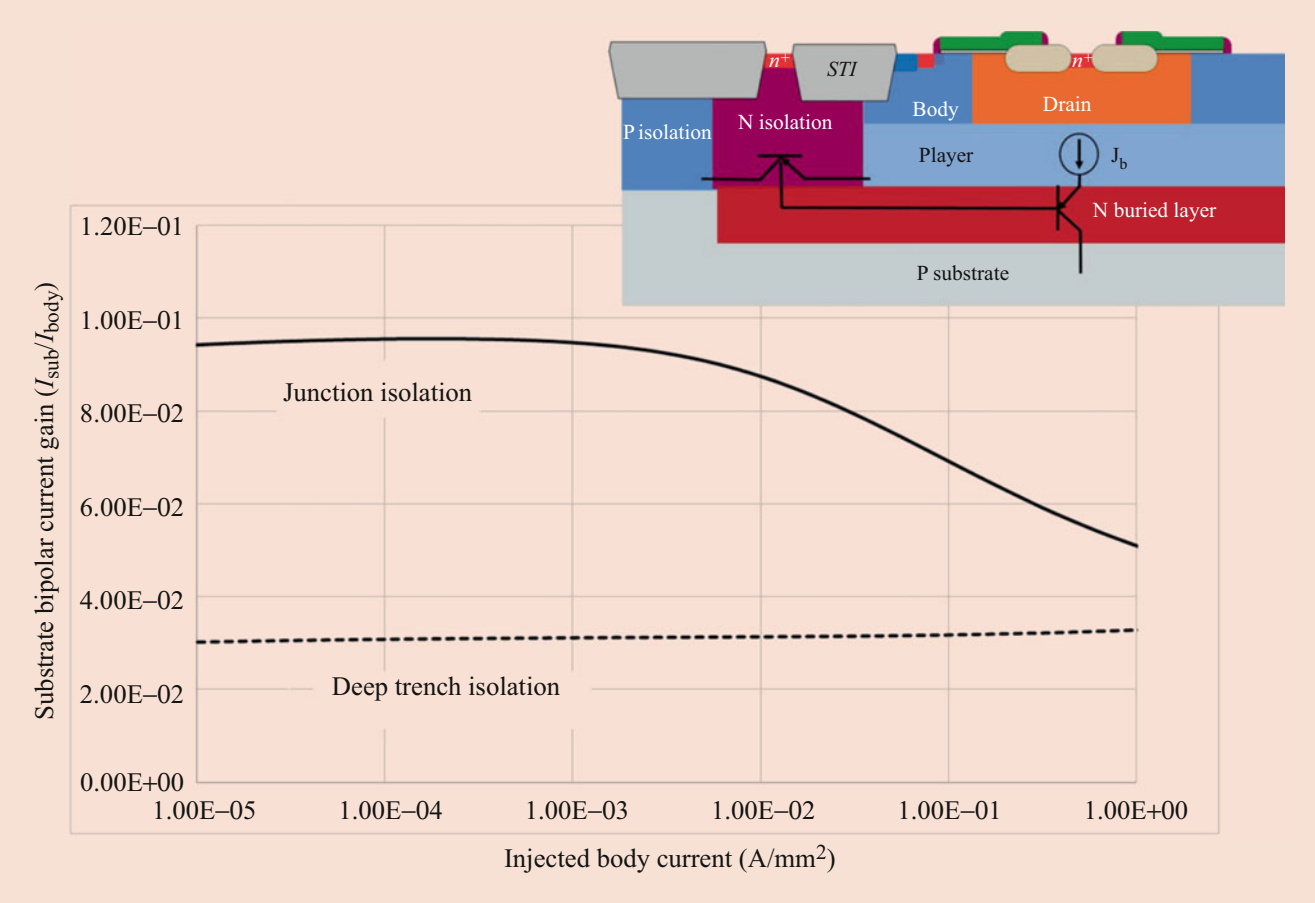

Fig. 3.10 Parasitic PNP bipolar gain (I_{sub}/I_{source}) as a function of the injected current density for JI and DTI. The maximum gain is observed in the lower current range due to the maximum lateral contribution. (Reference: ST proprietary BCD technology)

- P-type epitaxial layer secures compatibility with CMOS platforms, where this kind of doping is the common standard for this technology.

  The main drawback of this choice is the realization of high voltage components requiring thick epi since dedicated deep N-type layers should be added to connect N-type doped buried layer.
- N-type epitaxial layer enables an easier integration of high voltage components, but it may require dedicated implants for CMOS compatibility. Furthermore, P-type buried layers become mandatory with this option to provide N-type buried layer isolation between adjacent devices.

3.3.2 Deep Trench Isolation

Following epitaxial growth, in a possible integration scheme, deep trench isolation module is implemented.

First, a deep silicon etch is executed: depth and width are normally depending on the voltage requirements.

Following the silicon etch, thick oxide is realized to create the isolation layer. The filling may be completed by a dedicated poly layer that can act as stress relief and/or as a conductive plug contacting the substrate by removing the oxide at the trench bottom (Fig. 3.15). Recently, a BCD platform solution with two integrated trenches has been presented: one trench was suited for isolation and is filled with an oxide and an air gap, while the second one used to establish an electrical connection to the substrate is filled with a metallic layer (tungsten plug) realized at contact level [4].

3.3.3 Key Technology Features and Module Description

Following the process steps dedicated to the component isolation, BCD architectures are based on CMOS technology platforms with a modular approach to enable large process customization.

Thick oxide (*field oxide*) is deposited in order to suppress unwanted surface leakage currents among components, and the active areas are defined, adopting the concepts ported from CMOS technology baseline, depending on the specific lithographic node.

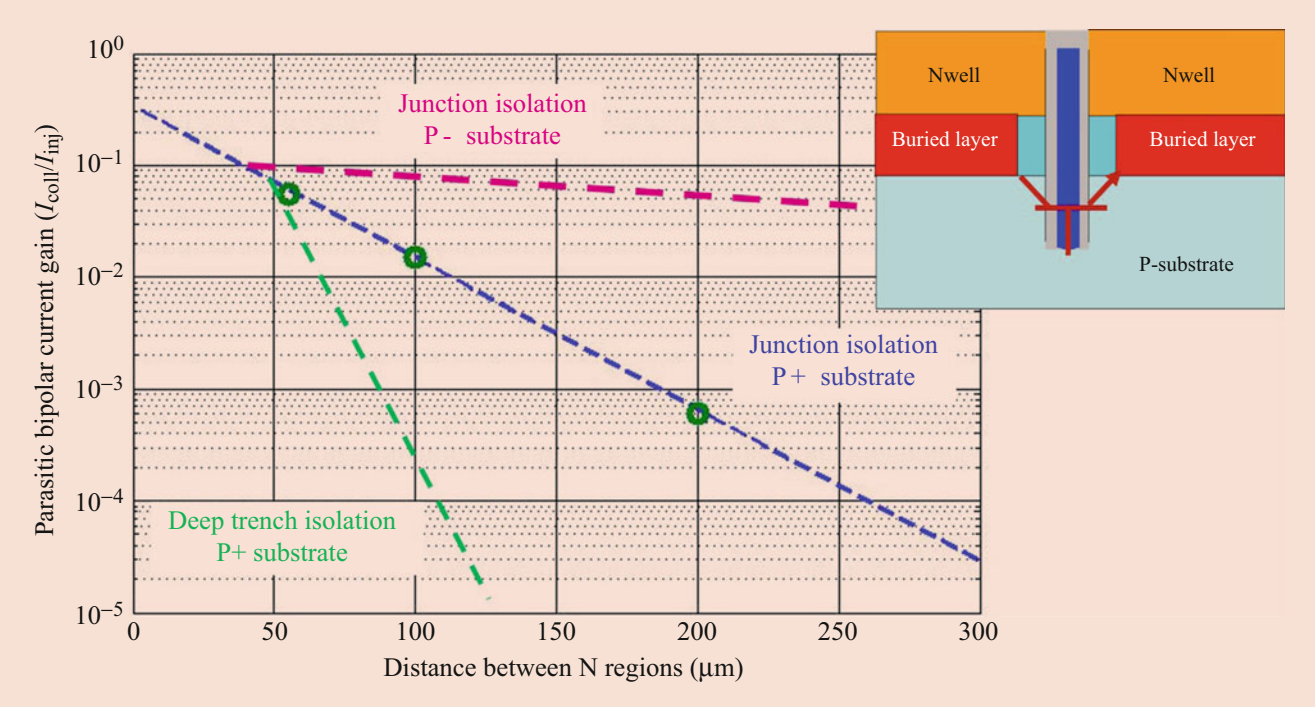

Fig. 3.11 Lateral NPN current gain ($I_{collected}/I_{injected}$) as a function of the distance between power and collecting device. Different substrate and DTI impact on electrons diffusion length is evident

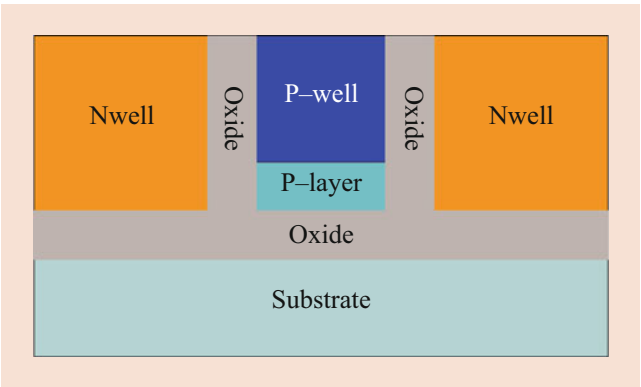

Fig. 3.12 SOI isolation architecture schematic cross section. Two adjacent N-type regions separated by oxide layer

Down to 250 nm node, the active area definition is realized with the well-known LOCOS (local oxidation of silicon) approach which is based on the selective growth of a thick oxide (field oxide) on a silicon surface masked by a patterned silicon nitride [1]. With this approach, a semi-recessed field oxide can be obtained, depending on the different specific techniques (simple LOCOS or poly-buffered LOCOS), but the transition between the thick oxide and the active area (*bird's beak,* see Fig. 3.16) has a non-negligible size. The thick oxide *bird's beak* shape is due to collateral oxide growth on the thin interface stress-relieving oxide layer placed between nitride and the silicon to reduce dislocation growth. Bird's beak shape and geometry depend on the thickness ratio between thin oxide and nitride layers.

As bird's beak inhibits pitch CMOS scalability (width and space), STI technique for active areas definition has been introduced to overcome this limitation.

Moving to minimum lithographic features smaller than 250 nm, a different scheme is used in order to reduce the size of the CMOS components: this scheme is called shallow trench isolation (STI), which is the preferred solution to increase the CMOS packing density, as it avoids the LOCOS bird's beak and realizes narrower isolation regions [5]. A trench etch is performed in silicon using an oxide-nitride hard mask, followed by an initial thin oxidation ("liner") and completed with a dielectric (silicon oxide) deposition providing adequate gap filling properties. The excess oxide is then removed with a chemical mechanical polishing (CMP) step obtaining a planarization of the wafer surface. STI geometrical top corner shape plays a key role to minimize the stress generated reducing the current kink in the CMOS sub-threshold region (Fig. 3.17).

The STI scheme permits to reduce the size of CMOS components as its horizontal size is significantly contained compared to the previous scheme (LOCOS) and because of the planarization of the wafer surface, resulting in finer dimension and pitch for the critical layers which are defined later on in the process flow, namely, the polysilicon layer for the CMOS gates and the contacts.

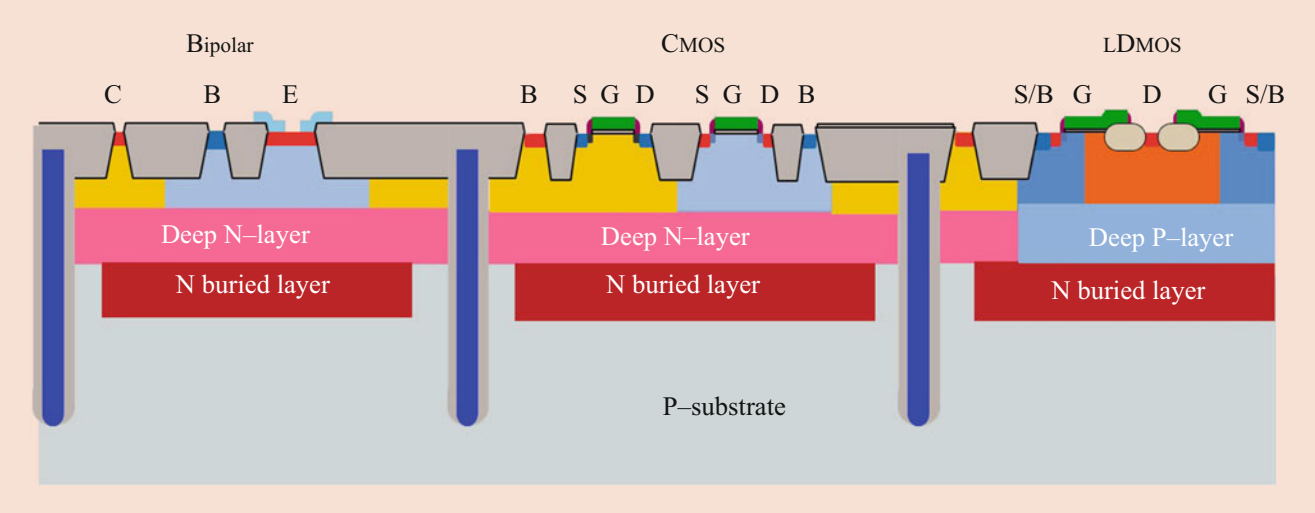

Fig. 3.13 BCD technology architecture

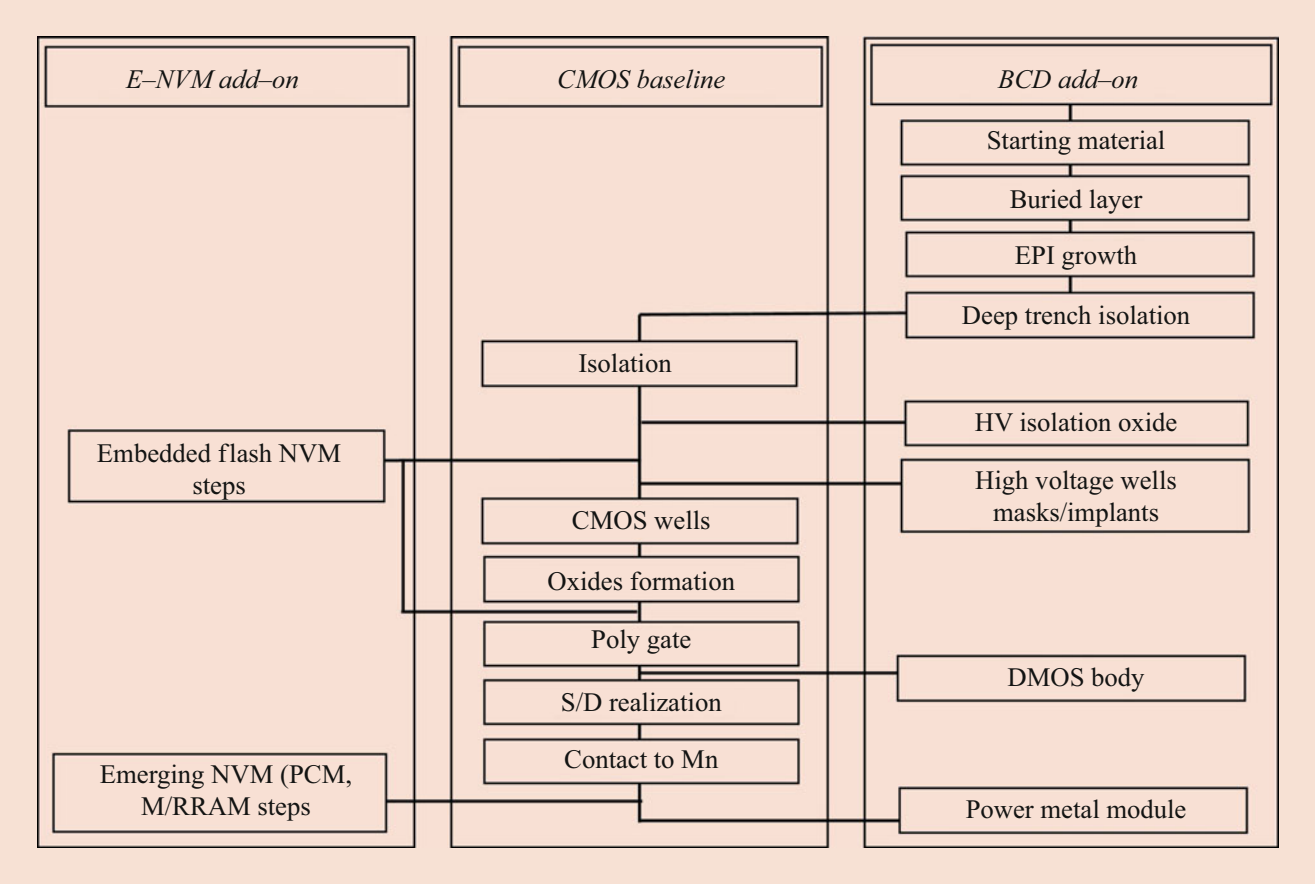

Fig. 3.14 BCD technology process flow

In a 160 nm BCD technology by ST (BCD8sP), in addition to STI for the isolation of the CMOS logic, a LOCOS scheme is present for the LDMOS power transistor blocks in order to optimize the device key performance parameters ($R_{on} \times A$, BV_{dss}), as it will be explained in more detail in Sect. 3.4.2. Therefore this BCD technology integrates two types of isolation: STI for the CMOS logic and LOCOS for the LDMOS power transistor blocks (Fig. 3.18).

After active area definition, the process flow continues with more specific construction steps aiming at the real-

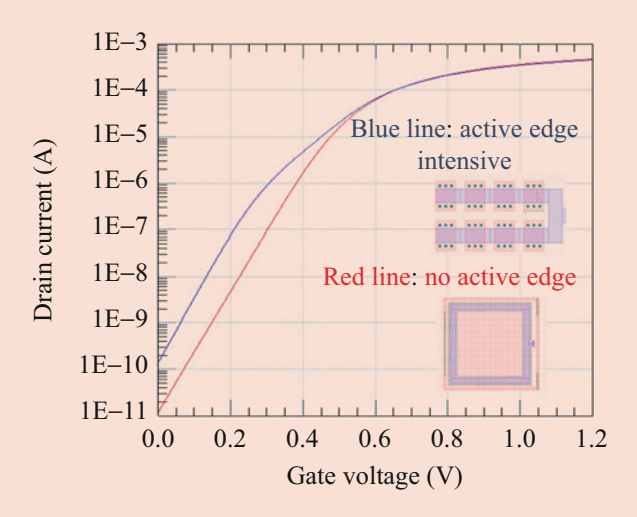

Fig. 3.17 Low voltage CMOS sub-threshold characteristic comparing an edge intensive transistor (blue line) vs a circular shape one without active edge (red line). The kink in the curve highlights a premature parasitic turn on at the active edge

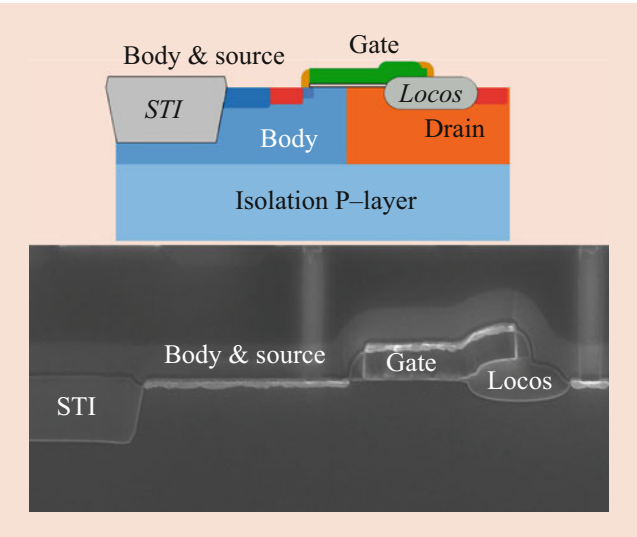

Fig. 3.18 160 nm BCD technology by ST (BCD8sP) integrating three types of isolations (STI, LOCOS, DTI)

ization of components and at the achievement of their performances: body layers for CMOS and high voltage MOS and DMOS components, specific wells, and deep layers to optimize components high voltage and isolation capability.

Multiple implants are today required to realize CMOS body region. Implant conditions are determined to fix the required threshold voltage values, short channel effects immunity and to guarantee latch-up robustness. For high voltage devices body formation, additional requirements must be taken into account: larger voltage capability and robustness against the activation of the parasitic NPN (Fig. 3.19).This implies more stringent constraints to the implant conditions

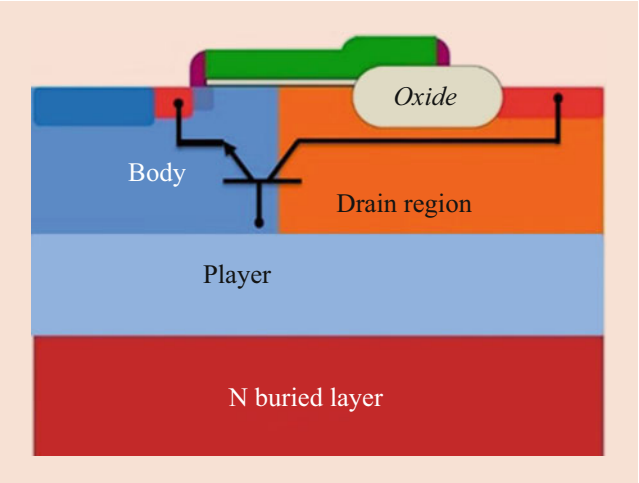

Fig. 3.19 Parasitic NPN in HV MOS transistor

for these layers, and therefore the re-use of the CMOS wells is not always the most appropriate solution requiring specific added implants for optimal component performance.

In addition to the well dedicated to body regions, N-type and P-type layers are introduced in the flow to realize the high voltage NMOS and PMOS components drain drift region.

High blocking voltage for components at minimum penalty for the active performances is driving the layers engineering: to this purpose the *Resurf* [6] principle has been progressively used not only in very high voltage application but also to realize components for a voltage operation <100 V. RESURF concept was introduced in the late 1970s: thanks to the simultaneous electrostatic effect of lateral and vertical diodes biased in reverse mode, very high breakdown voltages were recorded. A detailed description of this principle and on the advantages brought in the high voltage device design and performance is reported later in the chapter (Sect. 3.4.2). It's worth to mention that the adoption of this basic principle and its further refinements (single and double Resurf effect) imposes clear constraints on the final charge dose in silicon for the layers to be formed.

The dedicated deep layers enable to increase the versatility of the use of high voltage components, as they can be used to suppress the injection of parasitic current into the substrate when the drain terminals are forced to a negative biasing compared to the substrate ground potential, as it will be explained in more details in Sect. 3.4.2.

The gate oxide is then grown inside the active areas: multiple gate oxides are widely used. First oxidation step grows a thick gate oxide for high voltage MOS components, followed by the CMOS gate oxidation with a thinner thickness, which depends on the specific CMOS node. The thick gate oxide is adopted also to realize a higher

voltage rated CMOS (typically 5 V), needed for pins I/O, analog stages implementation, and for memory programming operation.

Ported from the most advanced CMOS process flow, gate oxide nitridation is introduced in order to cope with the need to avoid penetration in the channel surface region under thin gate oxide of the high energy boron implants for polysilicon doping and source-drain formation. Analog MOS performances (low-frequency noise) and threshold voltage stability of PMOS due to NBTI (negative bias temperature Instability) effect [7] are the drawbacks of such introduction. The NBTI is a degradation mechanism due to positive charge buildup in gate oxide and at Si/SiO_2 interface, which affects PMOS performances when stressed at negative gate voltage and at high temperature condition. The degradation is electric field dependent; it involves all relevant PMOS electrical parameters, in particular the threshold voltage (increasing in absolute value) and the drain current (decreasing in absolute value), and it is associated to the capture emission of semiconductor charge carriers on localized electronic states and to the weakening of Si-H bonds, which can be considered as oxide and/or interfacial defects.

According to the modular approach of BCD process flow, additional steps can be inserted at this stage to implement nonvolatile memory (NVM) cells: oxidation for tunnel oxide and possible second polysilicon level for dual-poly flash/EEPROM memories are the most peculiar steps of this module. When single poly EPROM or EEPROM are implemented, a single poly gate layer scheme on differential gate oxide is adopted (Fig. 3.20).

After the polysilicon layer deposition and patterning for the MOS gates, in many BCD platforms another peculiar step could be introduced: the body layer for the DMOS components. The layer is implanted self-aligned to the patterned polysilicon with conditions and thermal treatments to be defined in order to obtain the DMOS channel region as a difference between the body lateral junction length and the subsequent source implant lateral profile length. This way the DMOS channel length is independent of the technology minimum processable lithography [8].

The DMOS body formation evolved significantly in the last 20 years starting from implantation followed by prolonged high temperature diffusion step to solutions more compatible with advanced CMOS technologies with finer lithography and thinner gate oxides. The newer solution is based on a large angle tilt implantation performed without adding to the process flow any specific thermal treatment (Fig. 3.21). It was presented [9] that a 45° tilt angle implant gives the best trade-off between lateral and vertical body junction depth.

The subsequent process steps up to the formation of the metallization lines (*back end of line – BEOL*) are based on the advanced CMOS process flow of the equivalent lithographic node.

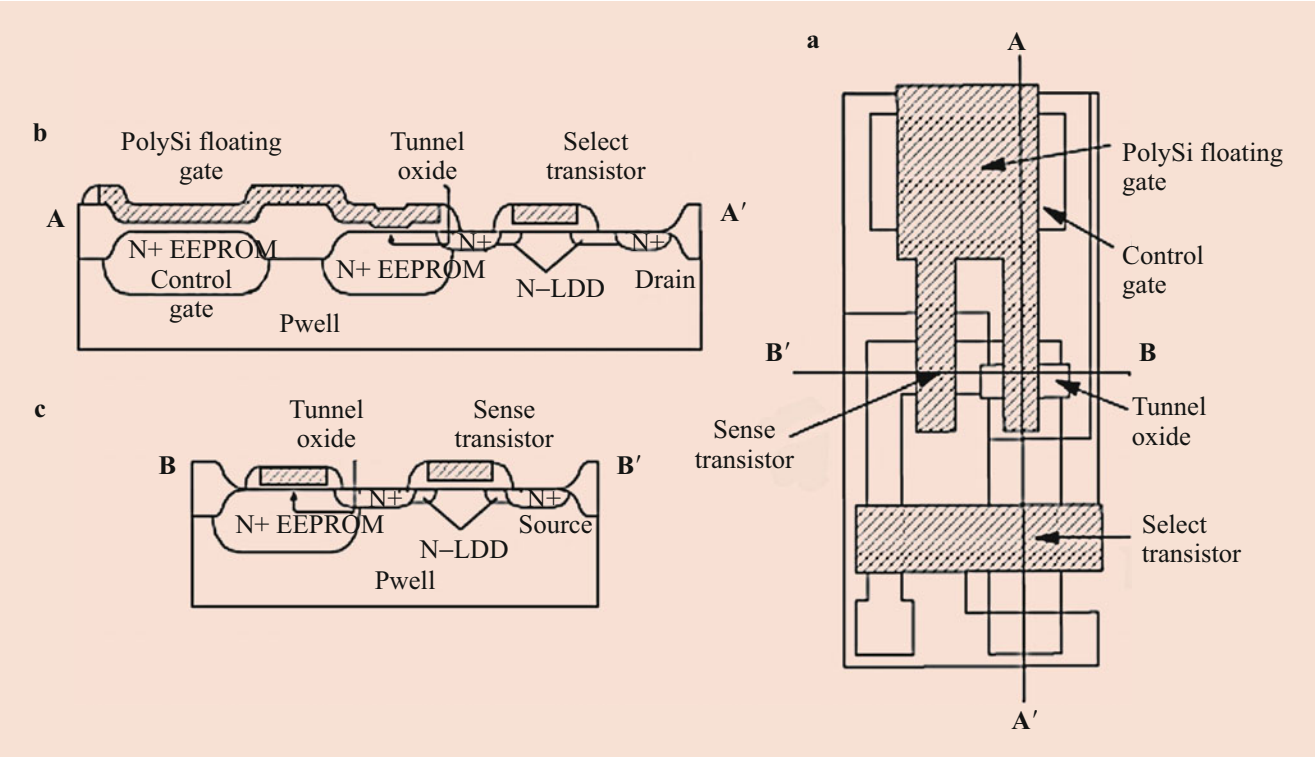

Fig. 3.20 Single poly EEPROM cell structure. (**a**) Top view. (**b**) Section along A-A′ line. (**c**) Section along B-B′ line

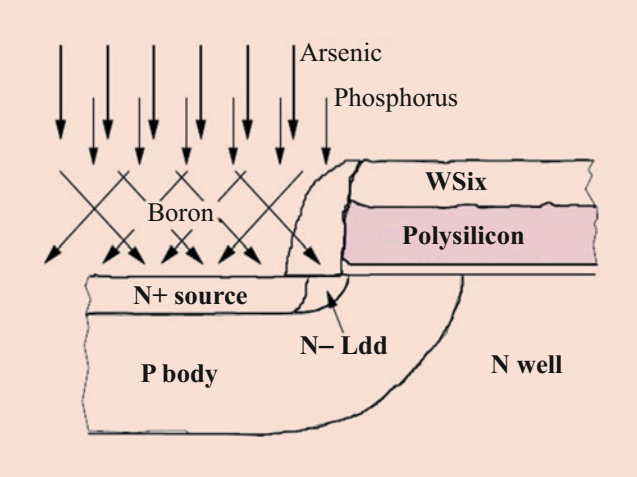

Fig. 3.21 Large angle tilt implant for DMOS body formation

Also the thin metal levels used in BCD technologies followed the advanced CMOS roadmap, evolving from aluminum down to 160 nm to damascene copper for 130 nm and below. The evolution to thin copper metal system provides an additional advantage in BCD technology enabling higher robustness under thermomechanical stress induced by high energy pulses of the power MOS section, as it will be shown in Sect. 3.4.3.

However, some peculiar requirements of BCD application force to introduce modifications to the BEOL scheme adopted in CMOS technology. The specific requirements to be fulfilled are related to the needed high voltage and high current capability, which have an impact on the thickness and materials to be used for the inter-metal dielectric layers, to provide the required isolation among metal lines, and for the metal lines, to guarantee the reliability against electromigration phenomena. Electromigration is a phenomenon of mass transport inside interconnections stressed with high current densities. The mass transport creates voids or hillocks. The voids can give rise to increased interconnection resistance or eventually evolve in open circuit after long stress time.

Emerging memories described in Sect. 3.4.1 are conceived to be added in the BEOL with the advantage to be modular and to not affect the architecture of the active components implementation. Their integration in the BEOL requires to add dedicated steps, as stacked contacts, specific and unconventional materials for programming and storage elements.

An additional aspect to be considered is the BEOL thermomechanical robustness against the stress related to the assembly steps, in particular in case of active components placed under wire bonding or bumping structures.

Very specific to BCD technology is the top metal level (*power metal*) due the multiple functions needed to be accomplished:

- High current capability.
- Low resistance.
- High electromigration robustness.
- Heat dissipation during power pulses.
- Mechanical stiffness for wire bonding with large diameter wires of different materials (Au, Cu, Al, Ag).

Historically the solution adopted by the silicon manufacturers has been based on a thick aluminum layer, with thickness in the range of 3–5 μm.

To improve the performances, thick copper metallization was introduced starting since the late 1990s [10–13].

The first presented solutions disclosed a realization scheme based on the so-called *patterned* copper approach, capable to grow thicknesses in the range of 10–20 μm [14, 15].

The process starts with the deposition of a barrier layer (usually realized with TiW alloy) and of a copper thin layer to be used as a seed for the successive growth (Fig. 3.22). A thick photo-resist layer is then span on the wafer surface and patterned to open the areas where the copper will have to grow. An electroplating technique is used to grow the copper at the required thickness, followed by the photo-resist removal and by a copper seed and barrier etch. In this way, the process is completed and the different metal lines are defined.

The patterned approach is common to the copper redistribution layer (*RDL*) solutions adopted for chip scale package (*CSP*) and has the flexibility to grow different copper thickness in function of the application requirements.

The drawback is the large copper line pitch (width + space) that limits the routing capability of this metal level: typical pitch values are in the range of 20–30 μm, depending on the copper thickness.

A different approach has been therefore developed based on the advanced VLSI CMOS BEOL scheme: damascene thick copper processes providing a thickness up to 5 μm are feasible and enable a top metal line pitch in the range of few μm, giving therefore great advantage in the routing density for power buses, compared to the patterned scheme.

Depending on the selected type of the top metal scheme architecture, several and diversified approaches can be found for the front-side finishing of the wafer in order to provide suitable solutions for the electrical connection to the package and for protecting the die from the external environment.

Smart power products peculiarity must be considered: loads sinking high current requiring large bonding wires connections, assembly in stressing packages for power dissipation and applications in harsh ambient conditions.

In case of applications in packages using wire connections, the top thick aluminum layer or an aluminum layer capping the copper top metal in the bonding area are the simplest solutions, the latter ported from CMOS technology (Fig. 3.23).

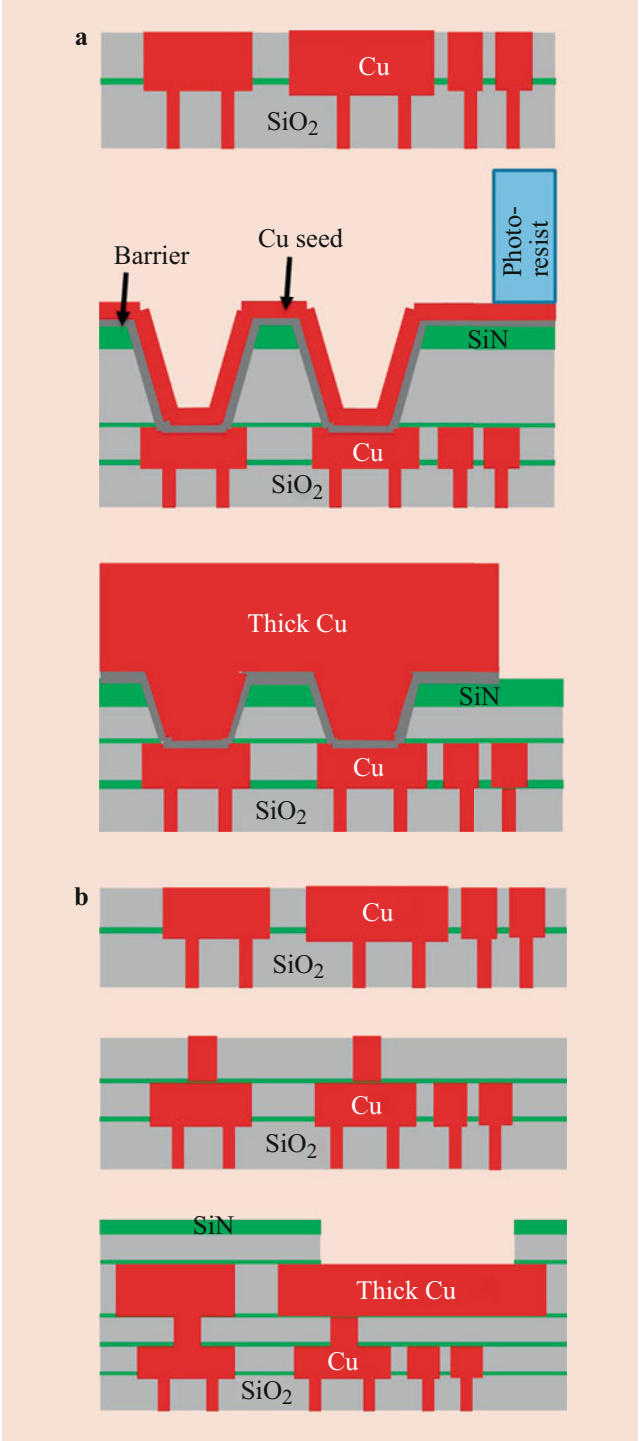

Fig. 3.22 Thick Cu process flows. (**a**) Patterned Cu. (**b**) Damascene Cu

An alternative more robust structure can be realized with a different metal layer stack composed by nickel, palladium, and gold, grown over the aluminum or copper bonding area by electroplating or by electro-less plating techniques [16]. This layer stack is generally called over pad metallization (OPM, Fig. 3.24).

The protection of the die from the external environment is provided by the deposition of final inorganic layers (*passivation*), preferably realized with silicon nitride which has superior sealing properties against moisture absorption, and of organic polymeric coating layers (*polyimides*) to planarize the die top surface and to act as buffer layers against the thermomechanical stress induced by the packaging materials.

In case of the patterned thick copper scheme, where the top metal is grown over the final passivation, a metallic coating solution can be adopted, realized with nickel and palladium (and gold) grown by electro-less plating and encapsulating the thick copper strips (Fig. 3.25). This solution permits to provide both mechanical protection during wire bonding for the underlying structures and to inhibit copper corrosion from the external environment.

3.3.4 Latest ST Technology Platforms

BCD technologies offer a wide possibility of integration capability. They allow to cover more and more single-chip solutions and the integration of digital CMOS, analog, and power stages in very flexible configurations (low side power, high side power, half/full bridge, etc.).

As an example, this paragraph describes the key characteristics and electrical features of BCD9s (110 nm), a proprietary STMicroelectronics technology specially conceived for power applications, with voltage rating ranging from 20 to 100 V.

Due to the flexibility and modularity, the technology can be applied to power management, industrial, and automotive applications.

The technology is modular and allows the best trade-off among performances/application needs/cost; masks can be added according to the application and the required voltage ratings.

In the basic process option, the technology features a voltage rating up to 40 V, with two gate oxides:

- 12 nm gate oxide for 5 V analog CMOS and for the gates of the high voltage power components which are optimized for a very low on resistance
- 3.5 nm gate oxide for 1.8 V digital CMOS with ~500 kTransistors/mm^2 gate density, which is suitable for digital intensive applications.

The voltage rating of the high voltage and power components can be increased up to 60 V, 80 V, and 100 V adding dedicated doped wells and adopting specific component architecture.

The technology is conceived with a deep N+ buried layer for robust and safe driving of inductive loads.

The metallization scheme implements a full copper solution that includes four metal levels, three thin damascene

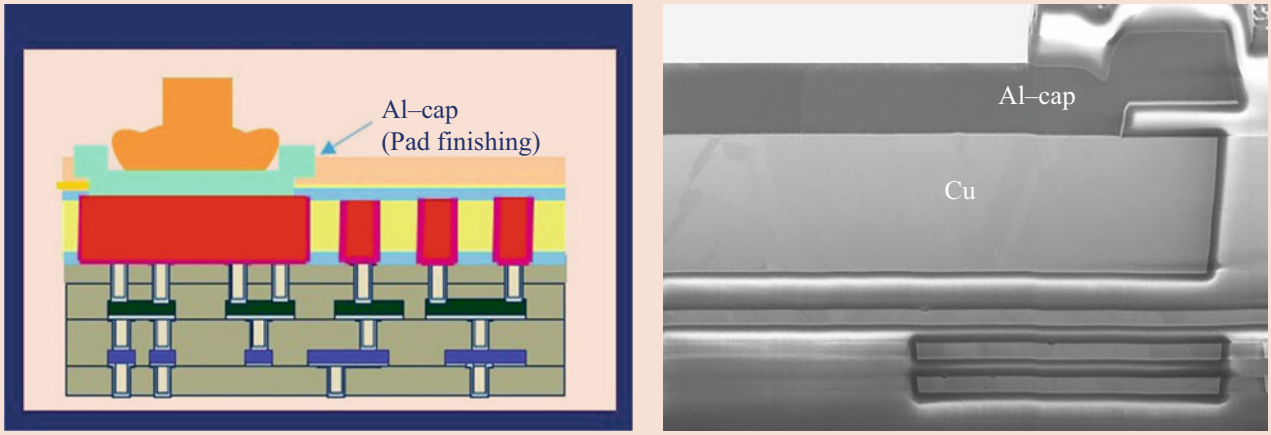

Fig. 3.23 Damascene thick copper + aluminum cap wire bonding pad

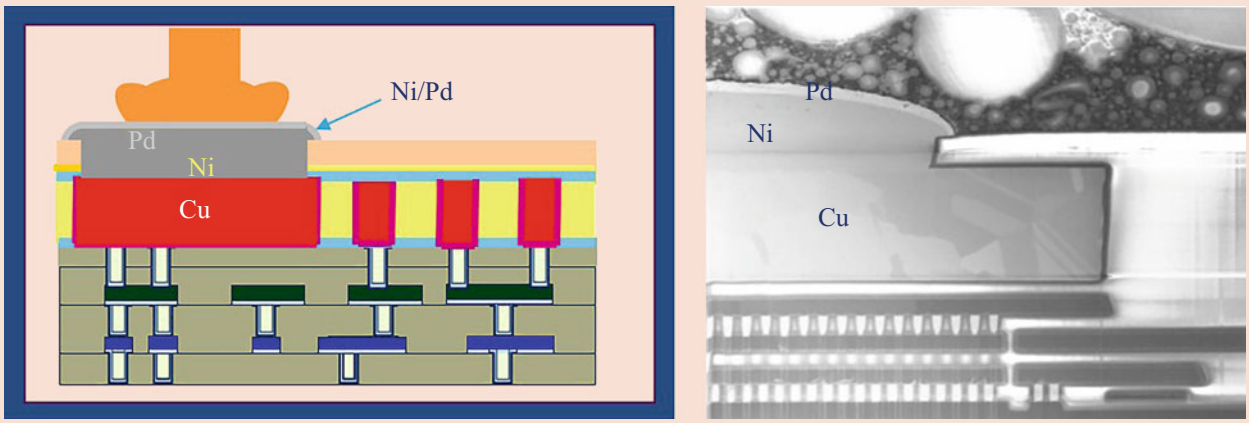

Fig. 3.24 Damascene thick copper + over pad metallization (OPM)

copper metals for signal routing, and one thick copper metal for power routing.

The technology architecture allows, for all the high voltage classes available, low side and high side configuration; hence it is possible to implement in a single-chip half bridges and full bridges topology (Fig. 3.26).

Table 3.1 summarizes the main technology options.

3.4 New Technology Enablers for Application Evolution

In the following paragraphs, the main enablers driving BCD technology evolution will be addressed.

Initially, the path toward denser BCD technology nodes will be presented highlighting the benefits associated to the introduction of some key CMOS technology modules and the widening of applications enabled by nonvolatile memory architectures.

Power and high voltage device architecture evolution is then widely described focusing on the key enablers to boost continuous performance improvement. Thanks to the achieved performances, on latest generations larger current and energy levels have to be handled requiring specific solutions for power metallization and assembly.

Finally, passive technology modules for high precision, analog, and high voltage applications will be described as additional enablers for function differentiation.

3.4.1 Increase Digital Processing Capability: Lithography, Logic, and Memories

Since its origin, BCD technology has followed with some delay the evolution of CMOS roadmap securing a continuous scaling of logic blocks offering increased capability for digital processing. This trend was originally straightforward: new

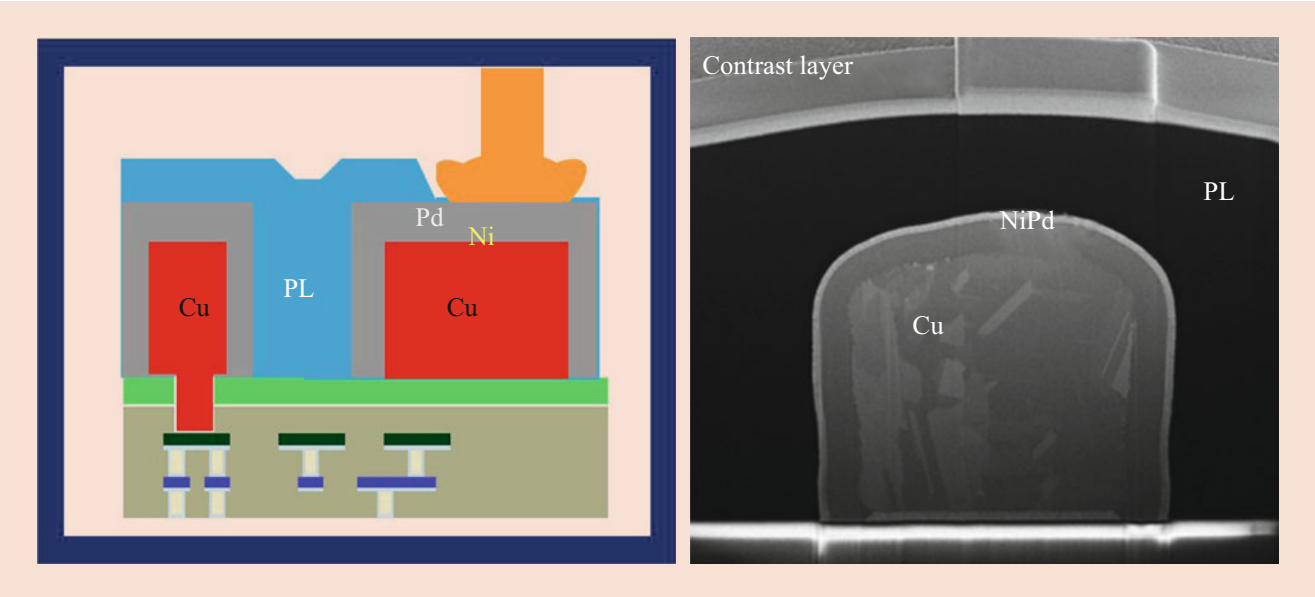

Fig. 3.25 Patterned thick copper + metallic coating

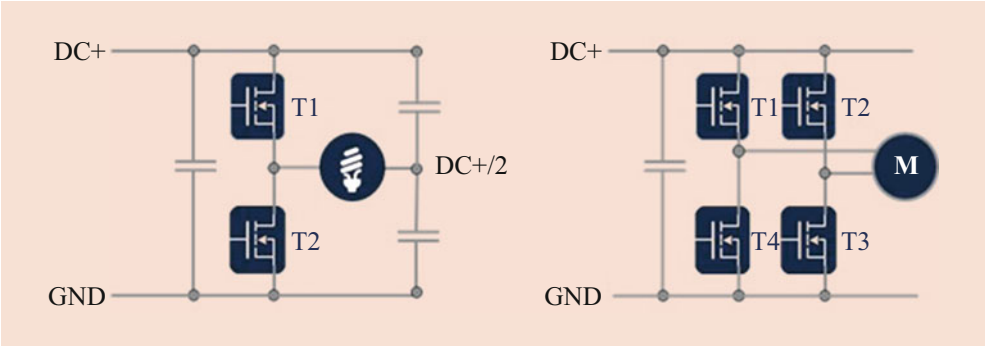

Fig. 3.26 Half bridge and full bridge topologies. Examples of lamp ballast and motor driver applications

BCD process generation was built starting from the CMOS baseline (Fig. 3.14) and the geometrical rules scaling coming from the new lithography node was bringing an overall area (and cost) reduction of all the integrated functions. On top of this reduction of area coming from the new generation, the introduction of some new features in the CMOS evolution enables the improvement of analog and power stages realization:

- Epitaxial substrate (P-/P+) offers the possibility to improve the isolation among the functions thanks to the low resistive substrate bulk.
- Reduced CMOS isolation spacing thanks to LOCOS evolution and STI integration allows the reduction of the high voltage devices drain region extension improving specific R_{on} [17].
- High energy implantation enables the possibility to introduce deep N-/P-type buried layers from the surface offering improved vertical isolation without dedicated epi growth.
- Thinner gate oxide and specific polysilicon layers improve CMOS analog key parameters (noise, matching) offering the possibility to realize precise stage without the need of high-performance bipolar devices.
- Self-aligned silicide (SALICIDE) module used to reduce CMOS access resistance offers the possibility to minimize source to body shared contact area in power devices.

In the early 2000s, 250/350 nm BCD process technology was announced by many integrated device manufacturer (IDM) players [18, 19], and at the same time 130/90 nm technologies were announced as latest CMOS technology platform [20, 21].

During the last 15 years, the speed of CMOS evolution has not changed significantly (new generation every 2 years) driven by high-performance and low power computing re-

Table 3.1 BCD9s (110 nm) main technology features

BCD9s (110 nm) main technology features		
Base options	CMOS	1.8 V CMOS Digital density ~ 130 kTransistors/mm^2
	Low voltage	5 V NPN, 5 V Zener 5 V poly capacitor Polysilicon resistors (600 **Ω** /square) FTP EEPROM

		100 V: 160 m**Ω** × mm^2

quirements sustained by new emerging applications (smart phone, data centers, communication infrastructure).

BCD technology evolution toward advanced CMOS nodes has been slowed down since the integration cost has increased significantly and the POWER IC applications' needs for digital capability have not increased at the same pace.

More recently the natural cost reduction of the manufacturing assets used for the advanced CMOS ASIC is enabling new BCD technology platforms (90/55/40 nm) offering a cost-effective solution for some applications requiring the integration of microcontrollers in a power IC.

Digital power management for mobile application processor, intelligent motor drivers for automotive and industrial markets, high efficient audio amplifier for car radio and mobile phone, mobile wireless charging systems, and novel USB power delivery systems are some key applications requiring high integration level including state-of-the-art microcontroller together with the possibility to drive low to medium power external loads.

Microcontroller is normally requiring a nonvolatile memory solution to store execution code and data. The need for a cost-effective nonvolatile memory solution has triggered the integration of different options depending on the product need in terms of programmability (number of write/erase cycles) and size.

- Dense One-Time Programmable (OTP) or Few-Time Programmable (FTP) Memory

  Low added mask solutions enabling dense one-time programmable (OTP) or few-time programmable (FTP) memory are obtained minimizing the number of extra process steps in the flow. Single poly memory cells are widely used for FTP solutions [22]: electrons are stored in a floating gate normally realized using same poly layer used for CMOS gate over the thicker gate oxide available in the process (the one required for I/O realization). This solution is widely used since no dedicated process steps are required. Different solutions [23] have been recently presented to overcome the potential charge retention challenge for latest technology platforms given the I/O MOS voltage rating scaling and consequent gate oxide thickness reduction (≤50 A).

  Anti-fuse/fuse approaches are widely used for OTP realization.

  Anti-fuse-based memory uses an insulating layer as storage element: process gate oxide is the most popular solution. In the natural nonprogrammed state, the electrical conductance is very low. Gate oxide breakdown is the physical mechanism used for programming: a voltage pulse is applied to induce the dielectric breakdown with the consequent irreversible increase of the electrical conductance. Thanks to the gate oxide scaling, this solution has recently gained a lot of traction since the programming voltage requirement has become compatible with the existing CMOS voltage capability: gate oxide breakdown voltage (V_{bd}) has become lower than CMOS drain to body junction breakdown (BV_{dss}) simplifying the programming circuitry.

  Electric fuse-based memory is using process conductive layers as storage elements. Silicide poly or metal layers are widely used: in the natural not programmed state, the layer electrical conductance is high. The physical mechanism used for programming is the atom migration induced by an electrical pulse (electromigration):

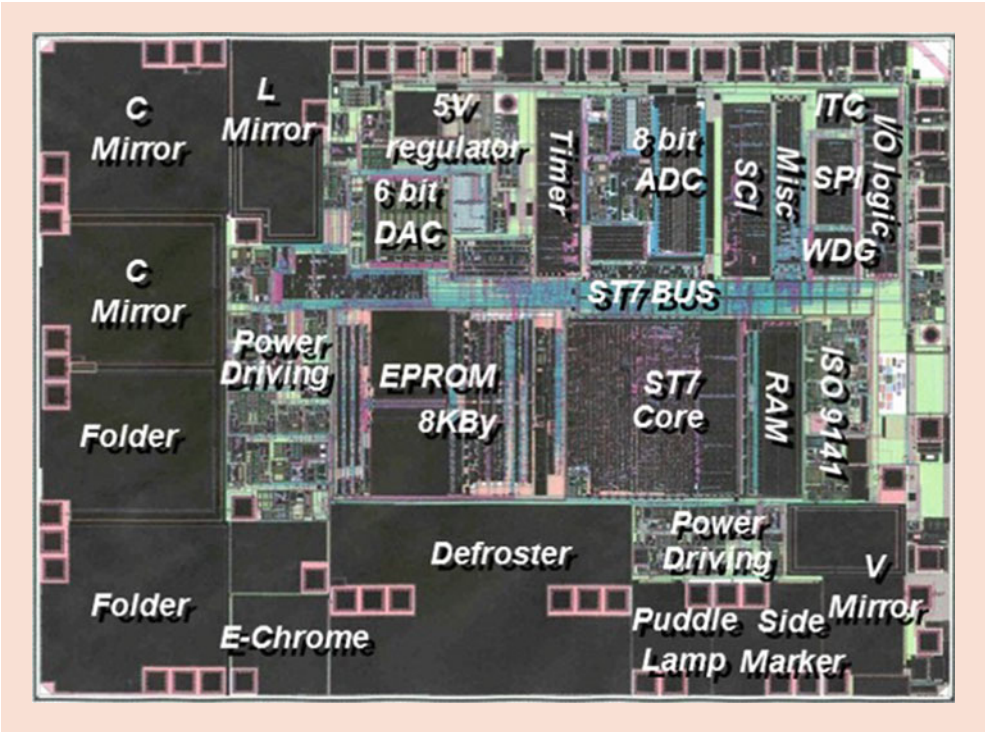

Fig. 3.27 Single-chip solution embedding microcontroller with embedded NMV (BCD5 technology)

the memory is programmed by applying a current pulse leading to an irreversible conductance drop. One of the key challenges of these fuse solutions is the applied power pulse control to avoid local melting inducing physical damage to the involved layers (conductor and surrounding insulating layers) that may lead to some potential conductance instability during the product lifetime. Recently a fuse solution based on silicide material migration assisted by the local electrical current/temperature during the programming pulse has been presented [24]: this solution should secure a wide conductance variation in the silicided poly layer without any physical damage creation.

The solutions described for OTP and FTP realization are not requiring specific process steps, and therefore they are offering a cost-effective solution to embed nonvolatile memory array up to 32/64 kBytes with a maximum number of write/erase cycles in the 1 k (1000) range for FTP memory.

- Nonvolatile Memory (NVM) Based on Dense Floating Gate Transistors

  This solution has been widely shared and used by many players. In Fig. 3.27 a picture of a complete system on chip (SOC) realized on an older technology node by STM is reported. EEPROM (128 Bytes) and EPROM (8 Bytes) were integrated to serve as microcontroller memory in a complete motor driver chip serving automotive market. More recently, Infineon announced dense NOR flash integration in its proprietary 130 nm BCD generation [2] targeting single-chip solution embedding high-performance microcontroller with power drivers for automotive applications (window lift, power seats, sun roof, etc.). RENESAS announced the integration of 1T MONOS flash cell in an advanced 90 nm BCD technology [4] addressing array up to 512 kBytes [25].

  Other players have recently announced dense flash memory capability in their latest BCD technology platform such as Global Foundries (split-gate SST solution on 130 nm BCD [26]) and ROHM (dual poly NOR flash on 130 nm BCD [27]).

  Integration of a dense and high-performance flash-based NVM is offering a mature solution requiring the introduction of specific process steps: tunnel oxide, dual poly, constraints on high voltage circuitry for memory programming/erasing, and specific needs of sealing layers for data retention.

  These extra steps are increasing the wafer cost putting some integration challenges especially in more advanced nodes because their impact on baseline CMOS performances could be meaningful, requiring potential redesign of libraries/IPs or additional process steps/modules that are making the integration cost even larger.

- Nonvolatile Memory (NVM) Based on Different Storage Mechanism

  In the last decade, different storage mechanisms have been investigated to offer an alternative solution to flash NVM allowing better performance (power, speed, density) and lower integration cost. Resistive RAM (ReRAM),

magnetic RAM (MRAM), and phase-change memories (PCM) are today gaining a lot of traction for advanced CMOS embedded solution thanks to the achieved performance and to their integration scheme. Indeed, they are integrated in BEOL of the process after the formation of the transistors having an almost negligible impact on the devices' performance. At the same time, they are not requiring large voltage for the programming operations and therefore no specific high voltage devices are needed.

One of the major challenges for these novel memory solutions is the data retention at high temperature exposure such as the product soldering in the final application board and the operative junction temperature peak typical of power ICs.

Resistive RAM memory [28] is realized with a metal/oxide/metal capacitors using resistive switching as physical mechanism for its operations. Memory operation is secured by the creation of a conductive path between the two electrodes by specific voltage pulse (forming). Once this path is created, switching among two stable states (high resistive/low resistive) is controlled by proper program/erase voltage signals. The choice of the materials for the realization of the electrodes and the insulator is key for the onset of the memory effect. Recently Adesto [29] has shown the evolution of a specific ReRAM flavor (conductive bridge RAM) to automotive compliant thermal profile with a specific error correction code scheme guaranteeing 20 years of data retention at 150 °C.

In a magnetic RAM memory (MRAM) [30], the storage element is realized by a magneto tunnel junction (MTJ): two magnetic layers are separated by an insulator. The electrical resistance of such structure depends on the relative magnetization directions of the magnetic layers: its value is low when magnetization directions are parallel while it is high when they are anti-parallel. The magnetization of one of the two deposited layers is fixed, while the second layer magnetic state is free to be changed (programmed) using different physical principles. One of the first used mechanism for programming is the generation of a magnetic field induced by an electrical current flowing in a conductor realized with a standard level of metal. A second widely used solution, spin-transfer torque MRAM, is using the electron current spin flowing through the MTJ to change the magnetization polarity: in this case the electrical current value and direction determine the switching direction (0 ➔ 1 or 1 ➔ 0). The realization of the storage element is quite complex since it is requiring many different layers for the realization of the MTJ that has to be properly engineered to comply with specific reliability requirements for memory operation. Recently Intel announced MRAM capability reaching good data retention up to 200 °C [31] and Qualcomm/TDK has shown MRAM integrated CMOS platform for Internet of Things (*IoT*) application [32].

Among all the different solutions, PCM-based NVM seems to be the only one compliant simultaneously with automotive high temperature operative requirements (data retention of several years at 150 °C) and able to guarantee code integrity after soldering reflow thermal profile (260 °C peak temperature) [33].

PCM can be integrated in a typical BCD flow after contact formation (Fig. 3.28). A chalcogenide ternary alloy, $Ge_xSb_yTe_z$ (GST), is used as a storage element and a thin metallic layer is used as a heater. The data storage is secured by the presence of two stable states in the storage element: amorphous state associated with

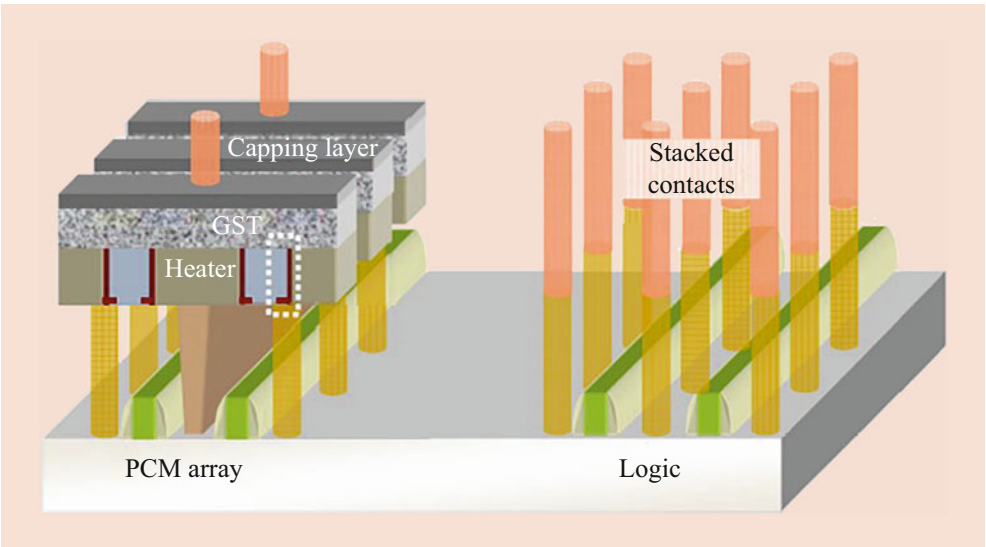

Fig. 3.28 Phase-change memory integration scheme section

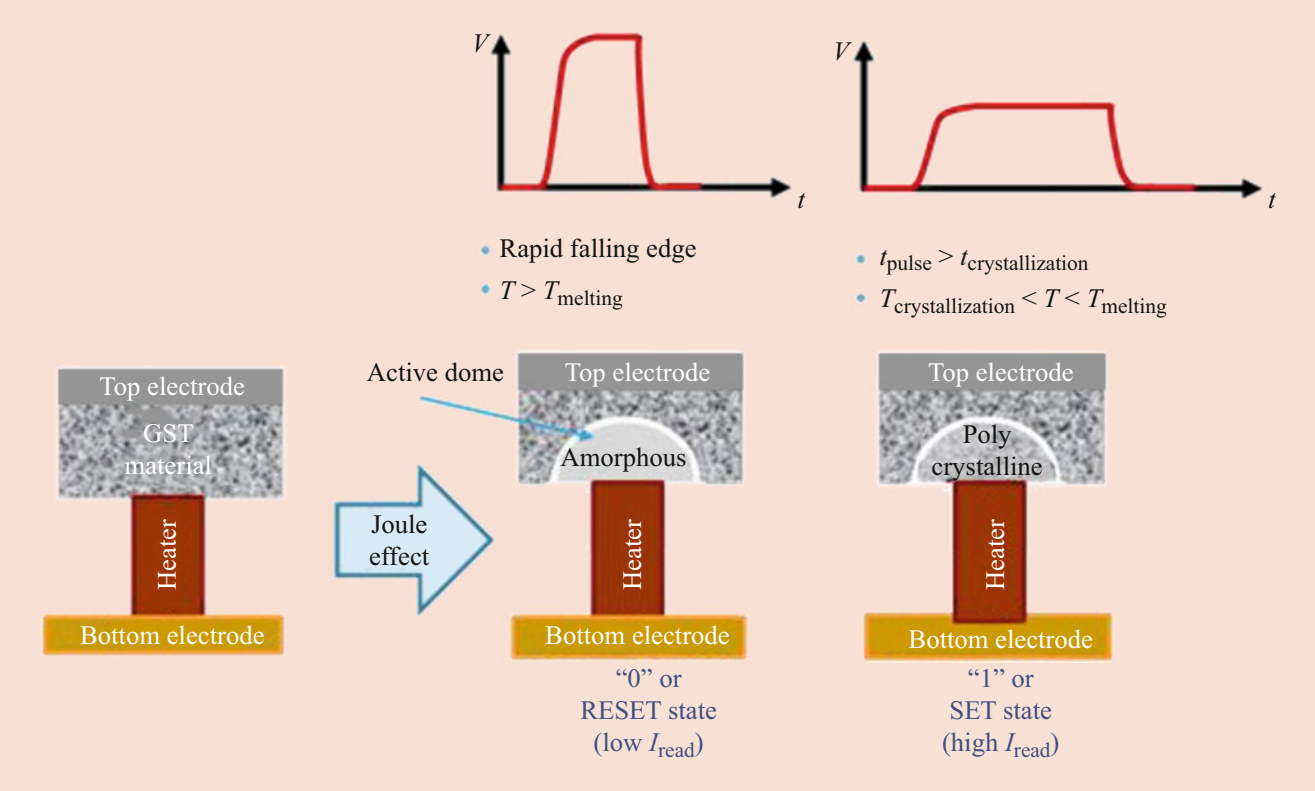

Fig. 3.29 Schematic representation of logic state 0 and logic state 1 in PCM cell

high electrical resistance (state 0) and a crystalline one with a low resistance (state 1). The switching between the states is realized with a tailored thermal pulse generated by the programming current flowing throw the heater. Baseline LV CMOS transistor is used as selector in the array realization (one resistor – one transistor).

Figure 3.29 shows a schematic representation of the PCM cell stack, with the top electrode, GST material, heater, and bottom electrode. In the active dome of the GST, an amorphous or crystalline status is generated depending on the local temperature reached as a consequence of the electrical pulse applied.

PCM is therefore able to secure a cost-effective approach to integrate a high-performance NVM scalable for future generations and compliant with the harsh BCD technology product temperature profile.

This integrated solution offers the possibility to embed in the same die all the functions needed to realize fully integrated system-on-chip IC (Fig. 3.30).

In Figure 3.31 a complete motor control system is shown in its evolution: from the simplest architecture (one full bridge in BCD1) to the full system integration (two full bridges, six external power drivers, ARM CortexM4 with 32 kBytes NVM based on PCM) in a smaller silicon area.

All these development activities currently running on quite advanced CMOS nodes (40 nm and below) may bring alternative competitive NVM options portable in the future on advanced BCD technology enabling the integration of more complex system on chip.

3.4.2 Power and HV Evolution: Device Architecture

Power devices are key elements of any smart power ICs: since the very early stage, they have been widely used to act as switch between supply and external loads. DMOS transistors have been integrated replacing bipolar devices thanks to their capability to deliver larger power to the external world given the wider safe operating area (no second breakdown) and reduced driving current consumption.

Originally vertical DMOS structure (Fig. 3.32) was integrated leveraging the power discrete structures and the availability of some key modules (high-doped buried layer and sinker) from bipolar technology. This integration scheme was built on N-type epi layer acting as drain extension to withstand the voltage: thickness and doping/resistivity were fixed by the highest voltage devices penalizing the performance of the lower voltage one. At the same time, a passive

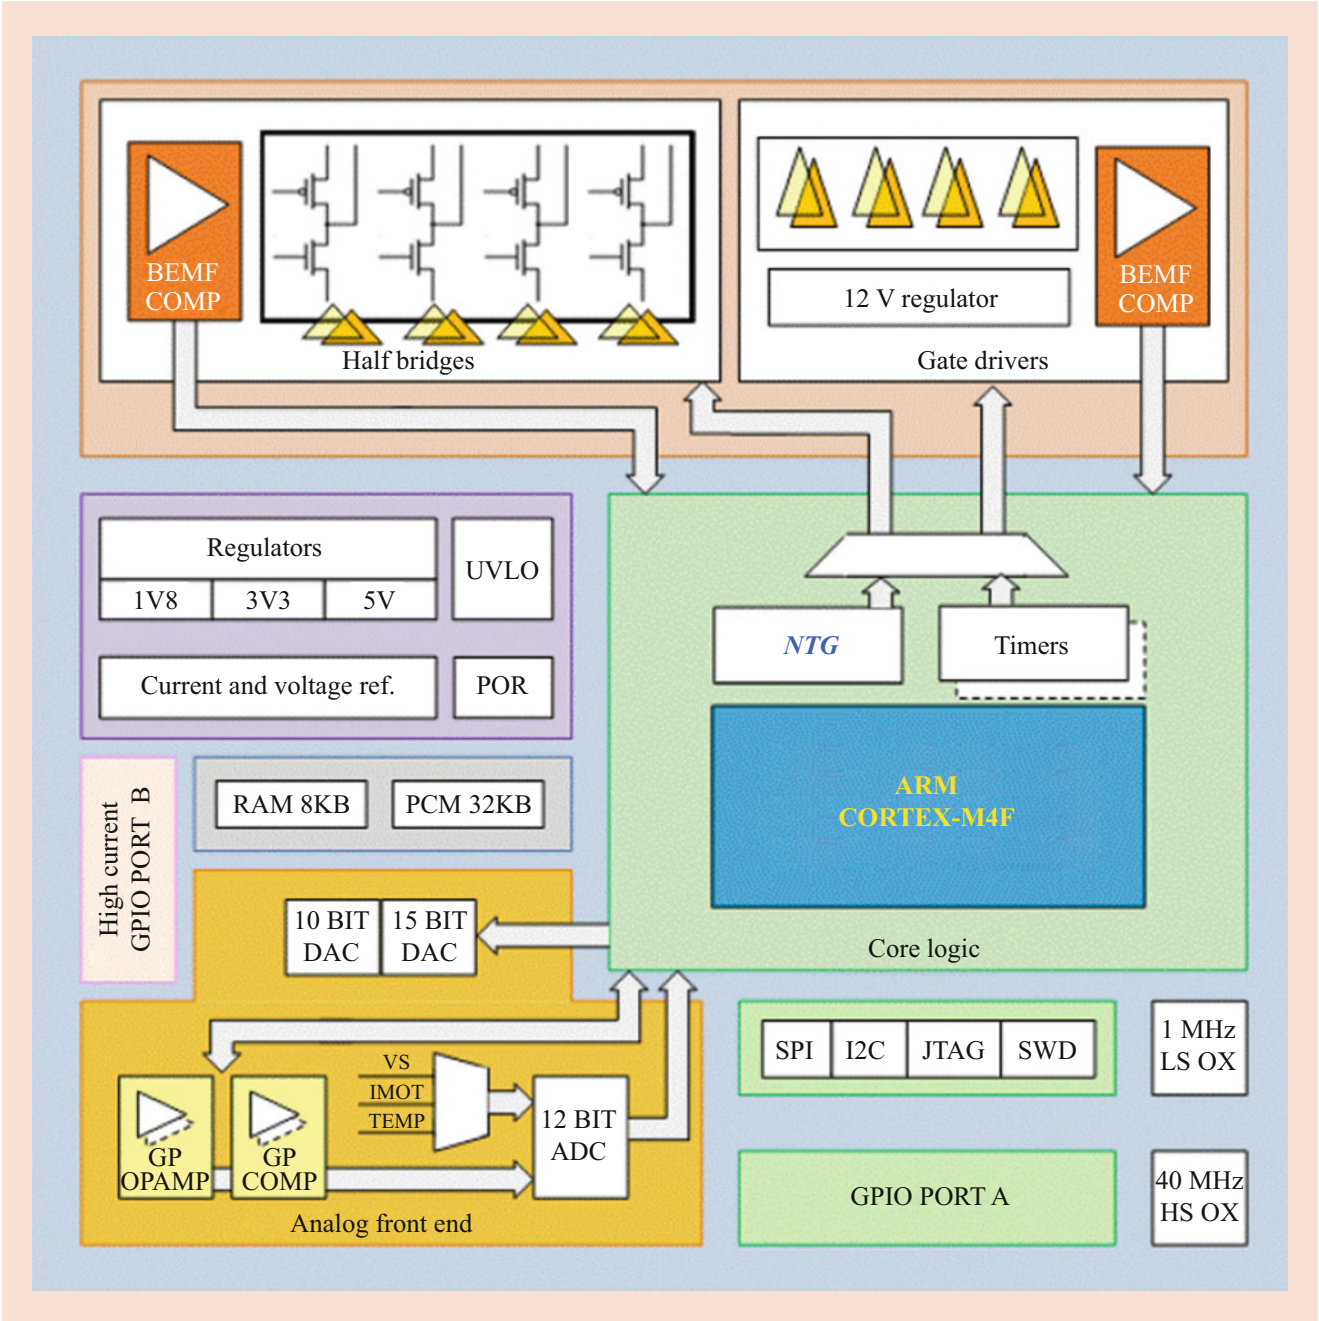

Fig. 3.30 Integrated complete motor control system block diagram

resistive path realized with N+ buried layer and N sinker was present to collect the current at the chip surface: this extra path was increasing the overall specific on resistance.

Lateral DMOS structures have become the standard architecture for power realization since the mid-1990s overcoming the limitation described above. In Fig. 3.33, a schematic cross section of a lateral N-type high voltage DMOS device is shown.

In this structure the current is flowing laterally between drain and source terminals.

Drain region is realized with a lightly doped N-type layer: doping level, drain extension length, and depth are tailored according to voltage capability. Higher doping and reduced length are securing a lower electrical resistance together with a reduced blocking voltage due to higher electric field.

Body region doping profile is another key element for the device realization. An optimum has to be fixed to meet threshold voltage and channel length requirements (the smaller, the better) avoiding the onset of source to drain anticipated breakdown coming from short channel

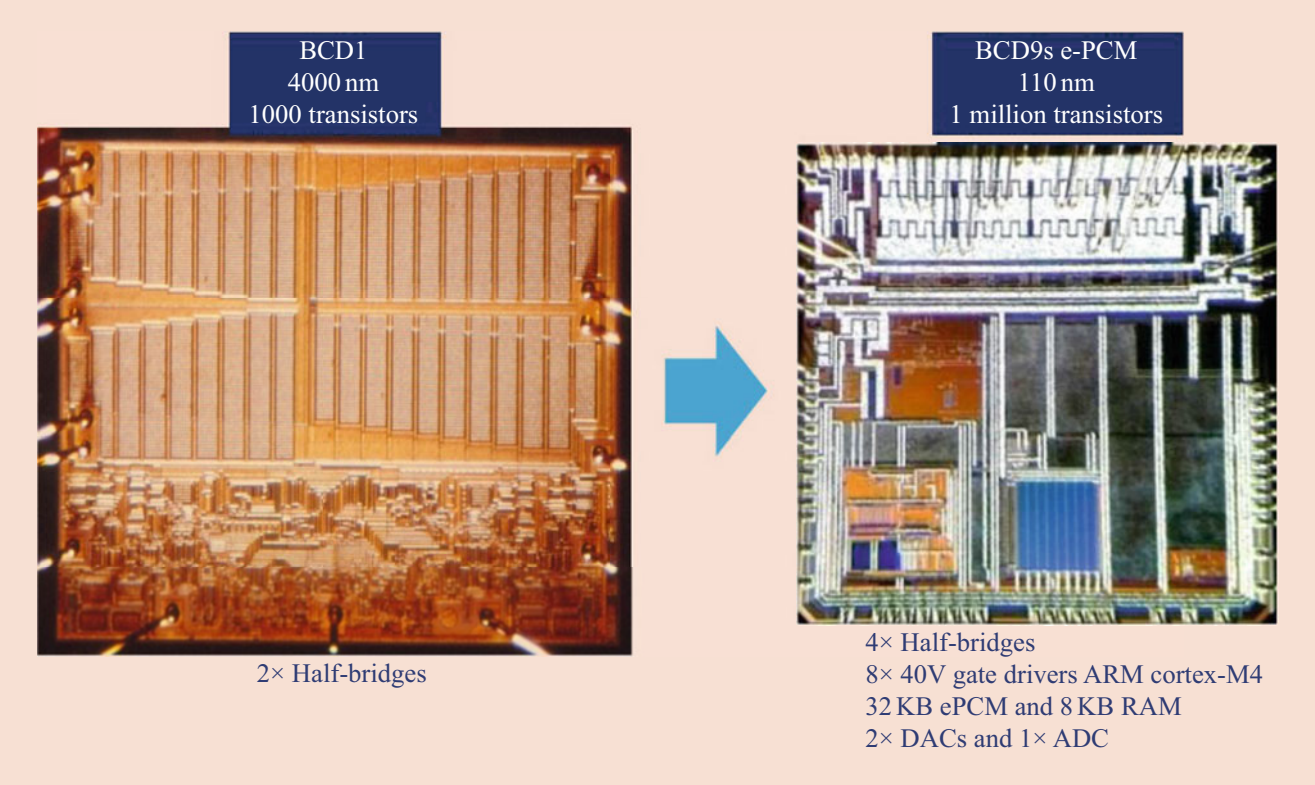

Fig. 3.31 Motor control evolution: from the simplest architecture (one full bridge in BCD1) to the full system integration (two full bridges, six external power drivers, ARM CortexM4 with 32 kBytes NVM based on PCM) in a smaller silicon area

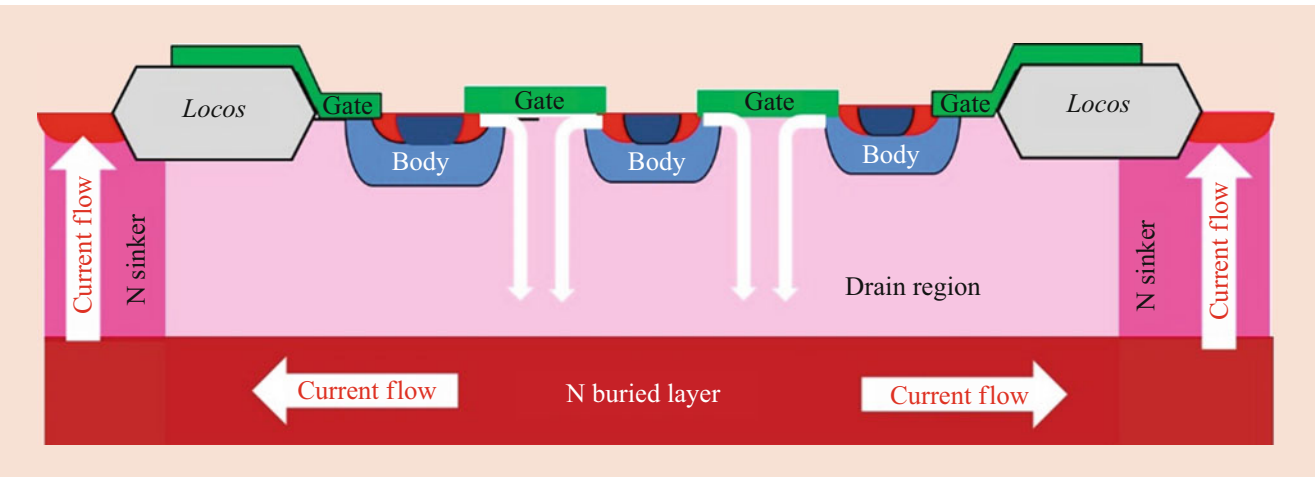

Fig. 3.32 Vertical DMOS schematic cross section

effect (punch-through). Specific care must be taken to avoid intrinsic parasitic NPN (source/body/drain – Fig. 3.19) turn-on triggered by multiplication current during device high voltage operations. For this reason, specific implant may be added to minimize the bipolar intrinsic base resistance.

In this architecture adopted for a very wide range of rating voltages, gate and drain terminals are isolated from each other by a thin oxide region usually realized with the gate oxide and by a thick oxide layer normally using the CMOS isolation module or a specific customized one as it will be detailed in the coming paragraph.

Overlapping polysilicon gate acts as a field plate to reduce the electric field at the body/drain junction. For higher voltage device, metal layers can be used to realize multi-planar field plate securing the high blocking voltage.

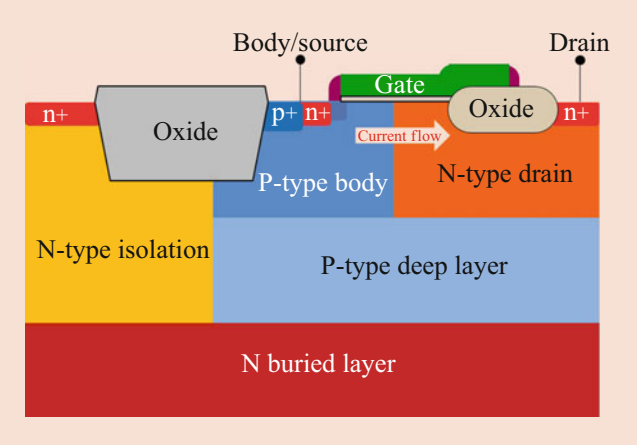

Fig. 3.33 Lateral N-type high voltage DMOS schematic cross section

N-type buried layer is present to provide a vertical isolation between the body and the P-type substrate. A deep P-layer underneath the drain can be present (as in Fig. 3.33) to isolate the drain terminal from the substrate allowing negative voltage operations.

CMOS N+ and P+ layers are used to realize drain, source, and body connection: body and source terminals are locally shorted to minimize the intrinsic NPN parasitic resistance.

Key electrical parameters for power switch devices are the voltage capability usually identified with the off-state drain to source breakdown voltage (BV_{dss}) and the specific on-state resistance ($R_{on} \times A$) that provide a direct measurement of the voltage drop and of the amount of power dissipated by the device when it is delivering the current to the load.

A trade-off between BV_{dss} and $R_{on} \times A$ has to be found with a proper architecture design solution since larger doping level required to minimize on-state resistance leads to a reduced blocking voltage.

Several models have been derived during the years describing the relationship between $R_{on} \times A$ and BV_{dss} for an ideal power device with different assumptions on the electrical profile in the drain extension region [34].

Basically a power law relationship is described:

$$R_{on} \times A = a \times BV_{dss}^{n} \quad (1)$$

This equation is related to the drift region layer, neglecting the channel and contact regions contribution to the area of the devices. This assumption is quite correct for higher voltage rating devices, while it can lead to a meaningful deviation for the lower voltage devices (60 V and below).

On standard CMOS technology at least down to 32/45 nm technology node, device scaling leading to continuous performance improvement has been achieved together with a supply voltage reduction securing same electric field across the elementary device [35].

On power device, supply voltage is strictly coming from the application requirements, and it has not changed during the years.

Automotive battery voltage is fixed since a long time (12 V), and the application-specific requirement (load dump) has been secured by a 40 V rated power since the very early stages.

Power stages requirement for laptop and data centers hard disk drivers is 20 V being limited by the supply line (12 V). All mobile applications are normally powered by battery systems: 5 V max supply has to be secured but larger current management is normally causing severe voltage spike bringing the power device requirement up to 8–12 V.

For audio applications, the voltage specification is driven by the loudspeaker power requirement: 20–60 V rated devices are needed.

In Fig. 3.34, the evolution of $R_{on} \times A$ for a 40 V rated power N-channel device is reported. Almost a factor 7 in reduction has been achieved keeping same voltage capability in the last 20 years corresponding to an average performance improvement close to 25% per each generation. For this specific voltage rating, the size reduction benefit from the new lithography generation capability is limited to the device contact regions; therefore, the performance improvement secured by the geometry scaling is really limited. Several architectural changes to the key device bricks have been adopted to sustain this continuous improvement in the new generations.

Body Region

The channel region contribution has been originally reduced thanks to the lower gate oxide thickness (i.e., larger inversion charge at fixed V_{gs}) and reducing continuously the channel length. Self-aligned large angle tilt body implant (Fig. 3.35, [36]) after gate polysilicon edge definition has been introduced in the late 1990s to tailor the body doping profile securing the amount of charge to prevent premature drain to source punch-through onset with a reduced channel length. At the same time, the lack of a dedicated high temperature step, originally used to diffuse the boron implant under the polysilicon gate, has assured the compatibility with advanced CMOS enabling the realization of power stages with thinner gate oxide.

In more advanced technology generations, thanks to the availability of new lithography tools with more accurate overlay control, body region can be realized adopting specific doping implant before polysilicon gate definition in a not self-aligned approach. Existing CMOS body wells can be used to save masking and implant steps paying specific care to the sub-surface doping vertical profile (body resistance pinched by source layer).

In a power device, the body region is the base terminal of an intrinsic NPN bipolar device that can be triggered by the

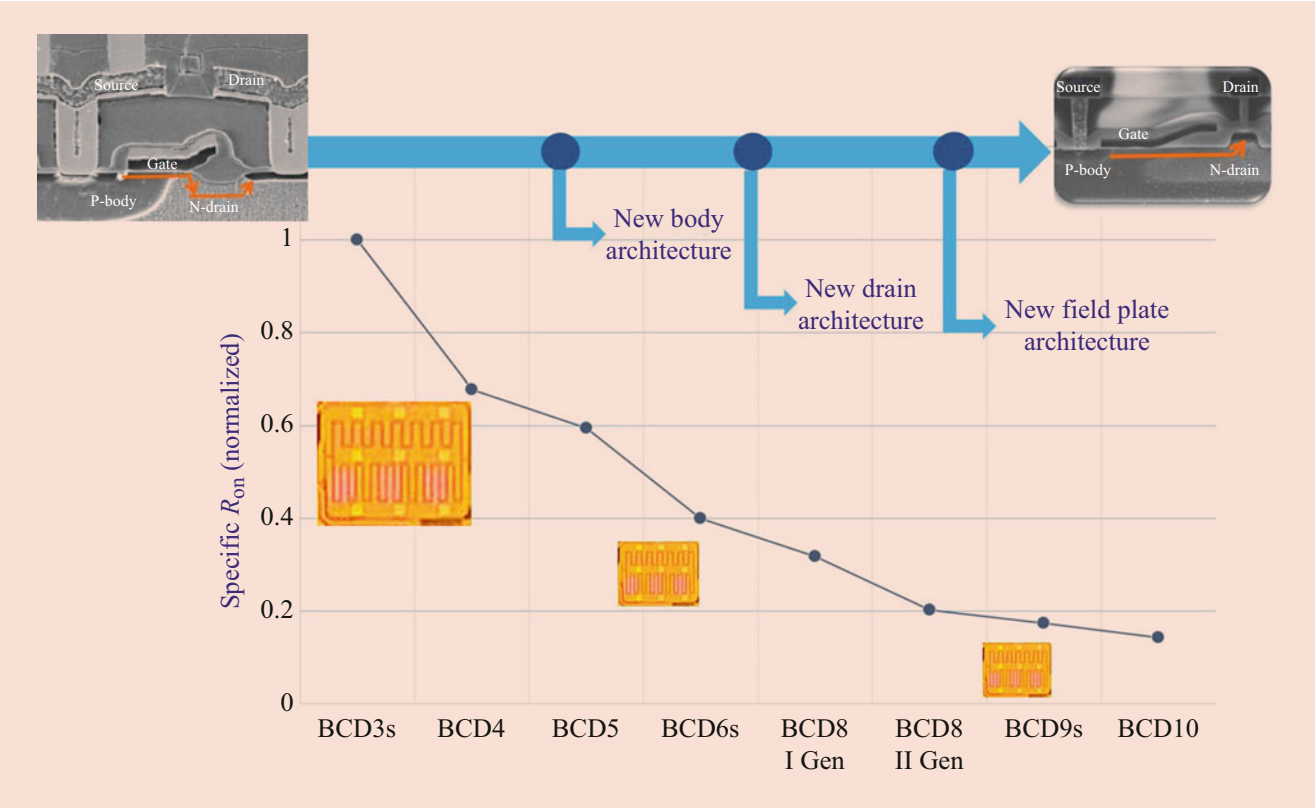

Fig. 3.34 ST BCD technology 40 V N-channel device specific R_{on} improvement in the latest generations. Value normalized to BCD3s (1 μm) technology

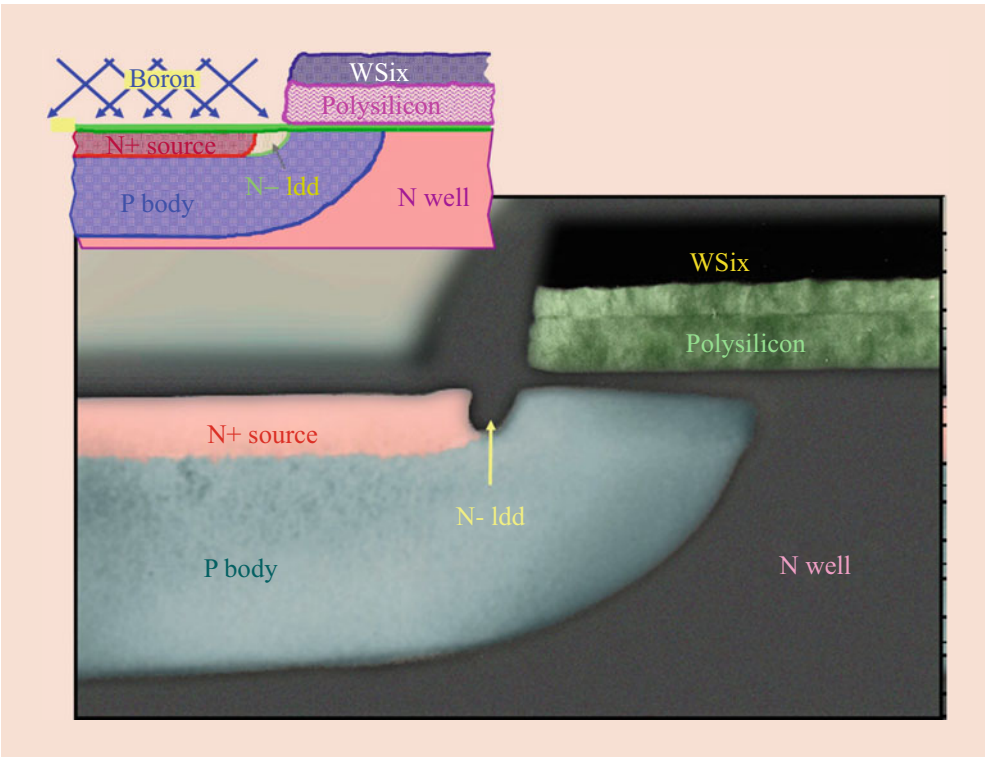

Fig. 3.35 Large tilt body implant realization in BCD5 ST technology. TEM detail of the body/source region

multiplication current present in the device when high drain to source voltage is applied in on-state operations ($V_{gs} > V_{th}$). The trigger of this bipolar transistor leads to device fail, and it limits the safe operating area (SOA). Body and drain regions must therefore be engineered to secure a wide SOA compliant with the required voltage capability: dedicated body profile has been proposed [37] to reduce the bipolar intrinsic base resistance.

When CMOS wells are used for the body realization, specific tailoring to the surface (IMP1 in Fig. 3.36) and subsurface implant (IMP2 in Fig. 3.36) can be carried out to increase the high voltage device SOA.

In the latest generations, the availability of LV CMOS devices using large tilt HALO/pocket implant at LDD (lightly doped drain) level has offered the possibility to further modify and improve the body profile increasing the NPN trigger current and minimizing the short channel effects with a self-aligned approach. In Fig. 3.37 a schematic cross section of the high voltage device source/body region is reported: the boron-doped pocket layer (HALO) is increasing the doping level under the body leading to a larger threshold voltage down to very short channel length.

Different strategies have been adopted for the realization of the body to source contact region to optimize the trade-off between two requirements:

- The electrical connection between the body and the source must secure minimum electrical contact resistance to avoid SOA penalization minimizing the NPN intrinsic bipolar base resistance.
- Body region size reduction to maximize channel density (i.e., effective width integrated in the unit area).

Self-aligned silicide (*SALICIDE*) introduction starting from 350 nm technology has enabled the possibility to improve the resistance minimizing the size needed for the connection (see Fig. 3.38): P+ contact region is placed in the middle of the body opening region and is shorted with the source layer thanks to the silicide layer.

The scaling of the body opening dimension is limited by the requirement of low resistance value associated to this region. Therefore new lithography generation would bring negligible gain, and different body region solutions have been proposed to overcome this limitation.

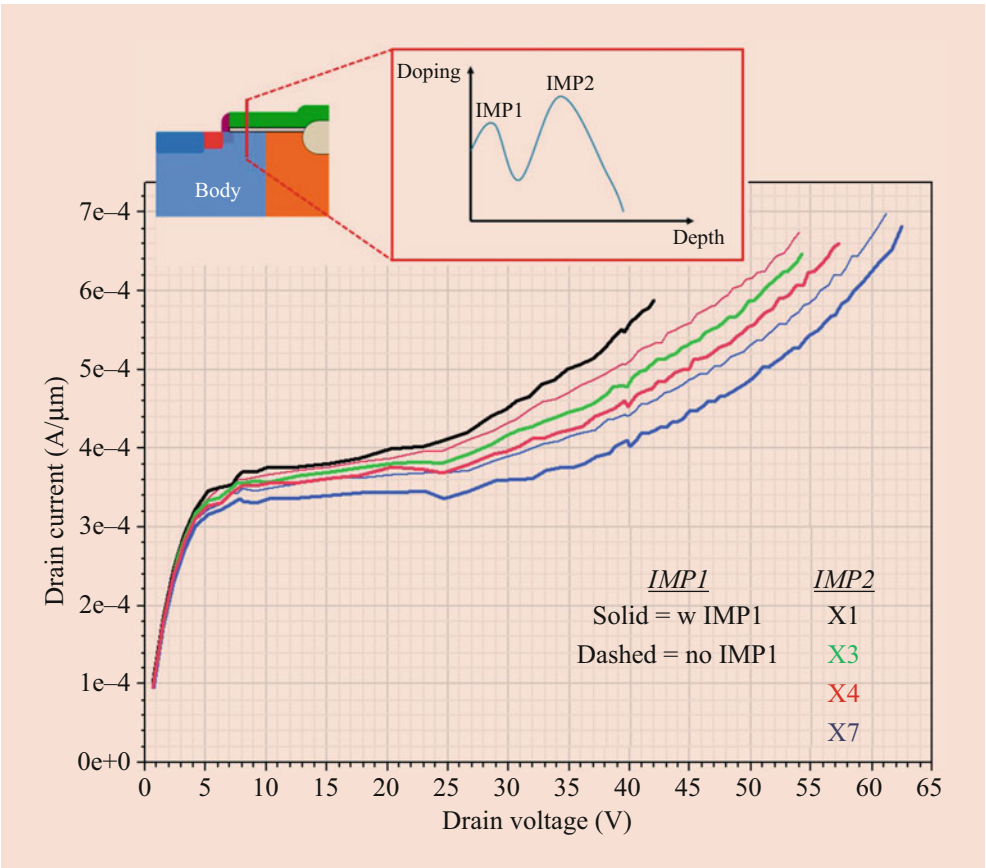

Fig. 3.36 High voltage device output characteristic. Impact of different body implant profile on safe operating area

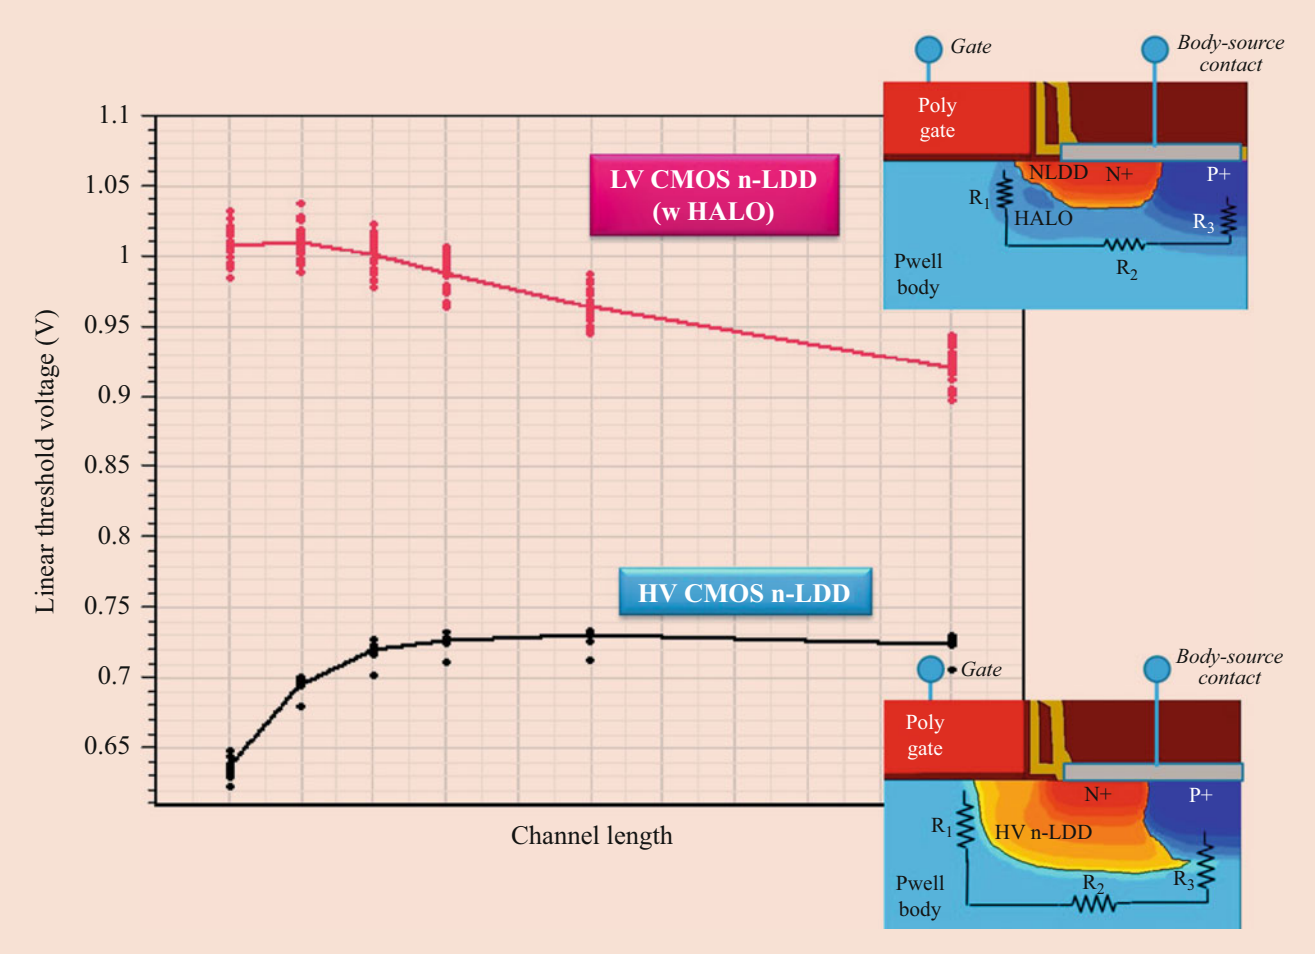

Fig. 3.37 (**a**) High voltage N-channel source/body junction profile under the poly edge: HV CMOS LDD (**b**) and LV CMOS LDD w HALO implant (**c**) and (**d**) Device threshold voltage as a function of channel length for the two different bodies

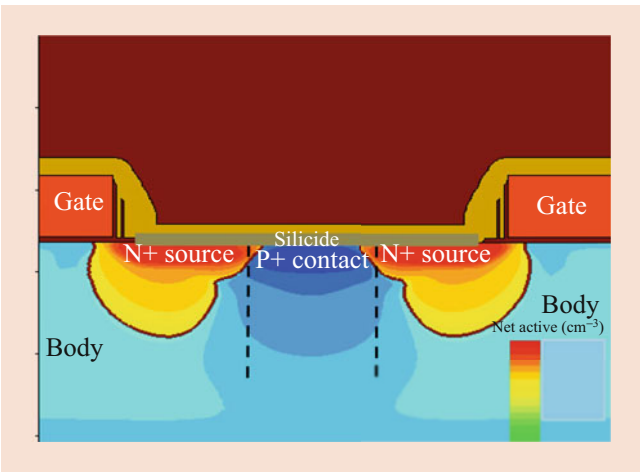

Fig. 3.38 Body to source contact region detail. A silicide layer is formed during the process securing a good conductive local connection between source and body contact areas

Alternating P+ and N+ strip across channel width (Fig. 3.39) reduces the device pitch: specific care must be taken in defining the minimum P+ area needed to avoid SOA penalization since this area is reducing the effective source width integrated penalizing device specific R_{on}.

Local connection through micro trench realization is today widely used in discrete power devices and may offer an interesting opportunity for reducing the device pitch, but dedicated process steps are needed for the realization leading to increased cost and complexity (Fig. 3.40).

Drain Region

The drain extension region plays a key role in the device realization: doping profile and geometrical dimensions are the parameters tuned during the development to optimize the performance according to the trade-off between voltage capability (BV_{dss}) and conduction losses ($R_{on} \times A$).

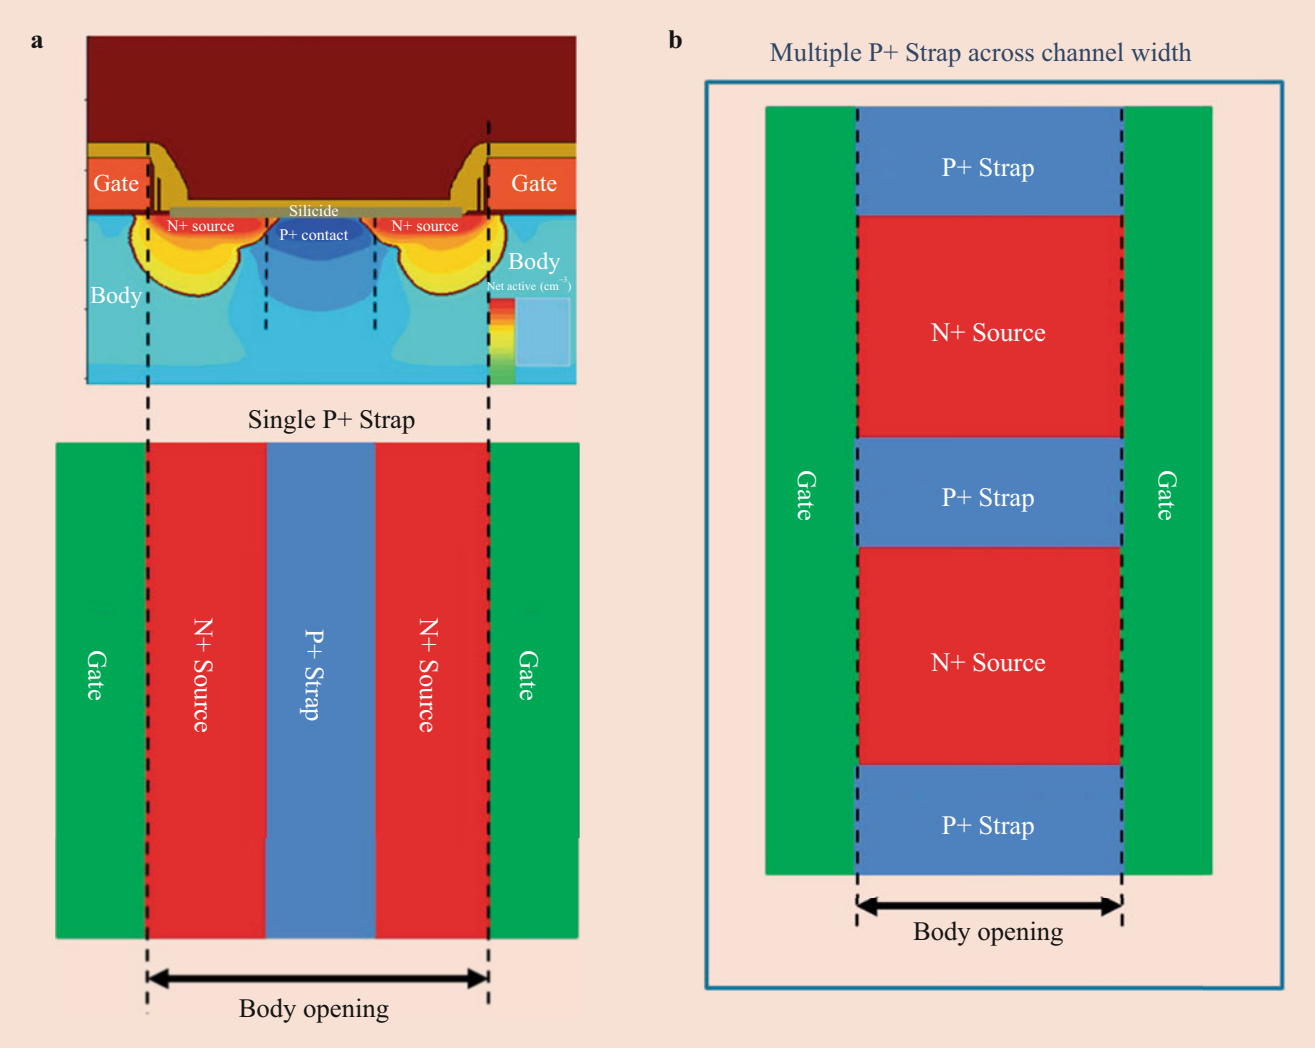

Fig. 3.39 Body to source contact region layout. (**a**) Single P+ strap. (**b**) Multiple P+ straps along channel width alternated with N+ source

RESURF technique is widely adopted to increase the drain doping level while keeping the same off-state breakdown thanks to the introduction of a vertical diode that enhances the depletion of the drain layer modifying the electric field profile [6]. In Fig. 3.41, a qualitative description of the P-layer impact is reported: thanks to the vertical P-layer drain diode effect a bell-shaped curve is obtained in the BV_{dss} vs drain dose plot.

Lower drain dose values are leading to lower off-state capability due to an electric field peak located at the drain region (red star) caused by the potential lines crowding in the higher doped drain terminal.

Increasing the drain dose, the electric field peak location is moving to the conventional surface region close to the oxide transition region (orange star): an optimum (i.e., maximum BV_{dss}) is reached when a perfect balance between the electric fields in the two regions is reached.

Increasing the P-layer dose the optimum point, i.e., the drain dose leading to the maximum off-state voltage, is moving to larger drain dose level leading to a device with same BV_{dss} but reduced $R_{on} \times A$ thanks to the increased doping level.

The limitation to the P-layer dose is given by the onset of other hot spots in the structure such as the vertical P-layer to N-type buried layer diode (Fig. 3.42). The multiple RESURF solution has been proposed during the years [34] with the purpose to maximize the depletion effects leading to an ideal electric field distribution with the maximum drain doping level.

Drain extension engineering is completed by the definition of the key geometrical parameters (see Fig. 3.43). Three main parameters play a role in the optimum device realization:

- Drain extension under thick isolation oxide (S in Fig. 3.43). Longer $R_{on} \times A$ gives benefit in terms of off-state voltage capability (larger BV_{dss}) independently of the region where the electric field peak is positioned.

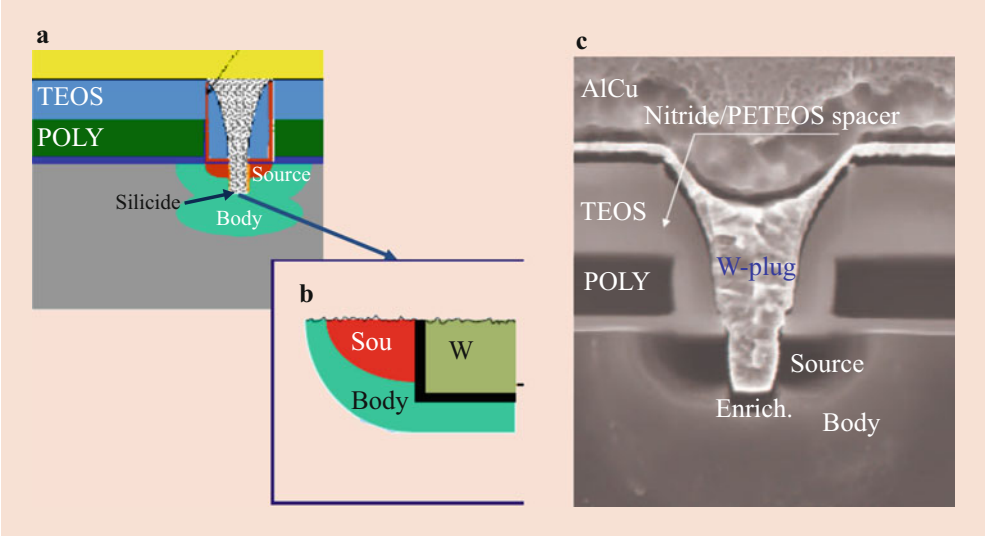

Fig. 3.40 (**a**) Schematic section of the Body to Source contact region in a Power Discrete device. (**b**) Zoomed view of the source and body diffusions with the contact region. (**c**) TEM cross section: local silicon micro trench is realized to secure the connection between the body and source terminals

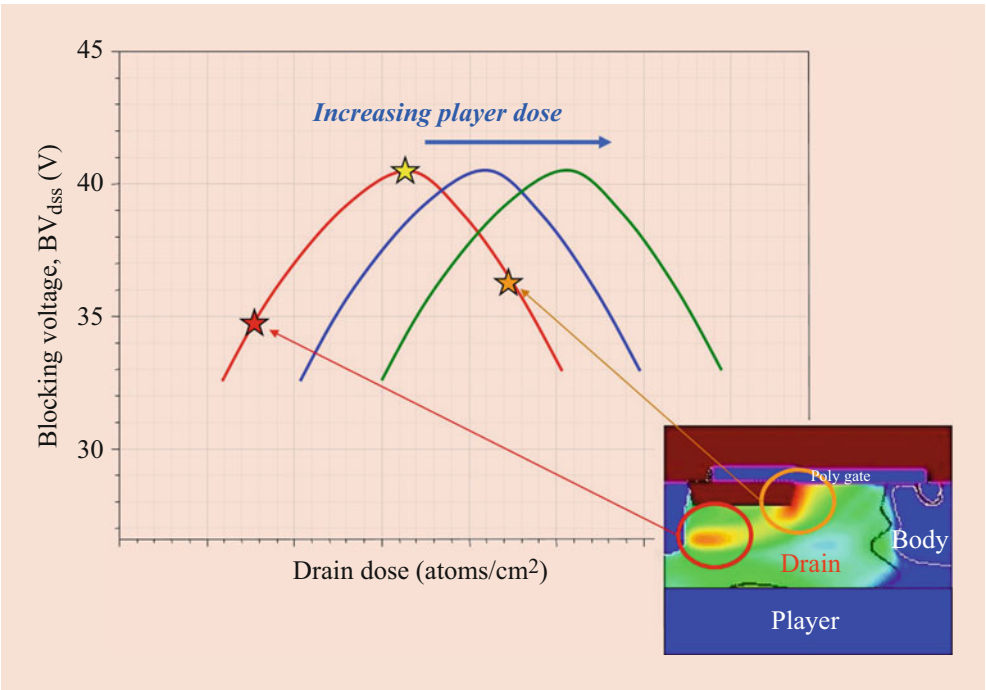

Fig. 3.41 TCAD simulation for off-state voltage (BV_{dss}) as a function of drain doping (dose) for a high voltage device with different buried P-layer dose for a fixed device geometry. In the inset, impact ionization distribution in the structure is reported

Clearly on-state resistance is penalized and the device is optimized by minimizing this value to secure the required voltage capability.

- Polysilicon gate overlap on thick isolation oxide (O in Fig. 3.43). Larger O reduces the electric field in the oxide transition region increasing BV_{dss} when the maximum avalanche generation is localized in this region. At the same time larger extension on the oxide may lead to a reduction of on-state resistance thanks to the accumulation of the drain region below. Too large extension increases the electric field on the drain side, therefore limiting the voltage capability due to the avalanche onset on the drain side. At the same time, the gate to drain capacitance is increased with an impact on the switching loss occurring during high-frequency operations. Optimum designs are generally looking to maximize this parameter since it plays a beneficial effect to mitigate some potential instability phenomena as it secures a "controlled" coverage of

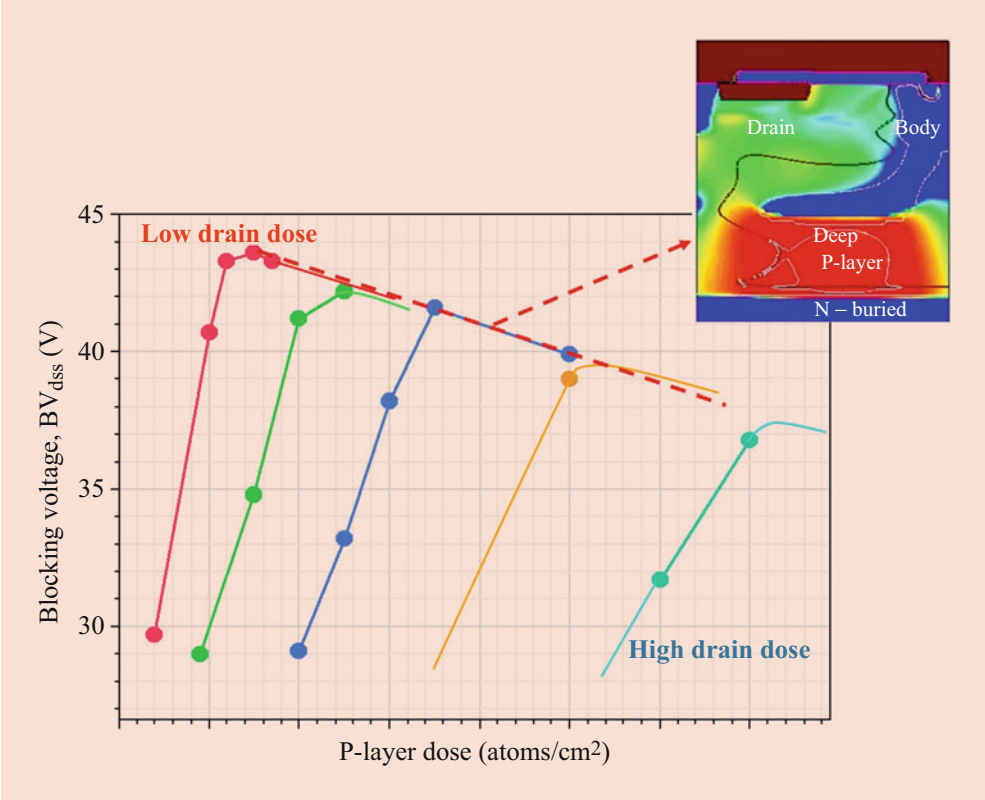

Fig. 3.42 TCAD simulation for off-state voltage as a function of P-layer dose for different drain doping for a fixed device geometry

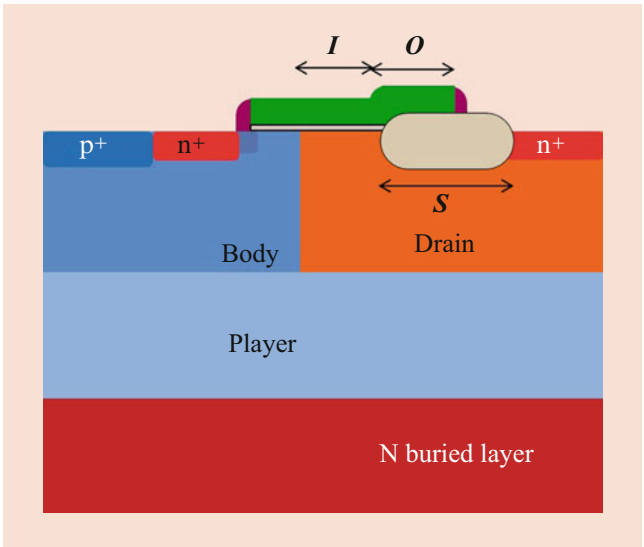

Fig. 3.43 High voltage lateral N-channel schematic cross section: key geometrical parameters highlighted

the drain extension region. This is particularly true for higher voltage rated device.

- Polysilicon gate overlap on drain in thin gate oxide region (*I* in Fig. 3.43). The reduced *I* value alleviates the electrical field in the transition oxide region thanks to increased drain depletion coming from the body/drain surface diode: BV_{dss} increase is therefore expected when the device is limited by this region hot spot (orange star in Fig. 3.41). At the same time, device switching loss benefits from the reduced gate to drain capacitance. *I* reduction is limited by the on-state resistance increase associated with the contribution related to the vertical current path. Indeed even in lateral device, a vertical current path is forced by the presence of the thick isolation oxide. Current flow section reduction is causing a sudden on-state resistance worsening when *I* is reduced (Fig. 3.44): the on-state resistance increase vs *I* is anticipated moving to lower drain doping level. Reduced *I* value is generally required for an optimum power switch but the scaling is limited by the on-state resistance increase. Both of these effects are strongly depending on the thick oxide region realization.

The availability of a deep P-type layer below the drain region enables the possibility to physically isolate it from the heavy doped buried layer (Fig. 3.45) thanks to a proper device edge construction. This configuration allows the usage of this device in all the power stages with limited negative supply rating: in fact the drain terminal can be negatively biased vs the grounded substrate provided that a proper (positive) bias

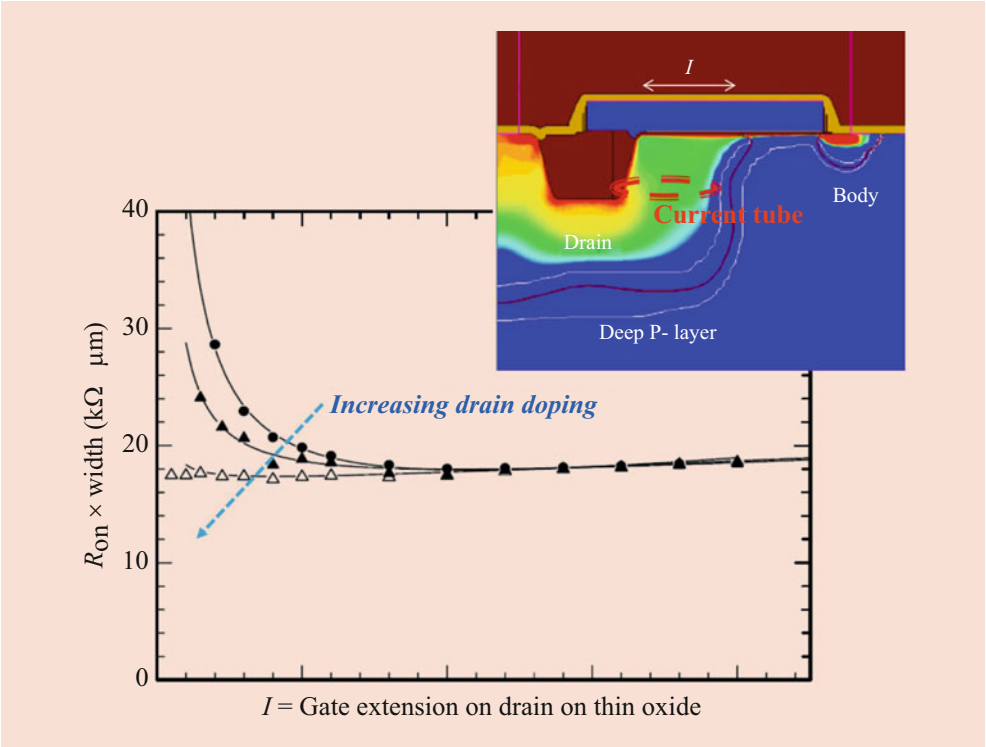

Fig. 3.44 Specific R_{on} as a function of I parameter for a 40 V rated lateral N-channel. Three different curves refer to different drain doping levels. In the inset current flow, color contour is reported when the device is biased in linear region

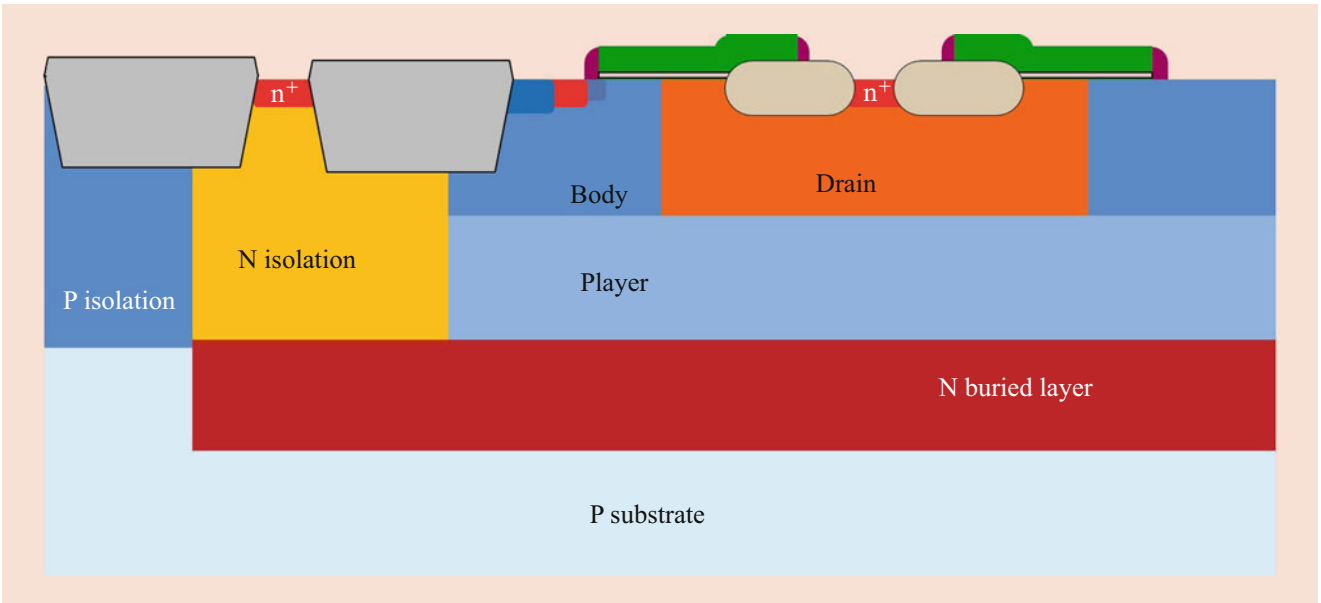

Fig. 3.45 High voltage N-channel isolated drain architecture. N-type drain regions are isolated by the N buried layer vertically by the deep implanted P-layer and laterally by a proper termination design

is supplied to the N-type isolation ring. The availability of an independent N-type isolation region offers the possibility to enhance the isolation capability during circuit operations.

More specifically in Fig. 3.46, some parasitic bipolar devices turned on during some transient period are highlighted in the inset. The availability of the isolation ring terminal can offer different possibilities in the power device stage design:

- N-isolation shorted to drain (blue line in Fig. 3.46). This is a standard situation for non-isolated device. In this

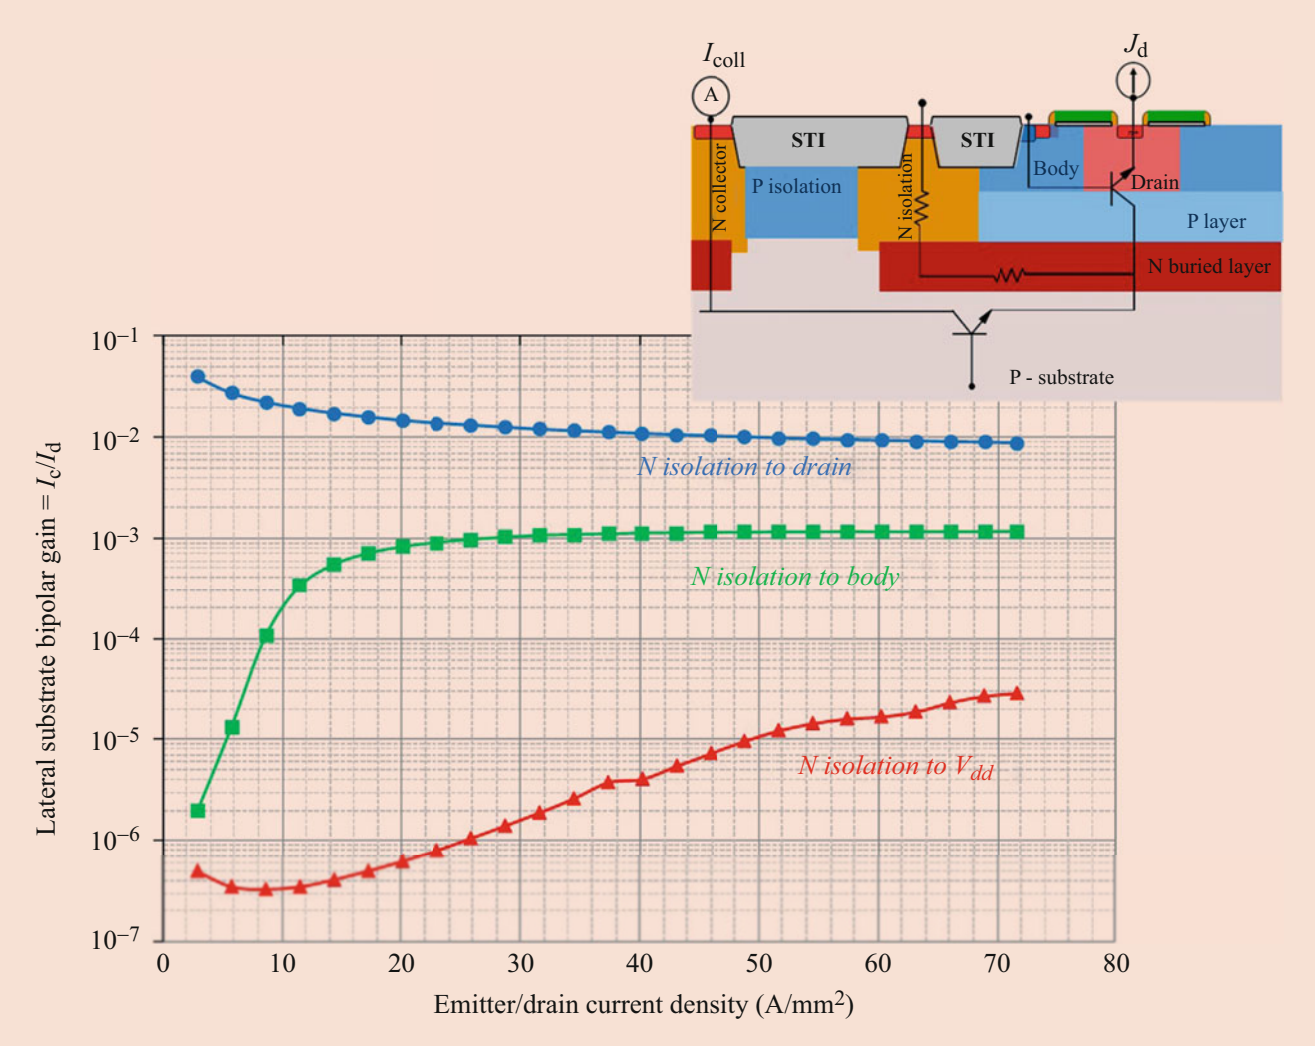

Fig. 3.46 High voltage N-channel isolated drain architecture: evaluation of external parasitic bipolar for different Isolation ring bias. Figure: collected current on an external pocket as a function of drain injected current density. Inset: architecture cross section with parasitic bipolar devices. (Reference: ST proprietary BCD technology)

configuration when drain terminal is biased negatively (vs source and substrate), a quite meaningful amount of current is collected by a neighbor device. The decay length is strongly dependent on the isolation architecture as shown in Fig. 3.11. This is clearly the most unfavorable connection strategy, but this solution may become mandatory when N-buried layer bias is fixed by overall device RESURF condition [38].

- N-isolation tied to high voltage supply (red line in Fig. 3.46). This is the most effective solution to protect the device closer to the power stage. In this configuration when the drain terminal is biased negatively, the internal NPN is turned on and the isolation region is acting as a collector. All the injected current is therefore locally collected with negligible impact on the region close to the power. To make this solution viable, the internal bipolar NPN safe operating area has to be carefully designed to secure no catastrophic event occurs during this period of large current/large voltage applied. The major drawback of this solution is the increased power dissipation when bipolar is turned on.
- N-isolation tied to body/source terminal (green line in Fig. 3.46). In the low current regime, this solution is equivalent to the previous one. However due to the internal collector electrical resistance (N buried layer and N isolation plug), the local N buried layer potential is dropping below ground turning on the lateral bipolar NPN and increasing the current collected by the external silicon region. Proper power device layout guidelines can increase the current level needed for turning on the external bipolar device: specific rules for sizing and placement of the N isolation plug are normally delivered for the optimum design depending on the application requirements. However this solution enables an increased level of protection without

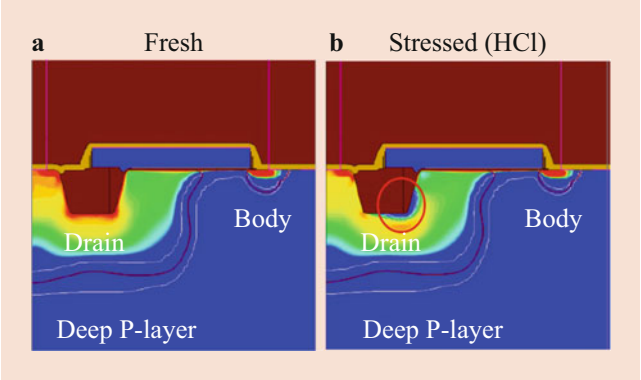

Fig. 3.47 STI terminated high voltage device linear current density plot. (**a**) Fresh device; (**b**) device after operation at high V_{ds} and intermediate V_{gs}. Red circle highlights the STI region where negative charge is trapped causing on-state resistance increase

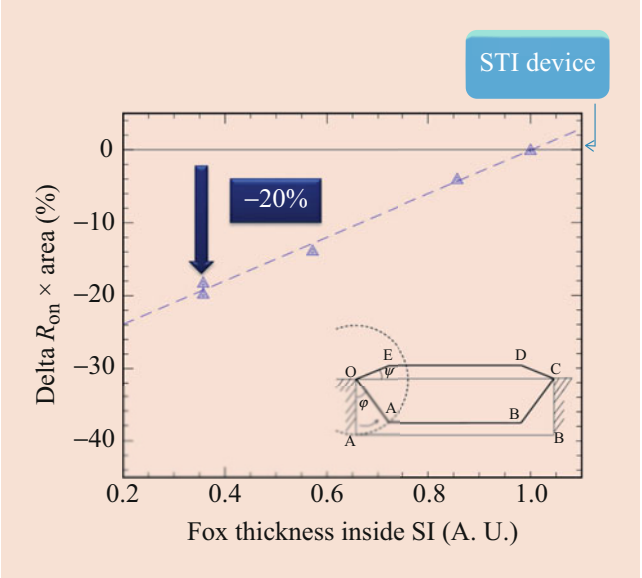

Fig. 3.48 Specific R_{on} reduction as a function of thick oxide penetration in silicon. Oxide thickness is kept fixed while moving the oxide out from the silicon starting from a vertical solution (STI like)

any power dissipation penalization and providing a faster diode recovery time.

Oxide Isolation Region

Thick isolation oxide layer is normally realized using the CMOS isolation module. The introduction of STI has given some benefits in the reduction of the drain extension length thanks to the vertical profile, but it has put a major reliability challenge for the realization of the high voltage devices [39].

During on-state device operations, when biased at high V_{ds} and V_{gs} above threshold, hot carriers are generated in the structure, and they may be injected in the gate oxide and/or generate interface states by de-passivating Si-H bonds [40, 41]. The resulting charge, associated with trapped carriers and charged interface states, modulates the drain extension width leading to an increase of the overall on-state resistance (Fig. 3.47). This phenomenon is adding a new constraint on the possible reduction of the accumulation region (*I* in Fig. 3.43) and further challenges for the device performance improvement.

To overcome this challenge, improved architecture has been presented in the latest year. Recessed gate structure has been recently reported as a viable solution to mitigate electric field at the STI bottom edge [42].

Dedicated customized thick oxide are widely adopted in many advanced BCD platforms. STI replacement with a dedicated oxide layer in power devices is mitigating the hot carrier-induced instability phenomena and is improving the device performance reducing the amount of oxide in the silicon leading to a reduced (vertical) current path. In Fig. 3.48 a theoretical analysis for a 40 V rated device is reported, keeping fixed oxide thickness: R_{on} reduction is reported as a function of the depth oxide into silicon.

While the benefits on devices' performance are evident, this solution has a few integration challenges.

Extra process steps are needed, and at the same time the compatibility with advanced CMOS process flow has to be carefully managed: in Fig. 3.49 an example of integration is presented in a 160 nm technology platform by STM [43].

A dedicated LOCOS module is realized just after STI realization: a dedicated nitride layer is patterned to protect the STI defined regions enabling the realization of the thick oxide layer in the power device. Thanks to the different profile, during high voltage operation, the electrical current flows "far" from the surface mitigating the hot carrier-induced instability (Fig. 3.50, [44]). This solution has enabled the realization of high-performance power device securing a meaningful scaling vs the previous generations.

Given the limitation coming from the latest CMOS isolation module (STI), the power device architecture has been therefore revisited with the final aim to continuously improve the performance while securing the long-term reliability and a wide safe operating area (SOA).

The gate to drain isolation region module has been re-engineered moving to a planar fully emerged power device architecture to further boost power performance scaling providing a straight current path between drain to source minimizing $R_{on} \times A$.

Within this framework, alternative device structures originally exploited for different voltage rating and usage have been re-engineered looking for an improved trade-off between integration cost and performance.

1. Planar dual oxide architecture with a tailored drain extension region (Fig. 3.51) covered by poly gate has been introduced since many years as the optimum solution for

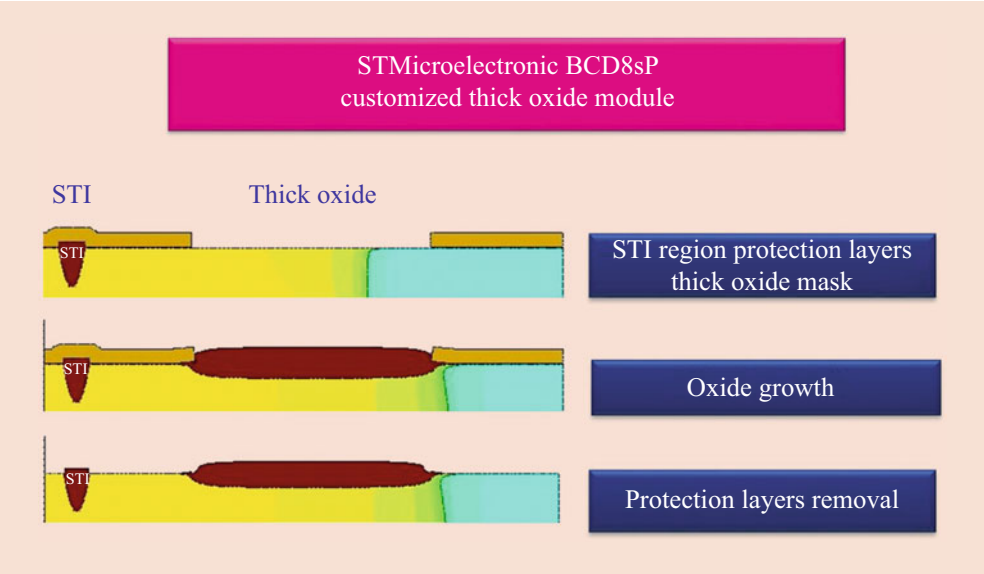

Fig. 3.49 Customized thick oxide integration in advanced BCD technology (BCD8sP, 160 nm)

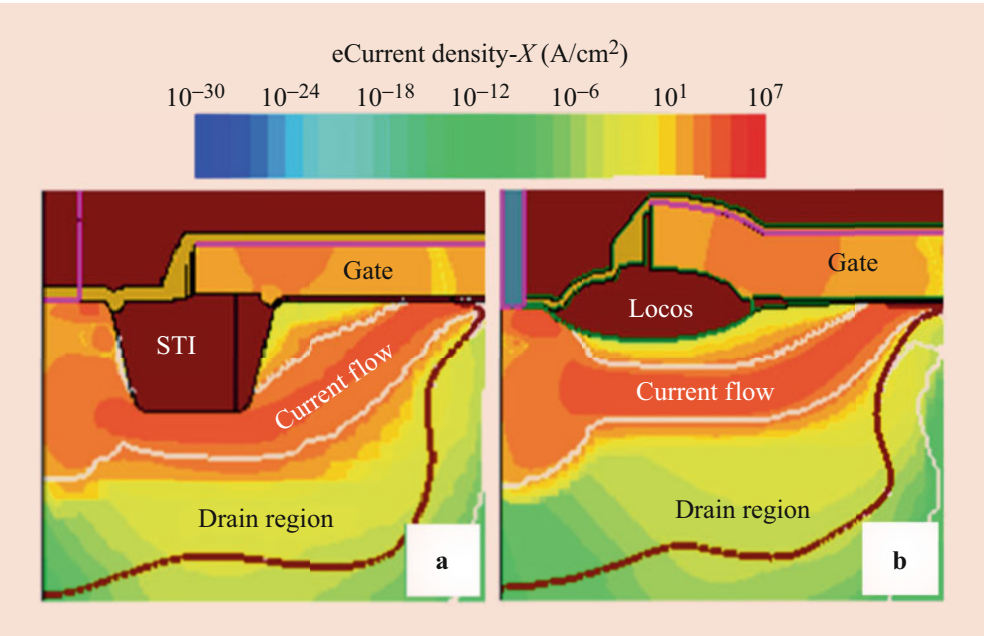

Fig. 3.50 Electron current density flow for (**a**) STI terminated high voltage device and (**b**) LOCOS terminated one. Device biasing conditions: $V_{ds} = 18$ V, $V_{gs} - V_{th} = 1$ V

minimizing gate to drain overlap capacitance in RF power LDMOS [45, 46]. This solution is currently adopted in many advanced BCD platform thanks to the improved process control leading to a better definition of the thin/thick gate oxide transition regions. Isolation oxide thickness is fixed by device voltage rating: higher voltage capability requires thicker layer to minimize the drain extension resistance. However, integration constraints (lithography depth of focus coming from non-planar surface, reduced pre-metal dielectric thickness) limit the maximum allowed value and therefore the maximum voltage capability. To overcome some of these integration challenges, a novel structure realized on the bottom of the CMOS shallow trench has been conceived and proven on silicon (Fig. 3.52).

2. Single oxide architecture (Fig. 3.38) with no specific thick oxide region is introduced minimizing the integration cost. Trade-off between gate oxide thickness and drain extension doping/length (*O* and *S* in Fig. 3.53) is key to achieve good performance up to 20 V. Recently

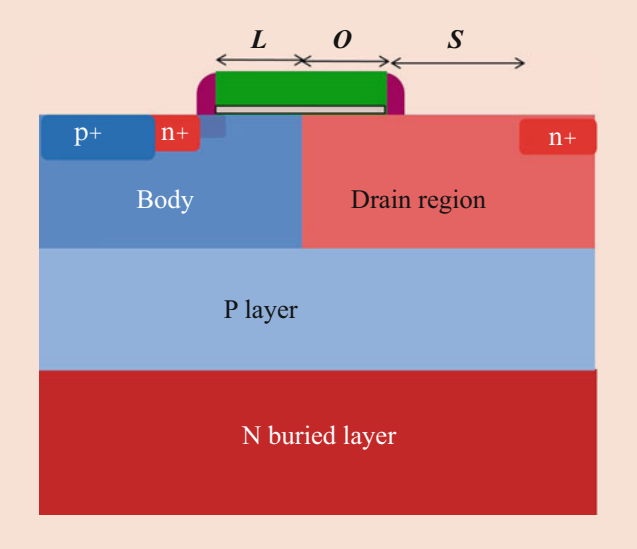

Fig. 3.53 Single active area architecture

contact layer is used as field plate on the uncovered drain extension zone to further improve performance and reliability [47].

High Voltage Power Devices

The evolution of power devices in the last 30 years has been driven by a continuous improvement in the elementary devices' architecture for classical voltage rating typical of a wide variety of applications in consumer, industrial, and automotive markets. In these segments, the main driver has been the continuous improvement of power device performances keeping the same voltage rating between 5 and 100 V.

There are many high power applications requiring larger voltage capability (Fig. 3.54). Home electronic systems connected to the AC power mains are requiring as first step an AC/DC conversion circuit to generate a stable DC voltage to supply the required current to the loads: this market is growing fuelled by the adoption of LED lighting and smart systems driven by energy-saving requirements. At the same time, high power delivery generated by high voltage battery systems is needed by car electrification and by industrial segment.

High voltage (600 V and above) system-on-chip integration is not today a viable solution. Power discrete devices are the preferred choice since monolithically integrated vertical solution for such rating voltage would require very thick epitaxial layer with high associated cost and poor performance given by the collecting path contribution. Thanks to RESURF, a lateral architecture would be the natural choice for power integration but the figures of merit ($R_{on} \times A$) of this architecture is relatively poor compared to discrete vertical power MOSFET.

In Fig. 3.55, a typical block of a high voltage system is reported: monolithic IC is realized to drive large size external power devices (IGBT or MOSFET). Together with power gate drivers, some functions are integrated in the same chip mainly for system diagnosis and control. High voltage (>600 V) platform availability enables the integration of high side gate driver and bootstrap diodes.

The management of such voltage is putting new challenges in the platform architecture conception. Very low doped substrates are required leading to an increase in the noise injected during the circuit operations. For this reason deep trench solutions can be introduced in the flow both to minimize the lateral isolation dimension and to decrease the ground collecting resistance reducing the cross talk between the different blocks [48, 49].

The high voltage device lateral architecture is very similar to the one presented above (Fig. 3.43): very light doped layers on a long drain extension (60–100 μm) are needed to satisfy the large off-state voltage requirement (BV_{dss} > 800 V). The low doping concentration makes this device very sensitive to the electrical charge distribution on the layers present above. For this reason, specific field plates are conceived to mitigate the sensitivity of the key electrical parameters (such as BV_{dss} and R_{on}) to the charge distribution (see Fig. 3.56). These specific field plate architectures play a critical role in securing the long-term stability of the device during operations [50].

In the latest years, new emerging applications are requiring larger rating voltage moving to 1200 V and even above. Recently 2000 V BCD platform has been reported using very thick SOI (12 μm oxide) for electric vehicle systems [51].

At the same time, the availability of depreciated manufacturing assets makes economically feasible the integration of advanced (180–350 nm) CMOS platform with high voltage capability [52]. Therefore more complex system can be realized integrating more functions and increasing the driving capability to manage larger power discrete devices (Fig. 3.57).

3.4.3 High Current and Energy Capability

State-of-the-art smart power technologies, thanks to the progresses in terms of microlithography and power devices improved architectures, are able to provide lower and lower $R_{on} \times A$ figure of merits in terms of power integration capability.

Even if a limit can be put as far as maximum current capability for an integrated power device in the range of 10–15 A (for higher currents, power discrete or VIPower technologies are more suitable [53]), the power density to be managed is continuously increasing.

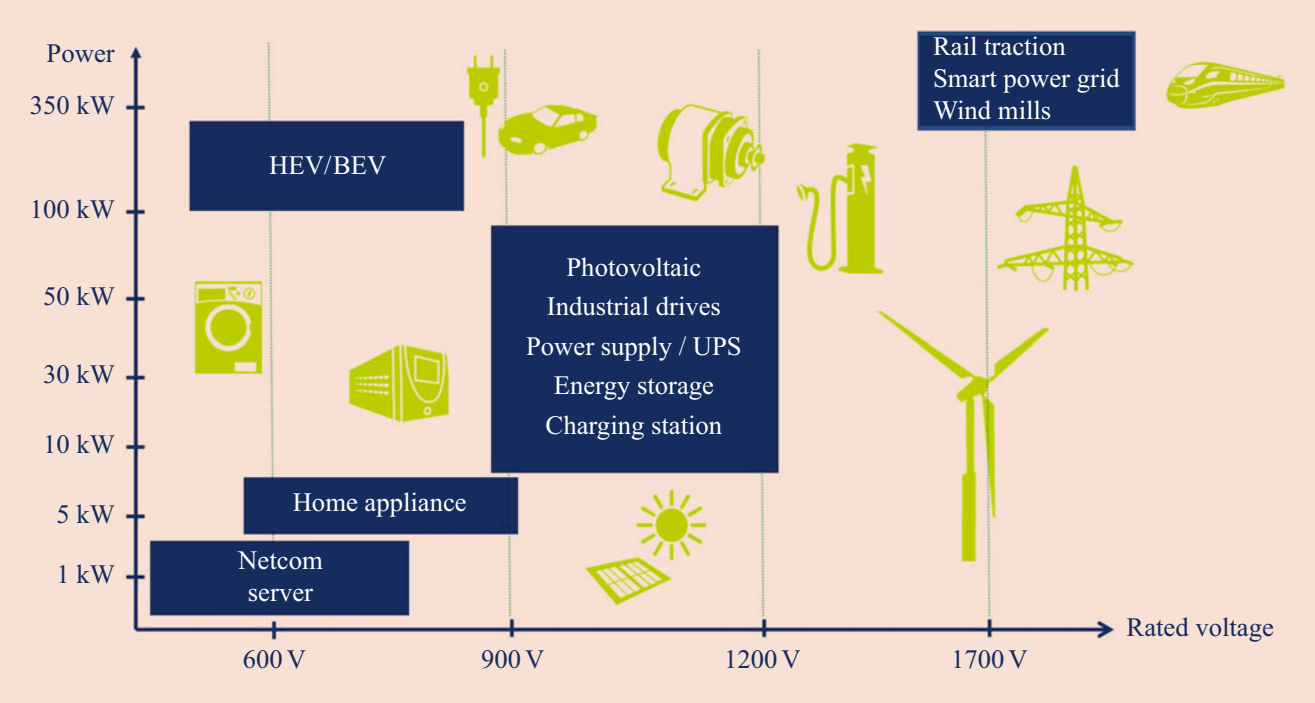

Fig. 3.54 High voltage/large power application map

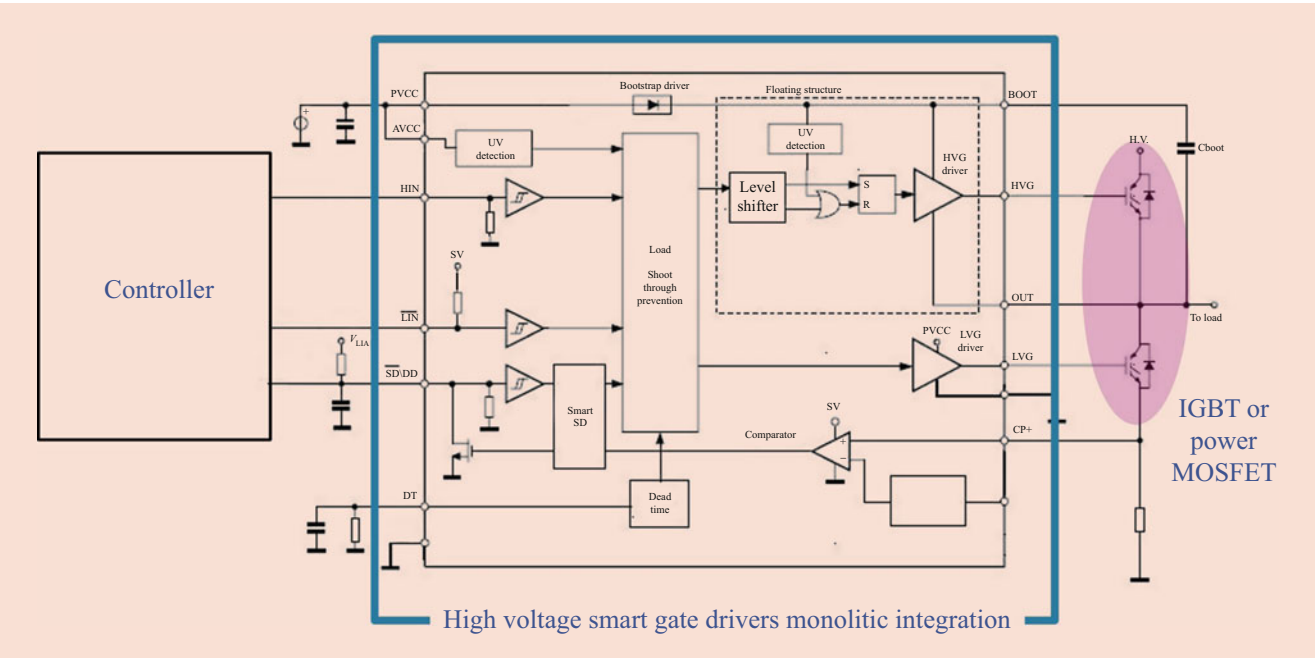

Fig. 3.55 High voltage system block diagram

These limits, together with the tough requirements of 15 years lifetime, 12,000 hours in power on and, moreover, power pulse cycling that are causing severe thermomechanical stress on inter-dielectric layers [54], are just a few examples of the main challenges to be addressed when designing smart power technologies and products.

Automotive products such as anti-lock braking system (ABS) and injector drivers are subjected to high energy pulses induced by re-circulation current of inductive loads. The pulse duration is typically in the range of 0.1–1 ms for the above applications. The energy pulses generate high temperature gradients inside the power components: due to

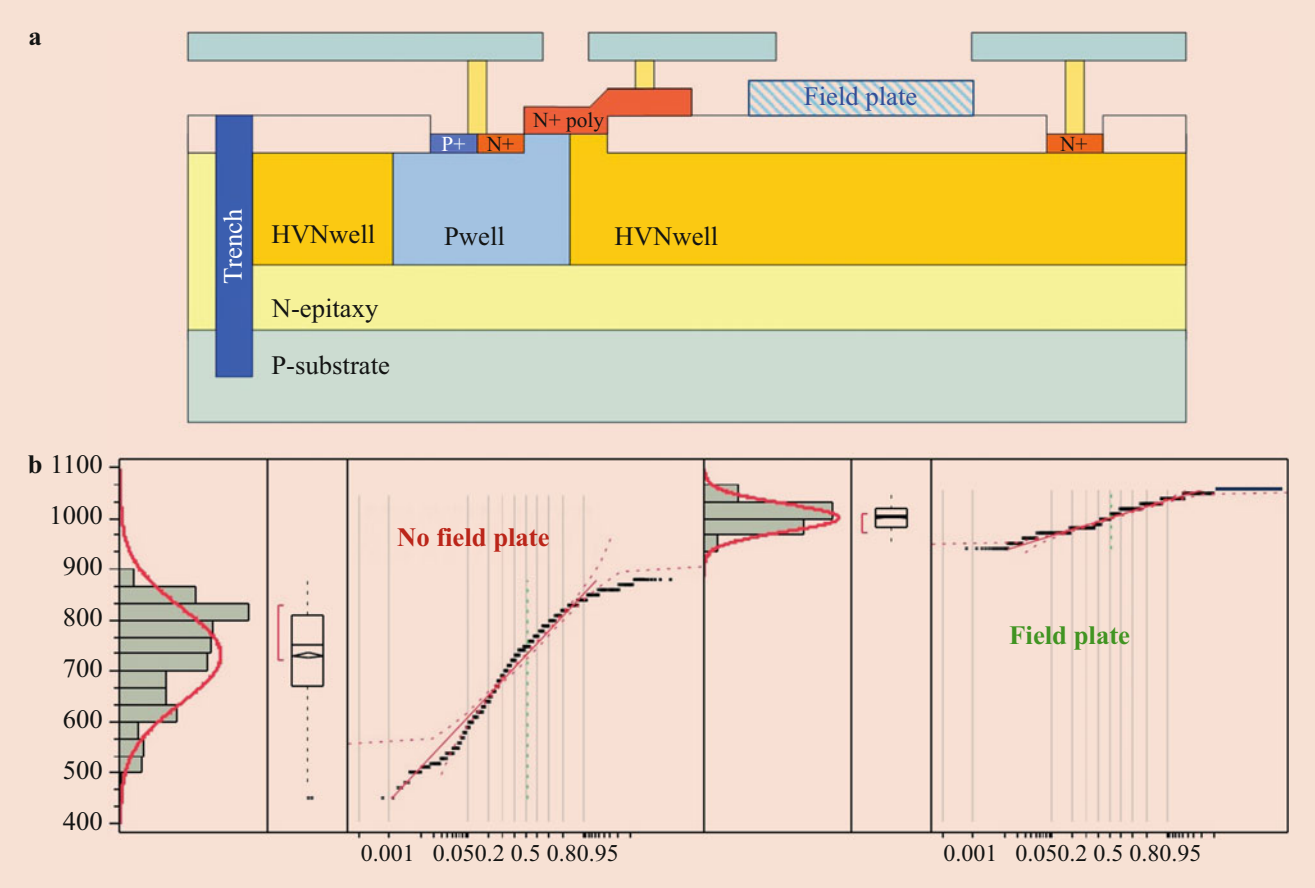

Fig. 3.56 (**a**) High voltage N-channel device in 800 V 350 nm BCD technology. (**b**) BV_{dss} distribution of two different structures with and without specific field plate on drain extension region

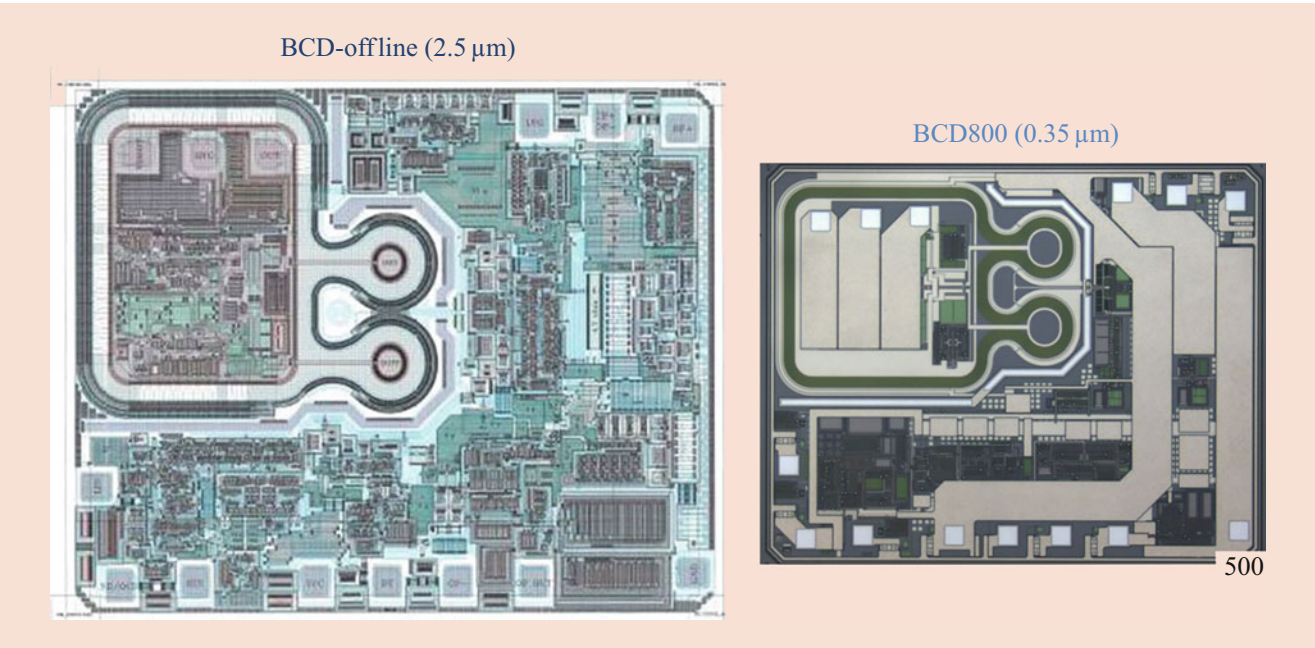

Fig. 3.57 High voltage gate driver monolithic IC evolution: from 2.5 to 0.35 µm technology platform. More integrated functions with increased gate driver capability in a reduced die size

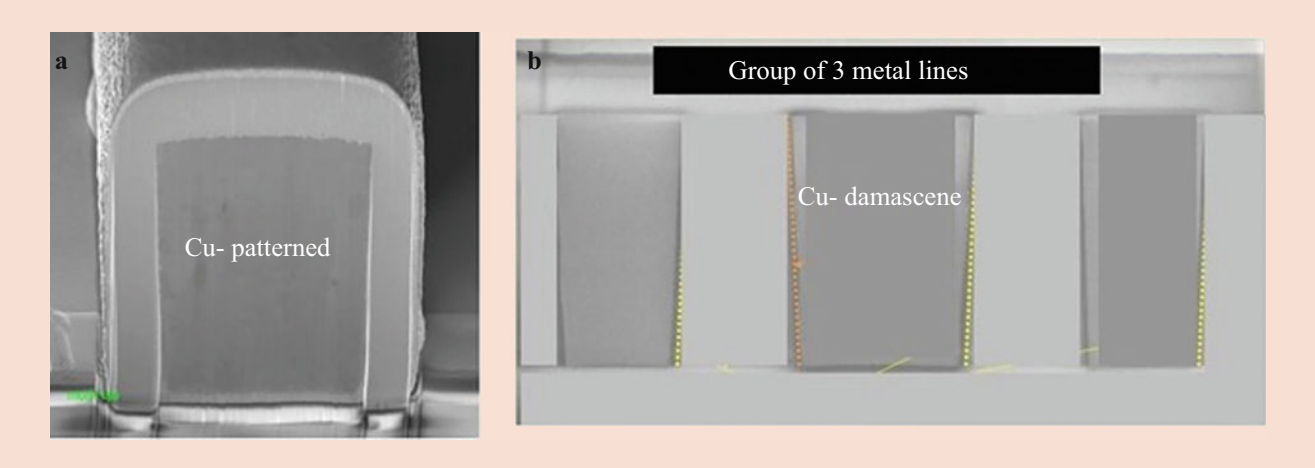

Fig. 3.58 Thick copper obtained by (**a**) patterned or (**b**) damascene electroplating

the device shrinkage, the peak temperature may be above 300 °C. Many phenomena that lead to the final device failure can be identified [55, 56], namely:

- Fatigue crack initiation within the oxide layers (high cyclic fatigue failure).
- Low cyclic fatigue failure due to alternating stress beyond the yield limit in the metal layers and ratcheting effects.
- Creep of the metal layers.

Thermomechanical stresses are induced by mismatch in coefficient of thermal expansion (CTE) in the materials coupled to a cyclic change in temperature owed to the heating power input into the system. Both material properties and geometrical parameters of the device packaging system strongly affect the thermomechanical stress state.

In general the understanding of the physics behind this failure mechanism is of utmost importance. Automotive field applications require strict mission profiles (in terms of number of pulses), and proper design guidelines are needed not to be "energy limited" in power devices sizing.

To overcome these failure mechanisms, new metallization solutions have been proposed and multilayer metallization [57, 58] and/or thick copper metal layers have been used [59]. Figure 3.58 shows two different solutions for thick copper metallization on smart power technologies: patterned and damascene.

The thick copper patterned electroplating technology allows higher thickness and is used for power metal and power bus routing. This patterned copper plating approach permits to achieve high thicknesses ($\geq$ 10 μm) for the thick copper top metal, which acts therefore more effectively as a heat sink, keeping the transistor colder at the same injected energy.

Furthermore, the low resistivity of this thick copper allows reduction of the contribution of the metallization connection to the overall on-resistance of the power device and minimizes any possible de-biasing effect on the gate-source applied voltage, especially when the power element size is so huge that the metal resistance becomes a meaningful parameter.

Table 3.2 Comparison between aluminum and copper material properties

Property	Aluminum	Copper
Electrical resistivity (μΩ × cm)	2.70	1.70
Resistance to electromigration	Low	High
Hardness (Mpa)	140–160	340–490
Young modulus (GPa)	50–70	110–130
Shear modulus (GPa)	25	46

Sources: www.matweb.com, www.memsnet.org

The thick Cu damascene technology is more VLSI oriented; it allows lower thickness but thanks to finer pitch can also be used for signal routing.

Advances in BCD technology to finer lithography (110 nm and below) brought thin Cu metallization from CMOS technology for signal routing. This thin Cu introduction demonstrated to be advantageous in further improving the energy capability of power devices, in addition to the well-known benefits associated to Cu metal lines, i.e., lower resistivity and higher electromigration robustness compared to aluminum.

The key material properties which make copper preferable for advanced BCD technologies are shown in Table 3.2 in comparison to aluminum.

The gain given by full Cu BEOL in the robustness of power devices against high and repetitive energy pulses is due to the lower plastic strain of Cu vs aluminum when submitted to thermomechanical stress, as demonstrated by the case study summarized here below [60].

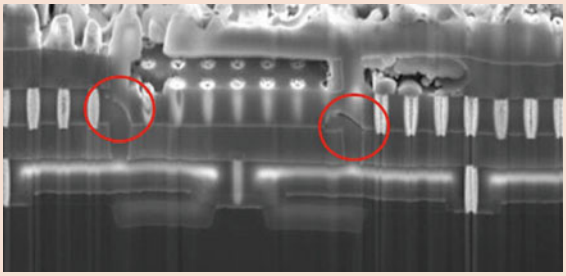

Fig. 3.59 Short between metal due to metal extrusion inside oxide crack. AlCu thin metal lines

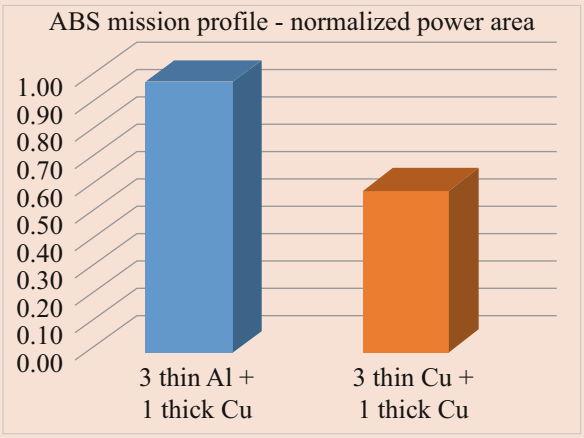

Fig. 3.60 Improvements in silicon area for energy pulsing capabilities (automotive ABS mission profile)

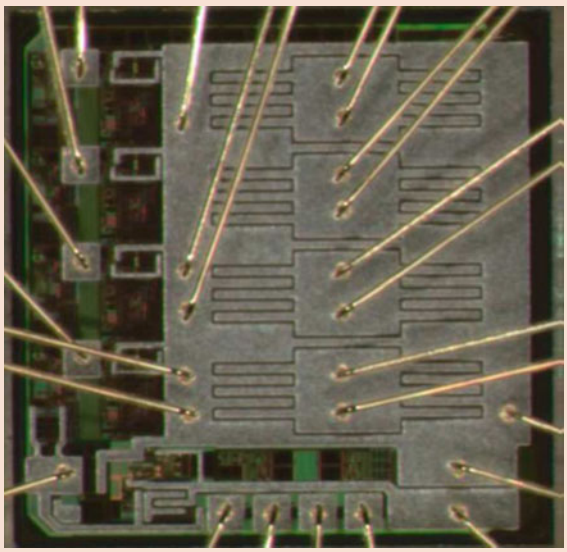

Fig. 3.61 Example of wire bonding connections on power devices active area

Repetitive power pulsing test results are reported for a power N-channel laterally diffused MOS (LDMOS) with active clamp and two differing BEOL metal configurations: (1) mixed Al thin signal metals and thick top copper power metal and (2) full copper. A 60 V power N-channel LDMOS on 160 nm BCD technology platform with active clamp has been submitted to repetitive power pulsing tests simulating the recirculation of an inductive load.

The power N-channel LDMOS has been designed with three thin metal levels plus a 4-μm-thick copper layer as top metal level. The first three thin metal layers are 0.3–0.5 μm thick for both BEOL configurations with full copper being latest BEOL scheme for 110 nm BCD technologies.

Repetitive power pulsing test is carried out until the occurrence of an electrical short: 1 ms pulses with 20% duty cycle were applied to power devices at 200 °C above the junction temperature reproducing aggressive automotive mission profiles.

As a result, the lifetime of the full Cu BEOL is improved by a factor ~10 to 100 with respect to the mixed Al and Cu BEOL.

Failure occurs because of inter-metal oxide cracking, due to metal plastic deformation, leading to metal short when the metal extrudes inside the crack (see Fig. 3.59 for Al thin metal).

The failure analysis carried out on several devices did not highlight any thin metal deformation in case of full Cu BEOL.

The effect of a full copper BEOL on the size of power components in case of an energy limited automotive application, the anti-lock braking system (ABS), is shown in Fig. 3.60: a 40% shrinkage of the power section, rated at 40 V, can be obtained.

Another limiting factor for the shrinkage of the IC size enabled by the BCD technology lithography reduction is given by the size needed for the pad structures which allow to interconnect the die to the external world. This limitation derives also from the higher pin count of advanced smart power products, which can integrate an increasing number of functions thanks to the higher digital and analog density of latest BCD technologies. Also the shrinkage of the IC area occupied by the power devices would be limited if the large bonding pads, needed for thick wires to handle the current, cannot be placed over the power transistors (Fig. 3.61).

Hence the need to move pads from passive die area to regions of the die where active components, including power transistors, are present, maintaining robustness and system reliability [61].

The use of thick copper in combination with over pad metallization (OPM) (Figs. 3.24 and 3.25) provides excellent reliability of the solder joint in high temperature applications with extended lifetime requirements and is capable to resist to the mechanical pressure coming from thick and stiff wires, reducing the stress propagation in the BEOL system and down to the active components [14, 62].

3.4.4 Passive Technology Modules for High Precision, Analog, and High Voltage Applications

The features and advances of specific applications in terms of performances (accuracy, noise), voltage domain, and safety require the introduction within BCD technology platforms of customized technology modules.

Analog accuracy demands for the availability of passive components as resistors and capacitors with excellent matching and stability capability. The basic passive elements available within the mainstream BCD flow suffer of significant parasitic contributions due to the implementation in the FEOL of the process and require also dedicated die area.

Solutions able to avoid these basic constraints can be obtained implementing such passive components inside the BEOL of the technology.

Resistors

The simplest and typical solutions can be realized with implanted layers requiring isolation versus substrate and therefore contributing significantly to the die size and with limited voltage capability and linearity due to the depletion of the doping layers.

Other resistors commonly used are made of polysilicon to be placed above the field oxide. Such kinds of resistors exhibit resistance variations upon applied voltage, high parasitic capacitance versus the silicon substrate and poor matching characteristics, which are not compatible with the specifications of the addressed functions.

Both diffused and polysilicon resistors are affected by the resistance variation as a function of temperature, usually taken into account through the temperature coefficient of resistance (TCR), defined as $(1/R)(\mathrm{d}R/\mathrm{d}T)$.

Thin film resistors integrated in the BEOL system overcome the described limitations, offering new solution for die size reduction on standard BCD technology [63].

In comparison to polysilicon or diffused resistors, they offer higher resistance values and precision tolerance, as well as lower TCR (<100 ppm/K) in the typical operation temperature range (–40 °C to 175 °C). Various materials are currently used as thin film resistors in IC applications, such as SiCr, NiCr alloys, and TaN [64–68], depending on the required resistance and TCR values (Fig. 3.62).

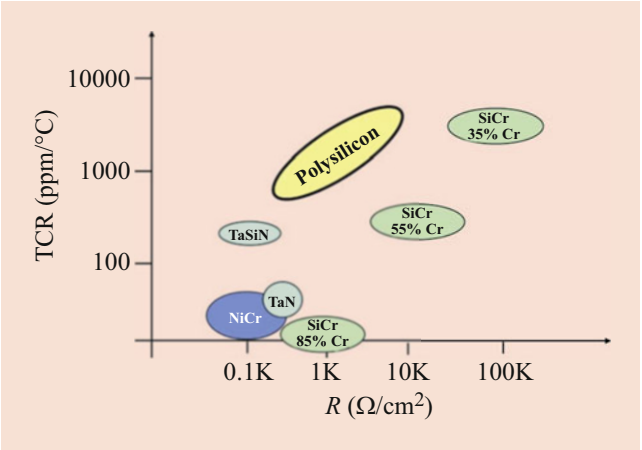

Fig. 3.62 Available thin film resistor mapping

The most interesting solution that provides very low TCR and high resistivity is the SiCr alloy, whose electrical properties can be modulated depending on the Cr content.

For SiCr resistors with 85% Cr content, 10 nm thickness and 600 Ohm/square sheet resistance, TCR in the range of 15 ppm/°C and matching accuracy within 0.5% are achieved.

Capacitors

In analog functions like decoupling, filtering, A-to-D converters, the main requirements on capacitors are the voltage linearity, the matching accuracy, and the precision control of the capacitor value.

Integration of such components demands other figures of merit to be met, namely, a small parasitic capacitance and access resistance, together with the need of a maximized capacitance density.

All of the above requirements can be fulfilled realizing metal-insulator-metal (*MIM*) capacitor structures within the BEOL scheme of the BCD technology.

Other types of capacitors commonly used, like poly-oxide-poly, poly-oxide-doped wells, or metal-oxide-metal (MOM) structures, can be implemented without adding extra process steps but are limited in terms of analog performances and of capacitance density.

MIM capacitors are realized dedicating one or two metal levels for the electrodes and thin high-K dielectric to maximize the capacitance density. To minimize the parasitic capacitance to the substrate, the MIM capacitor is preferably implemented between the upper metal levels of the technology BEOL.

Another advantage of this realization is the possibility to stack the MIM capacitor above active components, reducing the die size compared to other solutions.

Different kinds of high-K dielectric material have been presented for MIM application ranging from silicon nitride

to Al_2O_3, Ta_2O_5, ZrO_2, HfO_2, and $AlHfO_2$ with capacitance density spanning from 1 to 10 nF/mm^2 [69–71].

The MIM integration in BCD technology poses further challenges related to higher operating temperature conditions (150 °C) with reduced leakage constraints up to 5 V use. These requirements are in conflict with the increasing leakage behavior of HK insulators and therefore a trade-off must be identified.

Galvanic Isolation

Circuit isolation, usually named galvanic isolation, is a requirement in all electronic systems, where it is needed to inhibit the passage of unwanted current between two parts of the system under anomalous working conditions (voltage surges, spikes, transients) to protect equipment and users from hazardous situations.

At the same time, it is needed to transfer signal and power [72, 73].

Especially in the industrial domain, the isolation is becoming more and more needed in order to protect factory equipment which are highly interconnected with each other in the most automated factories. Automotive and medical are other application areas where high voltage isolation is required for a safe operation.

In the typical application, the low voltage signal driving the high voltage power components (IGBTs or SiC transistors) is passed through the inductive or capacitive coupling that provides also the galvanic isolation to the system.

Opto-couplers have been historically the most widely used solution for isolation purpose, but recent IC technology evolution introduced more compact, reliable, and cost-effective solutions.

The integration approach enables the isolation through a thick oxide using the dielectric layers of the BCD technology BEOL system and/or depositing additional layers on purpose. The oxide is therefore the insulating layer, with excellent dielectric and reliability features, placed between two metal layers to realize capacitive or inductive on-chip isolators.

The advantages compared to opto-couplers, which use molding compound based insulator layers, are the higher quality of the oxides deposited in IC front end manufacturing and the consequent absence of voids or large defects, which can give issues in the tests addressing the integrity of the insulating material (*partial discharge tests*).

Also in comparison to solutions using thick polyimide layer to provide the insulation function, the thick oxide approach can be considered superior due to its higher dielectric strength (2×–4×) and to the lower sensitivity to moisture absorption, which can degrade the lifetime performance of the insulator.

The system partitioning of an inductive insulator solution is shown in Fig. 3.63 and its on-chip implementation is presented in Fig. 3.64.

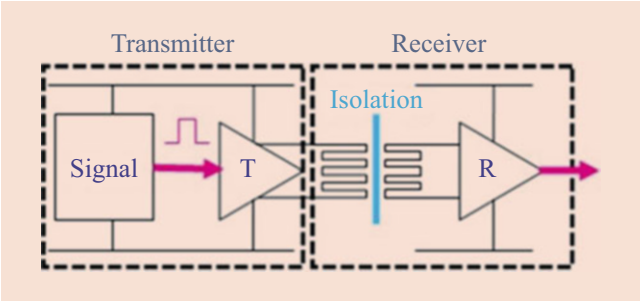

Fig. 3.63 Galvanic isolation system partitioning (inductive)

Hall Magnetic Sensor

Magnetic sensors are widely used in the industry for magnetic field sensing in very different technical domains.

Current sensing in industrial and automotive applications is an important segment where the substitution of sense resistor with magnetic sensors provides many benefits including avoidance of power losses.

Hall cells [74] in ICs are usually implemented by resistors, whose value is modulated by the presence of the magnetic field component normal to silicon surface.

Figure 3.65 shows the schematic realization of a Hall cell in a CMOS IC.

A resistive n-well layer, isolated into a p-well layer in a square shape, is realizing the Hall sensor cell.

When the n-well layer is biased between V_{dd} and ground, on the diagonal path of the resistive square, a flow of electrons is moving from the GND terminal to the Vdd terminal.

In presence of a magnetic field perpendicular to the plan, the Lorentz force applied to the electrons generates a movement of the electrons in the upward-right direction, causing the formation of positive charge in the bottom left area of the n-well layer; hence a voltage is generated between the OUT1 and OUT2 electrodes that is proportional to the magnetic field to be measured.

The addition of a magnetic concentrator [75] improves the sensitivity and allows sensing magnetic field components parallel to the silicon surface.

Figures 3.66 and 3.67 [75] show the implementation of magnetic concentrator in BCD IC.

3.5 Next BCD Development Challenges

BCD technology platform evolution has been historically driven by some main application segments:

- Hard disk drivers for computing.
- Motion control for industrial.
- Engine management, braking systems, and safety functions for automotive.

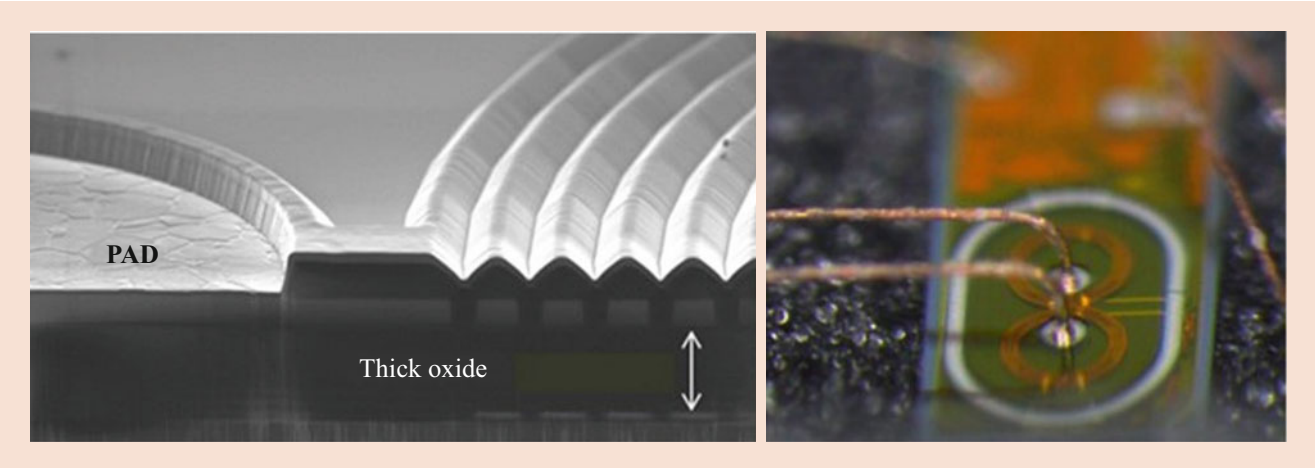

Fig. 3.64 Cross section and top view of an inductive galvanic isolation implementation

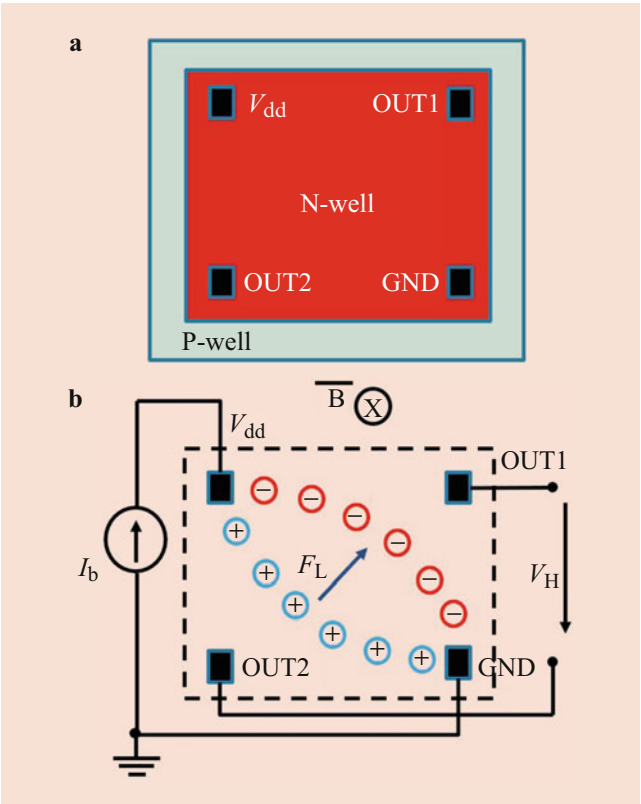

Fig. 3.65 (**a**) Top view of Hall cell in CMOS implementation and (**b**) scheme showing the Hall effect and the connections of the Hall sensor with surround circuit

- Audio systems for consumer and automotive.
- Power conversion for mobile and home appliances.

Some of these applications have reached a mature phase not requiring fast replacement of existing products with new features or functions: manufacturing efficiency is the driving force for the technology evolution to cope with the natural system cost reduction.

At the same time, new emerging applications with specific requirements are fostering the BCD technology evolution toward further lithography scaling.

The trend of increased data processing demands at very high MIPS rate for main application processor in high end mobile systems is raising the demand of high efficiency and sophisticated multiphase DC/DC power converters. These converters have consequently to integrate digital control loop with modular approach working at very high switching frequency (tens to hundreds of MHz) while delivering the large power required (tens of W).

Following the above trend, BCD technology found new applications at low voltage (5 V and below) requiring much finer lithography to meet digital complexity and speed requirement with the capability to deliver large current minimizing power losses.

Audio mobile signal processing is showing a similar trend.

Today BCD technology is offered at lithography node down to 55/40 nm taking benefit from the manufacturing perspective of depreciated plants and equipment.

Many technical challenges have to be managed to extend the possibility to use such technology platform to a wider power IC application spectrum:

- Integration of high-performance power devices targeting larger voltage capability (20 V and above).

  Due to reduced gate oxide thicknesses, larger gate to drain capacitance value and reduced drain doping layers are leading to a deterioration of the Key Performance Indicators: $R_{on} \times A$, $R_{on} \times Q_g$.
- Integration of high precision analog stages.

  The challenge is to cope with elementary devices analog performance deterioration due to ultrathin gate oxide

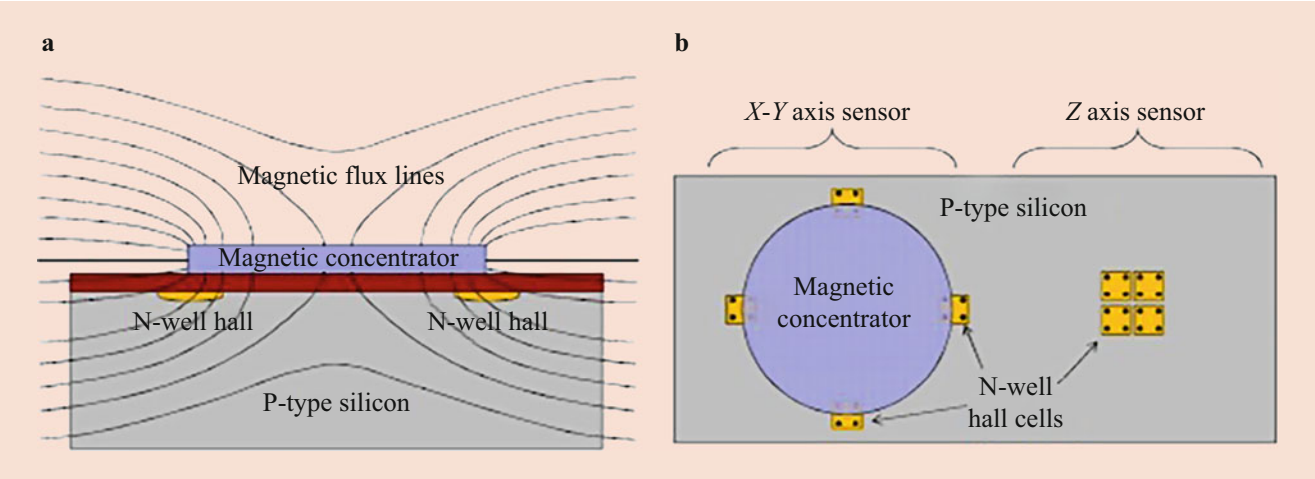

Fig. 3.66 (**a**) Cross section of an *X-Y* axis Hall sensor. (**b**) Top view of a *XYZ* axis integrated Hall sensor realized with a *XY* axis sensor and *Z* axis sensor, the last one with centroid symmetric multi-cell layout to reduce offset and noise

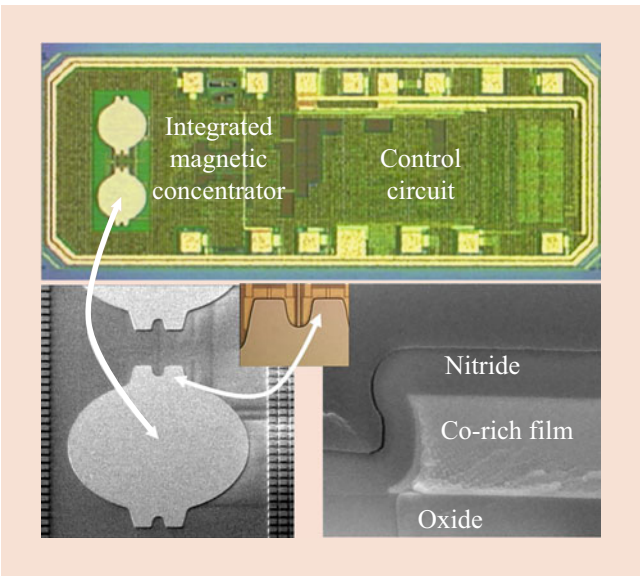

Fig. 3.67 Hall-based current sensor IC realized in advanced STM BCD technology integrating magnetic concentrator

with very cold processes leading to incomplete interface stabilization.

At the same time, the stringent layout constraints imposed by dense CMOS design rule requirements bring limitation in symmetric layout configurations (dummies placement, local density constraints, and mandatory parallel component orientation).

- High voltage signal management.

Severe limitations come from reduced isolation layer thickness and new dielectric materials with reduced permittivity and rigidity. In Fig. 3.68, the evolution of the minimum thickness between two metal lines is reported. A continuous scaling is driven by the minimum feature reduction together with the introduction of new materials with reduced permittivity. Given the fixed voltage requirement, an increase of the electric field is associated with this trend up to values that can cause detrimental effect on long-term reliability.

On the other hand, power device performance improvement is engaging significant efforts to identify novel architecture beyond the pure lithography scaling.

Since the further lateral shrinkage of the device critical dimensions (Fig. 3.43) is limited by the increase of the electric field, some very promising development lines are looking for an increase of doping levels, channel density, and carrier mobility.

Doping level increase at same voltage rating can be achieved through an optimization of the drain extension extending the usage of "Resurf" along all the dimension with the adoption of lateral super-junction solutions [76].

Super-junction architecture was first conceived on vertical power MOS to decrease on-state resistance at a given breakdown voltage originally for discrete devices with voltage rating in the range of 400–600 V.

A similar approach has been explored for the realization of integrated lateral devices (Fig. 3.69).

In this structure, the N-drain drift region is completely surrounded by P-type stripes providing a very effective depletion effect when biased in off state. A very uniform electric field is therefore obtained provided that an almost perfect compensation between the total dose present in the N and P doped regions is achieved by an optimum design of the structure (i.e., size of the regions and implanted doping dose). Exploiting this architecture, it is possible to increase the doping level of the N-drain extension region over compensating the loss of silicon area occupied by P-column and securing very low on-resistance performances close to silicon limit [77].

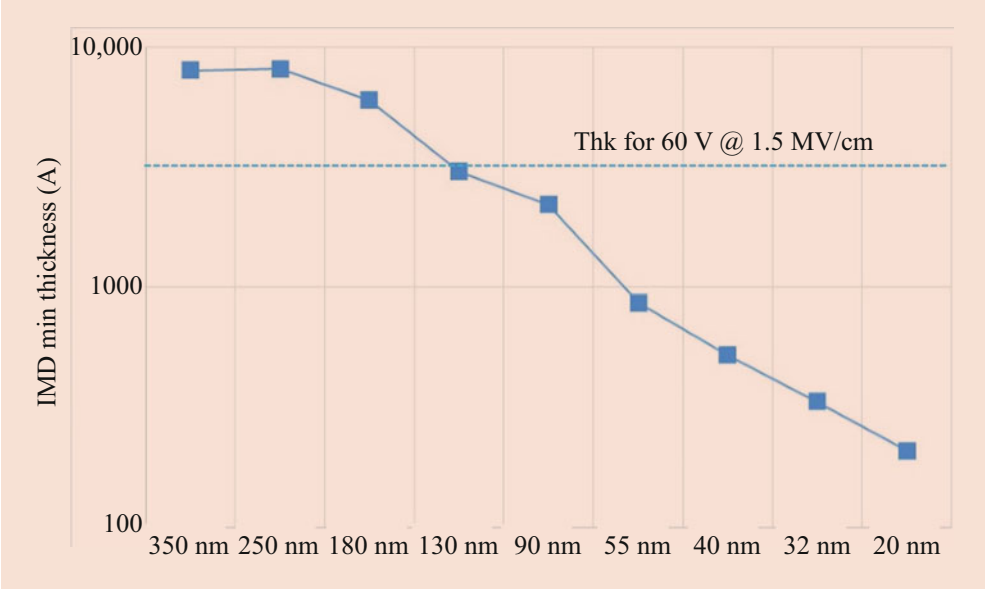

Fig. 3.68 Inter-metal dielectric (IMD) thickness evolution in different CMOS nodes. Line: minimum thickness required to secure 60 V between two subsequent metal lines with a fixed electric field

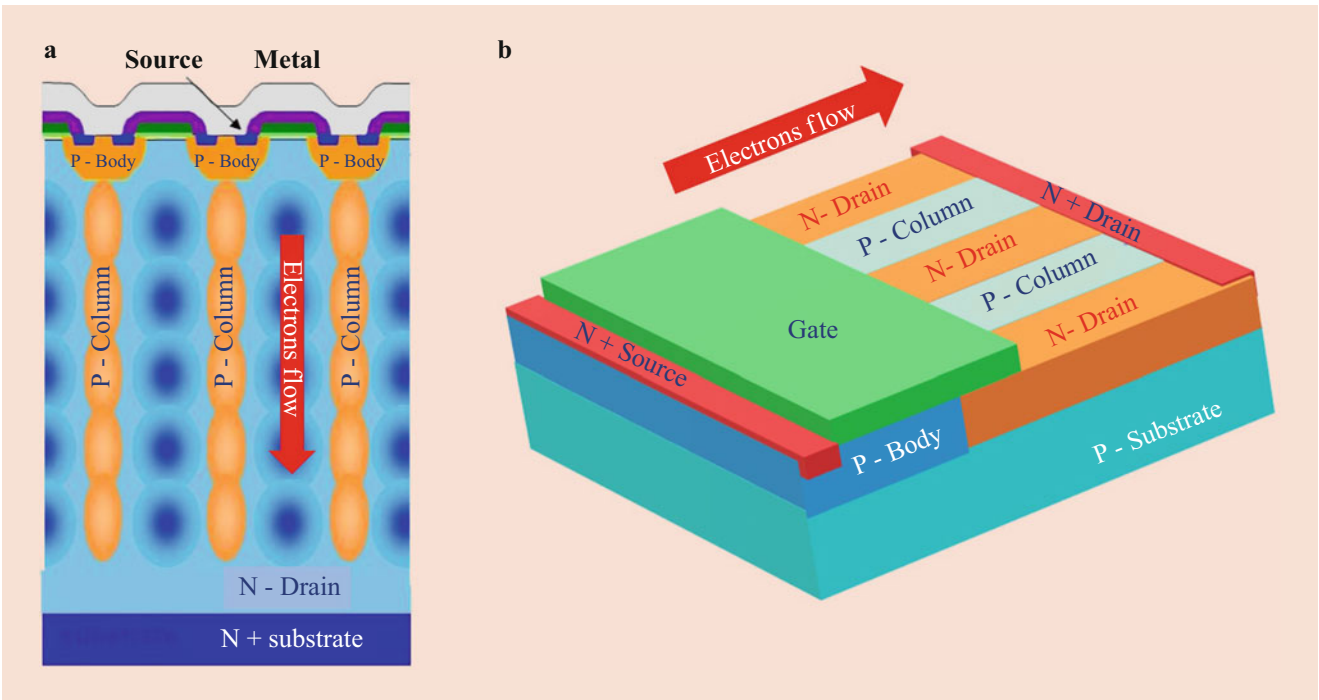

Fig. 3.69 Super-junction structure: solution for a vertical power discrete device (**a**) and extension to lateral integrated architecture (**b**)

Despite these solutions are expected to give major advantages for the higher voltage rating devices (>100 V) where the on-state resistance is dominated by the drain extension contribution, some research activities have been carried out to exploit the solution competitiveness for lower voltage integrated device [78].

Channel density (i.e., effective width integrated in the unit area) increase can be achieved exploiting the vertical dimension. Folded architectures have been presented for low voltage device [79] realization (Fig. 3.70): silicon etch is performed to realize a corrugated silicon surface covered by the gate oxide and polysilicon. From pure geometrical

considerations, density improvement is fixed by the vertical etch and the folding pitch: values between 30% and 50% seem achievable. Integration complexity and mobility control on the silicon sidewall are the limiting factors for the wide adoption of this solution.

Integrated trench FET architecture have been studied for boosting power performances in the 50–100 V rating voltage range [80]. This solution enables a drastic surface pitch reduction (Fig. 3.71) exploiting the vertical dimension for the realization of a trench-based MOS and drain extension region. This architecture is today the standard for low voltage (<100 V) rated power discrete device. The limitation for a wide usage of such architecture in an integrated BCD scheme derives mainly from the need of high conductive sinker regions and buried layers to minimize the collecting path resistance (Fig. 3.72). Integration complexity and the difficulty to scale the device for different voltage options narrows the usage of such architectures despite the meaningful performance improvement reported: factor 2–2.5 $R_{on} \times A$ reduction for a 60–70 V rated device.

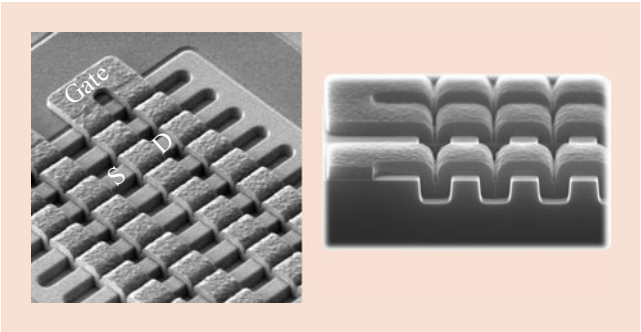

Fig. 3.70 Single active area folded architecture: planar SEM vision and section of silicon corrugation with poly gate

Carrier mobility enhancement thanks to silicon strain has been the dominant enabler to improve performance in CMOS technology evolution. The main obstacle to exploit the solutions implemented is coming from the very different lateral dimensions of the silicon areas to be strained. For this reason, few works have been so far published [81].

Wide bandgap materials advent in the power semiconductor sector is offering the opportunity for novel system architectures and performance. Silicon carbide (SiC) and gallium nitride (GaN) are compound semiconductors with some key basic material properties that make them a very competitive alternative to silicon for the realization of high-performance power devices.

Thanks to the larger energy bandgap (GaN: 3.4 eV, SiC: 3.3 eV, Silicon: 1.1 eV) the critical electric field for the avalanche breakdown on set is larger offering the possibility to realize high power devices with improved performance (better $R_{on} \times$ Area @ same breakdown voltage).

Silicon carbide-based power devices (diodes and power MOSFET) are realized on specific SiC starting material: substrate manufacturing process is quite complex and expensive and today 150 mm wafers are available on the market for devices realization. Process flow is requiring specific very high temperature process steps for the device real-

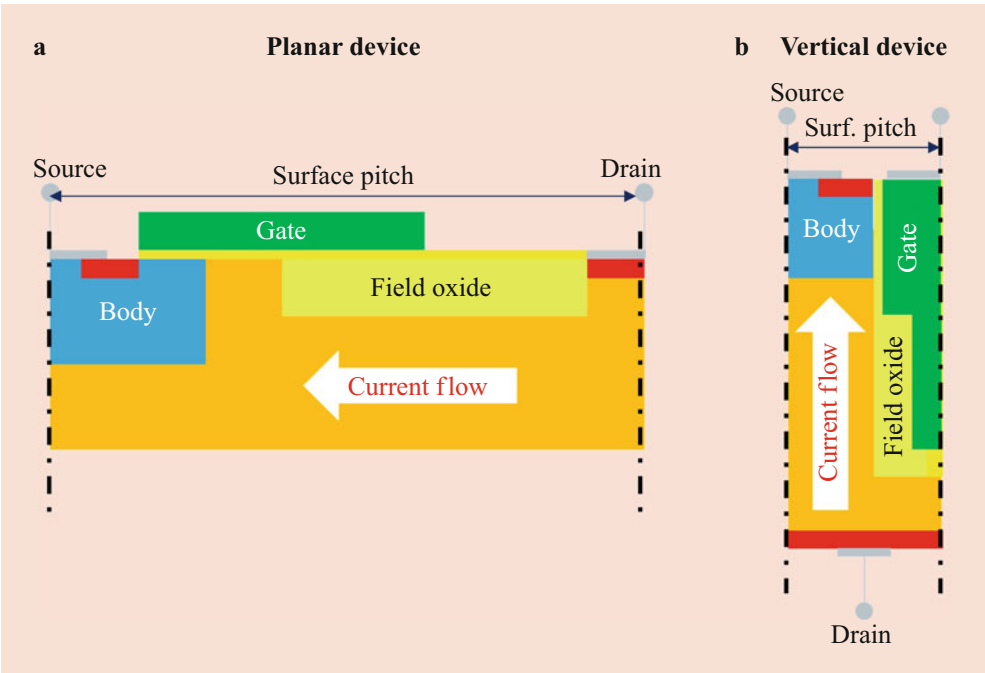

Fig. 3.71 Schematic cross section of a Vertical Trench based Device (**b**) derived from a Lateral solution (**a**). Surface Pitch scaling is obtained thanks to the vertical integration

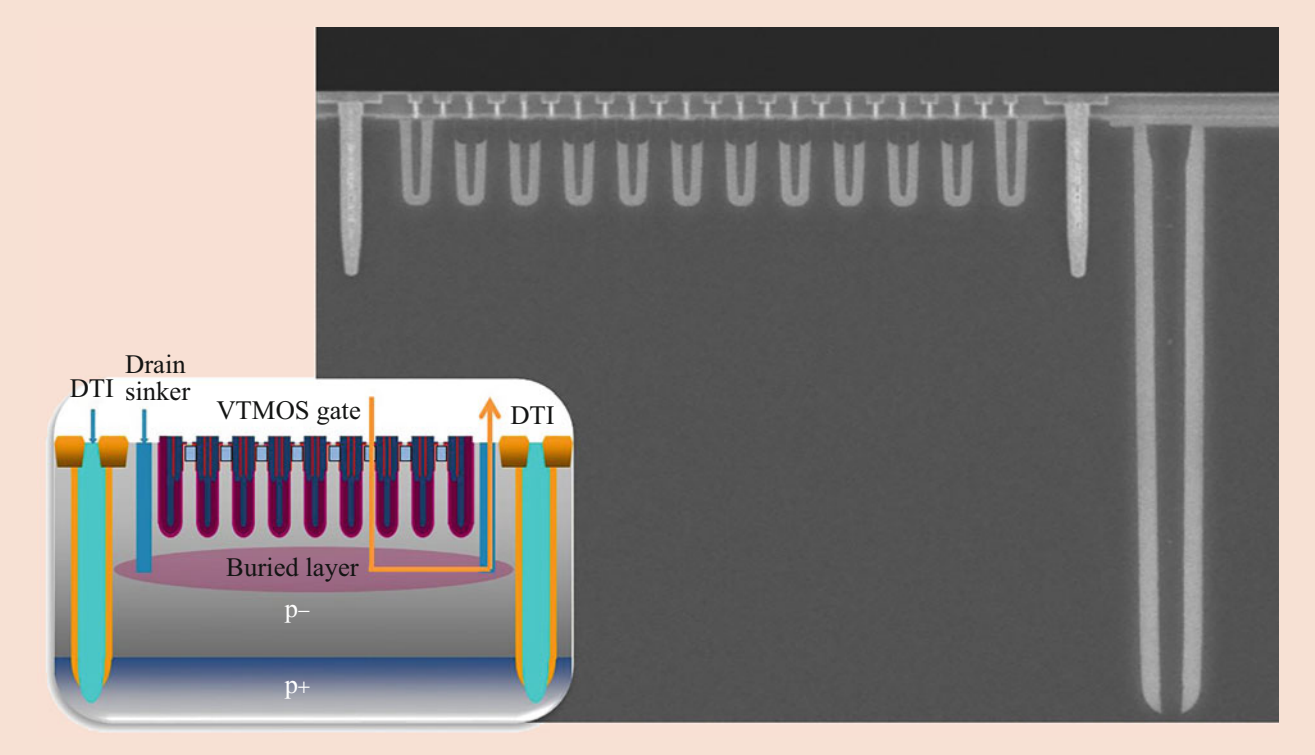

Fig. 3.72 Vertical trench power device integrated in an advanced BCD platform. High conductive sinker trench and deep trench isolation module are shown in the SEM section

ization. This is making this solution very competitive for very high power discrete application (600–1800 V rated, or even above) in some emerging markets (electric vehicle, power grid, industrial) where thanks to the meaningful performance improvement vs existing silicon devices (mainly IGBT) it enables an overall cheaper system cost solution.

Power high electron mobility transistors (HEMT) are realized using gallium nitride layers built on silicon substrate. Thanks to the possibility of realizing a good quality gallium nitride layer on a cheaper silicon starting material and thanks to the possible use of existing silicon manufacturing infrastructure, GaN-based power devices are today starting to get traction in many applications requiring large power (<600 V rated) or wherever the possibility of larger switching frequency operations is leading to a competitive market solution (passive miniaturization, LiDAR application in automotive, etc.).

Thanks to the compatibility of GaN-based power device with silicon manufacturing fabs, it is possible to imagine in the future a meaningful cost reduction together with the possibility of increasing the level of integrated functions.

First products with monolithic integration of GaN power device and gate drivers have been recently announced by different companies [82, 83] 0. The level of integration today reported is very limited due to the technology maturity and some specific limitation (lack of complementary MOS).

Optimized solutions to manage high power and energy dissipation need to take into account package technology.

Silicon and package technology must be developed in a concurrent way to get the best benefits at application level.

New packages with high pin count, high power dissipation capability, small outline, and low cost need to be conceived and developed; front end silicon and back end package technology compatibility is a major challenge that will become more and more important in the future.

3.6 Conclusions

The chapter described the evolution of BCD process technologies, today widely utilized in the industry to implement smart power IC's applications in automotive, industrial, consumer, and personal electronics field.

Introduced in the industry in the mid-1980s, BCD technologies followed three different development paths according to specific application fields, moving along three main axes: high voltage, high power, and high density.

Since its conception, based on the coexistences on the same chip of two main technology bricks (polysilicon gate CMOS and DMOS power architecture) and on the compatibility with bipolar components, it allowed the realization of SOCs, able to provide digital and analog control together

with efficient power sections, and put the basis for a sustainable innovation roadmap.

The evolution was driven by the continuous logic density increase, including the introduction of nonvolatile memories in different solutions, enabled by the lithographic shrinkage typical of CMOS roadmap, and to more and more efficient high voltage and high power integration thanks to innovation in power devices architecture.

Such trend was further supported by the introduction of new materials, such as the usage of thick copper metallization to improve current and energy capability, and new technology modules for the component isolation (Junction Isolation, DTI, SOI).

BCD technology roadmap was furthermore driven by differentiation with the introduction of technology options that allowed the integration of new functions like Hall sensing, galvanic isolation, and thin film resistors for accuracy.

As of today, BCD technologies are available with voltage rating spanning from 5 to 1200 V, with specific applications like galvanic isolation up to 6KV, and lithography features in mass production down to 90/55 nm.

New emerging applications with specific requirements are fostering the BCD technology evolution toward further lithography scaling down to 40 nm.

Future evolutions are foreseen to exploit heterogeneous integration for improved power devices integration, like GaN and silicon on the same chip.

On top of the classical BCD silicon roadmap, following the more than Moore approach, it is important to consider a complementary parallel path alternative to the monolithic integration, that is, system in advanced package solutions, like embedded die, where different silicon technologies including passive components can provide the best trade-off between performances and cost in a single package.

Giuseppe Croce received M.Sc. degree in electronic engineering from Pisa University in 1994. In 1995 he joineed STMicroelectronics, Agrate Brianza, Italy, where he has worked on the design and development of BCD (Bipolar CMOS DMOS) technology platform serving different applications starting from 1.2 um down to 90 nm. He is now Technology Line Manager in smart power technology R&D within STMicroelectronics.

Antonio Andreini graduated in Physics at the University of Milan in 1983. He started working in STMicroelectronics on discrete and mixed power technologies, contributing to initiate BCD technologies development, evolving then to the technical fields of reliability, ESD, and chip-

package interactions. He is now the director of technology qualification, ESD protections design, and front end/back end compatibility for smart power technologies within STMicroelectronics R&D.

Paola Galbiati got Laurea degree in Solid State Physics in 1979 at the University of Milan. She started collaboration with STMicroelectronics since 1980 in the Central R&D team on discrete technologies. In 1984 she has contributed to the development of the innovative BCD platform. In the following years, she participated the diffusion and evolution of the BCD platform with increasing responsibilities until the role of BCD Technology Line Director.

Claudio Diazzi graduated at Politecnico di Milano in 1979 in Nuclear Engineering. In 1980 he joined SGS-ATES (now STMicroelectronics) as Application Engineer for Power Discrete components. He developed his carrier in R&D, managing the development of power integrated circuits in the field of automotive, computer peripheral, lighting, and industrial. He is the director of BCD Smart Power Technology development in STMicroelectronics.

Abstract

A multiplicity of chemical (structure, composition, point and extended defects, impurities, etc.) and physical (carrier concentration, mobility, lifetime, band gap, core level energies, etc.) parameters characterize the behavior of semiconductors; some of them are more relevant than others according to the considered semiconductor and its use. The experimental technique suitable to measure a given physical or chemical parameter depends primarily on the chosen semiconductor, on its use as a device, and on the size and application of the device itself. For example, advanced silicon CMOS and SiC power devices require different measuring techniques. As it would be impossible to cover in a single chapter even the most important adopted techniques, we present just the basics of the following techniques: transmission electron microscopy (TEM), X-ray analysis, Raman spectrometry, scanning probe and atomic force microscopy, and basic electrical and optical parameter measurement techniques. Selected examples, taken from recent research activities, illustrate the capabilities and the potentialities of each technique. Most of the reported data refer to SiC, GaN, phase change materials, and Si nanostructures. For other subjects, a vast body of literature is available on the wide range of existing techniques for the characterization of basic semiconductor

4.1 Transmission Electron Microscopy

The fabrication of semiconductor devices requires the well-defined characterization of the adopted materials and processes. Transmission electron microscopy (TEM) is a direct technique for investigating a sample even at the nanoscale, providing morphological, structural, and chemical information. This section starts with a description of conventional TEM (CTEM) and of its use to investigate defects. The remaining part of the section deals with scanning transmission electron microscopy (STEM). The technique takes advantage of the narrow size of the electron beam, a fraction of angstrom and of the interaction with target atoms. Characteristic X-rays are emitted and adopted for elemental identification. The intensity of the scattered electrons at high angles gives information on the atomic number of the scattering centers (Z contrast) of relevance for the analysis of compound semiconductors. The determination of the atomic structure of misfit dislocations at the Si/Ge interface, of antiphase boundary in a 3C-SiC layer, and of different crystalline structures (rock salt and trigonal) in a phase-change alloy illustrates the technique. The simultaneous acquisition of different signals, characteristic of the probed element (EDX, energy-dispersive X-ray; EELS, electron energy loss spectroscopy), at the atomic scale has been used to determine the composition of AlGaAs multishell nanowire and the chemical bond of graphene layer on top of SiC as examples.

4.1.1 Conventional Transmission Electron Microscopy

The main relevant semiconductor parameters rely on crystalline and chemical properties, and TEM can straightforwardly give insights into the material properties [1–3].

From the structural point of view, extended defects as dislocations and stacking faults (SFs) play a crucial role in determining the mechanical properties of materials. Moreover, as for precipitates, grain boundaries, and point defects, they affect the electronic properties, because they act as scattering centers for charge carriers as traps or as radiative or nonradiative recombination centers. As far as extended defects are concerned, TEM analysis provides detailed information on dislocations, e.g., the type, the density, and their distribution. The main reason for using an electron microscope instead of an optical one resides in the resolution. As electrons are usually accelerated in an energy range between 60 and 300 keV, their corresponding wavelength is of the order of several picometers, well below that of visible light (400–700 nm). However, aberrations affect the focusing system of TEM, reducing the actual resolution to $\approx 50 \div 300$ pm.

In TEM, the source (gun) emits electrons by thermionic or field effect. Typical electron currents measured at the first focusing point in the microscope (the crossover) amount to several microamperes. These electrons are accelerated to a desired energy and managed by a system of electromagnetic lenses and dipoles for focusing and deflecting the beam respectively. As electromagnetic lenses are affected by aberrations, the TEM is also equipped with a set of multipole coils that correct part of the aberrations. By arranging the lenses in a proper way, the electron beam can be manipulated to illuminate the sample with a parallel beam or with a convergent beam.

In Fig. 4.1a, a very schematic sketch of TEM working in parallel mode is shown; in a real TEM instrument, tens of lenses and dipoles are present. All of them should be routinely tuned to work properly.

Electrons interact strongly with the atoms and then the specimen must be thinned to a few tens of nanometers before TEM analysis in order to have electron transparency and transmitted electrons. There are several methods to thin the sample: mechanical polishing, ion milling, wet etching, focused ion beam (FIB),, and microtome preparation. On the other hand, the strong electron interaction with the target atoms produces multiple secondary signals, such as characteristic X-rays. Their analysis gives information on the elemental composition of the sample. The most important effect, however, is regarding electron scattering and the phase shift of the incident electron wave.

In a crystalline sample, the transmitted electrons are deflected in well-defined directions, according to the Bragg diffraction criterion. For each direction, electrons are then focused on a different point of the back focal plane of the objective lens, to form the diffraction pattern (DP). Post-specimen lenses (not shown in Fig. 4.1a) can be tuned in order to show the DP or to magnify the image of the sample up to several millions of times.

The electrons emerging on the bottom of the crossed sample, if focused by the objective lens, form an image of the sample in the image plane. Although, naively, this recombined image resembles a 2D projection of the sample, the details of the micrograph contrast depend in a complex manner on the undulatory description of the interaction between the incident and the diffracted beam, and on the presence of inelastic scattered electrons. A detailed interpretation often requires simulations and/or considerations of sample

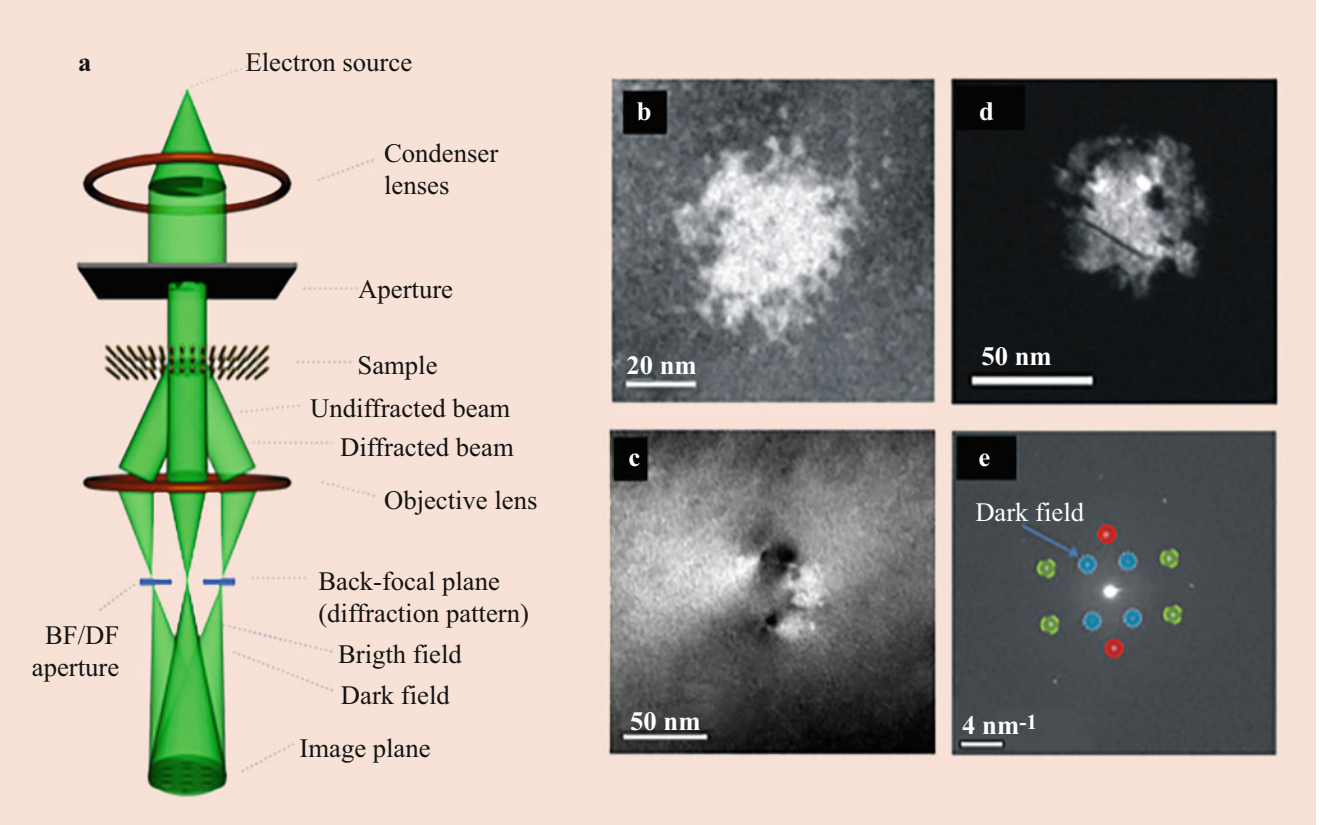

Fig. 4.1 (**a**) Sketch of TEM working in parallel mode; after crossing the sample, the diffracted and undiffracted beams are focused according to their direction by the objective lens in the back focal plane to form the diffraction pattern and then they reassemble to form the image in the image plane. A set of intermediate lenses (not shown) below the image plane can magnify either the diffraction pattern or the image. (**b**) Bright field micrograph of an amorphous area in silicon obtained by ion irradiation. (**c**) Cluster of point defects after rapid thermal annealing of (**b**). (**d**) Dark field of a twin defect in silicon obtained selecting the diffracted beam indicated in blue in the diffraction pattern (**e**). ((**b**–**e**) Reprinted from Mio et al. [4], with the permission of AIP Publishing)

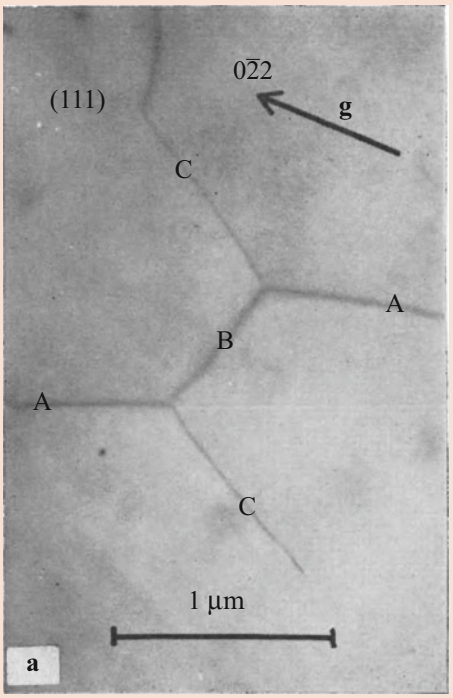
thickness, elements involved, crystalline phases, defects, etc. Indeed, until now we have presented a very simplified description. The system is actually very complex in terms of both data analysis and hardware. Specific textbooks are available for further insights [1, 2, 5, 6].

After interaction with the sample, the transmitted electrons can be exploited in several ways. For instance, by the use of particular lenses, the TEM user can obtain a magnified image of the sample from the undiffracted beam (bright field), Fig. 4.1b, c, or a diffraction pattern from a certain sample region (selected area electron diffraction pattern) or an image in which only electrons scattered/diffracted at a specific angle give a contribution (dark field) (Fig. 4.1d).

Conventional TEM is commonly used for extended defect characterization in the semiconductor. Main defects are dislocations and SFs. Dislocations are classified as pure edges, pure screws, or mixed, depending on the relative direction between the dislocation line and the Burgers vector, $\boldsymbol{b}$. CTEM allows the direction of $\mathbf{b}$ to be determined, through the $\boldsymbol{g}\cdot\boldsymbol{b} = n$ criterion [1, 2], where $\boldsymbol{g}$ is a vector of the reciprocal lattice and n is an integer.

This method is associated with the possibility of orienting the TEM sample, through a double-tilt TEM holder, in order to have only one diffracting beam $\mathbf{g}$, the so-called two-beam condition, in which the other beam is the undiffracted zero-order beam. If a dislocation fulfills the $\mathbf{g_1}\cdot\mathbf{b} = 0$ condition, i.e., $\mathbf{b}$ is perpendicular to $\mathbf{g_1}$, it disappears on both bright field and dark field micrographs [1, 2]. With a second $\mathbf{g_2}$ diffracting beam for which the dislocation disappears, $\mathbf{g_2}\cdot\mathbf{b} = 0$, the Burgers vector can be straightforwardly determined as $\mathbf{b} = \mathrm{k}\ \mathbf{g_1} \times \mathbf{g_2}$, where k is a real constant. An example of dislocation characterization is given in Fig. 4.2, where a dislocation completely disappears when a dark field is acquired selecting the -311 diffraction spot. However, several issues can affect CTEM contrast interpretation, even in this simple case. If $n > 0$, dislocation is characterized by double-line contrast [1, 7]. Excitation error from the diffraction condition, TEM lamella thickness, crystal anisotropy, dislocation type, and dislocation depth may also alter the contrast, making it difficult to exploit the $\boldsymbol{g}\cdot\boldsymbol{b} = n$ criterion [1, 8].

The CTEM contrast also permits the analysis of SFs with their typical fringe contrast. Figure 4.3 is obtained taking a



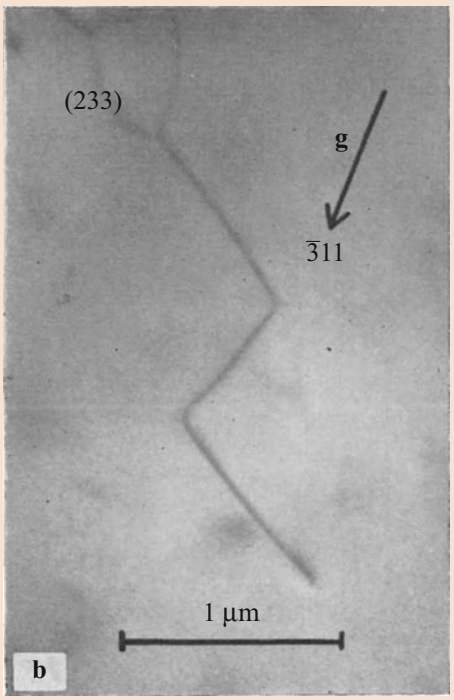


Fig. 4.2 Network of dislocations in Si with a nearly pure screw character. Dislocation lines are marked with A, B, and C. In (**a**) a dark field taken in 0–22 is shown. Under this condition the three dislocations are visible. On (**b**) the dark field is taken on the −311 and the A dislocation vanishes. This is consistent with a screw dislocation with Burgers vector ½[0–11]. Fig. 4.3 Dark field taken in 2–20 of (111) Si sample amorphized by ion irradiation (10^{16} Si^+/cm^2 at 200 keV performed at 77 K) and then recrystallized by laser annealing (2.5 J/cm^2 of a Q-switched Ruby laser, 50 ns single pulse). Fringes indicate buried stacking faults. (Adapted by permission from Springer Nature Customer Service Centre GmbH: Springer Nature, *Applied Physics* [10], Copyright 1978)

dark field on the spot 2–20 along the [1–11] zone axis. Under this condition, buried SFs on the plane (1–11) and (−111) are visible. Their projection is emphasized by a contrast modulation, whereas SFs on the (11–1) are hidden.

Transmission electron microscopy is also a valid aid for investigating the dynamics of material processes at the nanoscale. With an in situ holder, it is possible to explore the behavior of the specimen under externally induced stimuli (thermal heating, electrical/optical pulses, mechanical stress, etc.).

Figure 4.4a shows a plain-view TEM micrograph (bright field) of $Ge_2Sb_2Te_5$ 100-nm amorphous regions surrounded by crystalline $Ge_2Sb_2Te_5$ in the trigonal phase. The amorphous regions were obtained by ion irradiation using an electron beam lithography mask to produce selective damaging. The sample is then annealed in situ at 90° C and imaged several times (Fig. 4.4b–d). It is therefore feasible to follow the kinetics of the recrystallization, inferring the absence of nucleation and measuring the regrowth velocity. As this geometry (nano-amorphous regions embedded in a crystalline matrix) is typical of $Ge_xSb_yTe_z$ (GST)-based nonvolatile memories (CDs, DVDs, Blu-ray, PC RAM), this result is quite critical to understanding the data retention limit of such devices.

4.1.2 Scanning Transmission Electron Microscopy

Although CTEM is a powerful tool for observing and characterizing extended defects, the technique exhibits several

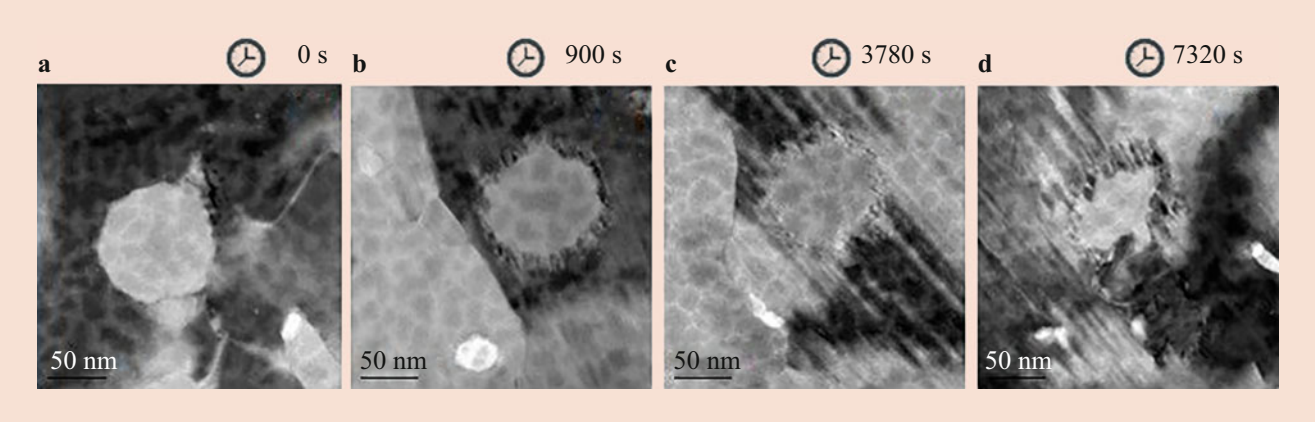

Fig. 4.4 Plain-view TEM micrographs (bright field) of 100-nm wide regions of amorphous $Ge_2Sb_2Te_5$ surrounded by crystalline $Ge_2Sb_2Te_5$ in the trigonal phase during in situ isothermal annealing at 90 °C. Crystalline regrowth proceeds from the a–c interface at the expense of the amorphous phase. (Republished with permission of IOP Publishing, Ltd., from Mio et al. [11], Copyright 2012; permission conveyed through Copyright Clearance Center, Inc.)

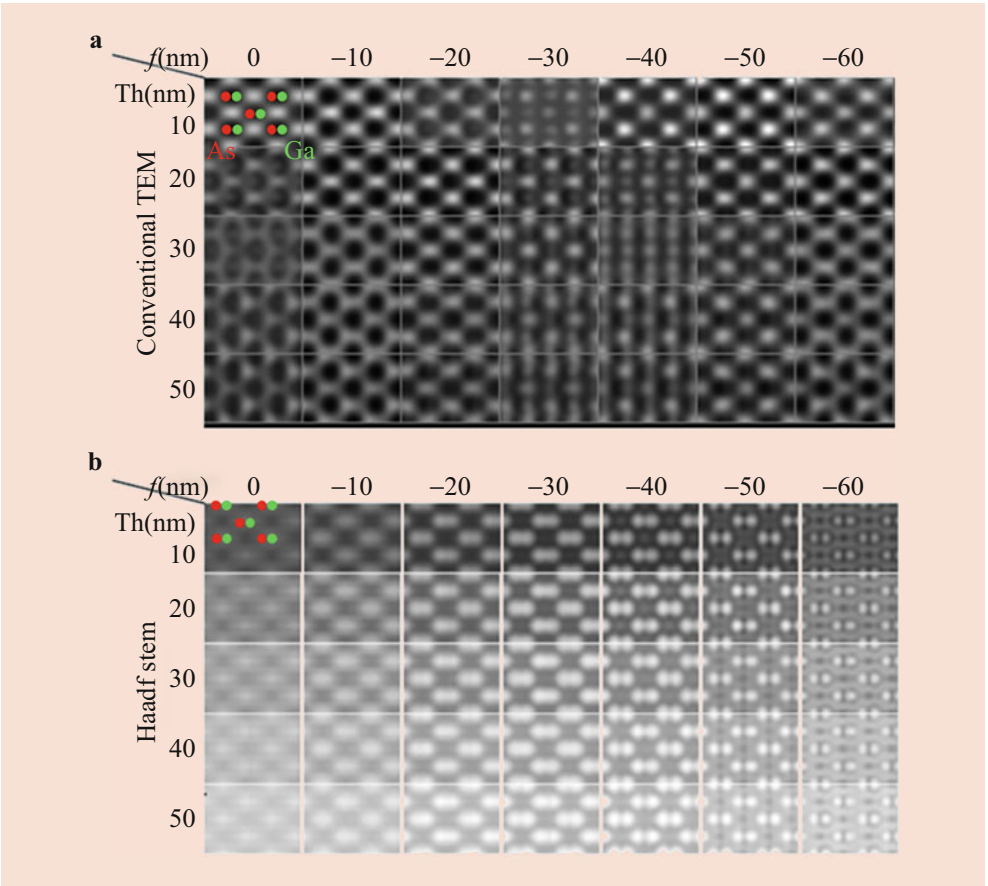

Fig. 4.5 (**a**) Conventional transmission electron microscopy simulation of GaAs bright field along the [110] zone axis (ZA). The micrograph contrast strictly depends on focus and sample thickness, resulting in a very hard comparison with the theoretical predictions. (**b**) High angle annular dark field scanning transmission electron microscopy simulation of GaAs bright field along the [110] ZA. The atomic positions As and Ga are indicated with red and green circles respectively. (Reprinted from Lamberti and Agostini [6], with permission from Elsevier)

limitations when the investigation is interested in a very local area, namely, below the nanoscale, toward the atomic scale. As the resolution of CTEM microscopes is usually 2–3 Å, the atomic structure cannot be resolved. Micrographs

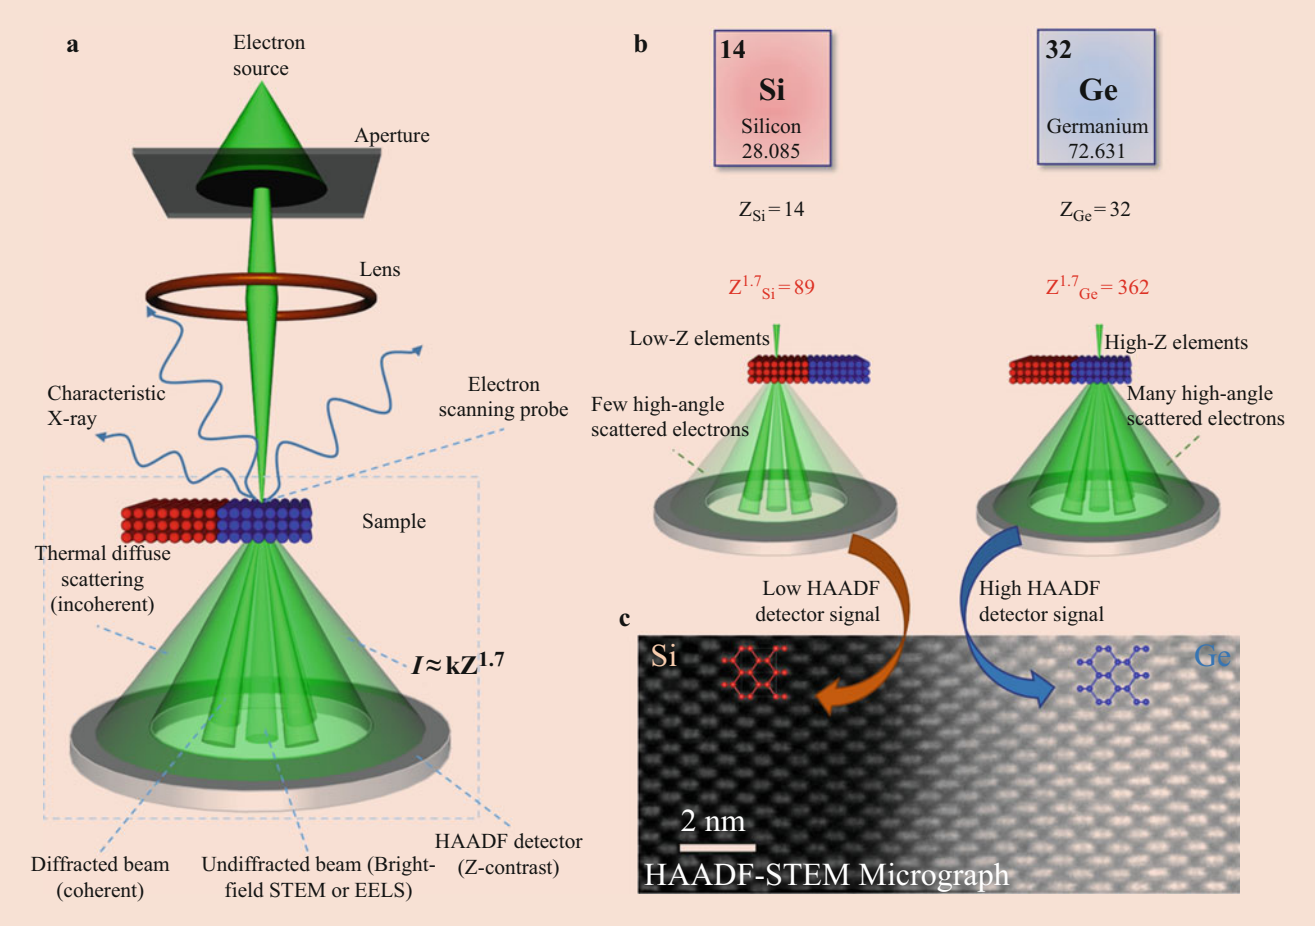

Fig. 4.6 (**a**) Schematic of scanning transmission electron microscopy (STEM): imaging and nano analysis. (**b**) High angle annular dark field STEM of the Si/Ge interface. Z-contrast permits Si and Ge to be distinguished and their atomic arrangement to be visualized. (**c**) A direct comparison with the theoretical atomic structure and the experimental raw data is shown. Si and Ge are represented with red and blue spheres respectively

are influenced by electron wave phase contrast. The strong electron beam–specimen interaction prevents a direct correlation of the intensity acquired on the phosphor screen or on the charge-coupled device with the specimen's atomic potential. In fact, the mapped intensity depends noticeably on the adopted focus and on the sample thickness as shown in Fig. 4.5a. The sample thickness should be less than 20 nm, to guarantee electron transparency, reduce inelastic scattering, and achieve better image quality. These conditions can drastically reduce the probability of selecting a particular localized defect during sample preparation.

The reduction of the effects of aberrations requires quite small objective apertures, which further influence the contrast modulation. As the intensity of the final image depends on the electron wave functions interference and on their heterogeneous dephasing, due to aberrations, or wave front cutting, due to apertures, direct micrograph interpretation is quite hard. Indeed, even changing two simple parameters, such as focus (i.e., the simplest aberration) and thickness, complete contrast inversion can occur [6, 12], as shown in the simulation reported in Fig. 4.5a. In fact, it is quite difficult in the case of interfaces to clearly define atomic positions below 3 Å. The periodicity of the crystalline lattice is preserved in the image, whereas the atomic position is generally shifted from the exact one.

In addition, with a parallel beam, it is quite difficult to perform chemical analyses, in particular in the case of high-Z elements for which energy-filtered transmission electron microscopy maps contain very weak signals.

In the last decade, STEM has been held up as a valid alternative to CTEM, as it is able to overcome the aforementioned limits. Although the first STEM was developed at about the same time as the first TEM, starting from the 1930s, for historical and technical reasons, its potential was only shown in 1970, when Albert Crewe used it to show single heavy atoms resting on a thin carbon substrate [13].

The working principle of STEM is very similar to that of scanning electron microscopy (SEM). A very narrow

electron probe is scanned over the sample (Fig. 4.6). From the electron–specimen interaction, characteristic X-rays are also produced and used for EDX mapping. The EELS of the transmitted beam also provides further information on the elemental composition at the nanoscale.

Bright-field STEM micrographs are acquired mapping point-by-point the signal (number of electrons) obtained from the direct transmitted beam. A dark-field image is obtained in a similar way collecting the electrons scattered at different angles. Typically, low-angle annular dark field detects electrons scattered from about 30 mrad, whereas those scattered at more than 50 mrad impinge on the so-called high-angle annular dark field (HAADF) [2].

One of the key advantages of STEM is the so-called Z-contrast, peculiar to the HAADF mode. In this setup the number of electrons impinging on the annular detector is roughly proportional to $Z^{1.7}$ [14]. The presence of an advanced spherical aberration corrector, available on the market since the 2000s in the last generation of microscopes, focus the electron probe well below 1 Å. This permits a direct image of an atomic structure and a direct comparison of the unprocessed micrograph with the theoretical atomic model. Quite interestingly, on the contrary with respect to the CTEM behavior, the contrast of an atomic HAADF micrograph does not strictly depend on the defocus and on sample thickness, as shown in the simulation reported in Fig. 4.5b.

Figure 4.6c shows a ball-and-stick representation of an interface between Si (Z = 14) and Ge (Z = 32), seen along the [110] ZA overlapped with a corresponding HAADF-STEM micrograph (raw data). The contrast difference between the two elements is straightforward, as well as the direct comparison with the atomistic model.

Also, for conventional semiconductor HAADF-STEM, direct imaging provides useful information on the structure of defects. Figure 4.7 shows, for comparison, a HAADF-STEM and a CTEM of 60°–60° dislocations in Ge near to an interface with Si. HAADF-STEM identifies the dislocations and their atomic position. Moreover, HAADF-STEM Z-contrast clearly distinguishes Si atoms (Z = 14) from Ge atoms (Z = 32).

In the case of SFs, HAADF-STEM permits the direct observation of their formation/annihilation mechanism, also giving insight into the local atomic rearrangement, especially near the region where different defects interact with each other. Figure 4.8a shows a series of SFs annihilated through the intersection of two {111} SFs. Figure 4.8b shows an antiphase boundary. The details of this defect are quite difficult to observe in CTEM, because the Bravais lattice remains unchanged. In the polytype 3C-SiC, the repetitive unit is a Si-C couple. When an antiphase boundary occurs, there is a flip between the Si and the C lattice site, but each unit position remains the same. As the Z-value difference between the two elements, HAADF-STEM clearly emphasizes this kind of change.

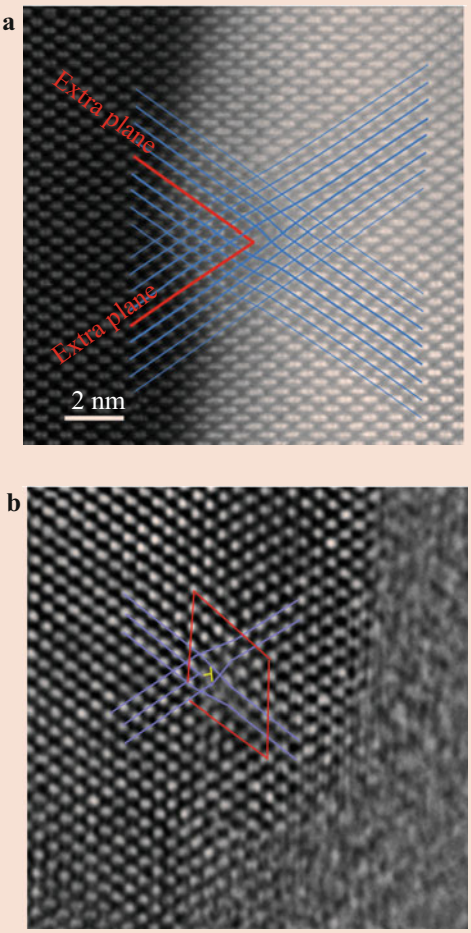

Fig. 4.7 (**a**) High-angle annular dark field scanning transmission electron microscopy micrograph, of a Si/Ge interface. Through Z-contrast, two misfit dislocations are clearly visible. (**b**) Conventional high-resolution TEM analysis. A pair of dislocations is also visible, but the atomic details are lost and the imaged bright spots are generally shifted with respect to the exact atomic position

A complex case of Z-contrast detection along the [110] ZA of $Ge_2Sb_2Te_5$, in the metastable rock-salt phase, is shown in Fig. 4.9a. In this ZA, the material stack follows an anion-cation-anion-cation layer pattern. The anion columns are composed only of Te atoms ($Z_{Te} = 52$), whereas the cation atoms are formed by randomly mixed Ge and Sb atoms and ≈20% of vacancies. Owing to the difference in atomic number between the two elements ($Z_{Sb} = 51$, $Z_{Ge} = 32$), the cations column will be brighter if the amount of Sb exceeds that of Ge. The measured spacing between two Te planes, with an intermediate plane of Ge/Sb, amounts to about 3.5 Å.

The vacancies in the cation sub-lattice play a relevant role in the electrical conductivity [16], being responsible for an unexpected metal-insulator transition (MIT) upon their ordering. This ordering happens when the GST system goes toward its stable trigonal phase, even if it is not necessary to fully reach this final state to have the MIT

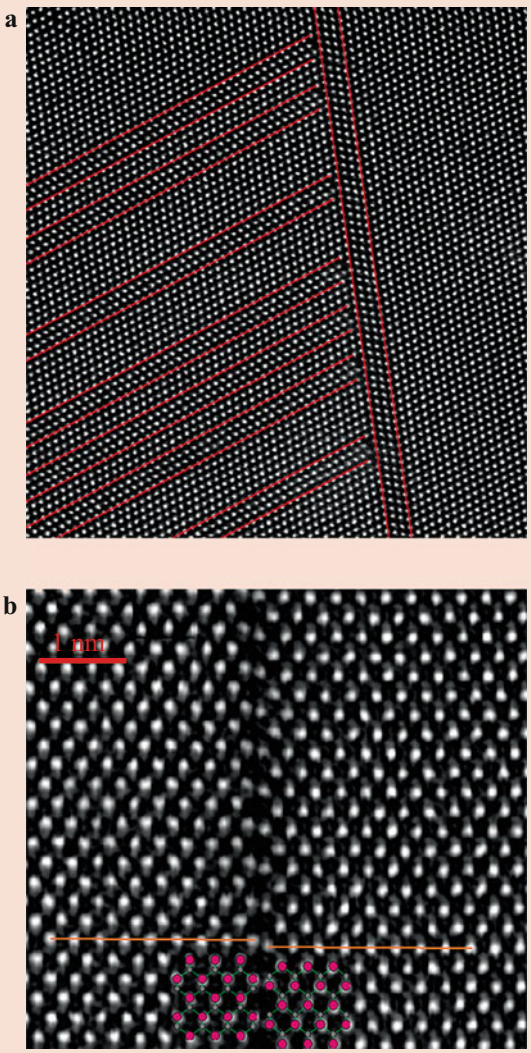

Fig. 4.8 3C-SiC High-angle annular dark field scanning transmission electron microscopy micrographs in [110] zone axis. (**a**) The annihilation of stacking faults (SFs) through the intersection of two {111} SFs (red lines) and (**b**) an antiphase boundary. Orange lines indicate the misalignment of Si atoms. A ball-and-stick sketch is shown to emphasize the Si(magenta)-C(gray) inversion

transition [17]. This property offers the opportunity to fabricate multi-level memories, encoding several resistance levels as well as different thermal resistance coefficients, maintaining lower power consumption. The same mechanism has been recently exploited to fabricate neuro-inspired prototype devices. By increasing the annealing temperature or changing the deposition parameters, the vacancies embedded in the rock-salt structure move away from the cationic sublattice and order in planes [18]. This process supports the crystal–crystal phase transition, from the metastable rock-salt phase to the stable final trigonal structure, characterized by vacancy-rich layers, the so-called van der Waals (vdW) gaps.

Cross-view HAADF-STEM micrographs of a sample prepared in the trigonal phase by epitaxial growth is shown in Fig. 4.9b. The image clearly shows dark layers that correspond to vdW gaps between two Te planes [19], as evidenced by the orange dashed lines. In the same micrograph, a twin defect is well recognizable. The image also provides compositional information. VdW gaps separate the alloy into blocks of different sizes, 9 and 11 layers respectively (see Fig. 4.9b), and each size corresponds to a different GST local stoichiometry. Blocks of 11 layers correspond to $Ge_3Sb_2Te_6$, blocks of 9 layers to $Ge_2Sb_2Te_5$. HAADF-STEM is therefore a very precise technique for detecting local variation in the stoichiometry.

STEM Nanoanalysis

Scanning transmission electron microscopy also offers significant microanalysis capabilities, as it is possible, at the same time, to acquire the aforementioned EDX and EELS signals [20] at the nanometer or even at the atomic scale using thin samples. As a rule of thumb, EDX is very effective at detecting high-Z elements, whereas EELS is better for low-Z atoms. Nowadays, however, new EELS detectors have an improved detection limit and sensitivity at higher energy loss, thus allowing the chemical characterization of heavy atoms with high core ionization energy.

An example of the simultaneous use of these different techniques is the analysis by HAADF-STEM and mapping by EDX of an AlGaAs multishell nanowire reported in Fig. 4.10. Al-rich areas are darker as Al is lighter ($Z = 13$) than both Ga and As ($Z_{Ga} = 31$, $Z_{As} = 33$). For the same reason, pure GaAs regions are brighter. EDX is a fundamental aid for locating elements at the atomic positions. Indeed, this should not be possible using only Z-contrast as the atomic numbers of Ga and As are too close.

The simultaneous EDS and STEM nanoanalysis in chalcogenides has recently permitted the correlation of structural defects with atomic stoichiometry heterogeneities. As already pointed out, different composition blocks, corresponding to the following local GST stoichiometries Sb_2Te_3 with five layers, $GeSb_2Te_4$ with seven layers, $Ge_2Sb_2Te_5$ with nine layers, $Ge_3Sb_2Te_6$ with 11 layers, etc., are present in a chalcogenide layer. These different blocks are connected via a particular kind of defect, called a bi-layer defect [21] (Fig. 4.11a, white box), which is very common in chalcogenides. They probably play a crucial role in layered GST used for interfacial phase change memory (iPCM) devices [22, 23], possibly enabling the swapping of two (or more) memory bits [21]. Indeed, these devices are supposed to switch between two resistance levels thanks to a crystal-to-crystal transition that could be promoted, changing for instance the block size through a bi-layer defect.

One key point is to understand how cations and anions are distributed along these defects. Although Ge and Te can be

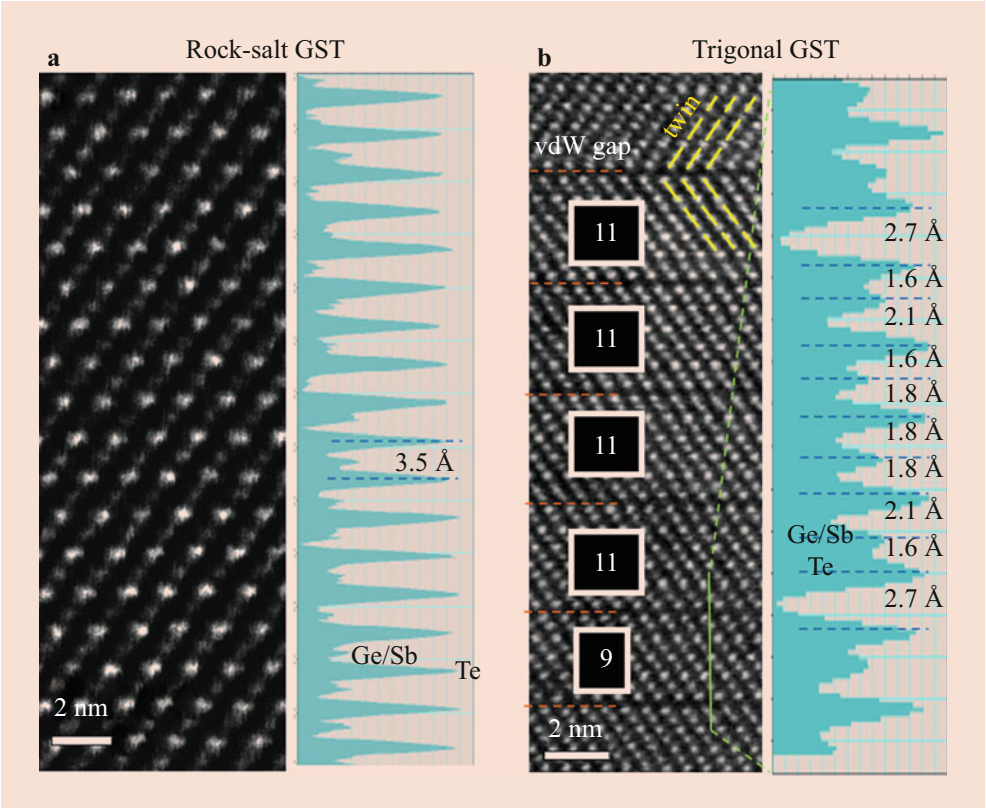

Fig. 4.9 High-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) micrograph of (**a**) rock-salt $Ge_xSb_yTe_z$ (GST) in the [110] zone axis (ZA). A line profile along the whole micrograph is also shown. (**b**) HAADF-STEM micrograph of epitaxial trigonal GST in the [11–20] ZA. Van der Waals gaps are clearly visible and highlighted by the orange dashed lines. Blocks of 9 and 11 planes are indicated, as well as a twin defect. (From Mio et al. [15], © IOP Publishing. Reproduced with permission. All rights reserved)

easily distinguished by Z-contrast, Sb and Te are too close in atomic number to be separated; therefore, another nanoanalysis technique is required. Very recently [21], thanks to the simultaneous detection of HAADF and EDX, these defects have also been chemically characterized. Figure 4.11 reports this mapping for $GeSb_2Te_4$. In particular, EDX mapping shows an intermixing of Sb and Te in the bi-layers.

As mentioned above, another technique often employed in STEM nanoanalysis is EELS. Compared with EDX, EELS has in general better detection for light elements and an energy resolution within the range of some tens of milli electron volts (the EDX resolution is ≈150 eV). The low energy loss sensitivity is thus relevant for plasmon detection and energy gap measurements. Moreover, EELS permits not only elements to be distinguished but also their chemical bonding. This technique is called energy loss near edge structure (ELNES) and is an excellent alternative to the X-ray approach of synchrotron light, as it has higher spatial resolution.

Figure 4.12 shows a series of EELS spectra at angstrom-scale resolution and the corresponding STEM image of C layers formed by graphitization at a high annealing temperature of SiC [24]. The electronic properties of each layer are studied by analyzing the intensity of the K-edge (Fig. 4.12a), and the shape of the ELNES. Two peaks compose the K edge of graphitic carbon (or graphene): the first, at 285 eV, corresponds to the 1s to π* electronic transition, associated with the sp^2 hybridization; the second at ∼295 eV indicates the presence of sp^3 hybridization (1s to σ*). σ* feature is sharp in crystalline graphitic C, whereas it is round and broader in amorphous or not pure C. The spectra show the formation of pure graphene on the surface of SiC (see the green, blue, and orange spectra respectively). In the first layer over the (0001) surface side (red spectrum) the π* intensity drops, owing to the sp^3 hybridization, typical of a buffer C layer with a strong bonding with the outermost Si atoms of the underlying SiC [25]. The absence of this bonding upon the $\left(11\bar{2}n\right)$ facets revealed a delamination of the buffer layer entailing the formation of pure graphene. This result helped to theoretically argue that the formation and stability of a buffer layer on top of the $\left(11\bar{2}n\right)$ steps of an off-axis SiC substrate correlates inherently with the angle between the (0001) and $\left(11\bar{2}n\right)$ planes [24].

While rastering the electron beam across a bi-dimensional area of the sample with the STEM probe, EELS spectra have been first collected pixel by pixel, of angstrom size,

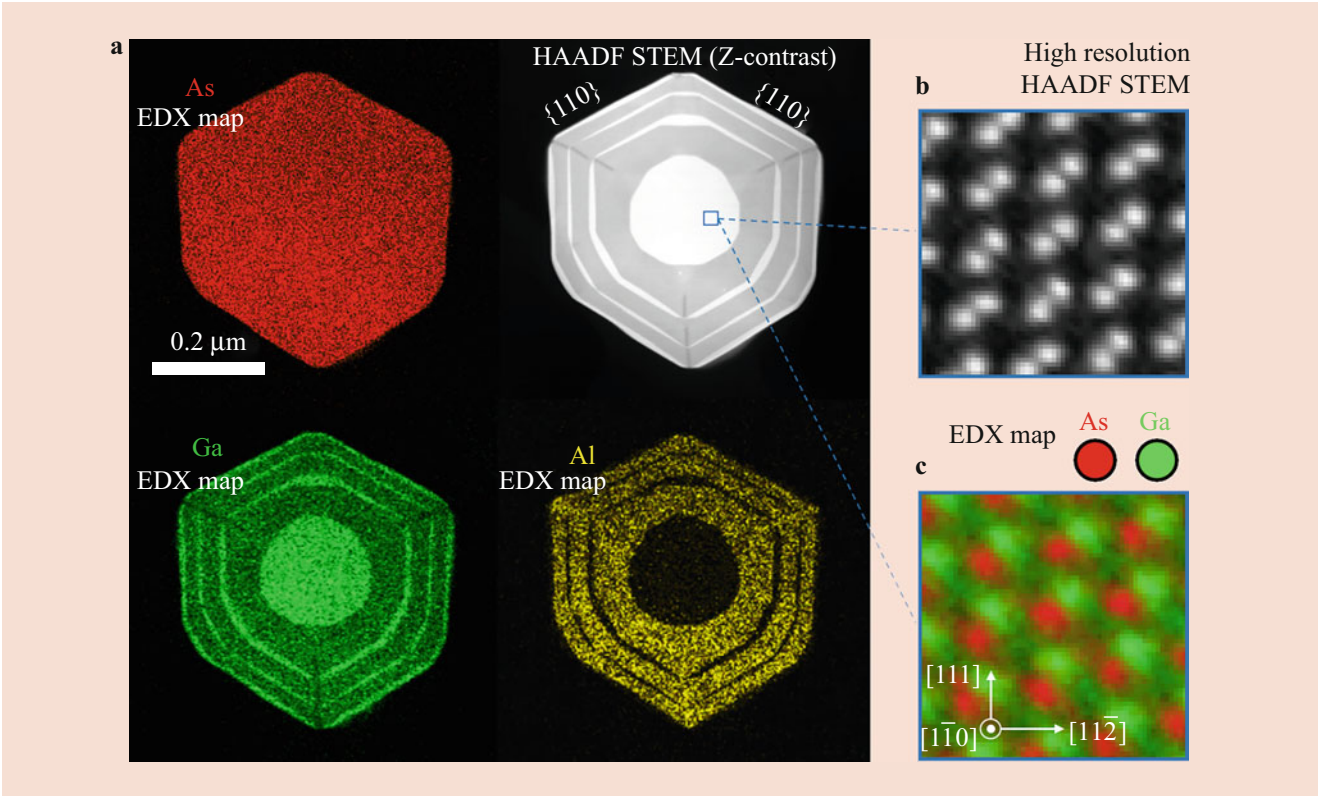

Fig. 4.10 (**a**) High-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) micrograph of an AlGaAs multishell nanowire (cross-view) and the corresponding energy-dispersive X-ray (EDX) maps. In HAADF-STEM, the dark gray areas are associated with the Al-rich regions, i.e., the lighter element in the system. (**b**) High-resolution HAADF-STEM of a pure GaAs region. As the two elements have very close atomic numbers ($Z_{Ga} = 31$ and $Z_{As} = 33$), they are indistinguishable by Z-contrast. Their identification can be performed through simultaneous EDX mapping nanoanalysis, as shown in (**c**). (Courtesy of Mario Scuderi)

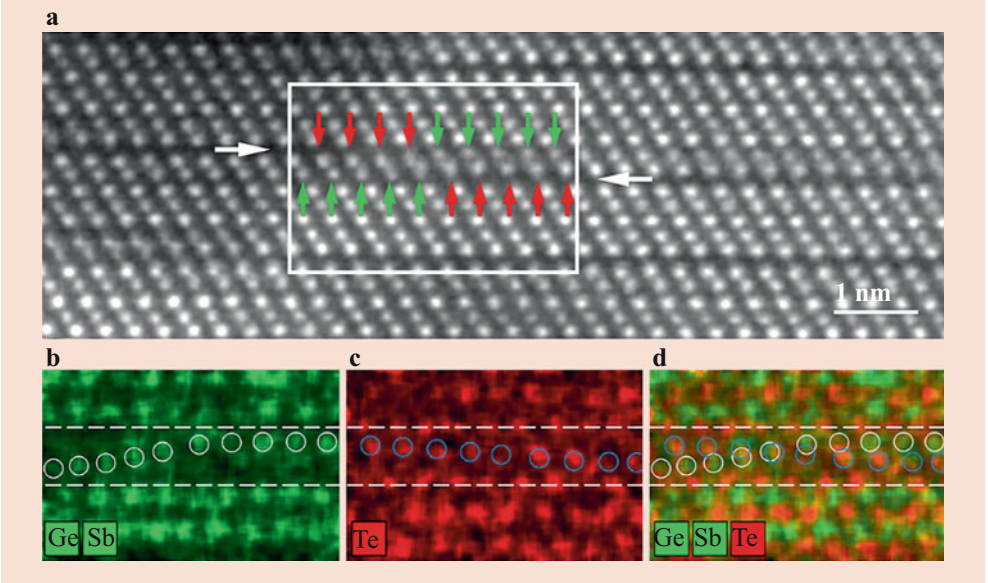

Fig. 4.11 The high-angle annular dark field (HAADF) image and the corresponding energy-dispersive X-ray (EDX) mapping of a bi-layer defect in a GST film. (**a**) HAADF image of bi-layer defect. Green and red arrows mark the Sb-rich and Te-rich layer respectively. (**b**–**d**) The corresponding EDX mappings of the area inside the white box marked in (**a**). The centers of each Ge/Sb and Te atomic column are marked with white and blue circles respectively. A smooth and continuous crossing of the Sb-rich and Te-rich layer is observed. The overlaid EDX mapping in (**d**) also indicates some intermixing of Sb and Te in the bi-layers. (Adapted with permission from Wang et al. [21], Copyright 2018 American Chemical Society)

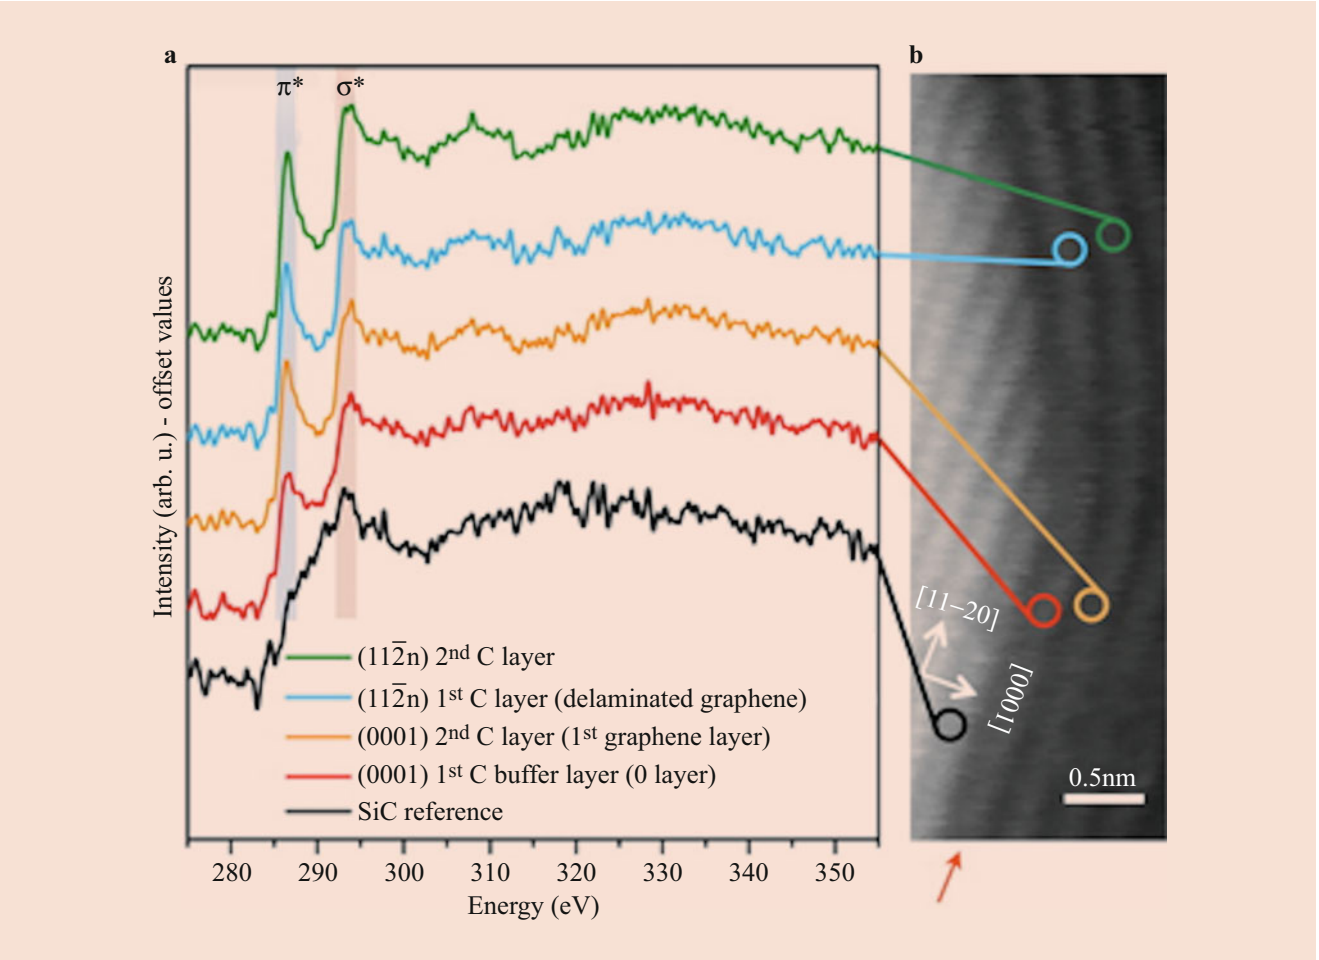

Fig. 4.12 (**a**) Spatially resolved electron energy loss spectroscopy in the K-edge of C, acquired in correspondence of different graphene layers, and (**b**) the related high-angle annular dark field scanning transmission electron microscopy micrograph. together with the corresponding HAADF signal (Fig. 4.12b). The spatial and energy data form a three-dimensional array called a data cube. Figure 4.13 shows a schematic of this procedure, taking the name STEM spectrum imaging (SI). Once the data cube has been filled up and stored, information can be extracted and the pixels binned along a segment or a bi-dimensional region in order to average and to increase the signal-to-noise ratio (SNR). Moreover, it is possible to extract compositional information from the elemental characteristic core-loss spectrum, considering the integrated signal produced in this spectral region and reassembling this signal value in a spatial bi-dimensional chemical map. Point-by-point, the signal intensity of each pixel is proportional to the chemical concentration of the observed element.

Depending on the microscope configuration, other techniques can be combined simultaneously such as EDX, cathode luminescence (CL), nano-diffraction (ND), and electron-beam-induced current (EBIC). The set of collected data is stored in a multidimensional matrix called a dataset instead of a data cube, where the matrix Δx by Δy maps the spatial STEM signal, usually the HAADF, and the Δz_n dimensions (where n is an integer correlated with the maximum number of associated techniques) encode the information acquired by the other techniques, including energy histograms for EELS or EDX, current values for EBIC, etc. A key advantage of STEM SI is therefore the possibility of processing a whole range of data *a posteriori*.

The study of the ELNES at the interface level gives direct information on the presence of dopants, defects, as well as of details on the bonds at the atomic scale. As an example Fig. 4.14 reports the analysis of HAADF-STEM and EELS SI techniques to localize stoichiometric defects at the 4H-SiC/SiO_2 interface. These defects are responsible for near-interface oxide traps [26]. The investigation of the semiconductor/dielectric interface is crucial to improve the performances of metal-oxide-semiconductor field effect tran-

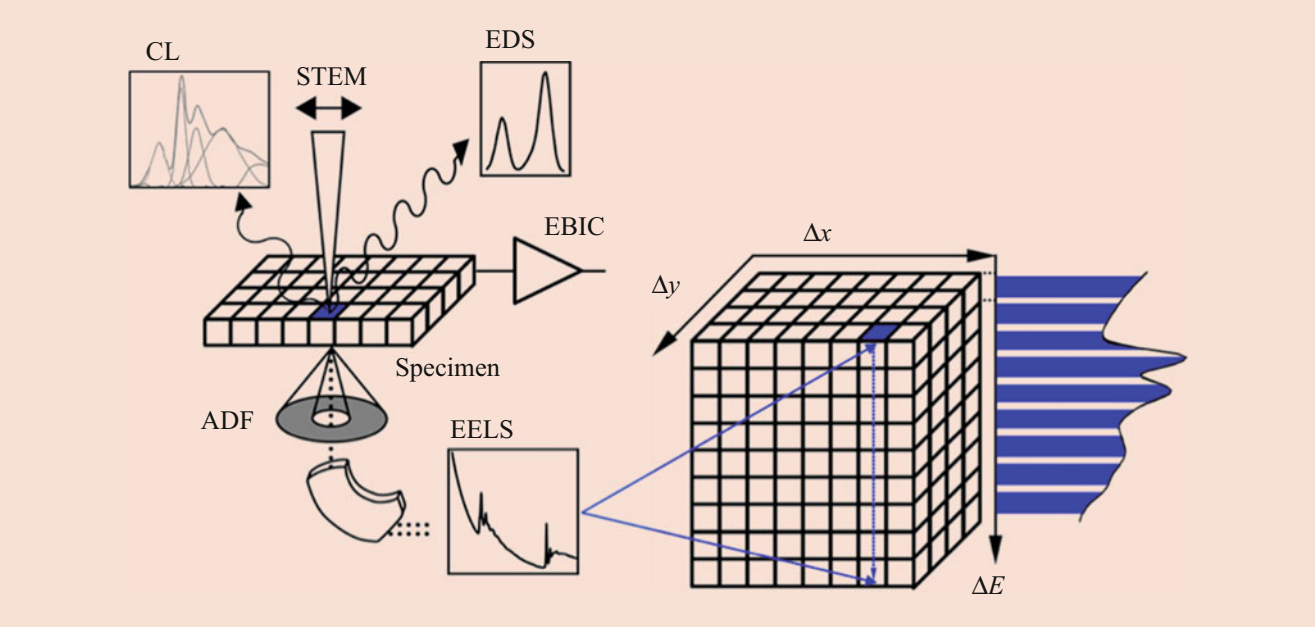

Fig. 4.13 Scanning transmission electron microscopy (STEM) spectrum imaging setup. A multidimensional array, the dataset is acquired pixel by pixel by scanning the STEM probe over a chosen bi-dimensional area. The STEM detector signal is stored in the Δx by Δy matrix. Data from a number of complementary techniques, such as electron energy loss spectroscopy, energy-dispersive X-ray, cathode luminescence, and electron-beam-induced current, are stored in the z_n dimensions

sistor (MOSFETs). Through EELS SI, spectra are acquired and collected in a data cube. Binning of the pixels is applied over rectangular regions (see inset in Fig. 4.14d) whose size is small enough to preserve the required spatial resolution but still sufficient for a good SNR. Figure 4.14d shows EELS spectra extracted from the SI dataset and integrated within the above rectangular regions located over three regions: the SiC bulk (blue), the interface between SiC and SiO_2 (red), and the SiO_2 (green). The energy of acquisition for all the EELS spectra ranged between 95 eV and 560 eV, wide enough to include all the chemical species of interest, i.e., Si, C, N, and O. The presence of a weak nitrogen K-edge peak, produced by post-oxidation annealing in NO, is revealed by an accurate background subtraction followed by multiple linear least squares fitting of the spectra.

From the software post-processing of the acquired SI dataset, the signals due to the chemical species (core-loss) are extracted and plotted in the two-dimensional chemical map, as reported in Fig. 4.14b. N accumulates at the transition layer between SiC and SiO_2. In order to localize the exact position of the N layer, the line intensity scan of each chemical signal is plotted and compared with that obtained from the Z-contrast HAADF-STEM image, which shows the exact position of the interface. All the line intensity profiles are reported in Fig. 4.14c. The analysis of the different signals indicates that nitrogen is trapped just below the last SiC atomic layer of the bulk crystal.

The smooth behavior of the other elements distribution along the interface is then confirmed by the chemical EELS analysis, indicating that SiC gradually gives way to nonstoichiometric SiC, in which C atoms are substituted with N and then with O. This is supported by the EELS chemical bond analysis for the C, K-edge (Fig. 4.14e). With respect to the SiC bulk, in the transition region the σ^* signal of carbon decreases and, at the same time, a non-negligible amount of π^* is present. This supports a mixed sp^2/sp^3 hybridization coordinating C with silicon, oxygen, and nitrogen atoms. The mixture is maintained for more than 1 nm from the nominal interface, before having a fully stoichiometric SiO_2.

4.2 X-Ray Analytical Techniques

X-ray-based techniques exploit the capability of the electromagnetic waves to deeply penetrate and interact with matter, thus providing structural information in their outgoing path. In this section, the main characteristics of the technique are illustrated, including a description of common apparatus. New frontiers of X-ray diagnostics extend the investigation to nanostructured materials taking benefit from the use of monochromatic and high-brilliance sources, and likewise from the development of modern analytical methodologies. As examples of thin film systems, the crystallization of a GeSbTe thin layer from the amorphous to rock salt and finally

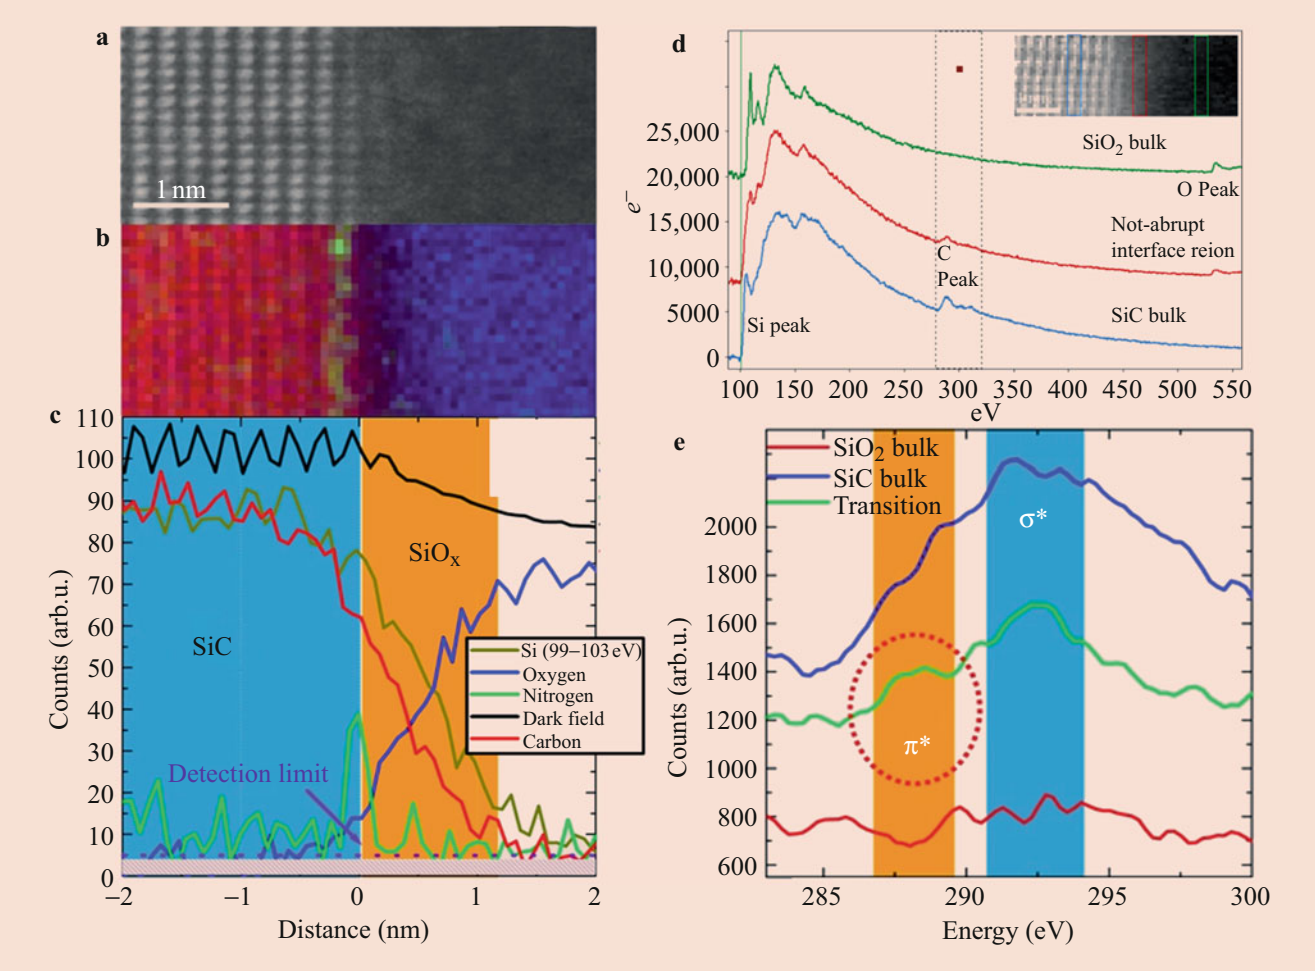

Fig. 4.14 (**a**) High-resolution dark-field cross-section scanning transmission electron microscopy (STEM) image across the SiO_2/4H-SiC interface. (**b**) Carbon, oxygen, and nitrogen superimposed electron energy loss spectroscopy (EELS) maps. (**c**) Dark-field signal, silicon, carbon, oxygen, and nitrogen EELS spectra averaged on all the scanned lines; bulk SiC is highlighted in light blue and the not-abrupt interface region in orange. In (**d**) raw EELS spectra are shown, in a wide energy range comprising silicon, carbon, and oxygen edge. The signal intensity is related to the element composition. In (**e**) EELS spectra of the carbon K-edge are shown, after background subtraction. The detail of the edge gives information on the contribution of the σ* and π* chemical bounds. (From Fiorenza et al. [26] © IOP Publishing. Reproduced with permission. All rights reserved)

to trigonal structure is tracked by the position/shape analysis of the diffracted peaks, the heteroepitaxial coupling of thin polycrystalline layers of silicides on (001) bulk silicon is investigated by polar figure analyses. In particular, the X-ray diffraction details the NiSi complex structure. Other reported studies are concerned with the shape-related analysis of silicon nanoparticles under high-resolution conditions; the stress field due to residual defects in ion implanted and annealed germanium wafer; and the formation and evolution of defects during the growth of thick monocrystalline layers (e.g., 3C-SiC, GaN). Nowadays, controlled growth of high-quality bulk and epitaxial semiconductors (SiC, GaAs, GaN, AlGaAs, etc.) represents a challenge for further advances in device architecture and performance following the previous narrative with silicon.

4.2.1 X-Ray Characteristics and Common Experimental Apparatus

The mainstay of X-rays resides in their associated wavelength being comparable with the atomic size and distances in the matter, which allows the wave front to be sensitive to the overall atomic arrangement. The outcoming beam indeed holds key information related to the lattice architecture and associated phases (interplane distances, lattice parameters, bond distances), to defects and accumulated strain, to the grain or nanoparticle size, mosaicity and texturing, to the electronic density, to the layer thickness and roughness, and to the material porosity. Depending on the method of decryption of the information, X-ray diffraction (XRD), reflectivity (XRR), scattering (WAXS and SAXS: wide-Angle and small

X-ray scattering), absorption (XAS: X-ray absorption spectroscopy), or fluorescence (XRF) techniques are dealt with. Although a degree of lattice order is required for diffraction, other X-ray techniques can even be applied to amorphous materials.

All mentioned methods can currently take advantage of exploiting high-brilliance sources at synchrotron radiation facilities. In conjunction with the more consolidated approaches, tomographic quantitative analyses by synchrotron radiation with progressively increasing resolution provides a representative case of current advances in the application of X-rays for materials at scaled dimensionality. Along the same track, laboratory equipment nowadays benefits from new-generation X-ray sources more frequently than in the past. The brilliance of a X-ray source, defined as the number of photons/second · mrad^2 · mm^2 · 0.1% BW (0.1% BW stands for the photons falling within a band-width of 0.1% with respect to the central wavelength) is $\sim 10^8$ in laboratory equipment, to increase to $\sim 10^{22}$ in synchrotron beam lines, as illustrated in Fig. 4.15a. In the same figure, a schematic of a laboratory *Kα*-Cu source with a wavelength of 1.5407 Å (Fig. 4.15b) and the penetration depth of this kind of beam into different materials (Fig. 4.15c) are also reported.

X-ray diffraction is a phenomenon based on the cooperative response of the matter under the external solicitation of an electromagnetic field with a wavelength within the angstrom range, in which each atom of the lattice behaves as a source of secondary spherical wave. If a medium- or long-range order is established, constructive interference among the outcoming waves is feasible at specific exit angles. Those angles are finally related to the interplanar lattice distances through the well-known Bragg's law (Fig. 4.16a). Diffraction intensities, linewidth, line-shape, and mutual peak positions provide detailed insights into the lattice properties of the probed matter.

High-resolution diffraction (HR-XRD) analyses of bulk materials and epitaxial layers require highly monochromatic beams. In laboratory Cu sources, the beam is accordingly wiped from its kα_2 components by the use of multiple-bounce germanium monochromators with improvement of the temporal coherence of the radiation. Point focus sources, high speed detectors, and the several rotational degrees of freedom of the setup are other key configurational parameters for spatially resolved HR-XRD (Fig. 4.16b). Multiple-axis X-ray diffractometers currently allow almost free movement through the reciprocal space for out-of-plane and in-plane

diffraction on the same probed area. The schematic of a typical multi-axis setup is shown in Fig. 4.16c. Shape and position analyses in the reciprocal space hand back information on internal stress, strain relaxation, displacement field around defects, compositional gradients, and mosaicity.

For polycrystalline thin films, a common analysis method is based on symmetrical $\omega - 2\theta$ scans, where the incoming primary beam and the outcoming secondary beam mirror with respect to the sample surface (ω is an angular parameter related to θ). With this geometry, the lattice planes stacked in the out-of-plane direction are detected. In order to instead access the in-plane components, φ and χ rotations are exploited, or, alternatively, an off-axis $\omega - 2\theta$ scan can be applied. Grazing incidence is tailored for thin-film analyses to partially confine the incoming beam into the probed layer. Figure 4.15c shows the penetration depth of a Cu-kα beam as a function of the incident angle in different materials. Rocking curves are ω-scans that complement the analyses on thin layers with information on the eventual preferential orientation (texturing) of the grains. In this case, polar figure analyses are carried out to provide key insights into the statistical distribution of diagnostic planes and on their eventual coupling with underlayers or bulk substrates. They are especially used for the heteroepitaxial structural coupling of materials.

4.2.2 Thin Film Analysis

GeSbTe Alloys

As a simple example of the X-ray potentialities, we report the analysis of the amorphous-crystal transition of the phase change alloy $Ge_2Sb_2Te_5$ viewed by out-of-plane diffraction [27] This transition is the basis of the working principle of optical or electronic nonvolatile memory. The amorphous phase is characterized by low reflectivity and high electrical resistivity, the opposite occurs for the crystalline phase. The high-low values correspond to 0 or 1 as binary code.

The crystallization of 50 nm-thick amorphous films deposited on a Si substrate is shown in Fig. 4.17a as a function of thermal annealing at 122 °C for different times. The analyses are carried out at a grazing angle <1° to account for the low-layer thickness. The pattern of the as deposited film shows a broad bump centered at 30° typical of the amorphous phase. The partially crystallized samples are instead identified by the (200) and (220) diffracted peaks of the metastable rock-salt (face-centered cubic, FCC) phase. Their intensity increases with the crystalline fraction. The full width at half maximum (FWHM) of the peaks is taken as a parameter to calculate the average grain diameter through the relation $d = \lambda/\text{FWHM}\bullet\cos(\theta)$, where λ is the X-ray wavelength and θ the incidence angle. In this case, the average final grain size amounts to 40 nm. Besides the metastable rock-salt phase that is observed at low annealing temperatures, a stable trigonal phase is formed after high annealing, as shown in Fig. 4.17b. The patterns relate to GST thin films after annealing at 150 °C and 400 °C with the corresponding phases labeled with different symbols.

Silicides

Silicides are widely used as conductive compounds in the semiconductor industry to mitigate contact and sheet resistance in devices. Although the long-lasting experience of the reaction and properties gained on silicon has been technologically transferred to SiC, specific critical issues have been raised and nowadays deserve a focused effort.

In the story of silicides, nickel-silicon compounds represent the latest choice that was basically motivated by their low

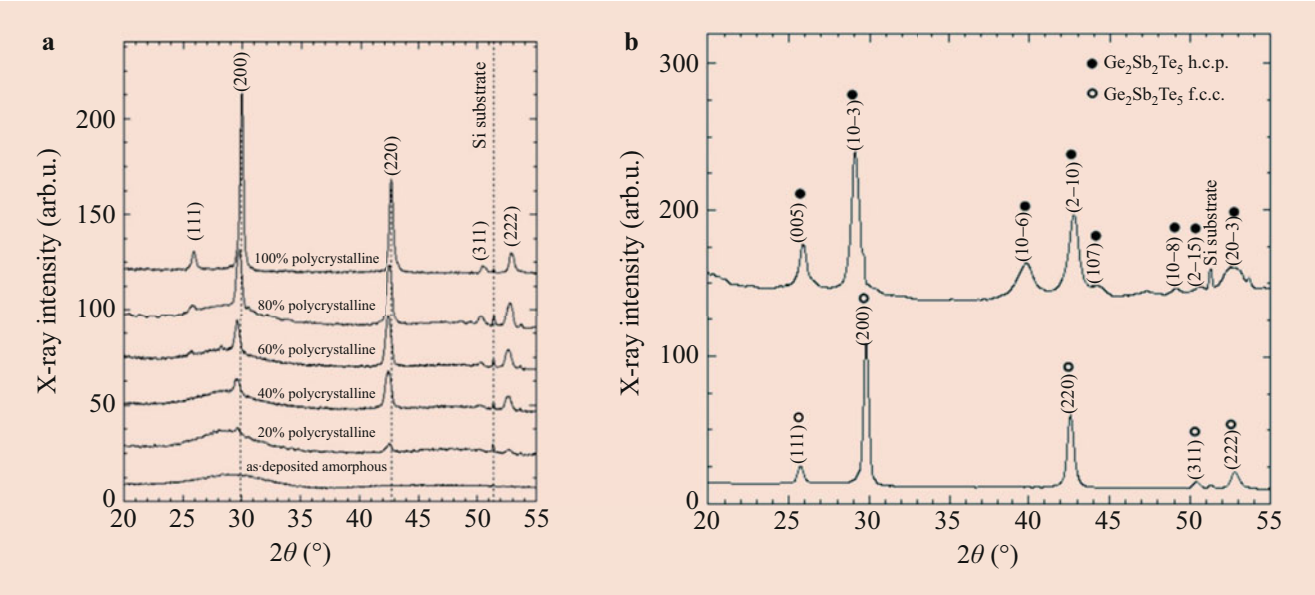

Fig. 4.17 (**a**) X-ray diffraction (XRD) of as-deposited amorphous $Ge_2Sb_2Te_5$ films at different crystalline fractions. [27], with the permission of AIP Publishing). (**b**) XRD pattern of $Ge_2Sb_2Te_5$ films on SiO_2/Si substrate after annealing at 150 or 400 °C for 10 min; the diffraction peaks indicate the presence of the rock-salt (open circles) and trigonal (full circles) phase. (Reprinted from De Bastiani et al. [28], with the permission of AIP Publishing)

formation temperature and excellent scalability. In addition, it has been demonstrated that a heteroepitaxial coupling of orthorhombic nickel silicides with cubic silicon is feasible by promoting the growth of transrotational structures [29]. Despite their formation demanding special care in the interfacial cleanness and deposition conditions (low deposition rate and deposition temperature ~70 °C), the advantages of exploiting the structural interfacial coupling with silicon are numerous, such as the down-scalability of the thickness that preserves flatness and thermal stability (~10 nm), the low formation temperature (≥220 °C), and the low contact resistance [30].

Figure 4.18a, b disclose the structural difference between a standard NiSi layer and a transrotational silicide of the same stoichiometry and thickness grown on [001] bulk silicon. Noticeable differences reside in the lack of grain boundaries and in the ordered electron diffraction pattern of the trans-NiSi layer [31]. In addition, trans-domains are easily traceable by the peculiar branched shape of the diffraction contours, which are called bending contours. Figure 4.18c shows the cross-section of the core of a trans-domain in which an atomic coupling is established between the metallic layer and the Si substrate. This coupling extends through the rest of the interface, moving from the core region, and involves the entire domain volume with progressive bending of the silicide lattice. This overall bending is a way for the thin metallic layer to account for the strain due to the mismatch and different lattice structure with silicon, thus representing the mainstay of a transrotational silicide architecture [29]. The kind of peculiar atomic matching established at the shared interface guarantees low barrier height for high-performance ohmic contacts, as shown in Alberti and Giannazzo [30]. The lattice configuration of thin trans-silicides can be unveiled by X-ray polar figure analysis, as shown in Fig. 4.18d. It produces specific features that account for the continuous bending of the crystallographic planes along the layer, in full agreement with the structural simulations represented by colored dots in Fig. 4.18d. Their relationship with the underlying silicon, whose contributions are marked by black squares in the same figure, is also specifically diagnostic of this kind of growth. In a complementary way, in-plane diffraction applies to further explore the trans-rotational coupling, as can be found in Alberti and La Magna [29], and likewise any kind of thin-film epitaxy.

The formation of trans-silicides on SiCs for backside metallization in currently produced power devices for microelectronics is a challenge. On the other hand, a standard silicide reaction on SiC has a bottleneck in the thermal budget to be applied for silicidation. It represents one of the last processing steps, which is further complicated by the extremely scaled wafer thickness. To overcome all those issues, laser annealing represents a reliable. Silicide reaction by laser annealing is currently in the spotlight owing to some challenges, mainly related to the carbon clustering after silicon release for silicidation and to the control of the overall composition and uniformity of the metallic contact [32].

4.2.3 Case Studies

Shape-Related Structure of Silicon Nanoparticles

Silicon nanoparticles can be applied in light emitting diodes, flash memories, and flat screen, with their synthesis usually carried out using chemical methods. Size control and shape analyses are often performed using X-ray diffraction [33]. In this specific case, nanoparticles are isolated octahedrons with a narrow distribution in size that allow very efficient scattering and trapping of incoming radiation. They are generated into an inductively coupled plasma-chemical vapor deposition (ICP-CVD) chamber and, immediately after, land on a flat substrate under high vacuum conditions.

The octahedron facets are framed by (111), (220), (311), and (100) silicon planes as expected for the minimization of the surface energy. Figure 4.19a shows a polar figure collected using a Cu-$K\alpha$ beam to probe the spatial configuration of the (111)-Si planes over half of the solid angle on a set of as-deposited octahedrons. In the figure, the distribution of the q-vector associated with (111)-Si planes is stereographically projected onto a two-dimensional image. The resulting figure shows an intense signal at $\chi = 0$ and a ring at $\chi = 70.5°$. Their combination and the related parameters are symptomatic of the shape and geometrical configuration (landing condition) of the nanoparticles, whereas the occurrence of a ring at $\chi = 70.5°$ flows from the rotational degree of freedom around the [111] landing axis (see Fig. 4.19c). A frame of the tomographic view of an isolated octahedron, taken by TEM, and its configurational schematic are shown in Fig. 4.19b, c respectively. This information is complemented by position and shape analyses of the X-ray diffraction peaks that disclose the octahedrons being defect-free, unstrained single crystals even at a low substrate temperature (50 °C). A feasible integration of the deposition process at any production step and the use of low-cost substrates are indeed guaranteed.

The assembly of silicon nanoparticles (NPs) allows growing layers with controllable porosity and surface-to-volume ratio. Those strategic properties are suitably explored by 3D-coherent X-ray diffraction imaging (3D-CXDI), a recently developed methodology that exploits synchrotron radiation beam lines. The method allows tomographic reconstruction and quantitative analyses through mapping of the electronic density into the probed volume as well as discriminating functional materials eventually hosted inside the porous scaffold. An example of two different assemblies of silicon nanoparticles is shown in Fig. 4.19d–g [34]. Lateral pore size

and correlation distance in a porous matrix are additional parameters accessible by using synchrotron lights and applying grazing incidence small-angle X-ray scattering [35].

Residual Defects in Ion-Implanted Ge

A second example of X-ray analysis applied to single-crystal semiconductors refers to germanium. As occurs in silicon-based technologies, dopant implantation and subsequent thermal treatments, used to form ultra-shallow junctions, leave interstitial-type end-of-range (EOR) defects that are difficult to investigate and detrimental to the carrier transport in devices. X-ray analysis can be applied in this field [38].

With respect to the local analyses that can be done by TEM, XRD provides complementary average information over square-millimeter areas. The analysis consists of collecting $\omega - 2\theta$ patterns under HR-XRD conditions around the (004) planes of the germanium lattice in the reciprocal space along the direction of the q_z vector and around the $|q_{z004}|$ value. Figure 4.20 reports the data item in a sample implanted with fluence 2×10^{14} Ge/cm^2 at 100 keV after annealing at 340 °C, compared with a reference diffraction pattern. The analysis highlights that, after annealing, the disorder of the lattice due to the ionic implantation is almost completely recovered, except for a shoulder at positive q_z. It is a marker of a displacement field around the defects that is due to interstitial atoms [39]. This extra-contribution to the diffuse scattering with respect to the reference signal, called I_{excess}, is shown in a double logarithmic plot as a function of $|\Delta q_z|$ in Fig. 4.20b. It is produced by the presence of interstitial clusters into the recovered Ge matrix as disclosed by its peculiar decay vs $|\Delta q_z|$. In particular, the log-log plot in Fig. 4.20b has a double slope with exponent $-2(\Delta q^{-2})$ owing to the Huang scattering from the lattice atoms near the defects and with exponent $-4(\Delta q^{-4})$ at high values owing to the Stokes–Wilson scattering.

End-of-range defects and strain induced by ion implantation, which represent critical issues for any semiconductor technology, are investigated in detail in Capello et al. [40] on implanted bulk silicon and studied using coupling synchrotron radiation X-ray scattering to XRD.

Extended Defects in SiC and GaN Epilayers

Epitaxial layers and bulk SiCs are in the spotlight for the new frontiers of microelectronics, especially for power devices.

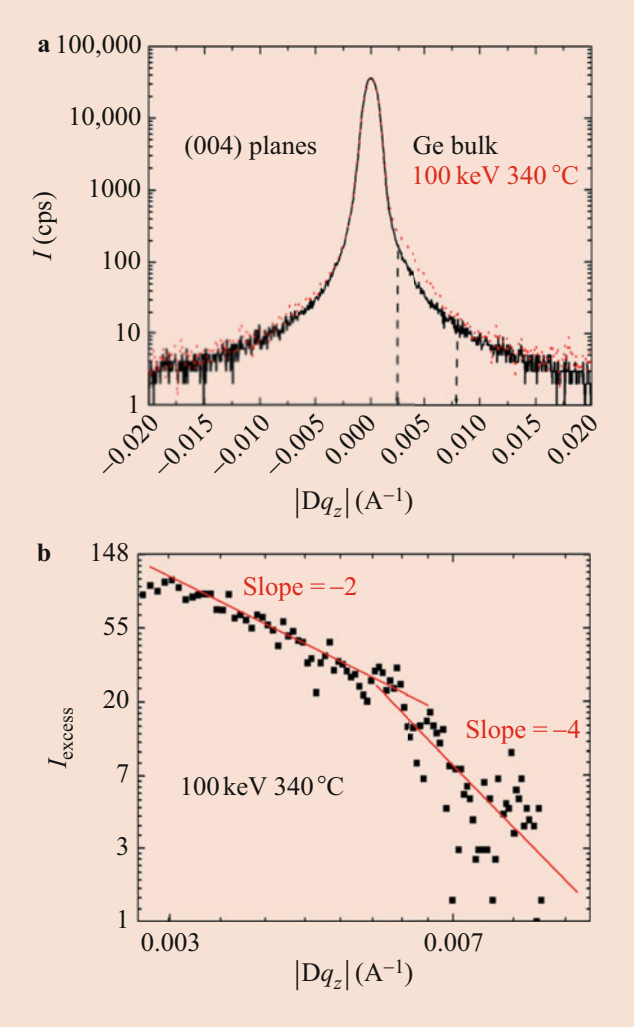

Fig. 4.20 (**a**) High-resolution X-ray diffraction pattern of a Ge sample implanted with a fluence of 2×10^{14} Ge/cm^2 at 100 keV after annealing at 340 °C, compared with the reference case. It has a shoulder at an angle above the Bragg angle owing to diffuse scattering from interstitial-type defects. (**b**) Log-log plot of the excessive intensity, in the region among dashed lines in (**a**), as a function of $|\Delta q_z|$. (Adapted with permission from Boninelli et al. [38], Copyright American Institute of Physics 2012)

Their structure, strain, defects, and coupling with other materials in the device architecture raise concerns to be addressed by newly conceived growth and deposition methodologies. Nonetheless, they remain critical owing to the high temperature of the processing steps, to the different stability window of the available polymorphisms (e.g., 3C, 4H) and to the difficulties of doping. In all those respects, XRD provides crucial insight to afford incremental improvement of the processes involved in device manufacturing.

Extended defect (e.g., SFs and dislocations) formation is especially crucial while growing 3C-SiC layers. Their qualitative evaluation is commonly addressed by measuring the FWHM of the rocking curves (Rc_s) collected at strategic peaks. As a major feature, the decrease in the FWHM of the Rc collected at the (002) 3C-SiC planes [41] is symptomatic of an overall improvement of the quality of the material. The FWHM is primarily linked by the layer mosaicity and to the presence of extended defects into the layer. Indeed, this parameter provides feedback for tuning the growth conditions. High defect density is not only detrimental to carrier mobility but even induces an internal stress field that bends the wafer, with a consequent increase in its brittleness [42]. Defect mitigation action starts from controlling the early stage of growth of epitaxial layers. The electronic density of the growing front is often measured by XRR and used as a diagnostic parameter for the compositional changes occurring during the process [42]. XRR is easily implementable in a laboratory diffraction setup.

A powerful tool for evaluating the quality of the as-grown layer is through a mapping of the q-vector associated with specific planes in the reciprocal space. An example of reciprocal space mapping (RSM) is shown in Fig. 4.21. As reported in Boulle et al. [43], the (002) 3C-SiC Bragg peak is sensitive to the density of SFs in the probed layer. They, in fact, produce streaks along the [111] directions that cross the main diffracted feature. The analysis procedure consists of extracting and simulating [43, 44] the intensity line profile along this streak as represented in Fig. 4.21. A density of defects (D) within the range of 400–450 SFs/cm, close to the value measured by potassium hydroxide etching and imaging is measured.

Gallium nitride is used for high-power and high-frequency devices with high-energy efficiency, having a large band gap (3.4 eV), a high critical field (>3 MV/cm), and high electron mobility in heterostructures (>1000 cm^2 V^{-1} s^{-1}). GaN technology, competing with its Si and SiC counterparts, has current open issues in epitaxial layer growth and device optimization that can indeed benefit from the use of X-ray diagnostics.

The nature and density of the defects in GaN epilayers can be faced by HR-XRD focusing on the growing planes. A case study is shown in Fig. 4.22: the sample is a 3-μm-thick n-type GaN epitaxial layer, with a nominal donor concentration $N_D \sim 1 \times 10^{16}$ cm^{-3}, grown onto a heavily doped (~1–5 $\times 10^{18}$ cm^{-3}) freestanding GaN substrate [45]. A family of (000 l) growing planes is investigated on purpose through $\omega - 2\theta$ scans and Rc_s by spanning over l = 2,4,6. In a non-ideal lattice with periodicity perturbed by defects, the FWHM of the Rc_s is related to the tilt angle and to the correlation length between domains [46]. The applied fitting procedure provides an average value for the screw dislocation density, 4.7×10^7 cm^{-2}. A corresponding density of edge dislocations can be inferred by exploiting the semi-empirical curve reported by Heinke et al. [47].

X-ray analytical facilities and methods have indeed been making huge progress since Max von Laue posed

the question: "What would happen if you assumed very much shorter waves to travel in the crystal?" We can partially answer that material science with its new frontiers is undoubtedly benefitting from the power of X-ray to interact deeply with matter.

4.3 Raman Spectroscopy

This section describes the working principle of Raman spectrometry, the experimental apparatus commonly adopted, and some applications. Identification of structure, either amorphous or crystalline phase and of disorder are the main characteristics of this technique. As an example, the structure of amorphous and crystalline Si and of chalcogenide alloys as analyzed by Raman spectroscopy are presented and discussed. Raman spectrometry is also a powerful contactless technique for studying the local transport properties in polar semiconductors. The method is based on the measurement of the frequency shift caused by the coupling of longitudinal optical (LO) phonon with plasmons (LOPC). The shift depends on the free carrier concentration and on the carrier mobility; these parameters can then be measured. The method is illustrated by measurements performed on SiC and GaAs heteroepitaxial layers.

4.3.1 General Aspects

Raman spectroscopy [48] is a technique adopted to determine the phases of several semiconductors and metals used in microelectronics. It is based on the interaction of light with molecules in some medium or atoms in a crystal. The Raman scattering is an inelastic process, i.e., a scattering process in which energy is transferred between an incident photon with energy $h\nu_I$ and the sample, resulting in a scattered photon with a different energy $h\nu_s$. The amount of transferred energy corresponds to the energy $h\nu_k$ of an elementary excitation in the sample, e.g., a phonon, a polariton, or a plasmon. The energy conservation law gives the correlation between incident and scattered frequencies of radiation:

$$h\nu_s = h\nu_i \pm h\nu_k. \tag{4.1}$$

The processes in which an elementary excitation is generated ($\nu_s < \nu_i$) are called Stokes processes, whereas those that imply the annihilation of an elementary excitation ($\nu_s > \nu_i$) are referred to as anti-Stokes processes. As the density of phonons for a mode κ is given by the Bose–Einstein distribution, anti-Stokes Raman scattering is a factor of $\exp(-h\nu_k/kT)$ less than Stokes Raman scattering [49].

Figure 4.23 shows the Raman spectrum of silicon, with Stokes and anti-Stokes bands.

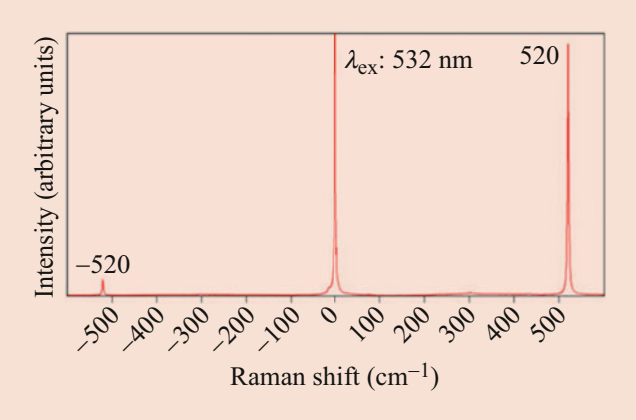

Fig. 4.23 Raman spectrum of silicon

In analogy to energy conservation, the quasi-momentum conservation law yields the correlation between the wave vector k_i of the incident light, k_s of the scattered light, and the excitation wave vector q_j:

$$k_s = k_i \pm q_j. \tag{4.2}$$

Raman spectroscopy employs a laser in the visible region with a wavelength that exceeds the lattice constant by a factor of more than 100. Therefore, the involved excitation wave vectors are within a few percent of the center of the Brillouin zone. In this region, the dispersion of optical phonons is negligible, and therefore the energy transfer $h\nu_\kappa$ is independent of the incident frequency. Actually, the conservation of momentum represents an idealized picture, which may be limited in real experiments because of the light absorption in the sample. Indeed, the attenuation of penetrating light is equivalent to a spectrum of different momentum values, thus leading to a spectral band of solid-state excitations fulfilling the momentum conservation rule. Moreover, in real crystals impurities and dislocations are responsible for momentum nonconservation, which causes a corresponding broadening of the spectral lines observed. Therefore, the line shape of phonon peaks observed in Raman spectra characterizes the degree of disorder into a solid.

As the vibrational modes of the material determines the energy shift, Raman spectroscopy distinguishes between phases with the same composition, because they are characterized by phonons with different energies.

4.3.2 Experimental Setup

In Raman experiments the energy spectrum of scattered light is very close to the energy of the incident light but usually many orders of magnitude smaller in intensity. Therefore, very good suppression of the elastically or quasi-elastically

scattered light is required. The essential parts of a Raman setup are thus a laser, which is a stable monochromatic source with considerably high intensity, a double or triple monochromator, a spectrometer, and a very sensitive photon detector. In spite of the monochromatic character of the laser light, a spectral filter into the laser beam path eliminates nonlasing emission lines. The scattered light is collected through a lens system and focused onto the entrance slit of a spectrometer.

As the intensity of the Rayleigh scattering is high enough to completely hide the Raman signal, the scattered radiation must be filtered before reaching the spectrometer. This, traditionally done by means of a double or triple monochromator, can also be obtained by a holographic notch filter. This works as a beam splitter, reflecting almost 100% at the wavelength of the laser beam and transmitting up to 80% at the other wavelengths.

The wavenumber of transmitted Raman light is tuned by tilting an interference filter. The Raman scattered light is then dispersed using a diffraction grating, which reflects a particular wavelength range to the detector. The detector is a photomultiplier, or a multichannel detector system with a very high efficiency.

A computer, usually outputting a graph of intensity versus wavelength, then processes the information. The wavelength is commonly given in relative wavenumbers (cm^{-1}) to the laser wavelength. The value is calculated by taking the inverse of the laser wavelength (in centimeters) minus the inverse of the Stokes Raman shifted wavelength (in centimeters). The relative wavenumber shift for a particular molecule or crystal is a constant no matter what laser wavelength is used as source. Raman spectroscopy thus takes advantage of this wavelength shift and allows for identification of different molecules or crystalline structures, which all have different shifts and intensities relating to the particular bond.

A large improvement in spatial resolution can be achieved using a light microscope as optics for both focusing the incident beam onto the sample and collecting the scattered light (micro Raman). For this purpose, the microscope contains a beam splitter, inserted between the objective and the ocular lens system. With this setup, the lateral resolution is limited by the light diffraction. The lateral resolution is of great importance to distinguish two different crystalline structures, both present in the sample, or for characterizing patterned samples. In comparison with standard optics with lenses of long focal lengths in the centimeter regime, the microscope setup collects a much larger solid angle of scattered light. This results in much greater collection efficiency, thus enhancing the sensitivity, though decreasing the definition of the propagation direction of the scattered wave.

The spatial resolution is improved by using confocal optics, which measure at one time the intensity of the light reflected or transmitted by a very small area of the sample. A pinhole aperture, placed in the microscope objective image-plane, selects only the scattered light coming from the area of the sample illuminated by the laser spot, whereas the out-of-focus contributions do not propagate through the confocal hole. The vertical spatial resolution depends on the optical properties of the sample. For transmitting materials, it is better than 2 μm; in absorbing samples, it is determined by the light penetration depth.

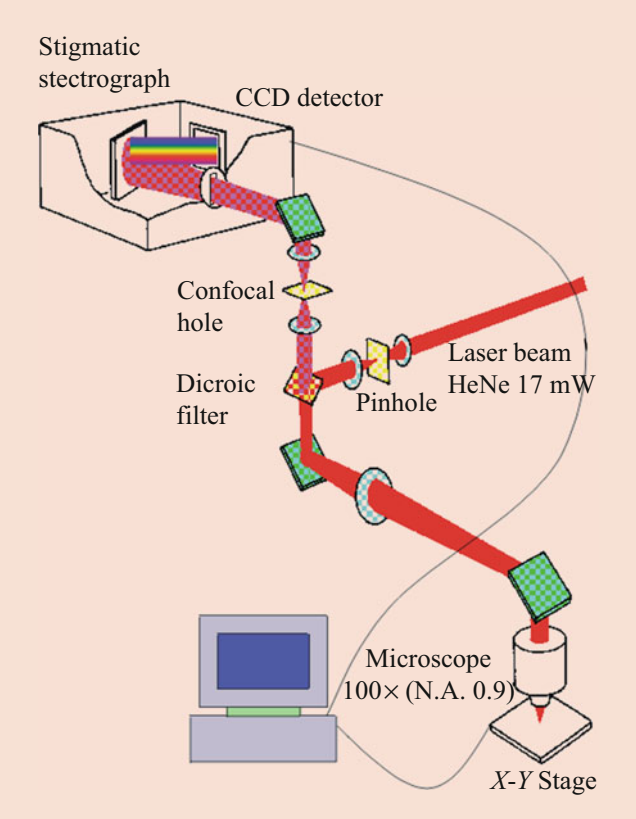

Fig. 4.24 Schematic of an experimental apparatus for micro-Raman spectroscopy and mapping

To perform spatial images of the distribution of different phases, samples are mounted on a computer controlled xy stage, which enables the sample position in steps typically less than 1 μm to be automatically changed.

Complete commercial Raman setups are available. Figure 4.24 shows a schematic of a typical setup.

4.3.3 Structure Analysis

Structurally, crystals differ from amorphous solids and glasses in that the former possess long-range translational symmetry whereas the latter lack any spatial order. Therefore, the Raman spectra of the materials in the crystalline or amorphous phase are usually different. Figure 4.25 shows Raman spectra of single-crystal and ion-implanted Si. Ion

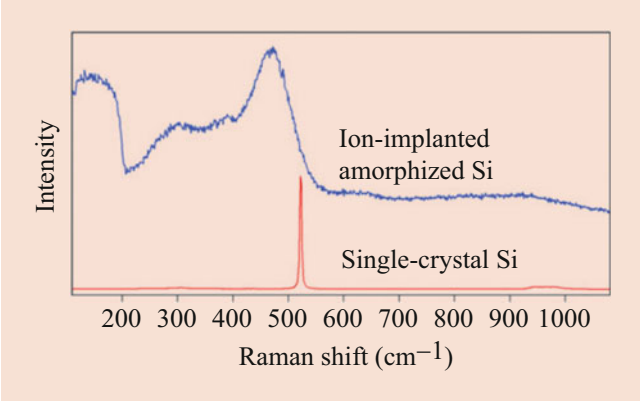

Fig. 4.25 Raman spectrum of ion-implanted amorphized silicon, and of single-crystal silicon

implantation is a commonly adopted technique for silicon doping. Implantation at a high dose of heavier elements than silicon, such as As, produces severe damage and amorphization. The Raman spectrum of single-crystal Si consists of one triply degenerate optical phonon at 520 cm^{-1} along with much weaker second-order transverse acoustic and optical modes that appear at approximately 305 cm^{-1} and 975 cm^{-1} respectively. The selection rules for first-order Raman scattering from crystalline solids dictate that only those optical phonons at the Brillouin zone center are Raman active. Consequently, the first-order Raman band at 520 cm^{-1} is very narrow, with a full width at a half maximum of only 4 cm^{-1}. The Raman spectrum of the As-implanted Si consists of very broad bands below 550 cm^{-1}. The reason for the detection of Raman scattering over this broad region is that the Raman selection rule for crystals restricting Raman scattering to phonons at the Brillouin zone center no longer holds in amorphous Si and all of the phonons from the Brillouin zone center to the edge are now sampled. The Raman spectrum of amorphous Si looks very much like the calculated populations of phonon energy states within the first Brillouin zone of crystalline Si [50].

A peculiar case is represented by phase change materials, such as GeSbTe alloys, recently employed for the manufacturing of phase change memories. As shown in Fig. 4.26 [51], the crystalline phase with rock-salt (FCC) structure, formed upon annealing within the range 125–175 °C, exhibits Raman peaks wider than in the amorphous phase, in contrast to what is usually observed in other materials (see Fig. 4.23 for Si). This is due to the high degree of disorder that characterizes the crystalline structure, in which a Ge, Sb, or a vacancy, randomly occupies the cationic lattice.

Raman with a focused micrometer beam spot can be employed to obtain a spatial image of the distribution of different phases. Figure 4.27a shows an optical image of a resistor of $Ge_2Sb_2Te_5$ with different phases. The Raman spectra taken in

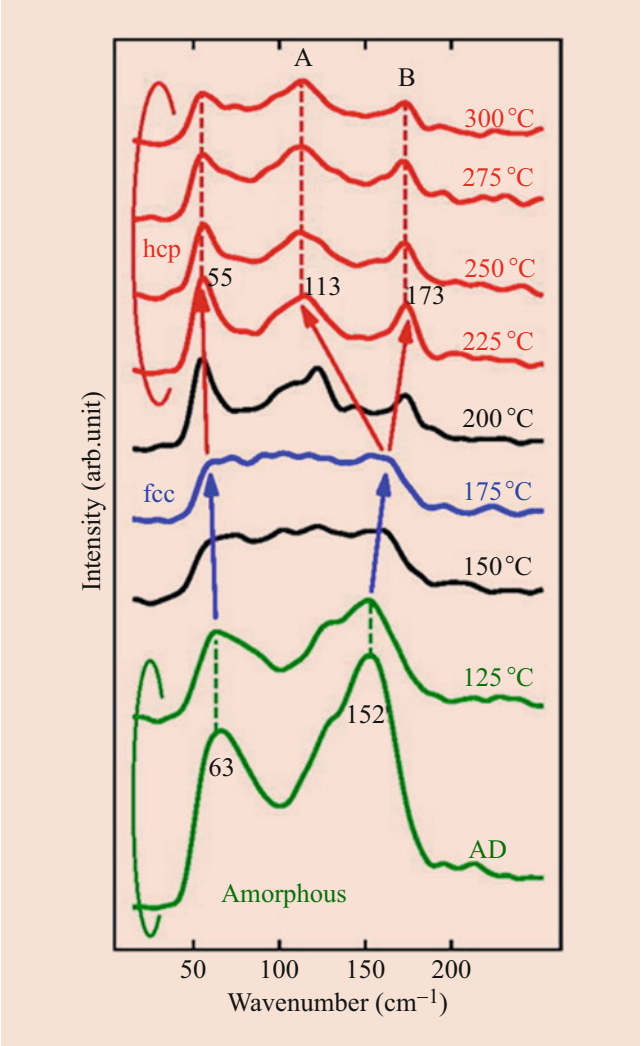

Fig. 4.26 Raman spectra of $Ge_2Sb_2Te_5$ as a function of the annealing temperature, from the amorphous phase to the crystalline structures (face-centered cubic at 175 °C and hexagonal close packing at 250 °C). (Reprinted Guo et al. [51], with the permission of AIP Publishing)

different regions, shown in Fig. 4.27b, indicate the presence of the trigonal stable phase and the amorphous phase. Figure 4.27c, d show the intensity of the integrated Raman shift in the region 100–120 cm^{-1}, corresponding to the trigonal phase, and in the region 140–160 cm^{-1}, characteristic of the amorphous phase respectively. The 2D Raman imaging clear indicates that the amorphous phase is located at the center of the resistor.

4.3.4 Carrier Concentration and Mobility Measurements

Usually, electrical characterization is performed by the Hall effect and resistivity measurements. These procedures need

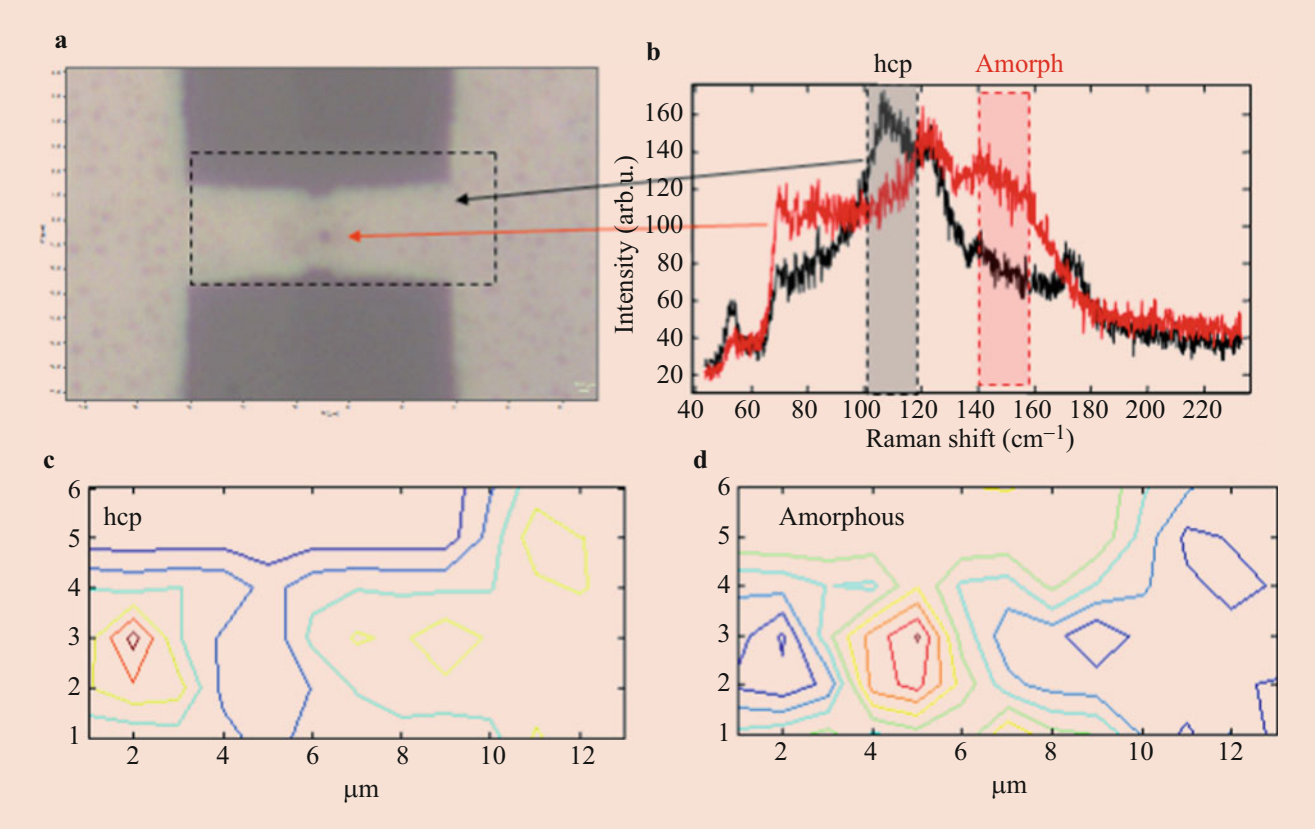

Fig. 4.27 (**a**) Optical image of a resistor with the composition $Ge_2Sb_2Te_5$. (**b**) Raman spectra taken in different regions of the resistor in (**a**), as indicated by the arrows. (**c**) and (**d**) Integral of the Raman signal corresponding to the trigonal phase or to the amorphous phase respectively. (© 2014 IEEE. Reprinted, with permission, from Privitera et al. [52])

electrical contacts and give information on the transport properties averaged over relatively large sample volumes. Local non-invasive probes are of high interest, particularly those that do not need destructive sample preparation, substantially reduce the measurement time, and provide information on very small volumes. Raman spectroscopy is a powerful technique for studying the local transport properties in polar semiconductors such as SiC and GaN [53–55].

A great deal of attention has been devoted to the analysis of LOPC modes in SiC. The Raman frequency of the LOPC mode was used to determine the free electron concentration and its measurement was used as a fast method to study the distribution of the net donor concentration ($N_D - N_A$) over the surface of a wafer [56].

More recent Raman studies, on graded doping 4H-SiC crystals, have shown a linear relationship between the peak frequency of the LOPC mode, ω_{LOPC}, and the free carrier concentration n in the range between 2×10^{17} and 3×10^{18} cm^{-3} [54, 57]. As for 4H-SiC the LOPC band shifts only by 0.8 cm^{-1} for a carrier concentration change of 1×10^{17} cm^{-3} [57] a more careful Raman measurement is needed to precisely determine the carrier density in the range below 10^{17} cm^{-3}.

The relationship between $\Delta\omega$ and n is given by a simple equation in the case of 4H-SiC [57]:

$$N = 1.25 \times 10^{17} \times \Delta\omega. \tag{4.3}$$

The plasmon-damping constant, γ_p, is expressed as a function of the carrier mobility, μ, by the following equation:

$$\gamma_p = e/m^*\mu, \tag{4.4}$$

where m^* is the electron effective mass. Equations (4.3) and (4.4) show that both free carrier concentration, N, and mobility, μ, can be calculated from the ω_p and γ_p data obtained from the fit of the LO peak [58] by taking ω_p and γ_p as the adjustable parameters.

The local information of doping and mobility is extremely interesting in several cases. For example, by analyzing the LOPC modes the electron bulk mobility (μ) of 3C–SiC layers grown on (111) and (100) Si substrates ranges between 10 and 510 cm^2 V^{-1} s^{-1}, whereas the electron carrier concentration (n) varies from 1.6×10^{16} to 5.4×10^{18} cm^{-3} [59]. These measurements indicate that the samples grown on Si (111) have a lower average mobility on a large area with respect to

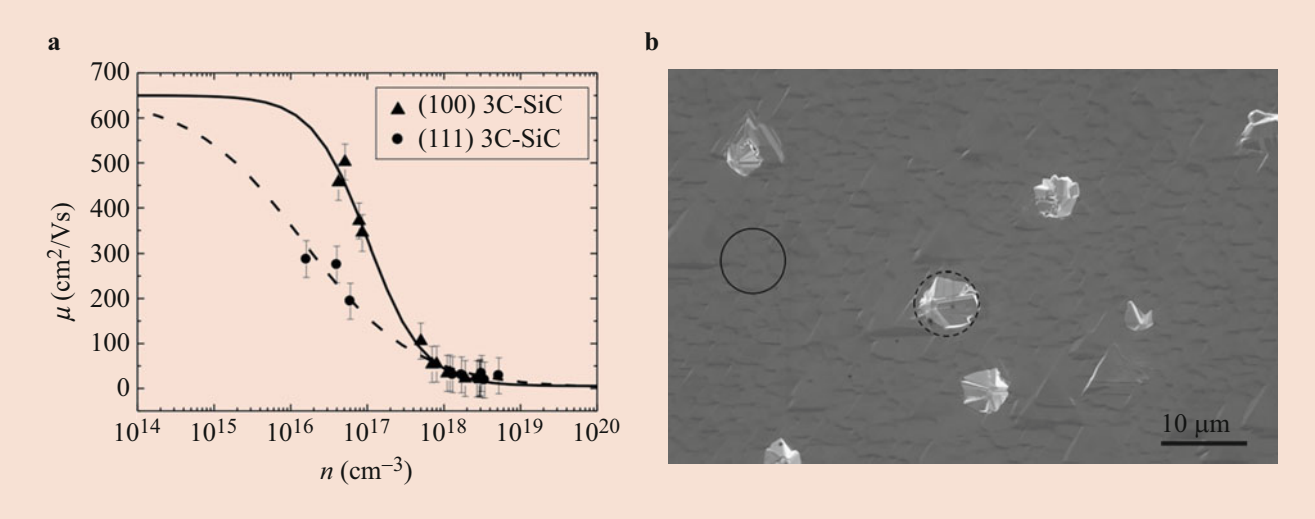

Fig. 4.28 (**a**) Electron mobility as a function of doping concentration in 3C–SiC. Solid triangles and circles represent the mobility values of samples grown on (100) and (111) Si respectively. A dashed line for (111) and a solid line for (100) are curves obtained by fitting the data. (**b**) Scanning electron microscopy image of 3C–SiC film grown on off-axis (111) Si substrate; the hexagonal defects lower the average mobility. (Reproduced from Piluso et al. [59], with the permission of AIP Publishing)

those grown on Si (100), as reported in Fig. 4.28a. The local measurements show clearly that the lower mobility of the (111) 3C-SiC layers is due to the presence of the hexagonal defects (see Fig. 4.28b). Instead, the mobility measured in free defects regions of 3C-SiC (111) is equal to that of the 3C-SiC (100) layers.

As reported in the literature [60], at high optical excitation dense electron-hole plasma forms in many semiconductors (e.g., GaAs and GaP). Under these conditions, the LOPC mode has been detected and measured in undoped GaP crystal [61]. In this context, the excess carriers, induced by laser pumping, are characterized by a carrier lifetime and electrical mobility, which can easily be measured by Raman tools. Crystallographic defects alter these properties so that a systematic study of the local (induced) carrier density variation can be used to detect crystallographic defects [62].

Based on these considerations, a new Raman methodology analysis, called induced-LOPC (i-LOPC), was designed [63]. A laser with a wavelength lower than the material band edge, at different power densities, was used to study the effect of a crystallographic defect, such as SF or point defects, on the carrier density. In the case of SFs in 4H-SiC (laser HeCd at 325 nm, 4H-SiC band-gap at 388 nm), LO Raman mode did not change on or out of the SF when the laser power was 1 mW, a value that is too low to increase the carrier density. Conversely, when the laser power increased to 10 mW, the spectrum on the SF showed a consistent reduction of the Raman shift, suggesting the trapping of free carriers. Such an effect detects the presence of defects through Raman inspection.

Figure 4.29 shows the detection of an SF in a 4H-SiC by using photoluminescence (PL) and i-LOPC techniques. The spatial morphology and the PL spectrum determine the crystal structure of the defect. In particular, the triangular shape together with a PL signal centered at 2.7 eV are related to 4SSF, which is associated with a (4,4) stacking sequence in Zhdanov's notation [64, 65]. The width of the defect along the 11–20 direction indicates that it was formed close to the epilayer–substrate interface (see Fig. 4.29a). The map in Fig. 4.29b was obtained from analysis of the LO Raman mode shift performed across the same region analyzed using the PL method. An evident modulation of the LO Raman shift is observed with the expected triangular shape. An additional LO Raman shift was observed around 4SSF. Such a variation was related to another SF with different energy characteristics (PL peak) and thus not clearly seen using the PL technique (they are seen in Fig. 4.29a merely as darker areas).

Point defects such as interstitial and vacancies act as scattering or recombination centers, reducing the average mobility or lifetime of the carriers in the epitaxial layer [59]. The Raman technique detects with good accuracy these changes of lifetime [63].

In general, the effective electron-hole pair density (n) is controlled by the equilibrium conditions between carrier generation (G) and recombination processes (U); this steady state is expressed by the following expression:

$$U = G = (n - n_0)/\tau, \tag{4.5}$$

where n is the steady-state concentration, n_0 is the initial carrier concentration, τ is the minority carrier lifetime, and G is the carrier generation rate due to the laser exposure

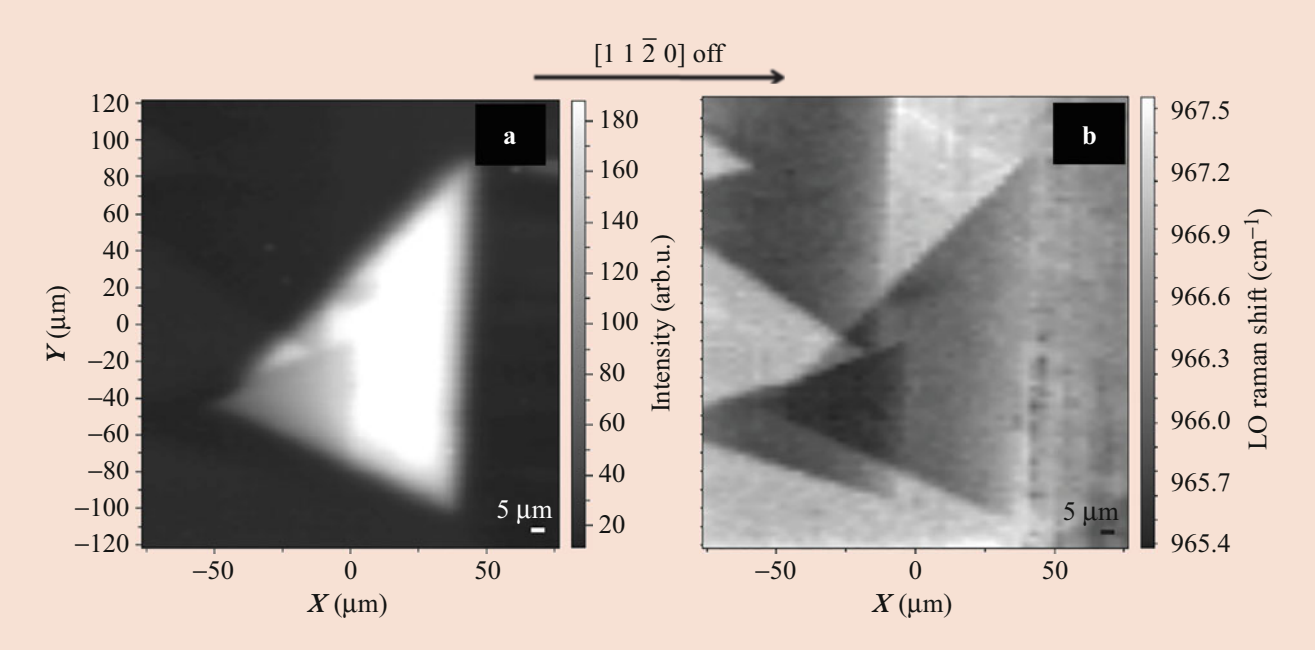

Fig. 4.29 (**a**) Stacking fault (4SSF) observed at 2.7 eV using photoluminescence. (**b**) 4SSF observed at 965 cm^{-1} using the Raman technique. Other defects are also detected. (Reproduced from Piluso et al. [63], with the permission of AIP Publishing)

$$G(x) = \Phi\alpha e^{-\alpha x}, \tag{4.6}$$

where Φ is the laser flux, α the absorption coefficient, and x is the distance within the epitaxial layer at which the carriers are generated. In the case of a highly doped epitaxial layer, low laser densities or low carrier lifetimes, $G\tau \ll n_0$, so that $n - n_0 \sim 0$, and no carrier generation is revealed. Under these conditions, the standard Raman LOPC determines the film doping (n_0). On the other hand, in the case of layers with low doping ($n_0 < 10^{15}$ cm^{-3}) and for high carrier injections ($U > 10^{17}$ cm^{-3} s^{-1}) substantial carrier generation is observed and from Eqs. (4.5) and (4.6) the carrier lifetime can be extracted.

The highest value of the LO Raman shift was observed in the oxidized sample, which has a larger carrier lifetime. An evident conclusion is that decreasing the point defect density increases the electronic free path, determining a longer carrier lifetime than the "as-grown" sample. As an example the data of Fig. 4.30 clearly demonstrate the strong reliability of the Raman method.

In conclusion, these results suggest that micro-Raman spectroscopy, through the i-LOPC method, provides carrier concentration, lifetime, doping, and mobility of 4H-SiC epitaxial films.

4.4 Electrical Parameter Measurements

Resistivity is one of the most important electrical parameters of semiconductors. This section starts with the basic physical relations concerning bulk resistivity. The main electrical measurement techniques are then described: the four-point-probe technique and the van der Pauw technique, together with the main assumptions on which they are based. Special attention is given to the transmission line model (TLM) technique that, besides its typical application to determine the specific contact resistance, can also be used to extract semiconductor resistivity. This technique is widely used on wide band gap (WBG) semiconductors, such as SiC and GaN, where temperature-dependent TLM measurements also enable insight into the ionization energies of the dopant species to be obtained. Detailed examples are reported to illustrate the potentialities of the technique. The remaining part of the section briefly describes the methods of measuring the carrier concentration profile, the mobility, and the carrier lifetime by capacitance-voltage and Hall effect measurements [66].

4.4.1 Four-Point Probe

The DC *electrical resistivity* ρ, expressed in units of [Ω cm], is one of the main parameters of the charge transport in a semiconductor, which is given by the following expression [67]:

$$\rho = \frac{1}{q\left(n\mu_n + p\mu_p\right)}, \tag{4.7}$$

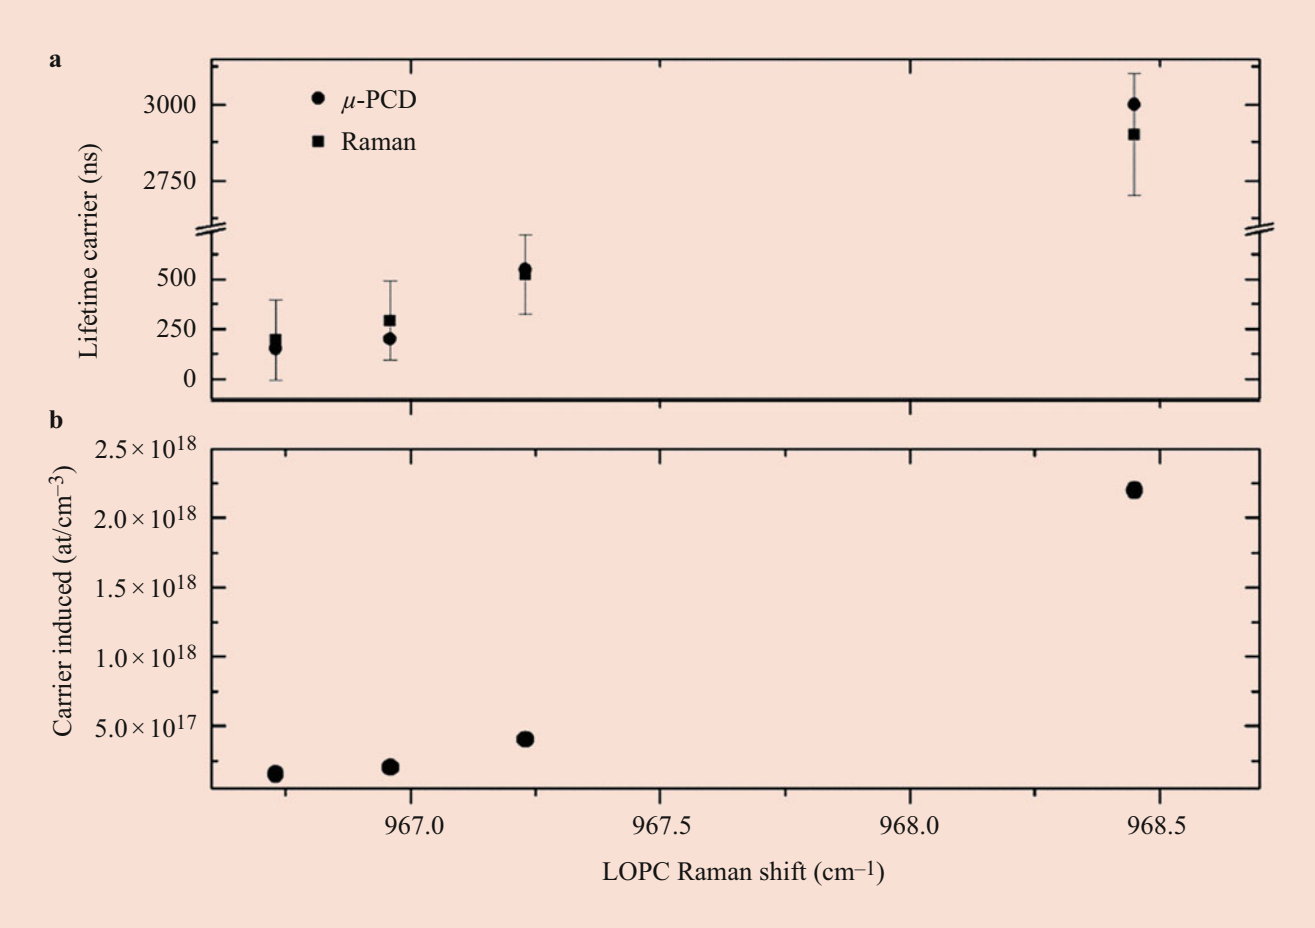

Fig. 4.30 (**a**) Comparison between the evaluation of carrier lifetime (τ) values obtained by μ-PCD and i-LOPC techniques respectively. (**b**) Evaluation of the carrier density (n) induced by laser pumping. (Reproduced from Piluso et al. [63], with the permission of AIP Publishing)

where q is the elementary charge, and n, μ_n, p, and μ_p are, respectively, the electron and hole concentrations and mobilities. It is a relevant parameter for devices and affects many electrical parameters (e.g., barrier height, specific contact resistance, and threshold voltage). The resistivity of a semiconductor can be tailored by the introduction of dopant impurities (e.g., donors or acceptors), either during the crystal growth or in selective regions of the device by ion implantation followed by a thermal treatment. Although in Si the resistivity is usually modified by ion implantation of the dopants, a different situation occurs in other materials, such as in WBG semiconductors. As an example, in SiC, owing to the extremely low diffusion coefficient of the dopants, ion implantation followed by high-temperature annealing (>1600 °C) is the unique method of achieving selective doping of the layer. In gallium nitride (GaN), ion implantation is not well consolidated, owing to the difficulty in avoiding material decomposition at the typical temperatures required for electrical activation (>1000 °C). In this case, selective epitaxial regrowth is preferred.

In a semiconductor in which the majority carrier density is much higher than the minority carrier density, the resistivity is expressed as:

$$\rho = \frac{1}{qn\mu_n} \tag{4.8}$$

for a n-type semiconductor ($n \gg p$) and as

$$\rho = \frac{1}{qp\mu_p} \tag{4.9}$$

for a p-type semiconductor ($p \gg n$).

From the above relationships, the carrier density and mobility must be known to determine the semiconductor resistivity. Otherwise, direct measurement techniques must be adopted, often requiring the fabrication of appropriate test patterns. Usually, the measurements are performed by forcing a known electrical current and by measuring the resulting voltage drop. One major issue for such measurement is to render negligible the contact resistance. This is achieved

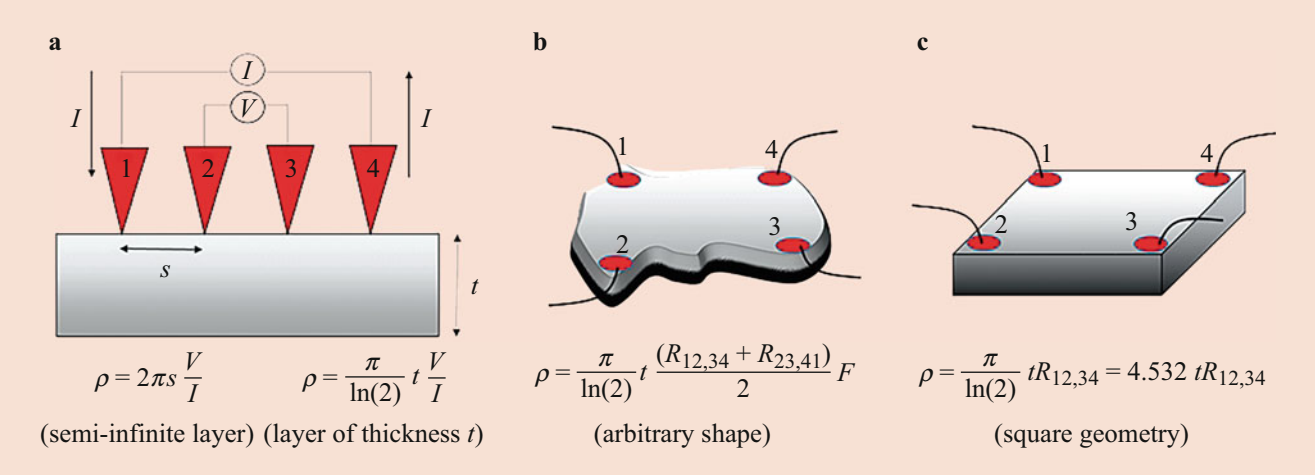

Fig. 4.31 Schematic of (**a**) the collinear four-point probe measurement to determine the semiconductor resistivity, (**b**) an arbitrary shaped sample, and (**c**) a typical square geometry used for Van der Pauw measurements

by using the Kelvin configuration with four contacts, with two separate contacts to force the current I and the other two to sense the voltage drop V. Moreover, for the voltage drop measurement it is necessary to use electrometers with a high input impedance much larger than the sample resistance. Various configurations can be used, among which the most common is the *collinear four-point probe configuration* [68], with all tips placed in line at a distance s, as illustrated in Fig. 4.31a. The two external tips force the current I, whereas the two internal tips sense the voltage drop V. The sample has to be planar and schematized either with infinite or infinitesimal thickness, t, depending on whether $s \gg t$ or vice versa $s \ll t$. For the two cases, the resistivity ρ results are as follows:

$$\rho = 2\pi s \frac{V}{I} \tag{4.10}$$

or

$$\rho = \frac{\pi}{\ln(2)} t \frac{V}{I} \tag{4.11}$$

respectively.

Thin semiconductor layers are often described by the so-called *sheet resistance* R_{SH}, expressed in units of [Ω/sq], which for uniformly doped semiconductors is defined as:

$$R_{SH} = \frac{\rho}{t} = \frac{\pi}{\ln(2)} \frac{V}{I} = 4.532 \frac{V}{I}. \tag{4.12}$$

This important parameter is a measure of the resistivity ρ averaged over the sample thickness t. In specific cases, R_{SH} is more representative than the resistivity. As an example, in AlGaN/GaN heterostructures, the presence of a two-dimensional electron gas (2DEG) [69] at the interface practically limits the current conduction in a sheet of material. In this case, the value of R_{SH} is a measure of the quality of the 2DEG.

If the sample to be characterized consists of a semiconducting layer on a semiconductor substrate (as in the case of epitaxial layers used for device fabrication), the uppermost layer to be measured must be electrically isolated from the substrate. This condition is satisfied when the layers have opposite conductivity (i.e., an n-type layer onto a p-type substrate or vice-versa), and the space charge region formed at the electrical junction guarantees the confinement of the current in the layer under investigation.

Such geometry requires the overall sample size to be infinite, that is, much larger than s, and the tips far from the sample edges. If this is not the case, numerical corrections to take into account the finite sample size are applied [68].

The collinear four-point probe method, however, is not always applicable. *Van der Pauw* developed the theoretical formulation for resistivity measurements on arbitrarily shaped samples [70]. The following assumptions were considered: (i) the contacts are very small with respect to the sample size; (ii) the contacts are located at the periphery of the sample; (iii) the thickness of the semiconductor layer is uniform; (iv) the surface is singly connected with respect to the current flows, i.e., it does not contain holes.

In this case, considering a semiconductor sample of an arbitrary shape, with contacts (1,2,3,4) located along the periphery (Fig. 4.31b), the resistances can be measured using current voltage measurements between different probes (e.g., $R_{12,34} = V_{34}/I_{12}$ or $R_{23,41} = V_{41}/I_{23}$). The resistivity ρ is given by:

$$\rho = \frac{\pi}{\ln(2)} t \frac{(R_{12,34} + R_{23,41})}{2} F, \tag{4.13}$$

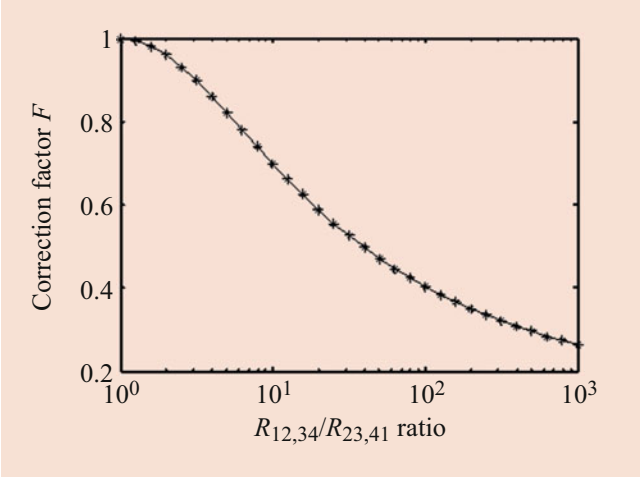

Fig. 4.32 Van der Pauw correction factor F as a function of R_r

where F is a function of the ratio $R_r = R_{12,34}/R_{23,41}$ implicitly given in Eq. 4.14 and plotted in Fig. 4.32:

$$\frac{R_r - 1}{R_r + 1} = \frac{F}{\ln(2)} \operatorname{arcosh}\left(\frac{\exp\left[\ln(2)/F\right]}{2}\right). \tag{4.14}$$

In general, for the characterization of semiconductor layers, symmetrical shape samples are used, e.g., with a regular square geometry such as that illustrated in Fig. 4.31c. As can be seen in Fig. 4.32, for this symmetric geometry $R_r = 1$ and $F = 1$ (more details can be found in Schroder [68]). Then, the expression of the resistivity ρ and of the sheet resistance R_{SH} becomes simpler and formally similar to the four-point probe method, i.e.:

$$\rho = \frac{\pi}{\ln(2)} t R_{12,34} = 4.532\, t R_{12,34}, \tag{4.15}$$

$$R_{SH} = \frac{\pi}{\ln(2)} R_{12.34} = 4.532\, R_{12,34}. \tag{4.16}$$

Other geometries used for determining the semiconductor sheet resistance by Van der Paw measurements are circular, Greek cross, cross bridge structures, etc. [68].

In performing resistivity measurements, a number of precautions have to be taken, the most common of which are the following: (i) the sample is placed on an insulating substrate, which does not contribute significantly to the charge conduction; (ii) the sample temperature is fixed and constant, thus requiring good thermal contact with a substrate of large thermal capacitance; (iii) the current source has to provide low power to the sample, in order to reduce sample heating; (iv) the current level has to be low in order to avoid high injection effects, i.e., injection of carrier densities from the forcing contacts in excess of the specimen carrier concentration.

Alternative approaches to resistivity measurement are contactless, generally applied to semiconductor wafers. The concept is to stimulate eddy currents in the sample under test and to measure the quality factor loss of the LC cavity through an inductively coupled secondary circuit. Such measurements require the additional evaluation of the wafer thickness, which can be done either by ultrasound-based techniques or by capacitive techniques. Contactless eddy current measurements are commonly used to determine the sheet resistance in AlGaN/GaN heterostructures grown onto insulating substrates and to obtain a wafer mapping of the homogeneity of the two-dimensional electron gas.

Although in Si the collinear four-point probe method is a suitable technique for determining the resistivity, in other materials such as SiC and GaN this technique cannot be used. In fact, owing to their wide band gap, it is not easy to make a good ohmic contact between the tip and the semiconductor [71, 72]. Hence, lithographically defined alloyed ohmic contacts must be formed at the sample periphery in Van der Paw structures in SiC and GaN.

4.4.2 Transmission Line Model

Alternative routes to the Van Paw method are adopted for these wide band gap semiconductors. The *transmission line model* (TLM) [73–75] is the method of choice for the determination of the specific contact resistance ρ_c (expressed in units of Ωcm^2) of ohmic contacts. Indeed, all the textbooks focus on the determination of ρ_c by the TLM method. However, in addition to the measurement of the specific contact resistance, the TLM structures enable the semiconductor sheet resistance to be extracted. Therefore, the method is particularly useful in WBG semiconductors, where the collinear four-point probe method cannot be easily applied.

The test structures for the TLM measurements consist of an array of identical metallic pads of length L and width W, at different distances d on a semiconductor surface, as schematically illustrated in Fig. 4.33a. The semiconductor is typically laterally isolated by a mesa etch, forming a resistor of width $W + 2\delta$.

When a current I is injected between two adjacent pads, the potential distribution under a contact in a certain position x will depend on the specific contact resistance ρ_c and on the semiconductor sheet resistance R_{SH}:

$$V(x) = \frac{I\sqrt{R_{SH}\rho_c}}{W} \frac{\cosh\left[(L - x)/L_T\right]}{\sinh\left(L/L_T\right)}, \tag{4.17}$$

where L_T is the so-called *transfer length*, defined as the distance at which the voltage drops to $1/e$ of its maximum value:

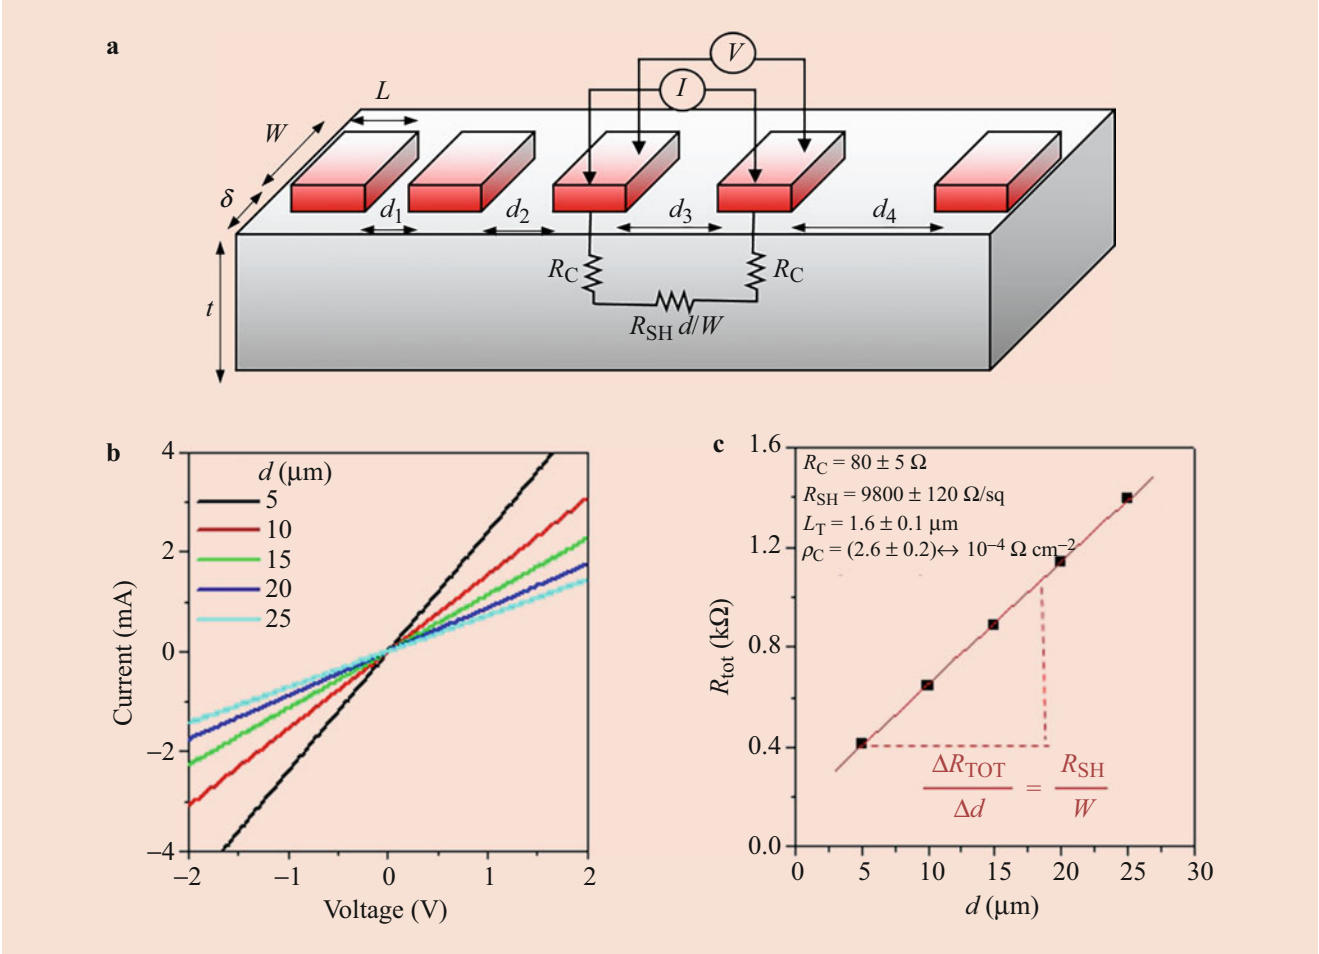

Fig. 4.33 (**a**) Schematic of a transmission line model (TLM) structure to illustrate the operation principle of the technique. (**b**) Example of I-V measurements acquired on adjacent TLM pads placed at different distances *d*. (**c**) Linear plot of the total resistance R_{TOT} as a function of the contacts distance *d*. The experimental data refer to TLM structures fabricated on a p-type implanted 4H-SiC layer (of thickness $t = 300$ nm), using Ti/Al/Ni thin film as ohmic contacts

$$L_T = \sqrt{\rho_c / R_{SH}}. \tag{4.18}$$

Assuming that $\delta \ll W$, the total resistance R_{TOT} between two adjacent pads at a distance *d* depends on both the contact resistance R_C and on the semiconductor sheet resistance R_{SH}:

$$R_{TOT} = 2R_C + \left(\frac{R_{SH}}{W}\right) d. \tag{4.19}$$

By performing current-voltage (I-V) measurements between adjacent pads, the total resistance R_{TOT} can be determined at various pad distances *d*. Then, from a linear fit of R_{TOT} values as a function of *d*, the intercepts with the *y*-axis ($2R_c$) and with the *x*-axis ($2L_T$) can be determined. Figures 4.33a, b show an example of I-V measurements and R_{TOT} vs *d* plot, carried out on TLM structures fabricated on p-type implanted 4H-SiC. From the slope of the linear plot R_{TOT} vs *d* plot in Fig. 4.33c a sheet resistance of 9800 Ω/sq is obtained. The resistivity of the 4H-SiC layer is given by $\rho = R_{SH}\, t = 0.29$ Ωcm [76].

For alloyed contacts, the *semiconductor sheet resistance under the contact* (R_{SK}) can be different from its bulk value R_{SH} measured outside the contacts (see Fig. 4.34a). Hence, the correct value of the transfer length L_T cannot be simply extracted by the *x*-axis intercept of the R_{TOT} vs *d* plot; it must be obtained by an additional measurement of *end-contact resistance* [74, 75]. The end contact resistance R_E can be seen as the resistance due to the voltage drop at the end of the contact length. The standard procedure to determine this parameter is to force a constant current (*I*) between two adjacent TLM pads and to measure the potential (*V*) between one of these pads and an opposite outside TLM pad (Fig. 4.34b) [75]. Contact resistance R_C and end contact resistance R_E are related by:

$$\frac{R_C}{R_E} = \cosh\left(\frac{L}{L_{TK}}\right) \tag{4.20}$$

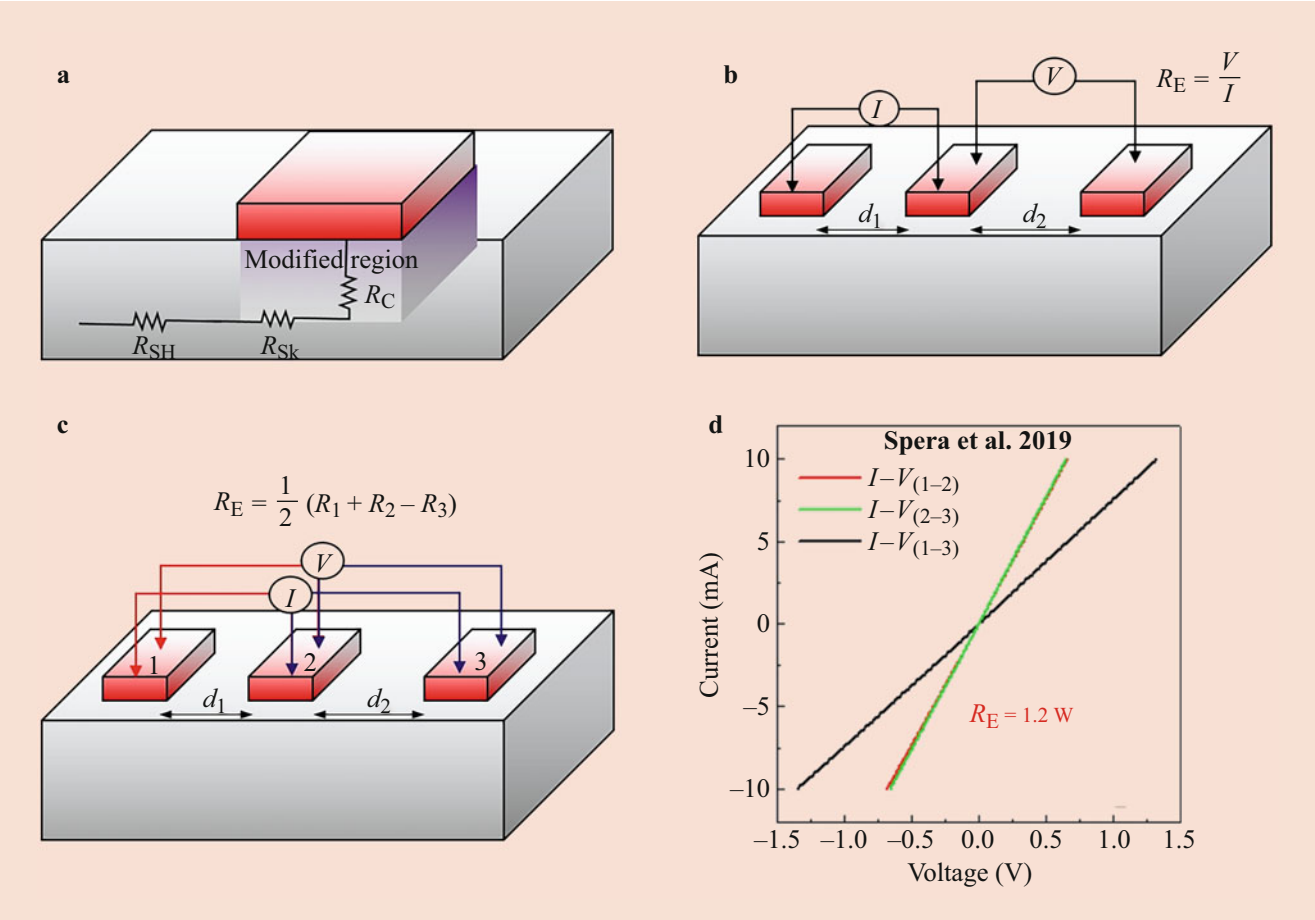

Fig. 4.34 (**a**) Schematic representation of the modification of the sheet resistance of a semiconductor material under the contact. (**b**) Conventional method of determining the end contact resistance. (**c**) Alternative three terminals procedure proposed in Reeves and Harrison [75]. (**d**) Application of the three terminals method for the determination of R_E in alloyed Ti/Al/Ni/Au ohmic contacts to AlGaN/GaN heterostructures. (Figure (**d**) is adapted with permission from Spera et al. [77], Copyright © 2017, Elsevier Ltd)

Hence, from a measurement of the R_E it is possible to extract the corrected transfer length L_{TK}, i.e., the transfer length in the case that $R_{SH} \neq R_{SK}$. Finally, the sheet resistance under the contact R_{SK} becomes:

$$R_{SK} = \frac{R_{SH} L_T}{L_K}. \tag{4.21}$$

However, measuring the end contact resistance from the voltage drop at the end of the contact is extremely difficult, owing to the very low values of the voltage drop. An equivalent procedure [75] to determine R_E from I-V measurements on a "three terminals test-pattern", is schematically shown in Fig. 4.34c. The measured resistances between the adjacent contacts 1–2 and 2–3 (R_1 and R_2) placed at a distance d, and between the two external ones 1–3 (R_3), give R_E by the relation:

$$R_E = \frac{1}{2}(R_1 + R_2 - R_3). \tag{4.22}$$

As an example, Fig. 4.34d shows the I-V characteristics acquired in the three terminals test-pattern to determine the end contact resistance R_E on alloyed Ti/Al/Ni/Au ohmic contacts to AlGaN/GaN heterostructures [77].

In most of the cases, the metal stacks for the ohmic contacts are subjected to thermal annealing, which can lead to reactions with the substrate and formation of new phases. Under these conditions, the sheet resistance of the semiconductor under the contact R_{SK} is modified with respect to its value outside the contact pad. Its knowledge is a useful input parameter for device technology computer-aided design (TCAD) simulation and a valuable insight into the physical effect of the alloying/sintering process of ohmic contacts. However, these kinds of measurements are not widely discussed in the literature.

Table 4.1 reports a survey of literature data extracted by TLM measurements on different semiconductor materials. As can be seen, a reduction of the sheet resistance under alloyed contacts is typically revealed by the end contact resistance measurements on TLM structures.

Table 4.1 Survey of literature data of sheet resistance R_{SH} and sheet resistance under the contact R_{SK} obtained by transmission line model measurements on different n-type semiconductors. The annealing temperatures and the adopted processes for ohmic contact formation are also reported

Semiconductor	Contact process	R_{SH} (Ω/sq)	R_{SK} (Ω/sq)	Reference
Si	Al; sintered	2100	430	[75]
GaAs	Ni/Ge/Au; alloyed	430	22	[75]

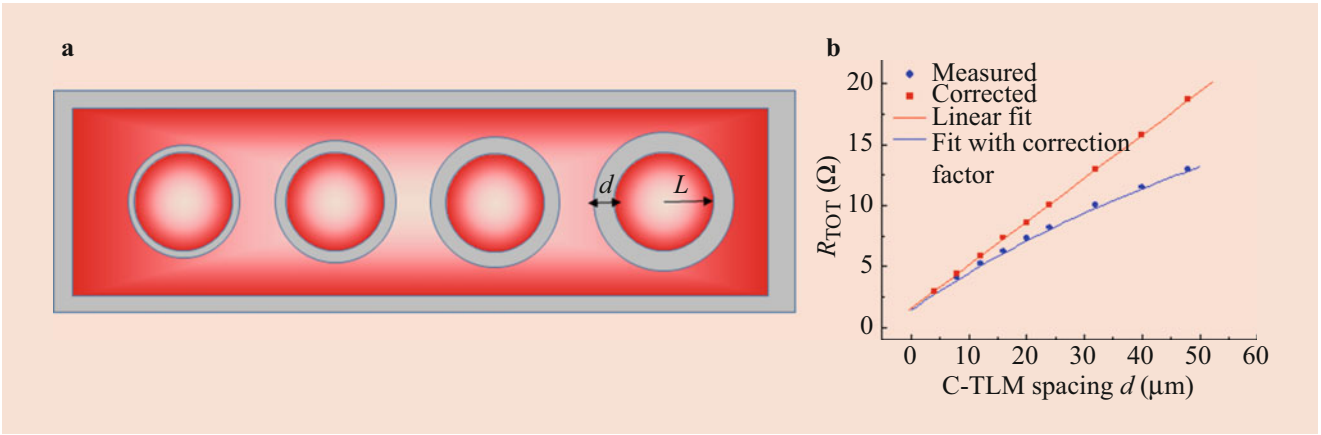

Fig. 4.35 (**a**) Schematic of a circular transmission line model (C-TLM) structure. (**b**) Example of total resistance R_{TOT} versus pad spacing d plot in C-TLM before and after the application of the correction factor

The TLM method is based on the assumption of identical contact pad and diffusion layer widths. However, in real cases the contact width W is smaller than the TLM resistor, thus causing lateral current crowding effects that reduce the accuracy of the analysis. In fact, lateral current crowding decreases the measured value of the total resistance R_{TOT}, owing to the presence of outer conductive paths, acting as a parallel conductance. Hence, the simple one-dimensional TLM analysis leads to a lower slope (i.e., a lower extracted R_{SH}) in the plot of Fig. 4.34c. To take into account these parasitic effects, correction factors are introduced or evaluated by complex two-dimensional models [82–84]. Practically, lateral current crowding effects can be avoided using the *circular transmission line model* (C-TLM) [68, 85, 86]. The C-TLM pattern is a sequence of symmetrical structures consisting of circles of radius L and annuli of varying width d, as schematically shown in Fig. 4.35a. By applying a bias between the external and the internal contact, the current will flow in the radial direction.

The analytical description of the C-TLM is rather complex. However, for large structures, $L \gg d$, the total resistance R_{TOT} measured between two adjacent contacts simplifies to [68, 86, 87]:

$$R_{TOT} = \frac{R_{SH}}{2\pi L}(2L_T + Cd) \tag{4.23}$$

where $C = \frac{L}{d}\ln\left(1 + \frac{d}{L}\right)$ is a correction factor.

Then, for $d/L \ll 1$, R_{TOT} assumes the following linear expression with the pad spacing d:

$$R_{TOT} = L_T\frac{R_{SH}}{\pi L} + \frac{R_{SH}}{2\pi L}d \tag{4.24}$$

Also in this case, from a linear fit of the R_{TOT} vs d plot, it is possible to extract the semiconductor sheet resistance R_{SH} and, hence, its resistivity $\rho = R_{SH}\, t$. An example of C-TLM measurement before and after the application of the correction factor is reported in Fig. 4.35b.

The fabrication of C-TLM test structures is easier than the linear TLM structure. In fact, in the C-TLM structures only one lithography mask level is required and no dry etching processes are needed to define the diffusion layer, contrary to the linear TLM patterns [71]. However, in the C-TLM extremely low metal sheet resistance is required to obtain measurement with good accuracy [87].

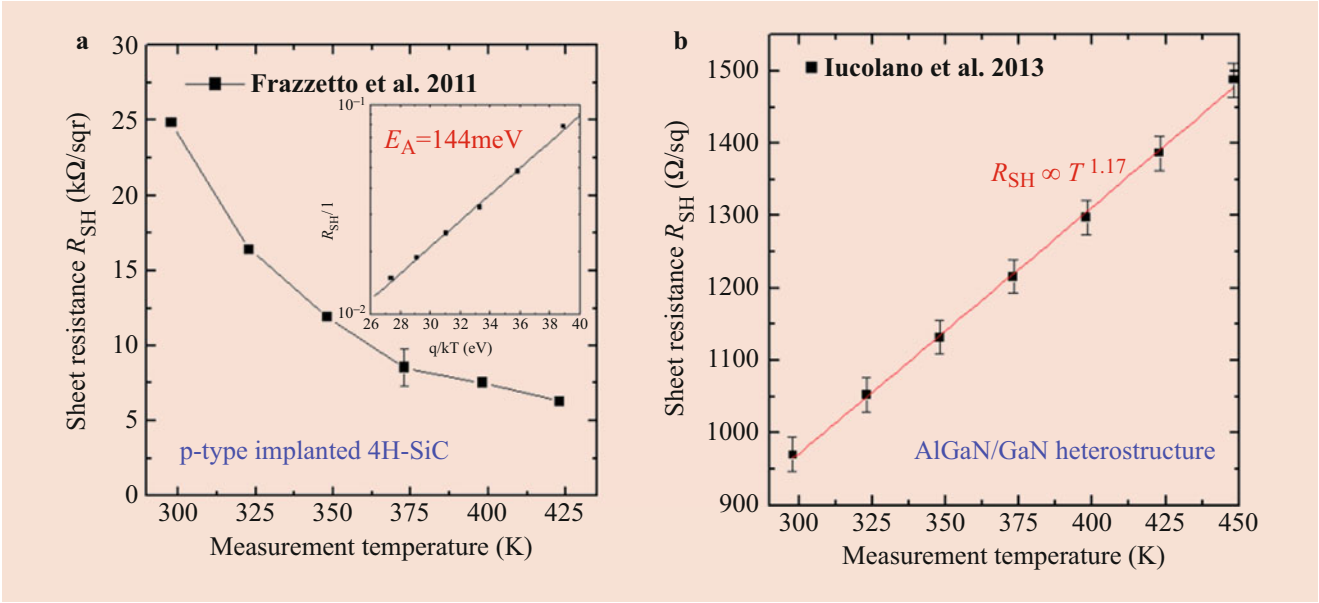

Fig. 4.36 Example of temperature dependence of the semiconductor sheet resistance measured using TLM structure for (**a**) a p-type doped 4H-SiC layer (reproduced with permission from Frazzetto et al. [88] Copyright © 2011, IOP Publishing) and (**b**) an AlGaN/GaN heterostructure. (Reproduced with permission from Iucolano et al. [90], copyright © 2013, AIP Publishing)

Temperature-dependent measurements on TLM structures provide additional insights into important parameters, such as the ionization energy of the dopant species and physical mechanism in semiconductors. The decrease in the semiconductor resistivity with increasing temperature is related to the increase in the ionized dopant concentration. This aspect is particularly important in SiC, where the wide band gap and the high ionization energy of the dopant (especially in p-type doped material) implies that only a small fraction of the donors or acceptors might be ionized at room temperature. In this case, the temperature dependence of the sheet resistance is mainly ruled by the exponential dependence of the active dopant concentration on the ionization energy E_A, i.e., $R_{SH} \propto \frac{1}{\exp(-E_A/kT)}$ [67, 68].

Figure 4.36a reports as an example the temperature dependence of the sheet resistance R_{SH} of a p-type implanted 4H-SiC layer [88]. An Arrhenius plot of the sheet resistance (see inset) gives the value of the ionization energy of the acceptors (aluminum): $E_A = 144$ meV. Recently, this method has been successfully applied to p-type implanted 4H-SiC layers subjected to different post-implantation conditions, demonstrating the dependence of the ionization energy on the acceptor concentration [76, 89].

In other systems, such as AlGaN/GaN heterostructures, the presence of a 2DEG induces "metal-like behavior" of the resistivity. In this case, as shown in Fig. 4.36b, the sheet resistance R_{SH} measured on TLM structures increases with increasing temperature, following a power law $T + \beta$ (with $\beta = 1.17$) [90].

4.4.3 Carrier Concentration Profile

The determination of the electrically active dopant distribution within semiconductor materials is a key requirement for the fabrication of electronic devices.

Secondary ions mass spectrometry (SIMS) is the most commonly employed technique for 1D dopant concentration profiling in semiconductors, owing to its excellent sensitivity, good quantification properties, high depth resolution, and ease of application [91–93]. For routine applications, SIMS measurements are carried out on blanket samples on a rather large analysis area (from ~20 × 20 to 200 × 200 μm^2), in order to collect a large number of secondary ions (10^8–10^9 for an average profile) with excellent signal/noise ratio and statistical relevance. This method has been widely employed to study dopant incorporation and diffusion in silicon technology, as well as in compound semiconductors.

On the other hand, the depth distribution of the electrically active dopants can be determined by several electrical profiling methods, including capacitance-voltage (C-V) measurements, differential Hall effect (DHE) measurements [94], and the spreading resistance probe (SRP) [95].

The C-V profiling method relies on a Schottky or metal-semiconductor junction, and information on the depth distribution of the majority carrier concentration, i.e., the active dopants ($N_D - N_A$) in the semiconductor is achieved by progressively increasing the junction reverse bias, i.e., the width of the depletion region. In fact, if $W(V)$ is the depletion

layer thickness of the junction under a reverse bias V and Q_s is the semiconductor charge, then

$$Q_s = qA \int_0^W N \mathrm{d}x \tag{4.25}$$

where N is the net doping density, in equilibrium equal to the net carrier density, and A the junction area. The differential capacitance C is given by:

$$C = -\mathrm{d}Q_s/\mathrm{d}V \tag{4.26}$$

and

$$C = k\varepsilon_0 A/W, \tag{4.27}$$

where ε_0 is the vacuum dielectric constant and k the low frequency relative dielectric constant. It follows that:

$$N = -\frac{C^3}{qk\varepsilon_0 A^2 \mathrm{d}C/\mathrm{dV}}. \tag{4.28}$$

The $N(W)$ function is obtained by using Eqs. (4.27) and (4.28) and the C-V curve data in reverse bias. Note that Eq. (4.28) has a strong dependence on the area, so A has to be known with good accuracy for an accurate N profiling. The metal-semiconductor C-V technique for carrier profiling can be performed by depositing a metal structure on the planar semiconductor or by using an Hg probe. The latter in principle does not require sample preparation for the metal–semiconductor junction geometry formation, but in any case, much care has to be taken in order to verify that the contact to the semiconductor is ohmic or of a very large area, in order to provide a negligible contribution to the measured capacitance. Clearly, because of this working principle, this approach can work only for relatively low-doping concentrations ($N_D - N_A$ up to 10^{17}–10^{18} cm^{-3}).

A very similar approach can be used in metal–oxide–semiconductor (MOS) junction structures, although in such cases Eq. (4.27) should be modified to take into account the oxide capacitance in series with the semiconductor capacitance C, still given by Eq. (4.27). Moreover, the MOS junction should be driven into deep depletion, the reverse bias ramp has to be quickly compared with the time required for the MOS inversion layer build-up. This time T is given by:

$$T = 10\, N/n_i \tau_g, \tag{4.29}$$

where n_i is the intrinsic carrier concentration and τ_g the generation lifetime. Note that T is much larger than the carrier lifetime, depending on the ratio of the active doping concentration and the intrinsic carrier concentration. The MOS C-V technique for carrier profiling can be also extended to the case of an air gap rather than a complete MOS junction. Such an approach is therefore a contactless carrier profiling technique, and it only requires special probes to realize a metal–air–semiconductor junction and proper semiconductor surface preparation.

Another technique for the carrier concentration measurement is the Hall effect technique. The Hall coefficient is experimentally determined by the ratio

$$R_H = \frac{tV_H}{BI}, \tag{4.30}$$

where t is the sample thickness, V_H the Hall transverse voltage, B the magnetic field, and I the forced current. In Hall geometry, for hole conduction, the magnetic field, the current density, and the Hall field are oriented according to the right-hand rule. For electron conduction, the Hall coefficient has the opposite direction. Therefore, the Hall effect allows a distinction to be made between hole or electron conduction in a semiconductor or a metal. In general, it can be demonstrated that the Hall coefficient, in the approximation of an energy-independent scattering time, is given by:

$$R_H = \frac{\left(p - b^2 n\right) + \left(\mu_n B\right)^2 (p - n)}{q\left[\left(p - b^2 n\right)^2 + (\mu_n B)^2 (p - n)^2\right]}, \tag{4.31}$$

where b is the ratio μ_n/μ_p. The low field limit is when $B \ll 1/\mu_n$ for an p-type material, or when $B \ll 1/\mu_p$ for an n-type material. This means $B \ll 10T$ for a mobility of 1000 cm^2/Vs and $B \ll 0.1T$ for a high mobility material with μ of 1×10^5 cm^2/Vs. Generally, for semiconductors such as Si with $b < 10$ and μ_n 1000 cm^2/Vs or less, and with B of $1T$ or less, the Hall coefficient simplifies into $R_H = 1/q(p - n)$. In fact, by taking into account an energy-dependent scattering time, one finds that for an n-type material:

$$R_H = -r/qn \tag{4.32}$$

and for a p-type:

$$R_H = +r/qp, \tag{4.33}$$

where $r = <\tau^2>/<\tau>^2$ is the scattering factor. r depends on the scattering mechanism: $r = 1.18$ for phonon scattering; $r = 1.93$ for charged impurity scattering; $r = 1$ for neutral impurity scattering. In general, $r \to 1$ for $B \to \infty$. r can then be directly measured as the ratio $R_H(B)/R_H(\infty)$. In other semiconductor materials, the lack of experimental data and models often leads to the assumption that the Hall scattering factor is equal to one. However, this can lead to an overestimation of the carrier density. In the case of p-type 4H-SiC, the Hall scattering factor has been determined by correcting

the experimental carrier density determined by Hall measurements, with the doping and compensation levels extracted by independent *C-V* and SIMS measurements [96, 97].

The Hall effect, thanks to its experimental simplicity, is heavily used in semiconductor characterization for carrier density measurements, especially for the measurement of the carrier concentration as a function of temperature. This is particularly useful for identifying the temperatures of the intrinsic regime at a high temperature and for the carrier freeze-out regime at a low temperature. The DHE profiling relies on the combination of conventional Hall effect measurements with iterative chemical etching of the semiconductor surface, with the depth resolution defined by the etch rate. Both the *C-V* and DHE approaches have the advantage of being absolute methods, as they do not require calibration samples.

Finally, the SRP approach is based on resistance measurements carried out by two aligned probes moved on the beveled surface of the semiconductor sample, thus allowing depth resolved information. The SRP has been employed as a 1D carrier profiling method in silicon technology, owing to its wide dynamic range (from 10^{15} to 10^{20} cm^{-3} both for n- and for p-type doping). The quantification of the carrier concentration from the measured resistance profiles requires the minimization of the tip contact resistance contribution (achieved by applying a high pressure with the metal (tungsten) tips to Si) and the knowledge of the mobility dependence on the doping. Furthermore, an optimized preparation protocol of the beveled surface is required to minimize the effects of surface damage. In practice, quantitative carrier profiling by SRP relies on the use of proper n- and p-type calibration samples, consisting of CVD-grown multilayers with different independently measured doping concentrations.

The above-discussed electrical profiling techniques were developed and widely employed in silicon technology. On the other hand, extending their application to other semiconductors required proper optimization or the adoption of specific calibration samples, and, in some cases, it proved unsuccessful. As an example, SRP profiling in the case of SiC is prevented by the high contact resistance of the probes on this wide-band-gap semiconductor, as well as by SiC hardness, causing rapid degradation of the probes.

4.4.4 Mobility

From the measurement of the resistivity and the Hall coefficient in a material, given the relationship between ρ, μ, and R_H (see Eqs. (4.7), (4.31), and (4.32) or (4.33), one can deduce the carrier mobility. The Hall mobility is defined as the ratio:

$$\mu_H = R_H/\rho. \tag{4.34}$$

Therefore, μ_n (or μ_p) can be determined as the ratio μ_H/r.

Various sample geometries can be used, and one of the most frequently adopted is the Van der Pauw geometry, shown in Fig. 4.31b, with the magnetic field oriented orthogonal to the figure plane. It can be shown that μ_H is given by

$$\mu_H = \frac{t\Delta R_{24,13}}{B\rho}, \tag{4.35}$$

where $\Delta R_{24,13}$ is the difference of the resistance $R_{24,13}$ measured with and without the application of the magnetic field B. The carrier mobility can be measured by many other techniques, but these generally require transistor device structures such as MOSFETs, junction-gate field-effect transistors, metal–semiconductor field-effect transistors, high-electron-mobility transistor, etc. In this case, the effective mobility or the field effect mobility is determined from the device conductance or transconductance [68]. The extraction of these parameters is treated in other chapters of this book.

4.4.5 Carrier Lifetime

Carrier lifetimes in a semiconductor are related to the carrier generation and recombination processes. When these are bulk processes, the lifetimes are represented by characteristic recombination and generation lifetimes, τ_r and τ_g respectively. When such processes take place at surfaces or at interfaces, then the characteristic figures are surface recombination and generation velocities, s_r and s_g, which have the dimension of a velocity. Three processes rule the recombination: Auger (τ_{Aug}), Shockley–Read–Hall (SRH, τ_{SRH}), and radiative (τ_{rad}), and the overall τ_r is given by:

$$1/\tau_r = 1/\tau_{Aug} + 1/\tau_{SRH} + 1/\tau_{rad}. \tag{4.36}$$

An analogous relationship is valid for $1/\tau_g$, where instead of $1/\tau_{Aug}$, one has to consider the effect specular to the Auger, that is, the impact ionization, whereas for $1/\tau_{SRH}$ one has to consider the SRH generation processes. For the τ_r measurement, a number of techniques are available. Two techniques of great interest and of common use are transient photoconductance decay (PCD) and the quasi steady-state photoconductance (QSSPC) method. Both techniques are based on the measurement of the transient of the photoconductance during or after the application of an illumination stimulus. In general, in a p-type semiconductor the excess minority carrier Δn under uniform illumination is ruled by the continuity equation:

$$\frac{\partial \Delta n}{\partial t} = G - R = G - \frac{\Delta n(t)}{\tau_{eff}}. \tag{4.37}$$

In transient photoconductance decay, a light pulse with a sharp decay is applied. After the pulse $G \ll \mathrm{d}\Delta n/\mathrm{d}t$, and therefore

$$\tau_{\mathrm{eff}}(\Delta n) = -\frac{\Delta n(t)}{\mathrm{d}\Delta n(t)/\mathrm{d}t}. \tag{4.38}$$

In the quasi steady-state photoconductance method, on the contrary, a slowly varying light stimulus is applied. Then, $G \gg \mathrm{d}\Delta n/\mathrm{d}t$, and therefore:

$$\tau_{\mathrm{eff}}(\Delta n) = \frac{\Delta n(t)}{G}. \tag{4.39}$$

τ_{eff} is not directly the bulk lifetime τ_{r}, but rather a combination of τ_r and s_{r}, also dependent on the minority carrier diffusivity D and the sample thickness (see Schroder [68] for details). PCD can be affected by a contactless time-resolved measurement of the photoconductance, from which Δn is evaluated. This is done through an RF bridge or a microwave reflectivity measurement. For the QSSPC one needs to measure Δn, evaluated from the photoconductance, and G, evaluated from a calibrated photodiode.

A widely employed technique to determine the nature and concentration of defects responsible for SRH generation in semiconductors is deep-level transient spectroscopy (DLTS). The most typical DLTS technique measures capacitance transients in metal–semiconductor junctions. The concept is the following: a voltage pulse first forward biases the junction. During this phase, the defects in the semiconductor quasi-neutral region are filled with majority carriers. Then a sudden reverse bias step pulse at a constant voltage V is applied. Under such a condition, the junction is in depletion and the junction capacitance C is:

$$C = A\sqrt{\frac{qk\varepsilon_0 N}{2\,(V_{\mathrm{bi}} - V)}}, \tag{4.40}$$

where V_{bi} is the junction built-in voltage and N is the total net density of charged impurities. N is the net doping density plus the charged defect density in the depletion layer. During the period in which the junction is reverse biased N changes because the defects filled during the previous forward bias pulse can emit electrons to the conduction band or holes to the valence band, depending on the nature of the defect. Such emission changes N, and therefore C, and one therefore observes a capacitance transient. The sign of the transient, i.e., whether N increases or decreases with time, provides the nature of the emission process, i.e., whether one observes electron or hole emission. The capacitance transients are systematically analyzed as a function of the junction temperature, and from such study the defect ionization energy and carrier capture cross-section are measured.

DLTS measurements can be performed by monitoring capacitance, current or charge transients. DLTS [68, 98]. It is a very powerful technique, which allows the identification of numerous types of defects in various types of semiconductors, with excellent sensitivity. There are numerous other τ_{r} and τ_{g} measurement techniques, mostly based on semiconductor device structures, that are described in other sections of this book. More detailed descriptions of such methods are reported in Schroder [68].

4.5 One-Dimensional and Two-Dimensional Electrically Active Dopant Profiling

In the previous section, we discussed the basic relations between the relevant electrical parameters and presented simple experimental techniques. In the present section, a brief presentation of other methods adopted for the measurement of carrier profile in compound semiconductors is provided. The main part of the section deals with, in great detail, the electrical atomic force microscopy (AFM) techniques for the characterization of nanosized regions. Carrier concentration profiles and mobility can be determined by these methods at the nanoscale size, not only in silicon-based devices but also in compound devices, with some limitation, for example, the necessity of calibration curves. As examples, the analysis of 4H-SiC MOSFET, of AlGaN/GaN heterostructure, and of a planar MOSFET structure illustrates the possibilities of the technique.

4.5.1 Experimental Methods

The application of traditional carrier profiling techniques to other semiconductors beyond silicon on one hand and the extreme miniaturization of the state-of-the-art silicon devices on the other present several challenges. In the first case (compound semiconductors), two-dimensional (2D) or even three-dimensional (3D) characterization methods are required [99], which are able to furnish the 2D carrier and dopant distribution inside the semiconductor with high sensitivity (10^{14}–10^{21} cm^{-3}) and high spatial resolution (<1 nm). In this context, a 2D version of secondary ions mass spectrometry (2D-SIMS) and the atom probe tomography techniques have been developed for 2D/3D chemical mapping of dopants [99]. However, these techniques are difficult and extremely expensive to implement.

On the other hand, relevant efforts have been dedicated in the last 20 years to developing electrical characterization techniques based on AFM, in order to meet the requirements scheduled in the International Technology Roadmap for Semiconductors [100] for spatial resolution, concentra-

tion, and concentration gradient sensitivity in 2D carrier profiling.

Among the large number of electrical AFM techniques, *scanning capacitance microscopy* (SCM), *conductive atomic force microscopy* (CAFM), and *scanning spreading resistance microscopy* (SSRM) are the most promising ones for 2D carrier profiling, owing to their ability to carry out capacitance and current measurements with nanometer resolution [101–103]. Although these measuring techniques are currently implemented in commercial AFM microscopes, in most of the cases they are employed only for qualitative imaging of carrier profiles. On the other hand, only a few specialized laboratories worldwide developed dedicated sample preparation protocols and quantification algorithms for the conversion of the measured 2D maps in carrier concentration maps.

In the following, we limit the discussion to SCM and SSRM techniques, presenting the working principles; the application of these techniques to relevant case studies in silicon technology, as well as to other semiconductors, will be provided.

In SCM measurements, a conductive AFM tip is scanned, in contact mode, on the surface of a semiconductor coated with an ultrathin (few nanometers) insulating film (usually SiO_2, but also high-k dielectrics), thus forming a nanometric metal–insulator–semiconductor (nanoMIS) device, as schematically depicted in Fig. 4.37a. The tip is connected to a high-sensitivity capacitance sensor, which records the capacitance variations due to changes of the semiconductor depletion volume underneath the tip in response to the AC modulating bias. Owing to its nanoscale dimensions, the capacitance of the nanoMIS structure is to the order of 10^{-18} F. This is illustrated in Fig. 4.37b, showing the calculated C–V curves for an AFM probe (with a typical curvature radius of 20 nm) on p- and n-type Si (10^{15} and 10^{17} cm^{-3} respectively) coated with a 2-nm-thick SiO_2 layer. A SCM map is formed of a 2D array of values proportional to the derivative dC/dV at the fixed DC bias applied to the sample. The DC bias is usually fixed on the peak of the dC/dV curve, corresponding to the flat-band voltage condition. Obviously, the sign of dC/dV is negative for p-type doped semiconductors and is positive for n-type doped semiconductors (as illustrated in Fig. 4.37c), thus distinguishing between different types of doped areas. Moreover, the absolute value of the dC/dV curve decreases monotonically with increasing carrier concentration.

Two typical calibration curves [104], correlating the SCM signal (proportional to $|dC/dV|$ through the capacitance sensor gain) with the carrier concentration for p-type and n-type Si are reported in Fig. 4.37d, e respectively. The experimental points are measured on dedicated calibration samples, whereas the lines are calculated with a 3D model of the nanoMIS capacitor [104]. These curves show a sensitivity with a wide concentration range ($\sim 10^{15}$ to $\sim 10^{20}$ cm^{-3}), which is limited at the highest concentrations ($>10^{20}$ cm^{-3}) by the very small capacitance variations (i.e., no depletion of the semiconductor), and at the lowest concentrations ($<10^{15}$ cm^{-3}) by the oxide–semiconductor interface states [105].

The SCM lateral resolution is concentration dependent too, as the probed semiconductor volume underneath the tip is ultimately related to the maximum depletion extension W. As an example, for a tip curvature radius of ~20 nm and for carrier concentrations $>10^{18}$ cm^{-3}, the lateral resolution on a uniformly doped Si sample is set by the tip dimension itself, whereas for carrier concentrations $<10^{18}$ cm^{-3}, the lateral resolution is set by the depleted semiconductor volume underneath the tip. An improved depth resolution is achieved by the geometrical magnification of the sample region under investigation by angle beveling [106]. Quantitative carrier profiles with nanometric resolution (along the bevel direction) have been obtained using this method on unipolar-doped semiconductors [107]. However, some caution must be taken in the interpretation of SCM measurements on beveled bipolar devices, owing to the occurrence of the carrier spilling effect [108], determining a shift of the electrical junction position toward the surface.

The SSRM technique [109] is a variant of CAFM. In SSRM, a hard conductive tip (typically, a Si tip coated with a doped diamond film or a full diamond tip [110]) is scanned in contact mode applying a high force on the cross-sectioned sample's surface, whereas a DC bias is applied between the tip and an ohmic contact on the backside (see schematic in Fig. 4.38a). The resulting current is measured using a logarithmic current amplifier (with a typical dynamic range from 1 pA to 0.1 mA) connected to the tip. As illustrated in Fig. 4.38b, the total measured resistance R is the sum of the following contributions:

$$R = R_{tip} + R_c + R_{spr} + R_B + R_{bc}, \tag{4.41}$$

where R_{tip} is the resistance of the conductive probe, R_c is the tip–semiconductor contact resistance, R_{spr} is the spreading resistance encountered by the current to spread in the nanometric semiconductor volume underneath the tip, R_B is the resistance of the bulk semiconductor, and R_{bc} is the back-contact resistance. Among these contributions, only R_c and R_{spr} are related to the local electrical properties of the semiconductor and, under typical conditions, are much larger than the other terms, owing to the nanoscale size of the tip–semiconductor contact. In particular, R_{spr} is proportional to the local semiconductor resistivity ρ as $R_{spr} = \rho/4a$, where a is the effective contact radius. Hence, by minimizing the contact resistance R_c under proper experimental conditions, the resistance maps collected by SSRM provide information on the 2D resistivity distribution in the semiconductor.

(**c**) Typical calibration curves relating to carrier concentration and measured resistance for p- and n-type doped silicon. (Reproduced with permission from Vandervorst et al. [99], Copyright Elsevier 2017)

In the case of silicon, the R_c contribution is found to be strongly reduced by applying a high force (in the order of μN, corresponding to a GPa pressure) with the conductive AFM tip, as a result of a local temporary phase transformation of the silicon material from the diamond cubic structure to the β-tin metallic phase [111]. The dimension of this locally modified conductive region underneath the tip corresponds to the effective contact radius a, typically in the order of nanometers, thus resulting in a very high lateral resolution of the SSRM technique [99]. As the SSRM raw data are related to the local resistivity ρ, the quantification of the carrier distribution in the semiconductor requires the knowledge of the mobility dependence on the doping concentration.

This issue is typically addressed by using proper calibration samples, consisting of a set of epitaxial layers with known resistivity and doping concentration both for n- and p-type doped semiconductors [113]. Figure 4.38c shows two representative calibration curves, correlating the carrier concentration with measured resistance for p- and n-type doped Si, which evidences the wide sensitivity range (from $\sim 10^{15}$ to $\sim 10^{20}$ cm^{-3}) of the SSRM technique.

4.5.2 Applications of the Methods and Examples

The SCM technique has been widely used for 2D mapping of carrier distribution in silicon devices [112], in order to evaluate critical dimensions, such as the effective channel length of MOSFETs [106] or the effective base thickness in bipolar transistors [113]. Furthermore, it is extremely useful for investigating physical phenomena related to electrical activation and 2D diffusion of dopant species, such as boron, implanted in silicon at ultralow energy and in laterally confined windows [114, 115]. Besides silicon, SCM has been applied to other semiconductor materials, including Si_xGe_{1-x} quantum wells [116], and wide-band-gap semiconductors, such as SiC [117, 118], GaN [119], and AlGaN/GaN heterostructures [120].

As an example, Fig. 4.39 shows a schematic cross-section of a 4H-SiC power MOSFET (a) and the SCM map of the device active area (b). This image provides information on critical device parameters, such as the 2D carrier distribution of the p-doped body and n^+-doped source (obtained by Al and P ion implantation respectively) and the effective channel length. Such results are important, both as a feedback on the process conditions and input for TCAD simulations of the electrical characteristics of the device.

Scanning capacitance microscopy has also been employed on GaN to obtain nanoscale resolved information on the electrical behavior of typical defects (threading dislocations) of epitaxial GaN and their impact on Schottky diodes fabricated from this material [121].

Figure 4.40 shows an example of application to an AlGaN/GaN heterostructure, subjected to a selective area oxidation process at a temperature of 900 °C, which was demonstrated to result in a local suppression of the two dimensional electron gas (2DEG) at the AlGaN/GaN interface [120]. Figure 4.40a schematically illustrates the heterostructures with a partially oxidized and non-oxidized near surface region, whereas Fig. 4.40b reports a cross-sectional TEM analysis showing the thickness of the surface oxide. Finally, Fig. 4.40c, d show a cross-sectional SCM analysis comprising the non-oxidized and oxidized regions and two representative line-scans of the dC/dV signal in the two areas respectively.

As can be seen, in the non-oxidized region, the insulating GaN substrate, the n^+-GaN, the AlGaN barrier layer, and the 2DEG at the AlGaN/GaN heterointerface can be clearly identified. On the other hand, in the oxidized region, no difference exists between the insulating GaN substrate and the entire thickness of the heterostructure. This latter indicates that not only was the 2DEG suppressed but the GaN and AlGaN regions, including the highly doped n^+-GaN layer were also depleted. The high-temperature annealing of the uncapped surface during oxidation led to local compositional changes in the underlying layers, plausibly related to the Al and Ga losses associated with the formation of the oxide. Furthermore, owing to the high thermal budget, a relaxation of the AlGaN/GaN heterostructure can also occur, thus leading to the degradation or to the local suppression of the 2DEG.

Thanks to its high spatial resolution and wide dynamic range, SSRM has been used extensively to study doping technologies and active dopant distributions in planar transistor structures. A representative 2D resistance map obtained on a planar p-MOSFET structure is shown in Fig. 4.41, where the various regions (source/drain, extension regions, halo implants), as well as the gate electrode, are clearly visible [122].

Starting from its first demonstration in 1994 [123], SSRM has been continuously refined for applications in the measurement of ultra-scaled silicon devices [99]. Currently, one of the major limitations of conventional SSRM when applied to modern ultrascaled devices is its loss of sensitivity, especially at high carrier concentrations. This is because in 3D device architectures or in nanowire based devices, the nonlocal series resistance contributions of R_B and R_{bc} in Eq. (4.41) are not negligible with respect to the local R_{spr} contribution. To overcome such a limitation, a novel variant of SSRM, namely, fast Fourier transform-SSRM (FFT-SSSRM) has been recently introduced [124]. FFT-SSRM is capable of isolating the actual R_{spr} from all the nonlocal resistance components by modulating the load-force on the tip at a given frequency (thus effectively increasing and decreasing the radius of the tip/semiconductor nano-contact) and measuring the current at that frequency with a lock-in technique.

In order to reconstruct the 3D carrier distribution in complex device structures (such as FinFETs), a new approach with SSRM has been demonstrated, named scalpel-SSRM. This is a 3D tomographic technique based on a slice-and-view approach whereby the conductive diamond tip is used to perform subsequent SSRM maps and to remove Si material in a controlled way after each scan [125].

The SSRM technique has been initially developed and thoroughly assessed on silicon. However, it extends its application to other semiconductors, including Ge [126], III–V semiconductors (InP, GaAs) [127], ZnO [128], and SiC [129, 130]. In the case of Ge, the properties of the tip/semiconductor nano-contact have been modeled, and, similar to the case of Si, the formation of a β-tin metallic phase under high pressure has been identified. On the other hand, no detailed investigation on the nature of the nano-contact is available in the case of compound semiconductors, and the applicability of SSRM to these material systems mostly relies on empirical calibration curves determined on calibration samples.

Owing to their different physical working principles, the SCM and SSRM techniques provide information on the active dopant concentration and on the resistivity profiles

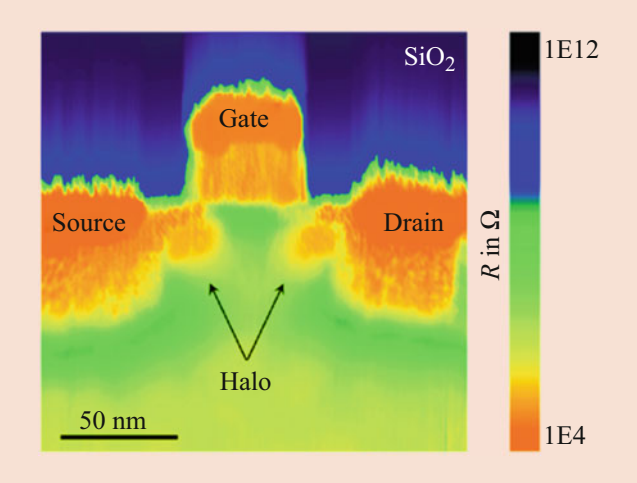

Fig. 4.41 Two-dimensional spreading resistance map obtained on a planar MOSFET structure. The differently doped regions (S/D, extension regions, halo implants) as well as the gate electrode are clearly visible. (Image reprinted with permission from Schulze et al. [122], Copyright Springer Nature AG 2019)

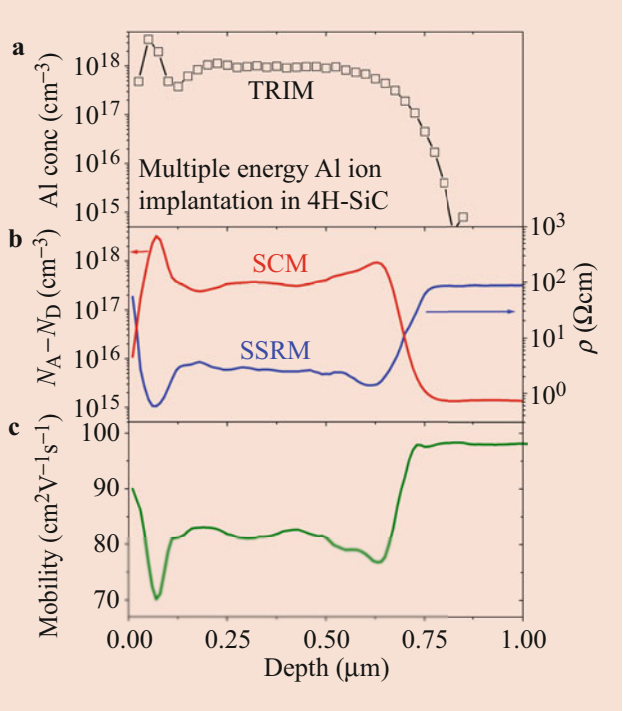

Fig. 4.42 (**a**) Simulated Al concentration profile in 4H-SiC implanted with multiple energy (40–550 keV) Al^+ ions at a dose of 1×10^{13} cm^{-2}. (**b**) Net doping concentration profile ($N_A - N_D$) from the SCM data (left scale) and resistivity profile ρ from the scanning spreading resistance microscopy data (right scale) acquired on the sample annealed at 1650 °C for 30 min. (**c**) Mobility profiles evaluated from the combination of the net doping concentration and resistivity profiles. (Figures adapted with permission from Giannazzo et al. [130], Copyright American Institute of Physics 2007)

respectively. Hence, the combined application of the two methods allows, in principle, the carrier mobility to be locally evaluated in semiconductors with inhomogeneous doping or defects concentration. This approach was employed in the case of silicon carbide (4H-SiC) implanted with multiple energy Al ions and subjected to annealing at 1650 °C [130]. Figure 4.42a shows the Al concentration depth profile, calculated by Monte Carlo simulations with the TRIM (transport of ions in matter) code. Figure 4.42b, left axis, reports the net active dopant concentration $N_A - N_D$ (with N_A the acceptors concentration and N_D the donor compensation, owing to electrically active defects) obtained by calibrated SCM analyses, whereas the resistivity (ρ) profile extracted by SSRM data is shown in Fig. 4.42b, right axis. Finally, Fig. 4.42c shows the depth resolved mobility, evaluated by a combination of the two experimental profiles in Fig. 4.42b, using the neutrality equation correlating $N_A - N_D$ with the hole concentration p and the well-known relation $\mu = 1/(qp\rho)$ between mobility, resistivity, and carrier concentration.

So far, applications of scanning probe microscopies to 2D electrical profiling in bulk semiconductors have been discussed. Obviously, thanks to their high spatial resolution and genuine surface sensitivity, these techniques are the methods of choice in low-dimensional materials, including quantum dots (0D), nanowires and nanotubes (1D), and 2D materials. In particular, SCM and CAFM have been extensively applied in recent years to explore carrier transport phenomena in graphene, semiconducting transition metal dichalcogenides, insulating hexagonal boron nitride, as well as their heterostructures [131, 132].

4.6 Optical Characterization of Semiconductors

The use of light is a powerful tool for material characterization because of its simplicity and because it needs no sample preparation. Of the techniques available, even the simplest one, i.e., the measurement of light intensity reflected and/or transmitted by a sample, provides essential information both for materials characterization and for process control. In what follows, we will provide the basics of the technique and a few illustrative examples concerning the determination of the band gap, and of the energy levels of defects, impurities, and dopant atoms.

4.6.1 Basic Concepts

The interaction of a plane wave with a sharp and flat boundary between two media with a different refractive index n_0 and n_1 can be understood by solving the Maxwell equations with the boundary conditions of continuity of the field at

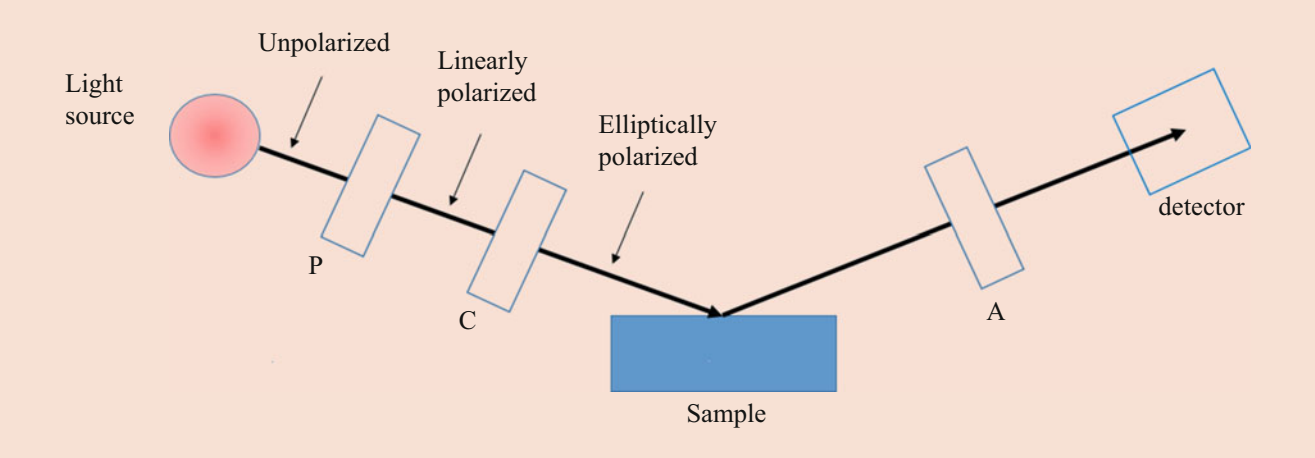

Fig. 4.43 Schematic arrangement of an ellipsometer apparatus

the interface [133]. This procedure gives the ratio of the amplitudes of the reflected and transmitted electric fields for the two components of the polarization vector, the so-called Fresnel coefficients. Keeping in mind that in general the refractive index is a complex quantity, the intensities will be given by the squared modulus of the respective coefficients.

In real life the second medium is not semi-infinite and the presence of (at least) a second interface gives rise to multiple reflections inside the sample. At a normal angle of incidence the Fresnel coefficients for the two polarizations are equal and if the coherence length of the light source is smaller than the sample thickness, interference effects are averaged out and the reflectance and transmittance can be approximated by

$$R = \frac{(n_0 - n_1)^2 + k_1^2}{(n_0 + n_1)^2 + k_1^2}; \qquad T = \frac{(1-R)^2 \mathrm{e}^{-\alpha d}}{1 - R^2 \mathrm{e}^{-2\alpha d}}, \tag{4.42}$$

where $\alpha = 4\pi k/\lambda$ is the absorption coefficient and k is the imaginary part of the complex index of refraction $\tilde{n} = n - ik$. It is also assumed that the measurements are taken in a transparent medium ($k_0 = 0$), as is usually the case. For thin films, interference effects give rise to characteristic oscillatory behavior that must be taken into account [134].

In principle, the simple R and T measurements allow the determination of the refraction index, which is in turn related to the material properties. This is true only when the substrate is transparent and hence the measurement of T is possible. For absorbing substrates, it is possible to use the Kramers–Kronig relations [133], but suitable extrapolations outside the measured wavelength range are required.

The Fresnel coefficients, either of a single surface or of a layered structure, are in general complex numbers. As a consequence, there will be a phase shift between the two polarization directions and then a change in the polarization state of the reflected light. This is the field of ellipsometry.

To work with polarization, it is important to control both the incident and the reflected state of polarization. In a typical setup, the light source is unpolarized and is followed by a polarizer and a compensator to control the polarization before the probed sample. After reflection, there is another polarizer that works as an analyzer of the state of polarization and then a detector. A schematic drawing is shown in Fig. 4.43. The incident and the reflected beam define the incidence plane.

In ellipsometry, it is customary to express the complex ratio of r_p and r_s as:

$$\rho = \frac{r_\mathrm{p}}{r_\mathrm{s}} = \tan \Psi \mathrm{e}^{i\Delta}, \tag{4.43}$$

where r_p and r_s are the Fresnel coefficients for p and s polarizations respectively (light that is polarized parallel to the incidence plane is named p-polarized, whereas light polarized in the perpendicular direction is called s-polarized) [133], and Ψ and Δ are called ellipsometric angles.

In modern instruments the optical elements, P or C or A, can be rotated continuously, and then the modulated signal is analyzed. For example, it is possible to show [135] that in the case of a rotating analyzer the light intensity at the detector is given by:

$$\frac{I}{I_0} = 1 + a \cdot \cos\left[2A(t)\right] + b \cdot \sin\left[2A(t)\right], \tag{4.44}$$

where $A(t)$ is the time-dependent angle of the analyzer and α and β are coefficients related to Ψ and Δ. It is then clear that a simple Fourier analysis of the detector signal will immediately give the ellipsometric angles.

Ellipsometry is a powerful and very sensitive technique and allows the accurate determination of very thin layers at the nanometer scale. As an example, Fig. 4.44 shows the

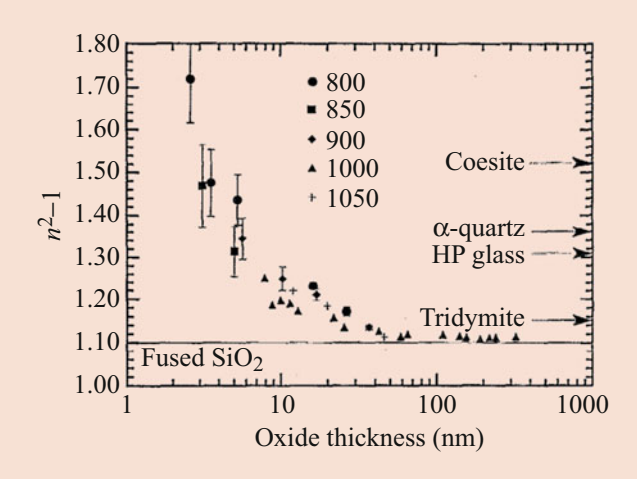

Fig. 4.44 Long wavelength limit of n^2–1 as a function of SiO_2 film thickness on silicon. (Reprinted from Jellison [136], with the permission of AIP Publishing)

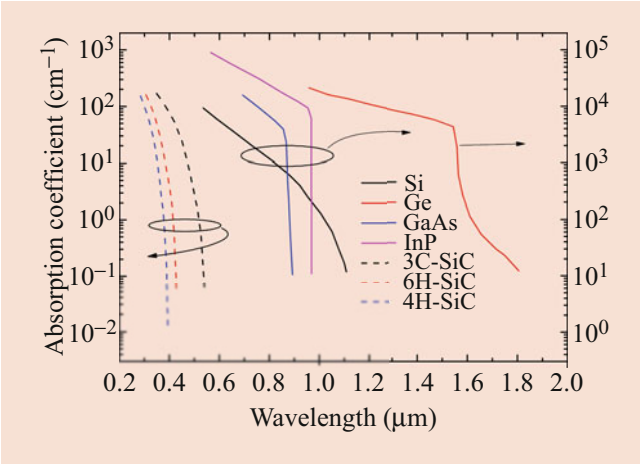

Fig. 4.45 Absorption coefficient of several semiconductors as a function of wavelength

dependence of the long wavelength limit of the quantity, n^2–1, of SiO_2 films on silicon as a function of layer thickness down to 2 nm [136].

4.6.2 Determination of the Optical Gap

Although the theoretical definition of the optical gap is clear, its accurate experimental determination is not straightforward. Indeed, even in an ideally defect- and impurity-free semiconductor, several factors influence the absorption coefficient α near the absorption edge, thus making it difficult to determine where α would go to zero. Just to name the two most important effects, near the absorption edge there are excitonic influences [137] and the presence of an exponential decay called the Urbach tail [138]. In practice, then, one has to model the response within a limited range of energy above the absorption edge and extrapolate it to $\alpha = 0$ [139].

It can be shown [137] that for a direct transition (same crystalline momentum value for the initial and final states in the valence and conduction bands respectively) in crystals α^2 is linear with energy, i.e., $\alpha^2 \propto (E - E_g)$, where E_g is the energy gap. Similarly, for indirect transitions (different crystalline momentum between the initial and the final state), the relation between α and E is $\alpha^{1/2} \propto (E - E_g)$. Extrapolation of these linear relations directly gives E_g. Figure 4.45 shows the absorption coefficient of several direct and indirect gap semiconductors to highlight the different energy dependence. For SiC, three different polytypes are considered.

This method is widely used and accurate enough to determine, for example, the narrowing of the band gap due to doping [140] or dependence on composition [141] or on external parameters [142].

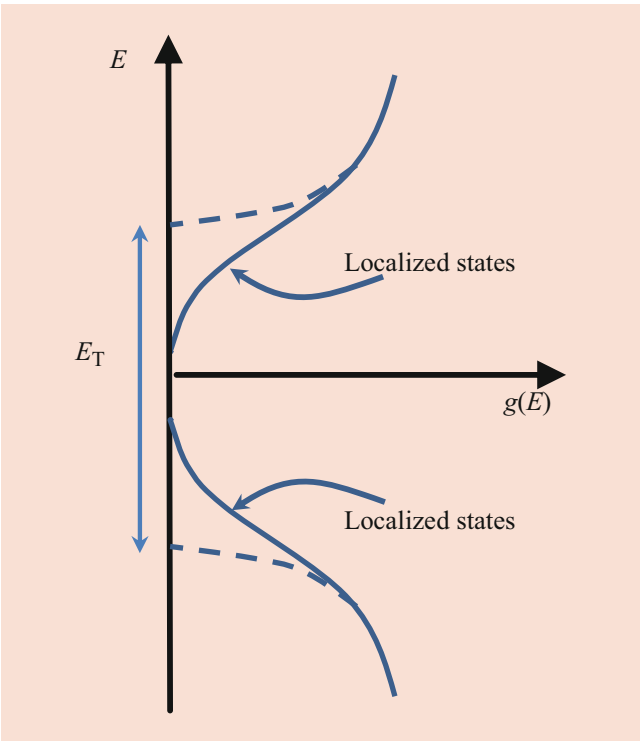

Fig. 4.46 Density of states in amorphous solids

The situations are different for amorphous semiconductors and glasses. It has been long recognized that structural disorder leads to the presence of long tails of localized electronic states, both below the conduction band and above the valence band [143]. The density of states can then be described as being composed of a parabolic part of an extended state followed by an exponential tail of localized states, as schematically represented in Fig. 4.46.

The presence of these tail states makes it impossible to have a univocal definition of the band gap. Following the

initial suggestion of Tauc et al. [144], it is customary to quote the so-called Tauc gap E_T as the energy difference between the extrapolation to zero density of states of the parabolic part of the conduction and valence band. As these states are extended [144], the absorption coefficient depends on energy as:

$$\sqrt{\alpha E} \propto (E - E_T)\,. \tag{4.45}$$

At energies below the gap, though, there is still significant absorption corresponding to optical transitions between localized states in one band and extended states in the other. These transitions give rise to an exponential tail in the absorption coefficient called the Urbach tail [138]. The origin of this tail has been much debated in the literature. As the tail is also present in crystals, it has been identified as being due to thermal disorder in a way similar to the Debye–Waller factor. In amorphous structures, topological disorder adds to the thermal effect and is treated similarly [145]. The width E_u of the exponential tail is then expressed as the sum of two terms in the average square displacement U, one due to temperature T and the other due to disorder X:

$$E_u\,(T, X) = K\left[\langle U^2\rangle_T + \langle U^2\rangle_X\right]. \tag{4.46}$$

Using the simple Einstein oscillator model for the temperature-dependent term, the above expression can be written as [146]:

$$E_u\,(T, X) = \frac{K\Theta}{\sigma_o}\cdot\left[\frac{1+X}{2} + \frac{N}{\exp\left(\Theta/T\right) - 1}\right], \tag{4.47}$$

where $\Theta = 3/4\ \Theta_D$ with Θ_D Debye temperature, σ an Urbach edge parameter, X a parameter related to $\langle U^2\rangle_T$, and N a parameter related to a possibly partial phonon occupancy. It is worth noticing that both the energy gap E_T and the Urbach width E_u share a dependence on temperature and disorder [145] and then are both useful for the characterization of amorphous semiconductors and oxides [147].

4.6.3 Dispersion Relations

The availability of spectroscopic instruments is of great help for optical characterization. Indeed, if suitable dispersion relations are available, the entire wavelength range dependence can be fitted with a few parameters. This procedure has proven successful and is now widely used.

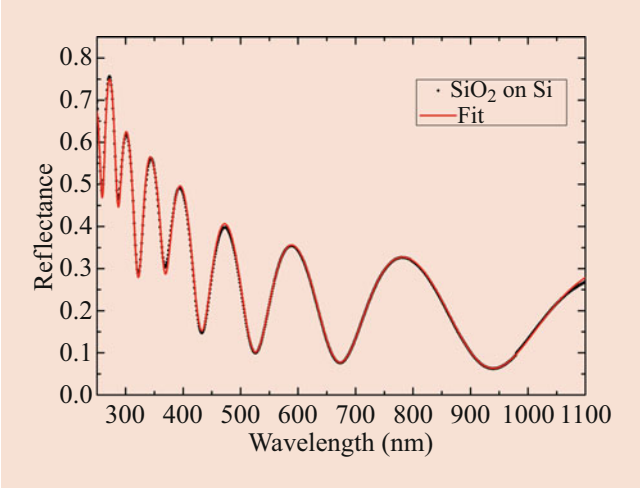

Fig. 4.47 Reflectance of an 800-nm-thick SiO_2 film on Si versus wavelength

For transparent layers grown on a known substrate, several dispersion relations have been proposed, the most widely used being the Cauchy [148] and the Sellmeier [149] relations. These empirical dispersion relations proved to be relatively accurate in describing the behavior of the index of refraction as a function of wavelength and then useful for the straightforward measurements of both the refractive index and the thickness of thin films. As an example, Fig. 4.47 reports the reflectance of a nominally 800-nm SiO_2 layer on silicon and the resulting fit using the Cauchy relation.

Based on more solid physical ground is the well-known Lorentz model that includes the so-called anomalous dispersion region and absorption. It can be derived from the classical response of a bound charge that behaves as a damped harmonic oscillator to the incoming electromagnetic wave [150]; the quantum-mechanical treatment gives basically the same result. In this model, the expression for the dielectric function is:

$$\epsilon = \epsilon_\infty + \frac{4\pi N q^2/m}{\left(\omega_o^2 - \omega^2\right) - i\Gamma\omega}, \tag{4.48}$$

where N is the number of oscillators, q the charge, m the mass, ω_o the resonance frequency, and Γ the damping constant of the oscillator. It is worth noticing that the Drude model for metals can be derived directly from the Lorenz model by putting $\omega_o = 0$, i.e., no restoring force. As the dielectric function is a linear response function, contributions from other oscillators simply add up.

This model can be applied to lattice vibrations in polar semiconductors [150]. Reflectivity measurements within the infrared range show the presence of the so-called Rest-

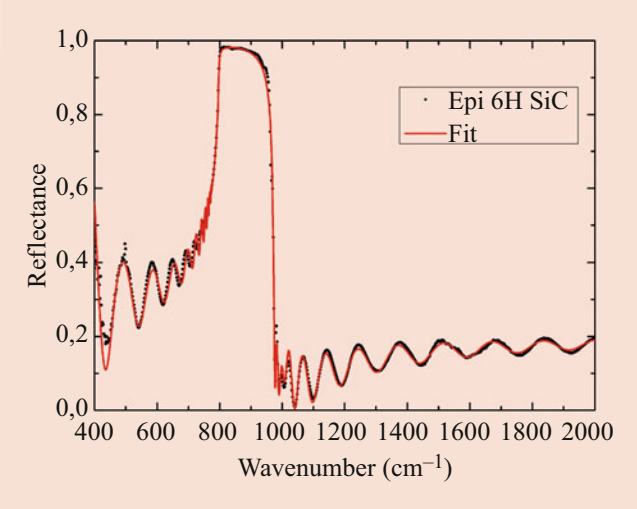

Fig. 4.48 Reflectance of a 10-μm intrinsic homoepitaxial 6H-SiC grown on a heavily doped substrate versus wavelength

strahlen band [151], a band of high reflectivity between the transverse (TO) and longitudinal (LO) optical phonon frequencies near the center of the Brillouin zone. The shape of the curve depends on Γ, which in turn depends on crystal quality. For example, it has been successfully applied to monitor ion implantation damage and recovery in 4H-SiC [152].

If the semiconductor is doped, a Drude-like term is added to the dielectric constant to account for the contribution of free electrons. The change in ε, due to doping, allows the measurement of the thickness of a low doped epitaxial layer on a highly doped ($N \sim 10^{19}$ cm^{-3}) substrate, as shown in Fig. 4.48 for a 10-μm low doped ($N < 10^{14}$ cm^{-3}) 6H-SiC epitaxial layer.

The absence of a charge in nonpolar semiconductors makes them unresponsive within the infrared range and only multiphonons [153] or impurity-related [154] processes are detected. Still, whatever the semiconductor type, in the presence of doping, the response of free electrons is clearly measurable [151, 155]. It is worth noticing that the parameter Γ, the inverse of a characteristic electron scattering time, is dependent on dopant concentration [155].

The simple harmonic oscillator model can also be used as a simplified model for interband absorption. The imaginary part of the dielectric function is related to the sum of all possible transitions from the valence to the conduction band separated by energy E_{CV}. This factor is called the joint density of states, which is given by [137].

$$D\left(E_{CV}\right) = \frac{1}{4\pi^3} \int \frac{\mathrm{d}S_k}{\left|\nabla_k \left(E_{CV}\right)\right|}, \tag{4.49}$$

where S_k is a constant energy surface. Singularities, called Van Hove singularities, are present at energies where $|\nabla_k(E_{CV})|$ is zero. Calculating the dielectric function in this formally correct way is somewhat cumbersome. In any case, absorption above the band gap is dominated by these transitions and then it should be possible to express the dielectric function as a sum of contributions from the known critical points. This has proven to be a useful approximation, even though it is not possible to assign each oscillator derived from the fits to a specific critical point [156, 157].

Whichever the adopted model, absorption at the critical points is sensitive to both doping and defects. It has been shown that in doped germanium absorption at the critical points depends both on doping level and dopant species [158]. Also, the residual damage after ion implantation can be followed through the continuous change in the dielectric function [159].

The Lorentz model works reasonably well at energy well above the band gap, but it cannot reproduce the behavior near it. Indeed, the absorption coefficient goes to zero aymptotically at low energies and not at the energy of the gap as expected, thus precluding its direct determination from the model.

4.6.4 Impurities and Defects Absorption

Imperfections in crystals due to the presence of impurities and/or crystallographic defects typically give rise to electronic states inside the energy gap and possibly to local vibrational modes (LVM). Both can be detected by optical absorption. The energy of the former depends on the characteristic of the defect and on the gap and may be within the visible or the infrared range; the latter, instead, always fall within the infrared range. In any case, always being at energies lower than the energy gap, they fall within the region of transparency of the semiconductor and are then accessible to transmission measurement. Being a vast topic, in what follows we will give just a few examples to highlight the capabilities of the technique, more details can be found in specialized books (see, for example, Pajot and Clerjaud [160]).

Carbon and oxygen are the two most abundant unintentional impurities in silicon single crystals. Carbon atoms are present both in interstitial Ci and in substitutional position Cs. Although Cs can be detected by infrared absorption owing to an infrared active local vibrational mode (LVM) at a frequency of 1107 cm^{-1} [161], no bands related to Ci have been univocally identified. On the contrary, oxygen atoms give rise to absorption bands both in substitutional Os and interstitial Oi positions around 510 cm^{-1} and 1100 cm^{-1} respectively.

These two impurities can be present in Czochralski-grown silicon at relatively high concentrations of the order of 10^{17} cm^{-3} for carbon and 10^{18} cm^{-3} for oxygen. After irradiation, they form CiOi complexes with several characteristic absorption bands between 529 cm^{-1} and 1116 cm^{-1} [162]. The CiOi complex has been found to efficiently trap self-interstitial silicon, which has its own LVMs at 936 cm^{-1} to 1020 cm^{-1} at room temperature [163].

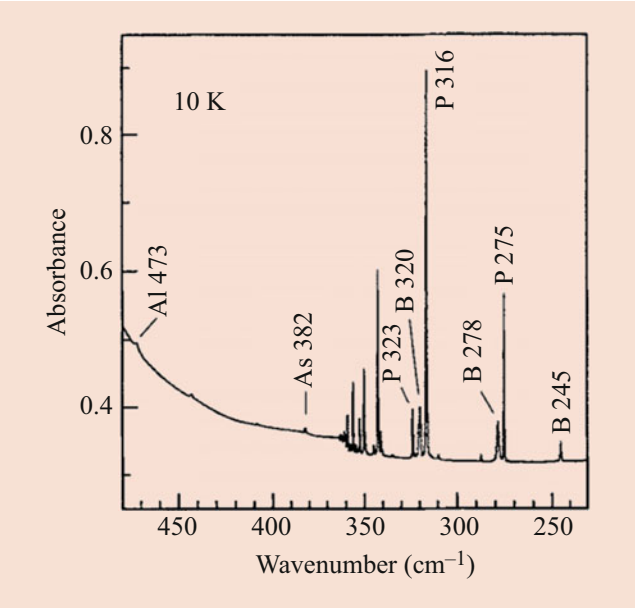

Fig. 4.49 Absorbance of As, P, and B impurities in silicon. (Reprinted from Alt et al. [162], with the permission of AIP Publishing)

Electron or hole transitions from a defect or dopant energy level to the nearest band can also be detected by optical absorption. The corresponding electronic structure can then be assessed and the concentration determined upon calibration from the integrated absorption of a band. If the level is relatively near the band, low temperature measurements may be required to increase the occupancy factor. In Fig. 4.49 we show an absorption spectrum in a single crystal of silicon containing B, As, and P impurities [162].

The integrated absorption of a specific band is linked to the number of oscillators by a well-known sum rule [151], and it is possible to calculate the latter from the former. In practice, though, the oscillator strength is typically poorly known and one has to resort to a calibration procedure. In this way, it has been possible to accurately measure the concentration of several shallow dopants in silicon down to 10^{10} cm^{-3} [162], as shown in Fig. 4.50 for boron and phosphorous.

Acknowledgments The authors want to acknowledge the colleagues of CNR-IMM in Catania (C. Bongiorno, S. Di Franco, P. Fiorenza, G. Greco, A. La Magna, M. Scuderi, and M. Spera) and STMicroelectronics (P. Badala', A. Bassi, F. Iucolano, M. Saggio, and P.Vasquez) for their participation in some of the theoretical/experimental activities discussed in this chapter.

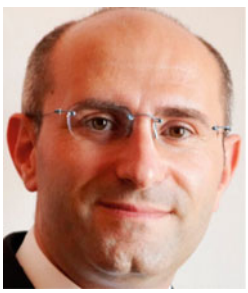
Alessandra Alberti graduated in 1996 and received a Ph.D. degree in 1999, both in Physics cum laude at the University of Catania. She joined CNR-IMM as permanent staff in 2001 to deal with physical depositions and X-ray diffraction analyses for microelectronics and photovoltaics. She is author of 130 peer-reviewed papers and Italian/USA patents, she is tutor of doc, post-doc, and fellow positions.



Filippo Giannazzo graduated in Physics at the University of Catania and received a Ph.D. from the same university in 2002. He joined CNR-IMM in Catania in 2005 and is currently Research Director. His interests are in scanning probe microscopy electrical characterization of advanced materials for electronics. He is author of 300 peer-reviewed papers, 10 book chapters, and 1 patent.

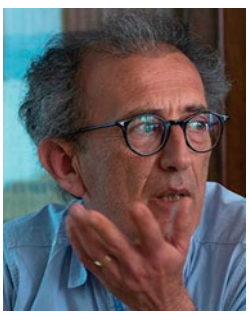
Francesco La Via was born in Catania, Italy, in September 1961. He received an M.S. degree in physics from Catania University, in 1985. In 2001 he became senior researcher and in 2020 Research Director of the CNR IMM and he is responsible for the research group that works on silicon carbide (SiC) epitaxial growth. He is responsible for several industrial research projects in this field.

Salvatore A. Lombardo graduated in 1989 and received a Ph.D. in Physics in 1994 from the University of Catania. He joined CNR in 1994. Since 2007, he has been Research Director of CNR-IMM. His research is in the field of semiconductors and photovoltaics. He is author of 10 patents, 10 review articles, and about 250 scientific peer-reviewed papers.

Antonio M. Mio graduated in Physics at the University of Catania and received a Ph.D. from the same university in 2012. He joined CNR-IMM in Catania in 2009, and since 2019 he has been staff researcher. His interests are in (scanning) transmission electron microscopy characterization of bidimensional systems and phase change materials for electronics.

Giuseppe Nicotra graduated in Physics at the University of Catania and obtained a Ph.D. in materials science after being a visiting student at UCDavis, NCEM, and BNL (USA). He has been a permanent staff scientist at CNR-IMM since 2012. His main field is transmission electron microscopy and related spectroscopic techniques for the characterization of advanced materials. He is author of more than 170 peer-reviewed papers.

Stefania Privitera graduated (cum laude) in Physics in 1998 and received a Ph.D. in 2002, from the University of Catania, Italy. In 2004, she joined STMicroelectronics. Since 2011 she has been Research Scientist at IMM-CNR, Catania. Her research interests include the development of semiconductor devices and structural/electrical characterization. She is author of 60 peer-reviewed papers, 2 book chapters, and 6 patents.



Riccardo Reitano graduated in physics and received his Ph.D. degree at the University of Catania, where he is now appointed Associate Professor. He has worked on laser and ion beam modification of materials and optical characterizations. More recently, his interests moved to wide-band gap semiconductors and innovative nanostructures.

Fabrizio Roccaforte graduated in Physics at the University of Catania and received a Ph.D. from the University of Göttingen. In 2001, he joined CNR-IMM in Catania, where he is Research Director. His interests are focused on wide-band gap semiconductors for power electronics devices. He has published about 350 reviewed technical papers, several review articles, 10 book chapters, and 5 patents.

Corrado Spinella was Head of the Italian Micro–Nanosystems Technological District, and he has been Director of the Institute of Microelectronics and Microsystems. He is presently Head of the Department of Physical Science and Technologies of Matter of the National Research Council of Italy. His research activity is focused on materials and processes for microelectronics and on advanced characterization techniques based on high resolution transmission electron microscopy.

Emanuele Rimini , Emeritus of Physics of Matter University of Catania, Associate Researcher at the Institute of Microelectronic and Microsystems CNR, is Fellow of the American Physical Society. His research activity is in the following areas: ion beam material modification and analysis, laser annealing, silicide, mesoscopic effects in low-dimensional material, phase change materials, graphene, and electroless deposition of metals on semiconductors.

Abstract

This chapter covers integration, performance, and three main process sectors concerning back-end-of-line (BEOL) wiring ("interconnect") process technology: intralevel dielectrics (ILDs), thin-film metals used in thin-film processing, and dielectric capping layers. The integration section contains an overview of patterning schemes used in damascene wiring fabrication and covers developments up to current leading-edge schemes which use extreme ultraviolet (EUV) lithography. Performance considerations are also discussed in Sect. 5.1, with a focus on BEOL metrics such as resistance and capacitance. The dielectric section reviews the history of materials used as BEOL damascene dielectrics and covers the history of low-dielectric constant ("low-*k*") materials as well as recent trends concerning air gap and porous dielectrics. The thin-film metals cover developments in physical vapor deposition (PVD) tooling and processes as well as chemical vapor deposition (CVD) wetting and cap layers. In the final section, modern trends in dielectric and selective metal caps are covered.

5.1 BEOL Integration and Performance

Back-end-of-line (BEOL) integration is a building process to wire the active transistor devices on the wafer to form functional electronic circuits. Figure 5.1a, b show 3D cross-sectional views of a complete BEOL build. Shown in the picture are multiple levels of copper line wiring with top aluminum level for terminal connections. "1× Cu" symbols marked in the image are the bottom Cu wires with minimum pitch built right on top of the FEOL devices. "2× Cu" symbols mark 2× pitch fat wires. Top level Cu wiring levels also called FBEOL (Far-BEOL) levels can have up to 25× or even 40× pitch wires depending on the complexity of the chip design. The total number of wiring levels also depends on the nature of the chip design. A CPU chip often has more levels than a chip only for a specific task. It is also possible to have memory devices as well as other types of devices integrated into BEOL levels, which will have separate process flows in addition to the wiring process flow. The standard wiring process flow may need to be modified to accommodate the embedded memory process. This chapter will only cover the basic wiring part without other embedded devices.

Figure 5.1b shows the multilevel copper wires in the build as well as the tungsten wire (gray color) underneath with dielectric material removed.

The process flow for building this structure is called "damascene" which is an ancient Jewelry-making process for fabricating an embedded pattern inside a host material.

BEOL damascene process was developed in the 1990s and is used when there is a need to planarize the wafer surface for finer pitch patterning. The CMP (Chemical-Mechanical Polishing) process for damascene integration scheme was invented first for the chip with aluminum wires and tungsten stud (via). Single damascene scheme was used at via levels with metal etch to pattern the aluminum line levels.

To reduce the metal line resistance, copper fabrication processes were developed to replace aluminum wire with copper wire. The dual damascene process to pattern the line and via together, using copper as the conductor, was also developed at the same time and soon became the industry standard. These methods for fabricating the wire and via together are also referred to as "dual inlaid" by some authors.

The following sections describe the basics of copper damascene processes used in microelectronic industry for BEOL interconnection integration. The detailed material stack and process flow used in actual chip manufacture may be somewhat different, depending on the chip manufacturing company, but the general principles are the same.

5.1.1 Copper Interconnect Single Damascene Scheme

A simplified schematic diagram (shown below) is used to show the general concept with the basic steps of a copper single damascene integration scheme:

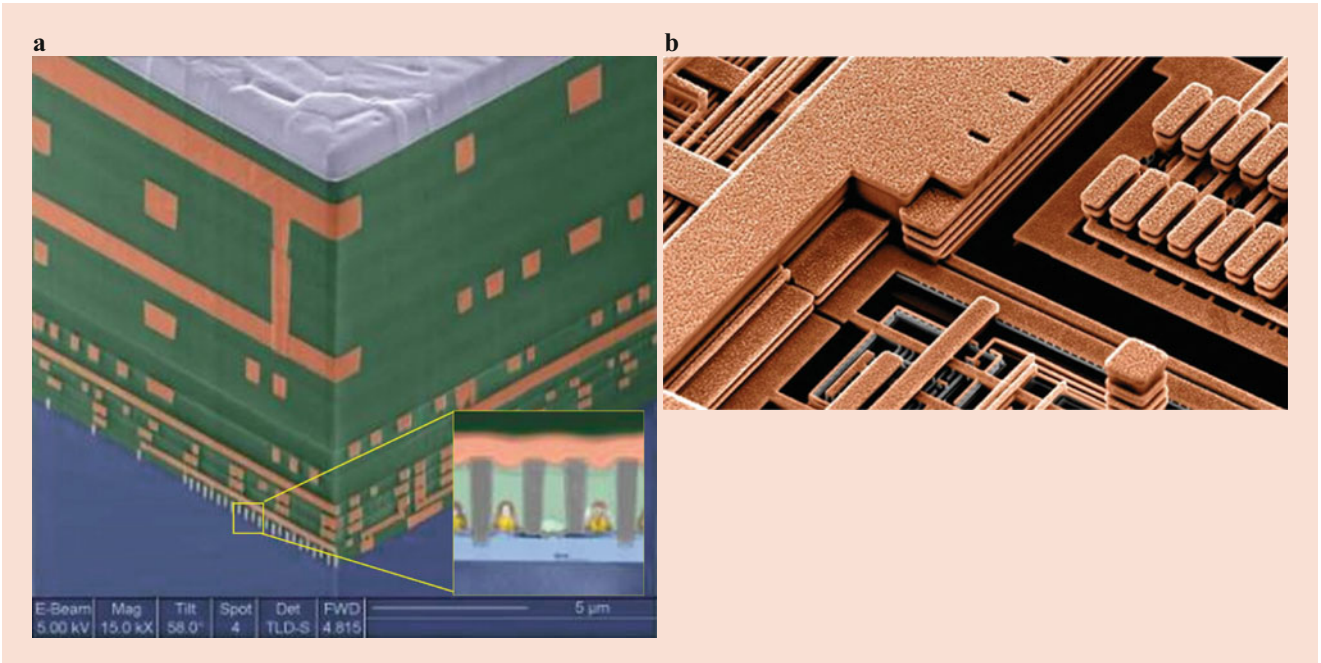

Fig. 5.1 (**a**) Focused ion beam (FIB) section of 90 nm logic chip illustrating multiple levels of Cu interconnects at multiple ground rules. The transistor structure is shown in the inset. (**b**) Dual damascene metal interconnects revealed by etching of the intralevel dielectric material. (Ref. [1], courtesy of Daniel C. Edelstein)

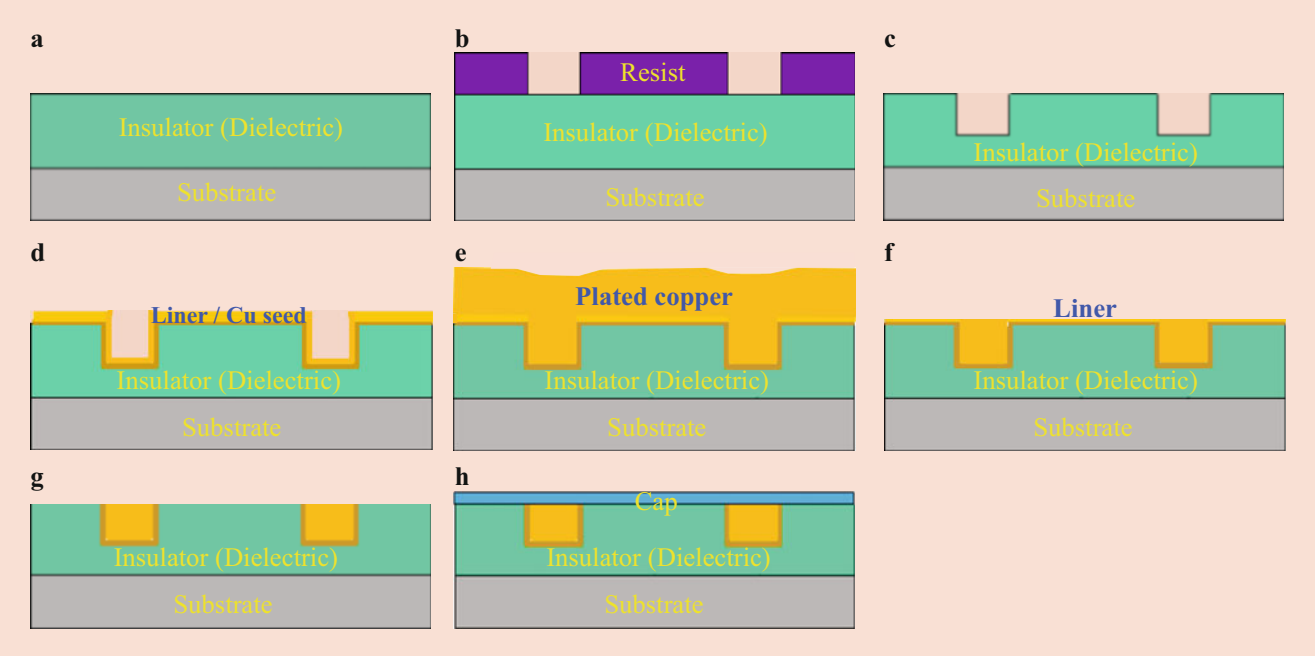

Fig. 5.2 (**a**–**h**) Schematic process sequence for single-damascene copper interconnects (see text)

Figure 5.2a depicts the dielectric stack deposition with thickness measurement. Additional etch hardmask material deposition may be needed on top of the dielectric stack; this will be addressed in later sections.

Figure 5.2b depicts the lithographic ("litho") process to print the pattern on the wafer. Additional material such as OPL (organic planarization layer) between the dielectric stack and resist may be needed to increase the etch budget as the resist thickness may not be enough to survive the targeted dielectric etch depth (see next section). Post-litho CD (critical dimension) measurement is needed for process control. This measurement usually shrinks the resist material, and re-measuring at the same spot will not provide the correct result. Typically, a specific CD measurement target is designed for CD control and usually placed across the chip to monitor CD uniformity.

Figure 5.2c illustrates the etch process used to create a recessed pattern in the dielectric, followed by a wet process to clean up the residues from the etch process. The post-etch wet clean process also removes the etch-damaged dielectric material. This will remove some sidewall material in the trench. The etch-damaged dielectric material usually has a higher dielectric constant compared with the pristine material. The effective dielectric constant of the dielectric material in the chip will be higher than the pristine material if the damaged dielectric material is not removed. As the result, the capacitance in the circuit will be higher, which will have a negative impact on the chip performance. However, the industry usually chooses not to remove most of the etch-damaged layer, as this may create a large undercut if there is a hardmask layer on top of the dielectric material for patterning purpose. The large undercut will make the metal filling into the trench more challenging. A post-etch pattern CD (critical dimension) measurement is needed, but it must always use a measurement location different from the litho CD measurement spot.

Figure 5.2d shows the deposition of the liner material. The liner material usually has two layers and acts as an adhesion layer and oxygen barrier layer. Typical materials used are Ta/TaN as the Ta/Cu interface provides a good adhesion while Ta does not mix with copper when the chip is operated at an elevated temperature, and the line resistance will not increase over the chip's lifespan. A thin copper seed layer on the liner material is needed for copper plating process. There is a requirement for minimum copper seed layer thickness as some copper may be dissolved in the copper plating bath during the initial phase of the copper plating process.

Figure 5.2e shows the fill of the damascene structures with electroplated copper. The plated copper thickness is typically much larger than the line trench depth to provide enough process window for the CMP process. A furnace anneal is used after plating to increase the copper grain size. This will reduce the line resistance and also improve the reliability.

Figure 5.2f illustrates the use of copper CMP to remove excessive copper and planarize the wafer surface. This part of the CMP process is usually designed to stop the polish on the liner layer with some overpolish, to make sure that no copper is left on the liner surface.

In Fig. 5.2g, liner CMP is used to remove liner and some dielectric material from the dielectric surface. Due to pattern-density variation across the chip, enough liner overpolish into dielectric material is needed to prevent the metal lines

from becoming electrically leaky or shorted. This step also removes etch-damaged dielectric top surface, if not protected by hardmask during the etch.

Following liner CMP, a defect inspection is performed (not illustrated). This process can be done post CMP or post cap (next step) when necessary. This is usually done after the cap layer deposition process if there is a queue time requirement which limits the time delay between the CMP and capping processes. Post CMP top of CD measurement can be done before capping.

Figure 5.2h shows the capping of the metal pattern. The cap serves as a copper and oxygen barrier. Typically, cap is a single dielectric layer with good barrier properties. SiN was used in early technologies and later changed to SiCN to reduce the interlevel capacitance. When the layer thickness scaled from generation to generation, it is often required to scale the cap thickness as well. When the traditional SiCN hits the thickness limitation as an effective barrier film, multiple layers of new materials may be used with thinner total thickness, still providing an effective barrier film. For very fine metal line patterning, a selective metal cap, such as Co (cobalt), may be deposited on the metal line top surface to improve the electromigration lifetime. This is common for 1× level, copper wiring post-14 nm technology. There is usually a queue time control to minimize the waiting time between CMP and cap process steps, especially for very fine Cu line fabrication in a porous low-*k* dielectric material. The queue time control is to prevent oxidation of the copper surface as well as moisture or other ambient contamination of the dielectric. The copper oxidation could also happen if the cap deposition chamber is not completely free of oxygen.

5.1.2 Additional Material Films Used in the Damascene Process Flow

As the technology evolves, it is usually necessary to add additional materials for the damascene integration scheme. Additional materials serve different purposes which will be explained in the following sections. This section will cover the most common additions.

Figure 5.3a shows the post-litho film stack. It is common to have a hardmask layer on top of the main dielectric layer, which will remain as an ILD (interlevel dielectric) after the build is done. It is common to use a metal hardmask ("MHM") on ILD, which is often needed for a trench-first integration scheme (see later sections). A typical metal hardmask material is TiN for good etch selectivity; it usually remains on the wafer after etch. It is also common to have additional thin dielectric hardmasks above and below the metal hardmask. The dielectric hardmask below the metal hardmask is often used to protect ILD material from processing damage during the metal hardmask deposition or during the etch process. The dielectric hardmask above the mask is usually used in the double patterning scheme (see later sections). As mentioned above, an additional OPL layer is used here to improve the etch budget, as resist alone may not survive the etch process to reach the targeted depth of the trench.

Figure 5.3b shows the post-RIE (etch) film stack. Typically, there will be some hardmask material left on the ILD material after etching. If the hardmask material is an insulator, it will be polished away during the CMP process. For the TiN metal hardmask, there is an option to remove it after etch using a wet clean process. For TiN hardmasks with better etch selectivity, the film mechanical stress is usually higher. This high stress could cause pattern deformation during the metal liner deposition process if the underlying dielectric material has low mechanical modulus; this has been observed with some ultralow-*k* materials. Also, there may be an ILD undercut below the metal hardmask when the etch-damaged ILD is removed by post-RIE, wet clean process. This can cause metal fill problems as it will be more difficult for the metal liner to cover the undercut area. In general, removing the metal hardmask before metallization can fix this metal fill problem.

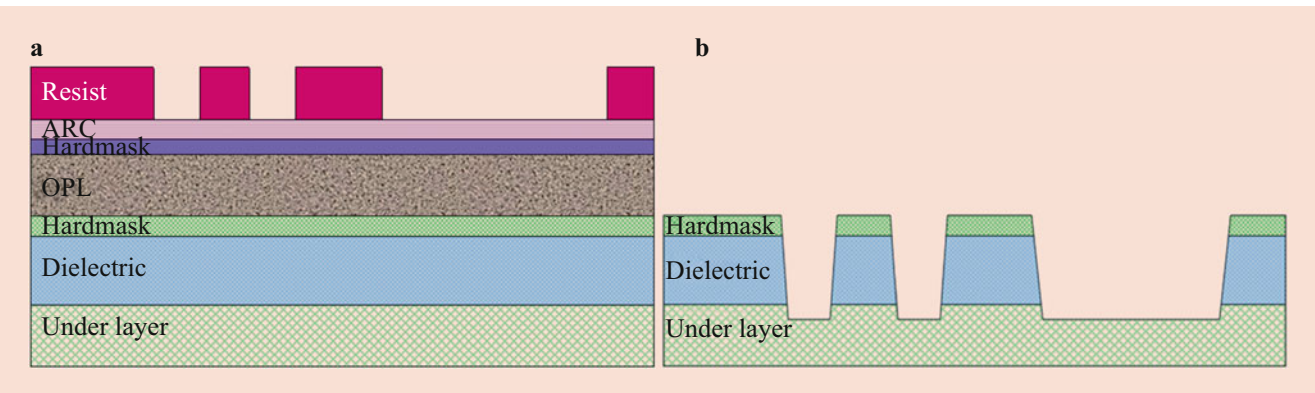

Fig. 5.3 (**a**, **b**) Damascene process sequence for metal hardmask (MHM) layer (see text)

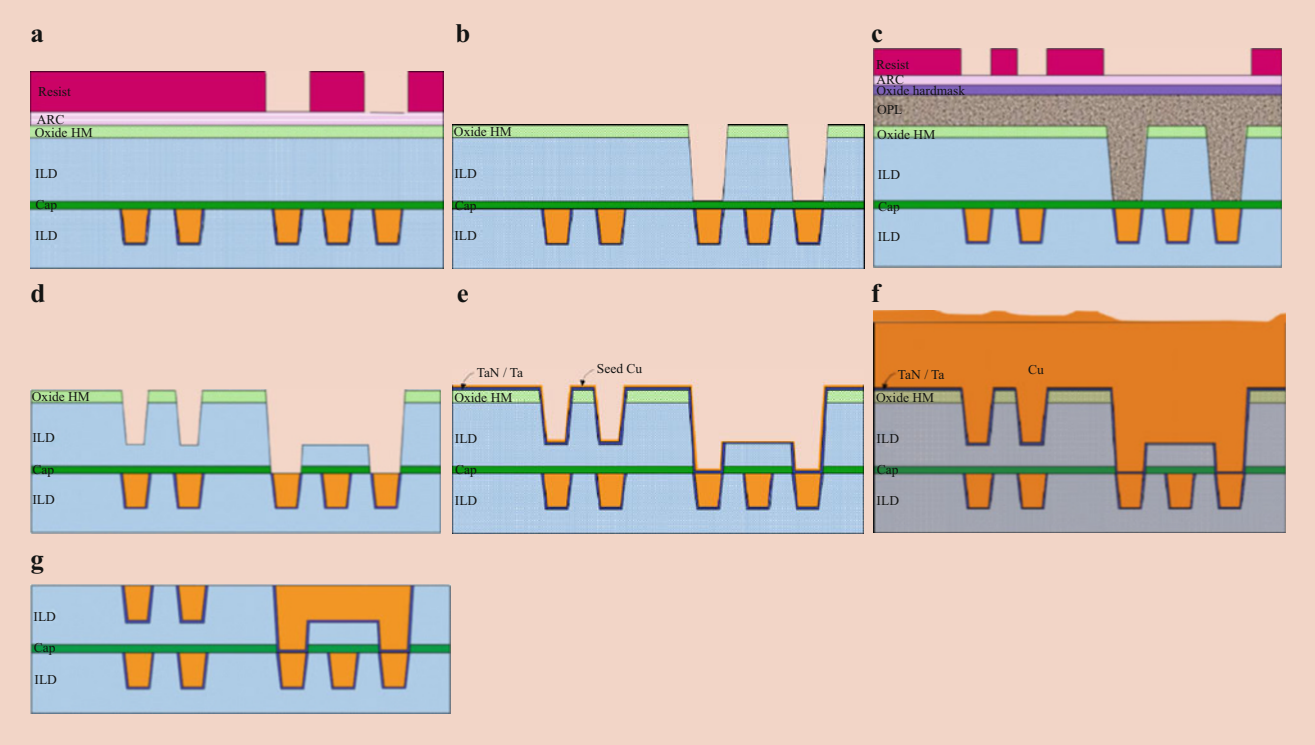

Fig. 5.4 (**a**–**g**) Process sequence for via-first dual damascene integration scheme (see text)

5.1.3 Via-First Dual Damascene Integration Scheme

The via-first scheme is the first dual damascene scheme developed. It was commonly used in earlier technologies. As technology evolved, it is still used in upper levels of the BEOL build in recent technologies as upper levels with larger feature sizes were qualified in previous generation technologies. Most fine pitch levels in late technologies are using the trench-first integration scheme described in the next section. For current technology, a complete BEOL build will have both via-first and trench-first dual damascene scheme in the process flow [1].

Below is a typical via-first dual damascene integration process flow:

Figure 5.4a depicts the start of the integration scheme with a via litho pattern on top of a full via/line ILD stack. Oxide hardmask on ILD is typical for this scheme.

Figure 5.4b shows the via etch stopped on the cap of underlying metal level.

In Fig. 5.4c, the via holes are filled with a spin on OPL material followed by trench litho.

Figure 5.4d depicts the structures after post-trench etch, strip OPL, and wet clean.

Figure 5.4e depicts the fabricated structures after metal barrier and Cu seed deposition.

Figure 5.4f shows the feature fill and overburden with electroplated copper.

Figure 5.4g shows the completed dual damascene level after copper and liner CMP.

5.1.4 Trench-First Dual Damascene Integration Process Flow

Figure 5.5a shows the post-trench litho. An OPL film may be added to improve etch process window.

Figure 5.5b shows the trench etch process to open the hardmask to form the line level pattern.

In Fig. 5.5c, the trench pattern is filled with OPL/HM followed by via litho.

Figure 5.5d shows the via etch followed by trench ILD etch. Metal hardmask wet removal is optional.

Figure 5.5e shows the completed wiring level, post metallization, and CMP.

5.1.5 Single Patterning Versus Double Patterning

Metal lines with pitch size smaller than 80 nm are required for BEOL interconnection beyond 22 nm device technology generation. Conventional 193 nm immersion lithography has

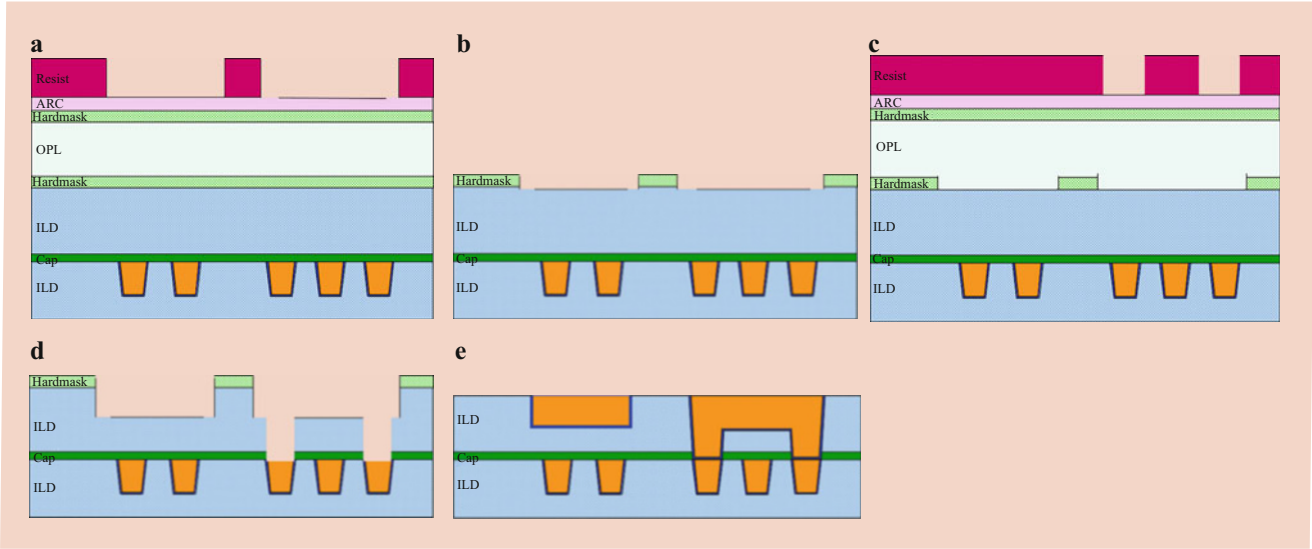

Fig. 5.5 (**a**–**e**) Process sequence for trench-first dual damascene integration scheme (see text)

difficulty resolving trenches below 80 nm pitch with single litho exposure. It is possible to continue the single litho patterning scheme using extreme ultraviolet lithography (abbreviated as "EUVL," or simply "EUV"). Figure 5.6 shows the post-CMP pattern of 36/48/64/72 nm pitch using EUV single exposure in the integration process flow. It covers the BEOL patterning need for 14 nm, 10 nm, and 7 nm generation technologies. However, high EUV litho manufacturing cost and delayed tool availability prevented the semiconductor industry from using it when the product was needed for the market. The double patterning techniques using the conventional 193 nm litho process were developed to meet manufacturing needs; they are described in the following sections [2].

5.1.6 Trench-First Pitch-Split Double Line Patterning with Self-Aligned Via Integration Scheme

Metal lines with pitch size smaller than 80 nm are required for BEOL interconnects beyond the 22 nm device technology generation. The conventional 193 nm immersion lithography has difficulty resolving trenches below 80 nm pitch with a single litho exposure. A patterning method with multiple litho/etch passes per level is needed to build desired BEOL structures, and several possible patterning methods have been proposed [3–6]. The example below demonstrates a patterning method that uses a pitch-split, double-exposure litho process to define the line patterns. Electric yield and reliability concerns associated with this particular patterning method are mainly the line-to-line and line-to-via spacing variation related to the litho double-exposure overlay errors. A self-aligned via (SAV) integration scheme usually is used to (a) minimize the via size variations, (b) minimize the via-to-line alignment errors, and (c) maximize the via-to-line spacing. The details of the SAV process will be described in the next section.

A. Trench pitch-split double patterning

Figure 5.7a shows the first line litho-printed 2× pitch line pattern.

In Fig. 5.7b, the first 2× pitch pattern is etched through hardmask 2.

In Fig. 5.7c, the second 2× pitch line pattern is printed.

Figure 5.7d shows the etching of the second 2× pitch pattern through hardmask 2 and then the etching of both 2× pitch patterns into hardmask 1 to form a 1× pitch pattern. To prevent ILD damage during the second hardmask open etch process, an additional hardmask layer could be added underneath hardmask 1.

Figure 5.7e below shows an example of the top-down SEM image of a post-hardmask, open RIE line pattern. Two 128 nm pitch line patterns (L1 and L2) were printed in sequence to form a 64 nm pitch line pattern. The image on the right shows the post full-dielectric etch trench pattern.

Figure 5.8 shows the post-CMP 64 nm pitch line patterns [2]. It demonstrates that 193 DUV (deep ultraviolet) litho double patterning is feasible.

B. Trench pitch-split double patterning with self-aligned vias (SAV).

Figure 5.9 shows the SAV process flow [7]:

Use pitch-split double patterning scheme to create line patterns in the hardmask.

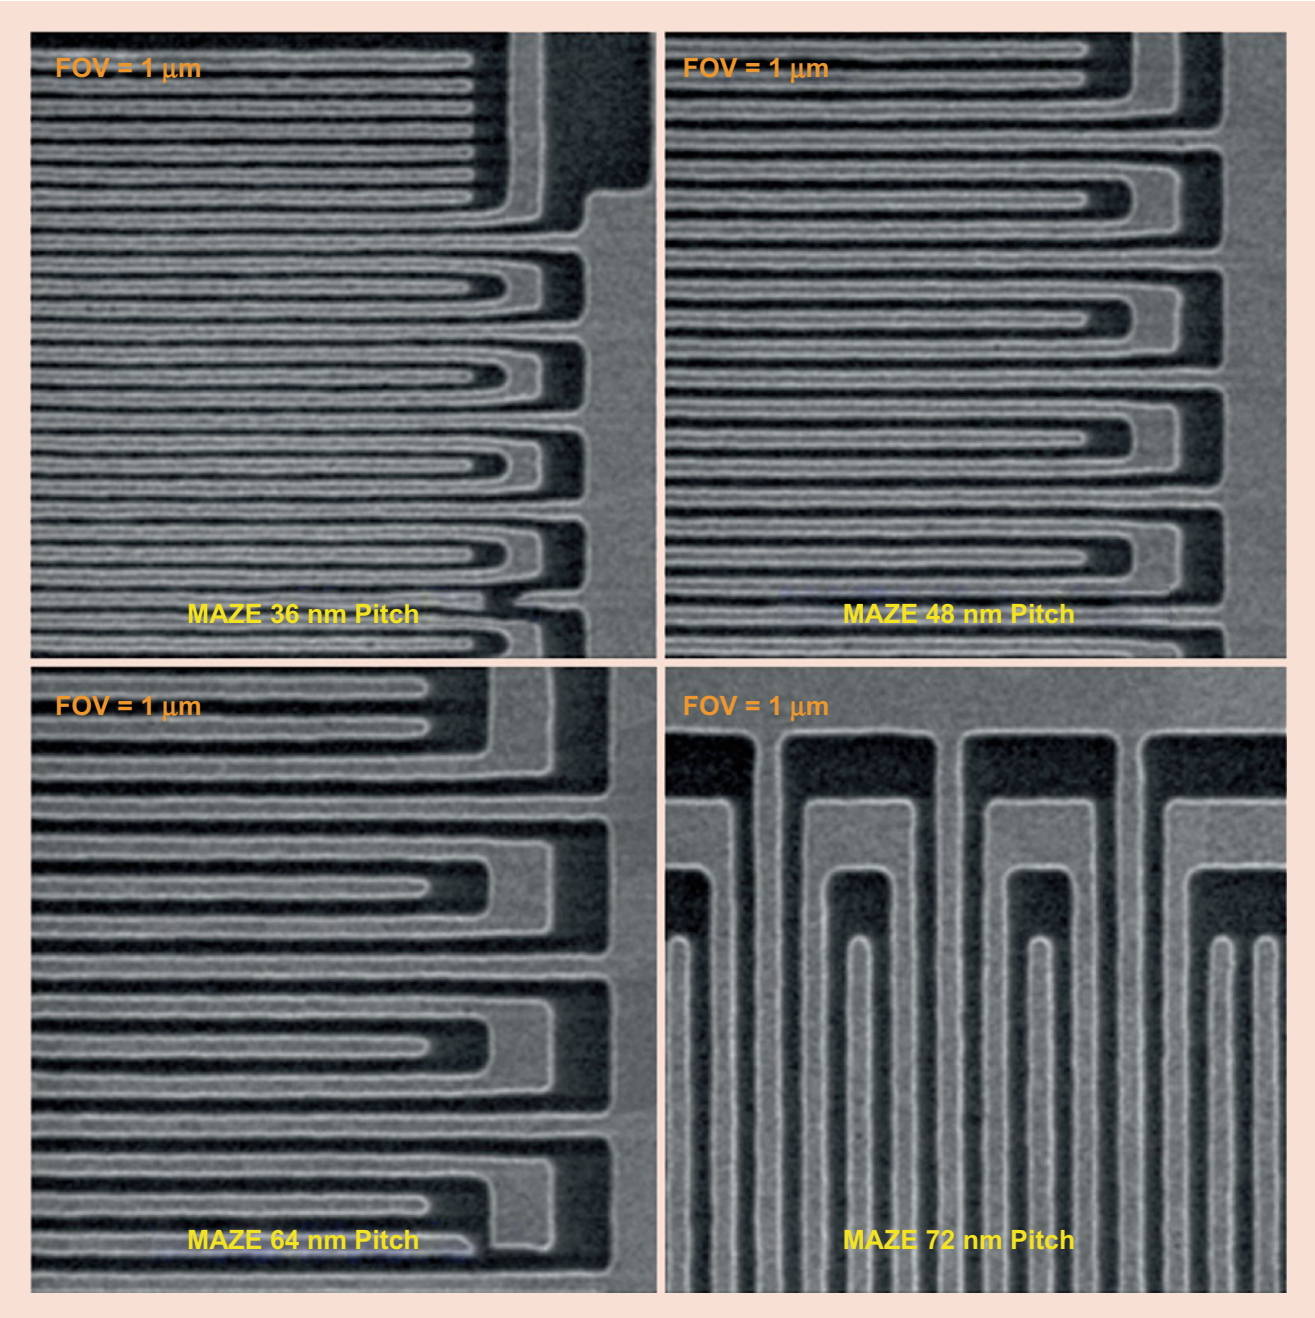

Fig. 5.6 Post-CMP SEM images of 36 nm, 48 nm, 64 nm, and 72 nm pitch wiring structures using a single EUV expose process flow

Planarize the surface with spin on OPL followed by via litho process. Vias are elongated across the line edge defined by the hardmask, i.e., the via litho CD is larger than the line CD.

Etch vias through the dielectric film stack, stop on the cap below. Metal hardmask also served as an etch mask to confine vias inside the line trench pattern.

Complete the line ILD etch and via bottom cap open etch.

Post full-etch SEM top-down image shows vias confined inside line trench patterns.

5.1.7 Self-Aligned Double Patterning (SADP)

As 193 nm DUV lithography is not capable of printing fine pitch patterns needed for 14 nm, 10 nm, and 7 nm node technology generations, double patterning techniques such as litho-etch-litho-etch (LELE) [1], litho-litho-etch (LLE) [2–6], and self-aligned double patterning (SADP) [4, 7] – also known as sidewall image transfer (SIT) – have been used to enable the fine pitch patterning. This section explores the nature of SADP technique. A

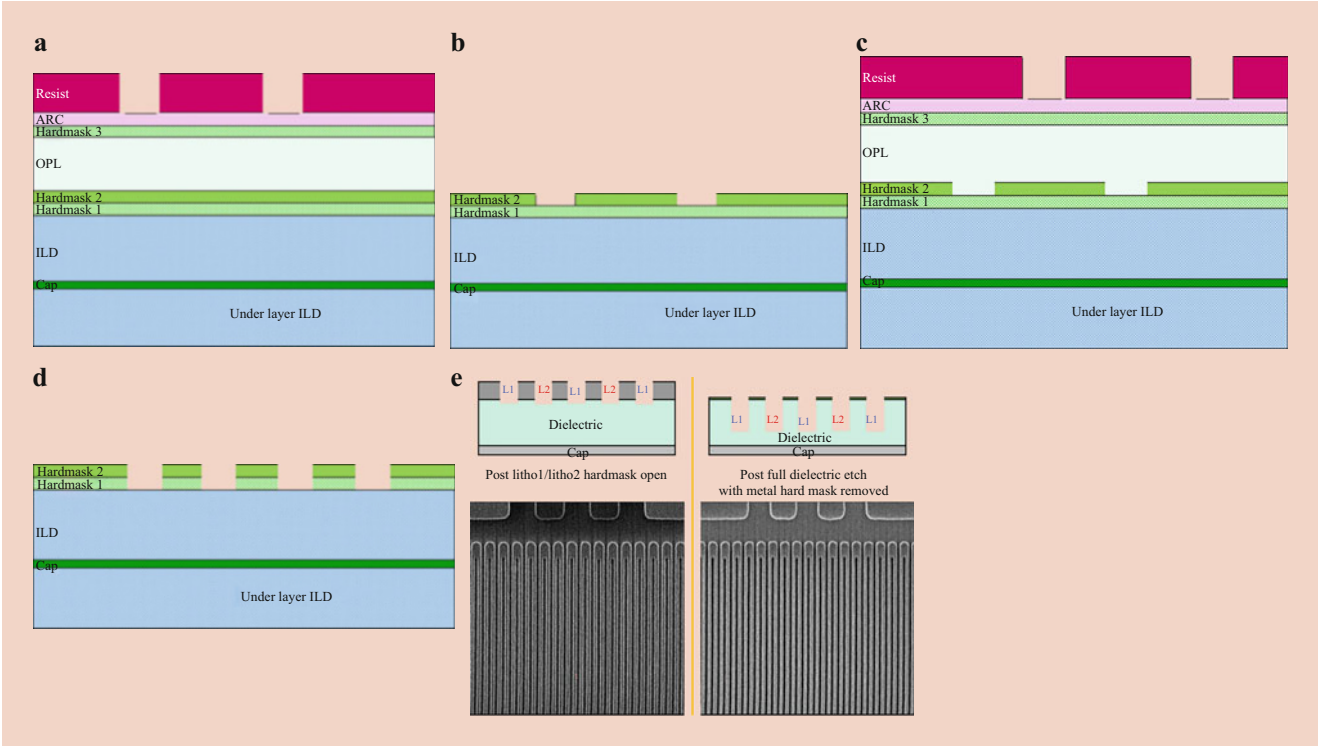

Fig. 5.7 (**a**–**d**) Process flow diagram for a trench-first pitch split patterning scheme. (**e**) SEM images of two 128 nm pitch line patterns (L1 and L2) forming a 64 nm pitch pattern (see text)

8. Metallization.
9. Cu CMP.

5.1.8 2D Versus 1D Self-Aligned Double Patterning (SADP)

The SADP process flow demonstrated in the last section is for 2D patterning. Because of the nature of the process flow, spacing between lines are fixed and determined by the spacer thickness. This means that even large size metal features will only have small spacing same as the minimum size features. This scheme often causes defect issues. Also, fine line features with tight turn around or cross shapes often have defects associated with these types of patterns.

As the result, it is common for chip industry to limit the pattern using SADP process to 1D only. This means that only straight-line patterns are allowed in one preferred orientation (horizontal or vertical). The level above or below will be the same with alternating horizontal and vertical wiring orientations. This simplifies the process but will require interlevel vias for signal transmission and electrical testing.

In general, a SADP, double patterning process flow is more complex than the pitch-split double patterning, but it may be able to provide a smaller final pitch pattern. It is also possible to combine both schemes to further reduce the

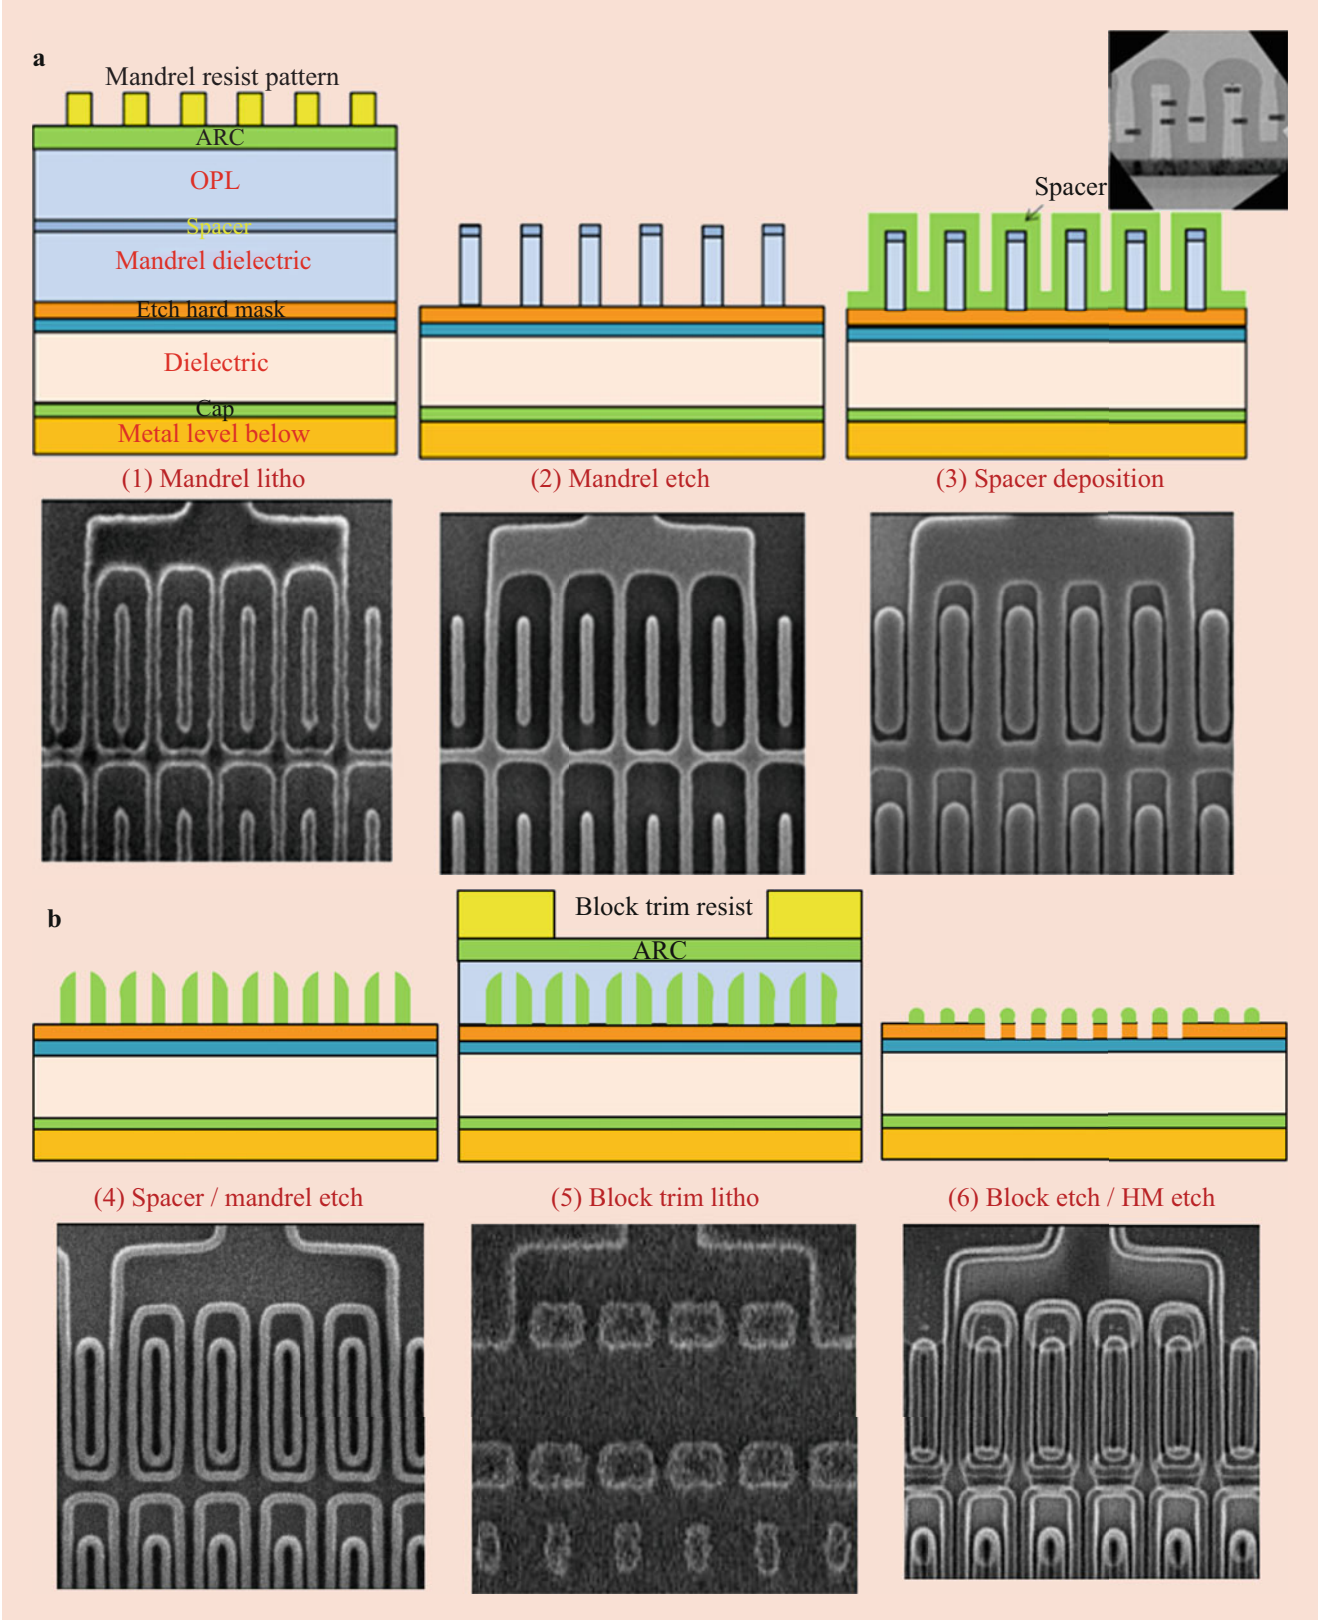

Fig. 5.10 (continued)

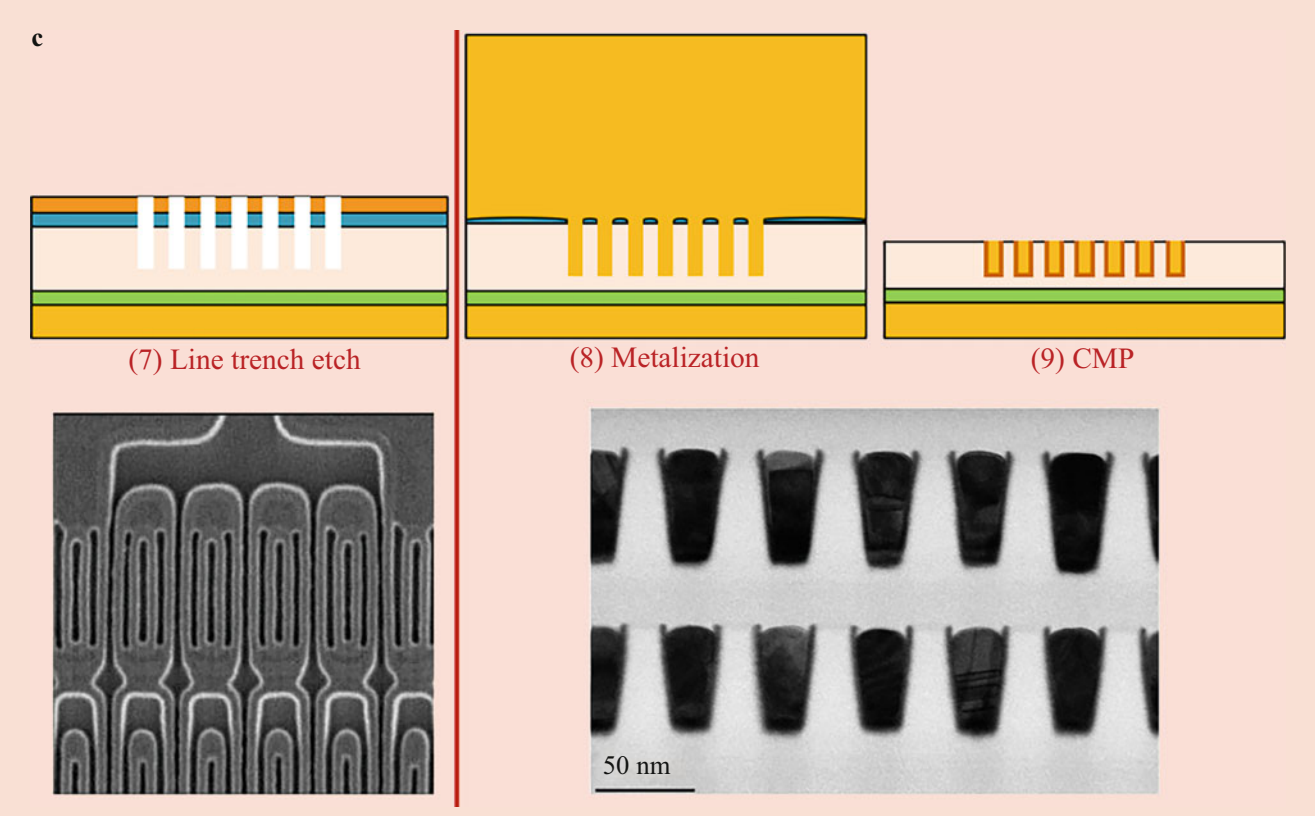

Fig. 5.10 Diagram of a self-aligned double patterning process flow with representative SEM images from each stage of the process (see text). (Ref. [8], reprinted with permission)

minimum pitch size. For example, one may use pitch split to create mandrel pattern for the SAHD process flow.

5.1.9 Future Outlook: EUV Single and Double Patterning

Future logic development at technology nodes of 5 nm and below will depend heavily on further development of EUV patterning schemes. With that in mind, several issues related to integration of EUV into BEOL will figure prominently.

EUV single patterning innovation will be critical. The EUV litho tool has evolved to print smaller and smaller feature size pattern with single exposure. With high NA (numerical aperture), it may be possible to print 20 nm pitch line patterns on the wafer. In this case, the pattern size on the mask would be 80 nm pitch, as traditionally the print reduction from mask to wafer is 4–1. This 80 nm pitch size may already hit the mask patterning limitation. To print details smaller than a 20 nm pitch on the wafer may require increasing this reduction ratio to over 4. For example, if the reduction ratio is 5 with new optics in the litho tool, it may be possible to print 16 nm pitch pattern on the wafer assuming that the photo resist is available for this feature size. EUV double patterning will also present opportunities. Just like 193 nm DUV litho double patterning, it is also possible to use EUV double patterning for integration. It would be much easier to print 2× pitch pattern using EUV litho tool.

Integration of advanced BEOL nodes at smaller ground rules will also open up other issues in integrating advanced lithography. Defect characterization and minimization will evolve. As pattern feature size becomes very small, it is more challenging to characterize the defects in the pattern and eliminate them. For very fine lines, copper may not be the best conductor material for the metal line. The traditional damascene scheme using a liner and copper fill metal may result in the higher resistance liner layers simply filling up the trench space, leaving minimal volume for the copper conductor to fill. Also, at small line widths, copper line resistance may not be smaller than other candidate materials, such as cobalt, ruthenium, etc. If choosing another conducting material to replace copper, the integration scheme may need to be re-engineered to adapt the new material. Some of these topics will be covered further in the metallization section later in this chapter. In summary, very fine pitch line patterning remains as a very challenging task, and it will require a significant amount of effort and resources to accomplish the mission.

5.1.10 BEOL Performance

Back-end-of-line (BEOL) interconnect resistance has a major influence on overall device performance in advanced CMOS technology nodes. As critical dimensions continue to shrink, interconnect line resistance increases due to reduced cross-sectional area available for conduction as well as because of the well-known resistivity size effect [9–12]. Tight process control is critical to minimize structural variations, which in turn impact line resistance and overall performance. Even relatively minor variations in interconnect geometry arising from line edge roughness, RIE lag, and CMP can have nontrivial impacts on overall performance [13].

Gauging the impact of minimum pitch interconnect line resistance on overall performance depends on several factors, including design architecture. For example, an inverter can have a variable fanout (FO) depending on how many inverters are being driven by the output of the first. In Fig. 5.11, we show schematic circuit diagrams for simple inverters with FO of 1, 2, and 3. It has also been reported that the impact of BEOL resistance modulation depends on the relative FEOL resistance, determined by the device architecture and driver size [14]. Device architectures with larger inverter drive strength have larger contacts and lower resistance, which increases the sensitivity to BEOL resistance.

In advanced technology nodes beyond the 7-nanometer node, BEOL loading represents an increasing percentage of the overall delay. In Fig. 5.12a, we show the frequency as a function of power for a four-fingered inverter with a three-way fanout. The loaded case assumes 30 nm pitch interconnects with line resistance estimated based on temperature coefficient of resistivity (TCR) measurements as reported in the literature [15, 16]. The unloaded case assumes zero BEOL resistance. The difference between the loaded and unloaded cases is quite large, indicating that interconnect delay is a major bottleneck in achieving favorable overall performance.

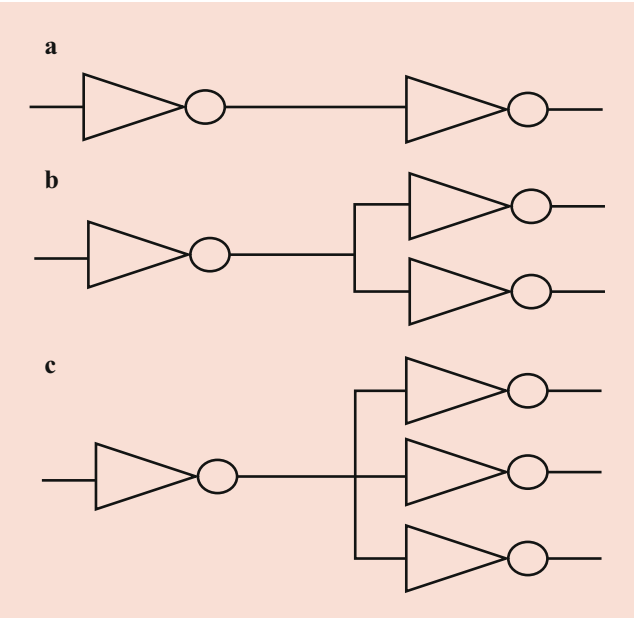

Fig. 5.11 Circuit diagrams for inverters with fan-out of (**a**) 1, (**b**) 2, and (**c**) 3 used for performance benchmarking

In Fig. 5.12b, we show the impact of line resistance reduction for a four-fingered inverter with variable fanout. We see enhanced sensitivity to line resistance modulation as the fanout increases from 1 to 3, since the BEOL load is being spread over more and more transistors. The performance uplift arising from a 50% reduction in line resistance at 30 nm pitch is between 10% and 15% depending on the circuit topology.

As technology nodes continue to shrink, the importance of BEOL parasitic resistance will grow ever larger. Significant innovation in metallization and the development of tight process control are paramount to enabling the successful scaling of future technologies.

5.2 BEOL Dielectric Films

In 1965, the first semiconductor device was fabricated at Bell Laboratories [17] to initiate a semiconductor industry that integrates various electronic components onto the same Si chip creating the integrated circuits (IC) and using the same materials in its structures. Today, the industry is integrating also various materials in the same chip, after extensive and prolonged development efforts to accomplish successful integration of the required new materials. Among these new materials are the dielectric insulators of the interconnects of VLSI chips.

For the last 50 years, the performance of the VLSI integrated circuits was progressing following Moore's law [17], by shrinking the dimensions of the individual devices and packing more devices in the same area. The decreasing dimensions of the devices made them faster with each new technology generation. Tremendous progress in the manufacturing of integrated circuits over the past 50 years has reduced the device feature size, which has gone from 10 μm down to 5 nm and beyond. The per transistor cost has decreased by eight orders of magnitude, and the maximum number of transistors per chip has increased by billions of times.

Figure 5.13 shows a diagram of a typical cross section of an advanced IBM 14 nm devices circuit and an illustrated graphic of an integrated memory/logic circuit that will be implemented for advance AI structure in the Cu low-*k* interconnect. Most of the device cross section's real estate is occupied by the interconnect back end of line (BEOL). These wirings are to connect between individual active devices,

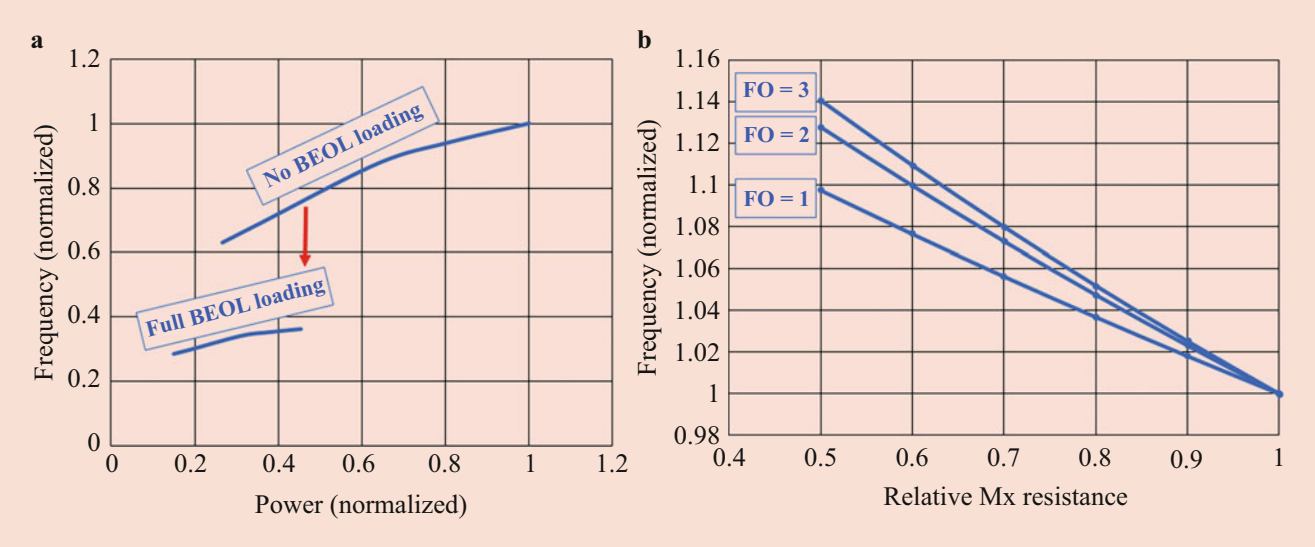

Fig. 5.12 (**a**) Overall device performance for a circuit with and without BEOL loading. (**b**) Performance impact of line resistance reduction for variable inverter fan out

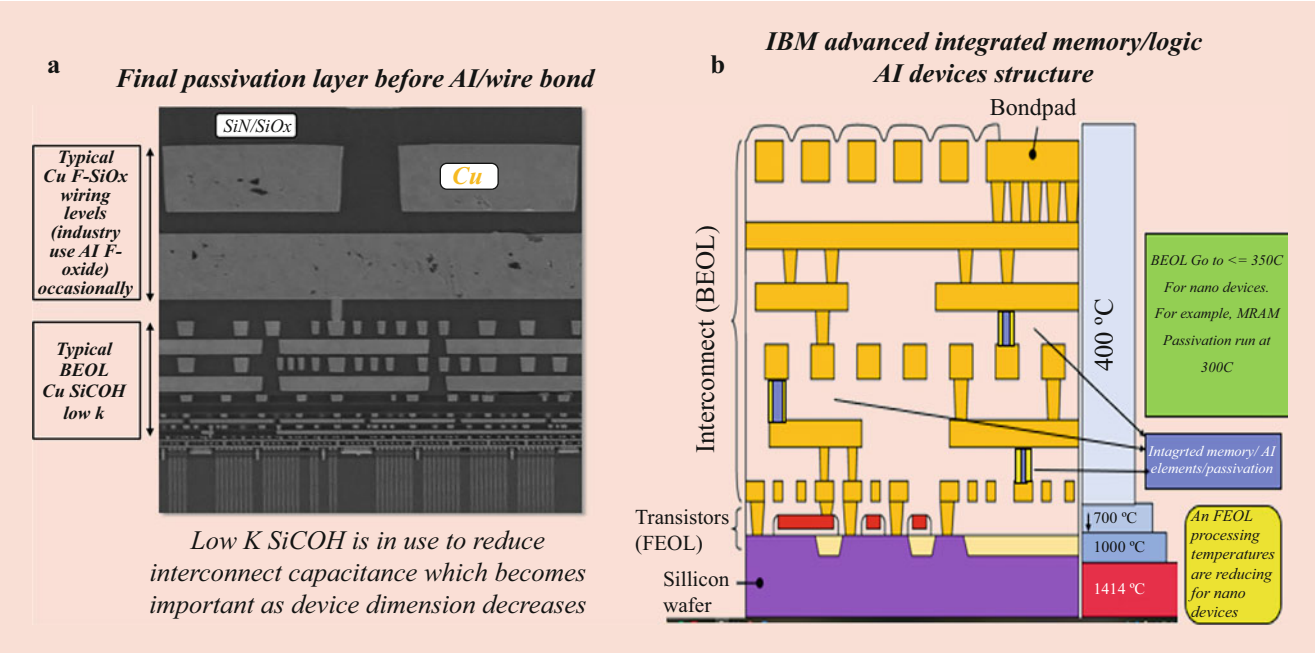

Fig. 5.13 (**a**) Scanning Transmission Electron Microscopy (STEM) picture of an Advanced IBM 14 nm chip. (**b**) Diagram of a cross section of an advanced integrated circuit, integrating both memory and logic using nano-dimension circuit with Cu/low-*k* interconnect

transferring signal between the logic/memory devices and eventually the outside of the chip as electrical current signal. For nano-dimension circuits, the signal delay between the active devices, the integrated memory and logic, and the cross talk between devices and the outside world strongly depend on the *RC* (R = resistance; C = capacitance) of the BEOL. Resistance R is directly related to the metal wiring (Al, Cu, Co, etc.) and capacitance C is directly related to the dielectric material used in the BEOL fabrication. Until the 0.25 μm generation, the interconnect was composed mostly of the elements Si, O, N, and F for dielectric and aluminum and polysilicon for wiring. At this technology node, the *RC* of the BEOL became a bottleneck to the improvement of the performance of the VLSI devices. The *RC* of a metallization level in the interconnect can be defined by [18].

$$\mathrm{RC} = 2\rho k\left(4L^2/P^2 + L^2/T^2\right)$$

where L = line length, P = metal pitch, T = thickness of metal line, ρ = metal resistivity, and k = dielectric constant.

The reduced dimensions of the devices resulted in the increase of both R and C to the extent that, while the active devices became faster, the interconnects did not. Since the original SiOx dielectric, the next material to be successfully integrated in a microprocessor was fluorinated silicon glass (FSG or SiOF), introduced in 2000 as the intra- and interlevel (ILD) dielectric at the 0.18 μm technology node [19, 20]. The fluorination of the silicon dioxide reduced its dielectric constant from 4.1 to 3.6, thereby reducing the capacitance of the interconnect and reducing the overall RC.

5.2.1 Fabrication of BEOL Low-*k* Dielectric Films

The promotion of a chemical reaction by an electrical discharge through gasses has been known for over a century. The first work specifically aimed at plasma deposition for microelectronic uses appeared in 1963 but 10 more years passed before commercial batch processing equipment was introduced [42]. Plasma-assisted deposition of thin films is widely used in microelectronic circuit manufacturing since the 1980s [43], and a comprehensive review of the previous generation of dielectric materials such as SiOx, SiNx, and F-SiOx before SiCOH generation, including high-density plasma processing, are included in these two reviews [43, 44]. In the early 1980s, IBM evaluated low-k SiCOH as plasma-deposited organosilicon polymer using various organosilicon polymers for lithographic measurement [45]. Early metal-insulator-semiconductor (MIS) electrical measurement showed that SiCOH organosilicon film with dielectric constant (k) value around 3.4 may be obtained for this SiCOH. Since the late 1990s, plasma-deposited processing has also been used to deposit SiCOH film with $k \sim$ 3–3.2 for advanced Cu/SiCOH microelectronic fabrication for 90 nm device node [25–28].

The first successful non-SiOx low-dielectric constant material in IBM was the organosilicate glass, SiCOH, deposited by plasma-enhanced chemical vapor deposition (PECVD) [21] with a dielectric constant k = 3.0. SiCOH 3.0 was successfully integrated in some 130 nm and 90 nm products starting in 2001 [22–24] and then in almost all the 90 nm node industry products since 2004 [25–27]. Figure 5.13 shows a typical advanced IBM 14 nm node chip and representative diagram of various layer and potential integrated memory element that can be implemented in advanced integrated memory-logic device structure. There are many polymers and dielectric materials that have been explored as low-k dielectrics over the years [28–30], but the most successful ones are plasma-deposited SiCOH and porous SiCOH that have been implemented widely in Cu/low-k interconnect BEOL by the semiconductor industry in the last 20 years. In this section, we will focus mostly to the plasma-deposited SiCOH and other potential plasma low-k dielectrics.

For plasma-deposited SiCOH dielectric materials, there are two main approaches that have been implemented to reduce the k value in the film: (1) insertion of carbon into the well-known SiO_2 bonding network for SiCOH film and increase of the low-polarity bonding and materials (increase C-C, Si-CH_3, Si-C-Si low polar bonding) in the SiCOH film to reduce the polarizability. (2) Creation/insertion of porosity into the SiCOH film by changing deposition process parameters and/or subsequent post-deposition film's treatment by low-temperature UV/E-beam or thermal processing.

The "carbon-doped" oxide (a-SiOC:H) material has a reduced dielectric constant value k in the 3.0–3.2 range, and the porous low-k SiCOH film has a dielectric constant value in the 1.8–2.8 range with 7–50% porosity. The slow progress in implementing highly porous, ultralow-k SiCOH ($k < 2.7$) into production has been mostly related to the weak mechanical properties of the low-k film. The difficulties in integrating these new materials into current metallization and patterning are well documented [31–41].

5.2.2 Low-*k* and Ultralow-*k* Porous pSiCOH ILD Dielectrics

Dense SiCOH and Porous pSiCOH ILDs

Plasma deposition of SiCOH interlevel dielectrics is normally achieved in a parallel plate reactor with a skeleton organosilicon precursor mixed with a porogen precursor in liquid (with carrier gas) and reactive gasses in the reactor during the deposition. Tetramethylcyclotetrasiloxane (TMCTS), octamethylcyclotetrasiloxane (OMCTS), and Tetramethyl Silane, Diethoxymethylsilane (DEMS) decamethylcyclopentasiloxane, or linear or branched compounds such as methyltriethoxysilane, methyltriethoxysilane, or vinyl variations of above are the widely used skeleton precursors (see Fig. 5.14) [46–48]. For porogen, unsaturated cyclic hydrocarbons like terpinenes or norbornenes as listed in Table 5.1 are widely used. These skeleton organosilicon precursors, especially the one with stable ring structure precursor as OMCTS and TMCTS, have a common stable structural property with a sufficiently low dissociation level under RF power. The stable structure retention with increased cross-linking bonding will increase overall SiCOH film's bonding density and subsequently enables the increased film's modulus and hardness for the produced low-k dielectric material. The porogen precursor is an organic molecule with enough volatility. Other precursors like linear alkenes, or molecules with strained rings like cycloalkene oxides or butadiene monoxide, have been explored but with limited use [40, 49]. The as-deposited SiCOH-CxHy organosilicon-hydrocarbon matrix films are normally deposited by plasma CVD process in temperature range below 300 °C. After the deposition, the film must be

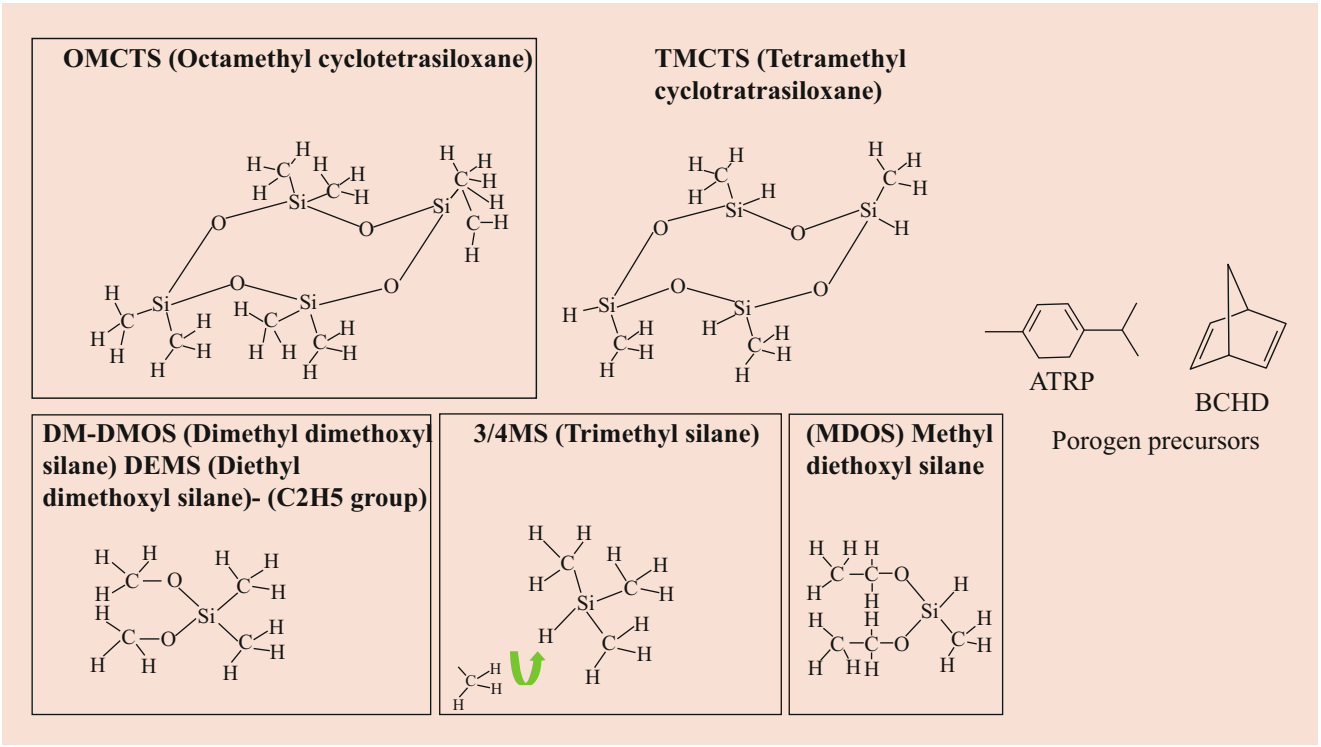

Fig. 5.14 Typical organosilicon precursors and two basic commonly used hydrocarbon porogens for low-*k* SiCOH dielectric and SiCN, SiC caps. The plasma CVD processes also uses various oxygen (O_2, N_2O, CO_2) and nitrogen (N_2, NH_3)-based gases

cured to remove the labile organic porogen fraction CxHy and form a porous film. The curing can be done thermally [50] or using electron beam or ultraviolet (UV) irradiation [51]. For Cu interconnect, the thermal cure is not in favor since it requires several hours curing at 400 °C and generally produces films of low mechanical strength. E-beam curing has been explored and generally found to cause some device damage. The semiconductor tooling industry has adopted instead broadband UV curing for the fabrication of pSiCOH dielectrics. The UV curing with 210–400 nm wavelength is normally done in a few minutes with limited device's thermal and radiation exposure of under layers and has become the choice process for the industry. For porous SiCOH film's formation, the UV curing process removes some weakly bounded porogen volatiles, breaks a fraction of mainly the Si-CH_3 (Si-Me) bonds, and rearranges and enhances the cross-linking of the skeleton. Better removal efficiency of volatiles can be done by UV-assisted curing. However, the temperature of the curing must be limited at ≤400 °C. The mechanical strength (elastic modulus and hardness) of the porous low-*k* SiCOH dielectric material is improved by UV-assisted curing due to the rearranging and enhancing of the cross-linking of the skeleton of the low-*k* SiCOH. Long UV cure may increase the modulus by increasing cross-linking bonding for even extreme porous low-*k* materials. However, long overcure can cause loss of too many Si-Me bonds and pore collapse, resulting in films of higher-*k* values [40].

For dense SiCOH ($k \sim 3.0$) and lightly porous SiCOH ($k \sim 2.7$–2.8), the film is normally deposited at the 350–400 °C temperature range [52, 53] with an adhesion layer of SiOx film to increase the adhesion strength between the SiCOH and the deposited under layer, e.g., the SiN or SiCN cap [54]. The reduced *k* SiCOH films with $k \sim 2.7$–2.8 is also deposited in a production-300 mm PECVD system using a commercially available, simple ring structure organosiloxane OMCTS precursor, and oxygen at 350 °C under the dual RF frequencies. Low-*k* SiCOH of 3.0 and lightly porous $k \sim 2.7$–2.8 film deposition using basically the same precursors and process equipment are utilized. The plasma deposition process parameters such RF power frequencies and densities, pressure, temperature, electrode spacing, and precursor ratio can be changed to deposit higher or lower-*k* values by changing the SiCOH film's porosity from none (dense SiCOH film, $k \sim 3.0$) to lightly porous SiCOH (7–8% porosity, $k \sim 2.7$–2.8). SiCOH films are characterized by using various electrical measurement and analysis techniques including nanoindentation for modulus (E) and hardness (H), four-point bending method for adhesion, Fourier transform infrared (FTIR) and nuclear magnetic resonance (NMR) for bonding structure, and X-ray reflection (XRR) for film density. The crack velocity and cohesive strength is also measured at this stage. The film structure analysis shows that the optimized films have 7–8% porosity and contain a high level of cross-linked Si-O and Si-CH2-Si bonding, which

is attributed to its overall lower-*k* and improved mechanical strength. The improved low-stress mechanical properties make SiCOH 2.7 implementation possible in various interlevel dielectrics of 65/45/32 nm Cu/low-*k* BEOL. Tables 5.1 and 5.2 show a list of film's properties of plasma-deposited dense SiCOH with $k \sim 3.0$ and lightly porous SiCOH with $k = 2.7$–2.8 range.

The fabrication of low- and ultralow-*k* SiCOH dielectrics in the BEOL interconnect structures of ULSI chips involves may complex stacks with multiple interfaces as shown in Fig. 5.13. Complex and reliable chips require strong adhesion between the different layers of the stacks. A critical interface in the dielectric stack is the interface between the standard diffusion cap (SiCN or AlOx/SiCO) and the SiCOH inter- and intralevel dielectric materials. In standard deposition of SiCOH process, the interface layer is weakened both by a low adhesion strength between SiCNH and SiCOH and by the formation of an initial layer of SiCOH with reduced cohesive strength. By modifying and engineering the gas and RF power during initial deposition process, the interface composition can be modified to obtain interfacial strengths close to the cohesive strengths of the bulk ILD [53]. The film integration into 65/45/32 nm ground rule structures is achieved by direct CMP and results in high-yield, low RC Cu low-*k* interconnect as representatively shown in 65 nm node, 10 levels BEOL Cu/low-*k* structures fabricated with F-SiO*x* ($K \sim 3.6$), dense SiCOH ($k \sim 3.0$), and lightly porous SiCOH ($K \sim 2.75$), Fig. 5.15. Capacitance reduction by various low-*k* dielectrics can be demonstrated by measuring the RC reduction in a single layer of 4× fat wire of 45 nm BEOL, as shown in Fig. 5.16.

Development of Advanced pSiCOH with Improved Properties

Further reduction of the dielectric constant of the above SiCOH 2.7 films requires further introduction of porosity higher than 10% in the low-*k* SiCOH dielectrics. Porous pSiCOH films can be fabricated by the *subtractive* methods [39] to achieve highly porous SiCOH film with $k \leq 2.55$ [39–41]. As mentioned above, the porous SiCOH films are

deposited as a dual-phase material, SiCOH-CHx with the UV cure, to obtain porous low-*k* film with improved mechanical strength (higher elastic modulus and hardness). The value of the modulus increases with longer UV cure; however, over-cure can cause loss of too many Si-methyl bonds and pore collapse, resulting in films of higher-*k* values. Mechanical robustness of low-*k* porous SiCOH can also be improved by controlling porogen decomposition prior to UV curing, to achieve significant reduction in the dielectric constant from 2.3 to 1.8 with Young's modulus in the range 4.6–5.2 GPa even at very high porosity levels, e.g., from 32% to 46% open porosity [55]. The increase in Young's modulus is attributed to an enhanced molecular bridging mechanism when the film is hardened without porogen. UV cure wavelength also has significant impact on pSiCOH film performance such as plasma processing-induced damage (PID) [57]. The choice of the UV curing light source ($\lambda = 172$ nm vs $\lambda > 200$ nm) has significant impact on the chemical composition of the low-*k* material and modifies the porogen removal efficiency and, subsequently, the material porosity [20]. However, the high and open porosity will cause a significantly high moisture absorption and diffusion, making the material too fragile for high-yield reliable nano integrated circuit fabrication.

Furthermore, high porosity in SiCOH film will have strong effect on the p-SiCOH electrical leakage and breakdown [57]. Under specific UV processing, the leakage current is found to be insensitive to porosity, suggesting a bulk conduction mechanism. However, the increasing porosity results in lower breakdown fields which indicate that porosity can degrade the electrical reliability performance of the dielectric materials. The impact of porosity into the electrical properties of SiCOH has been attributed to the complex change in the film's bonding structure with film's deposition process and UV cure conditions [57].

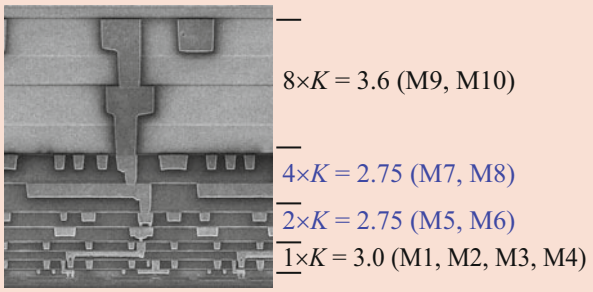

Fig. 5.15 Typical 65-nm node, 10 levels BEOL Cu/low-*k* structures fabricated with F-SiO*x* ($K \sim 3.6$), dense SiCOH ($k \sim 3.0$), and lightly porous SiCOH ($K \sim 2.75$)

BEOL Integration Challenges for Low-*k* and ULK SiCOH

For a successful SiCOH dielectric integration into nano ULSI electronic devices, the dielectric needs to meet many critical material and subsequent process integration steps to meet device performance, yield, reliability, and packaging requirements. Some of the main SiCOH dielectric material requirements are:

1. High interfacial strength (adhesion) to dielectric caps such as SiN, SiCN, and composited AlO*x*/SiCO cap. Strong adhesions between various dielectric cap layers are required during and after device fabrication steps, to maintain the integrity of the devices and the reliability of the ULSI chip in packaging [53].
2. Sufficiently high mechanical properties, i.e., a high elastic modulus, especially for chip packaging (or chip-package

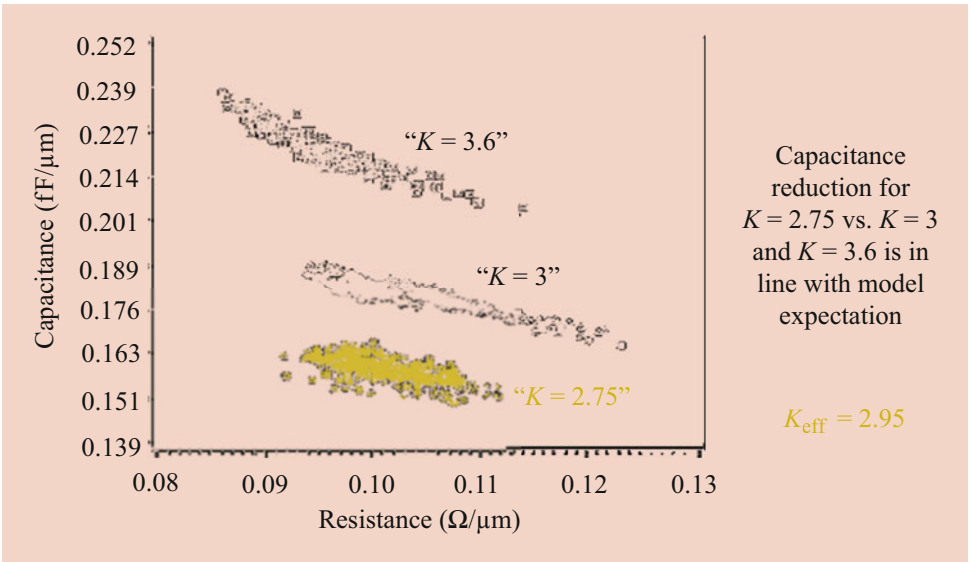

Fig. 5.16 Typical capacitance reduction in a 4× fat wire level of 45-nm BEOL using various low-*k* values for comparison

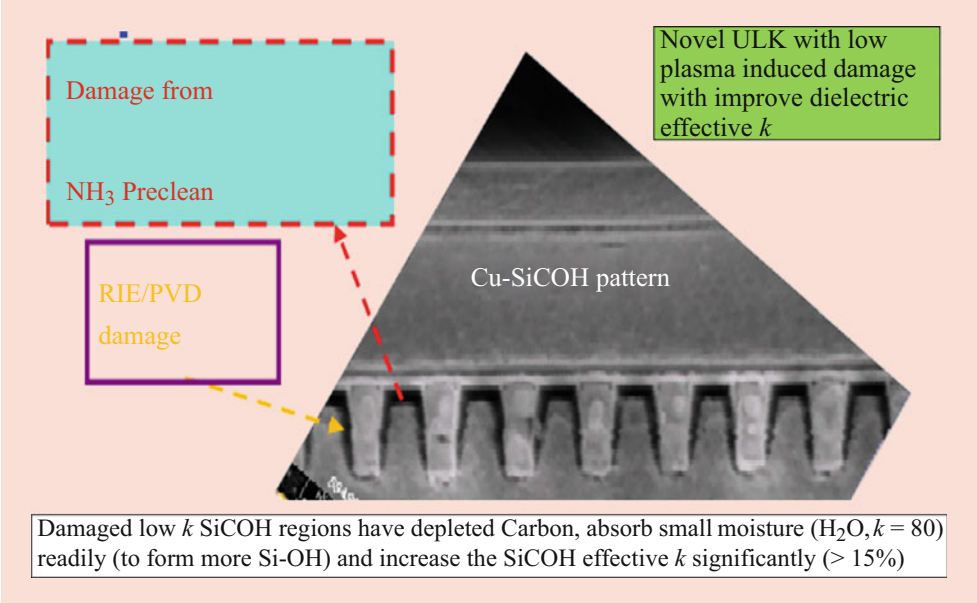

Fig. 5.17 Scanning Transmission Electron Microscopy (STEM) of a Cu/SiCOH nano-size structure showing plasma-induced damage to SiCOH by physical vapor deposition (PVD), reactive ion etching (RIE), and plasma surface treatments such as H_2/O_2 and NH_3 plasma

interaction, CPI), and high hardness for CMP. Low-*k* porous SiCOH films worsen the mechanical properties of SiCOH, due to the decrease in strong Si-O bonding by porosity and/or the reduction of the coordination number due to the replacement of some O with C in case of porous C-Rich SiCOH [41].

3. High resistance to process-induced damage (PID) during fabrication [58]. Other process-induced damages include damage to the ULK caused by CMP, PVD metal deposition, and especially during dielectric etching and photoresist removal by ashing. Figure 5.17 shows the scanning transmission electron micrograph of a sub-40 nm patterned Cu/SiCOH structures that have been highlighted with diluted buffered HF acid wet etching to reveal a typical SiCOH damage. Water moisture in air ambient (H2O, $k \sim 80$) can be absorbed readily into damaged SiCOH region and produces a significant overall increase of *k* (to more than 15%). If the damaged layer is removed by wet etching, then the CD control will be an issue for nano-size metal lines. A good ULK dielectric with good resistance to PID is required in order to enable control of critical dimensions (CD) and to preserve the initial *k* value.
4. Ultralow-*k* porous SiCOH with small pore size (<1.4 nm diameter, <28% porosity) and with minimal interconnectivity is needed to prevent penetration of liners and humidity into the dielectrics and maintain the low-*k* values and device's reliability.
5. Hydrophobicity is necessary to maintain *k* values. Penetration of humidity into the dielectric will increase the dielectric constant. C-rich SiCOH films normally have lower-*k* and higher hydrophobicity [41].

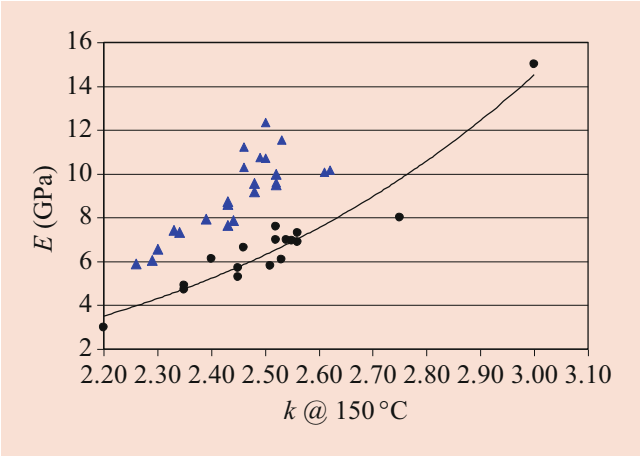

Fig. 5.18 Typical plots of the modulus versus *k* value for various dense SiCOH ($k \sim 3.0$) and porous SiCOH ($k \sim 2.2$–2.8) films, deposited by plasma CVD processing with and without UV. (Ref. [39], reprinted with permission)

All these requirements are quite difficult to achieve at the same time for specific ULK porous SiCOH dielectrics, as in the last decade the dielectric film's thickness reduced, with reducing device size, below 20 nm. For several years, most device manufacturer were stuck with SiCOH with *k* value around 2.5–2.7 range in device manufacturing, even if the lower-*k* pSiCOH can be deposited readily by PECVD process [40, 55–57].

For device integration, it has been very difficult to integrate porous SiCOH film with dielectric constant below 2.4 and porosity above 30%, due to the poorer electrical and weak mechanical and chemical properties of the lower-*k*, high-porosity pSiCOH film. For SiCOH film with dielectric

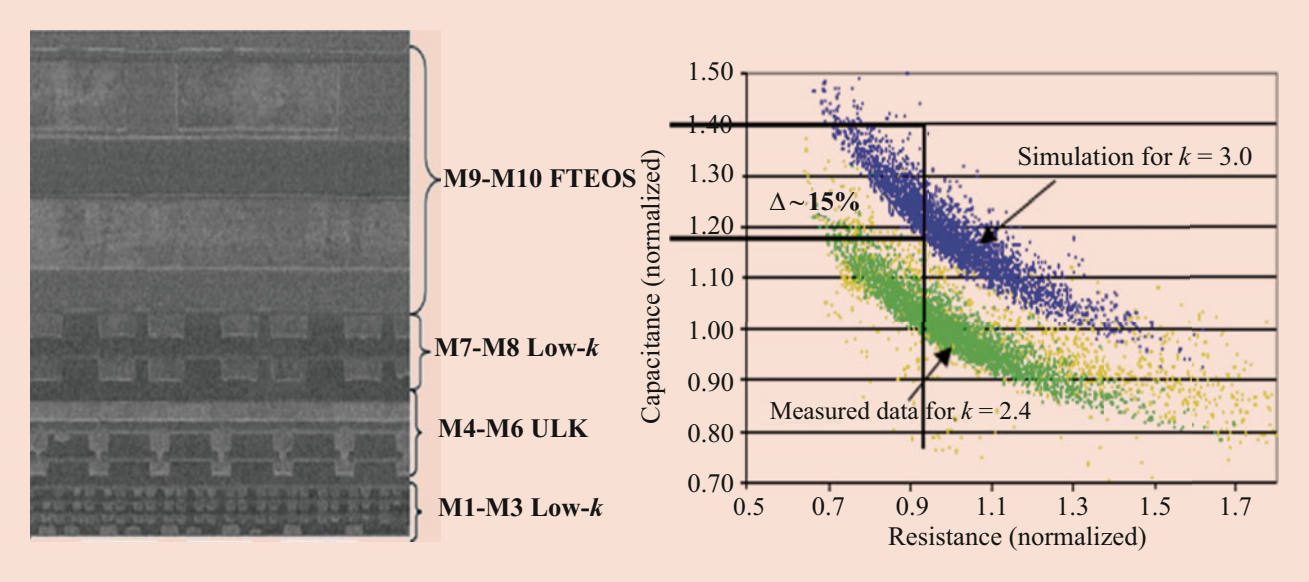

Fig. 5.19 Significant capacitance reduction (~15%) in 45-nm BEOL structures when metal M4-M6 levels change from low-*k* SiCOH ($k \sim 3.0$) to ultra-low-*k* porous SiCOH ($k = 2.4$)

constant in the range of 2.4–2.45, the typical dependence of SiCOH film's modulus vs dielectric constant value is shown in Fig. 5.18. For high-reliability and high-yield semiconductor device manufacturing packaging, high modulus (≥7 GPa) SiCOH dielectrics are preferable. Currently, SiCOH and pSiCOH dielectrics implemented in advanced BEOL semiconductors have been limited to *k* value above 2.5 with modulus higher than 7 Gpa. Our IBM process has used pSiCOH with $k = 2.4$ in device fabrication of 45 nm node BEOL for advanced high-performance power chip [36], to achieve significant capacitance reduction as shown in Fig. 5.19. Plasma CVD C-rich pSiCOH named as OEx SiCOH, deposited with single OMCTS precursor and UV curing, has also been used to deposit lower porosity, high hydrophobicity, and low PID pSiCOH with good device reliability for Cu/low-*k* interconnect [41]. The film has no porogen as a part of the initial deposition at low temperature and RF power to retain the original stable OMCTS precursor backbone bonding. There are no residue porogens to remain in the film after UV cure, and all carbon atoms in this C-rich SiCOH film are bonded in a stable Si-C and Si-CH2-Si bonding structure of the precursor, thus improving the pSiCOH film's stability and PID. Table 5.3 compares the relative PID, carbon, porosity, and other properties of the OEx pSiCOH 2.4 with other pSiCOH film. The overall dielectric reliability and performance are clearly superior to other pSiCOH dielectric with similar *k* value. The new OEx *k* 2.4 film shows comparable or better film properties than the reference $k = 2.55$ and other 2.4 films. The increased carbon content improves the resistance to process-induced damage, this resulting in better TDDB

Table 5.3 Blanket film properties of ultralow-*k* materials

Properties	Film			
	ULK 2.7	ULK 2.55	ULK A (*k* 2.4)	OEx
Dielectric constant	2.7	2.55	2.4	2.4
Porosity (%)	7	14	19.7	20
Pore diameter (nm)	1.1	1.2	1.3	1.3
%C	21.6	23.2	17.2	30
Modulus (GPa)	3	6.64	7.34	7
PID Ratio	0.33	0.57	0.65	0.35

performance over multiple semiconductor nodes. Higher carbon content, mostly incorporated and retained in the bridging bond (Si-CH2-Si), improves the modulus of the film. Apart from reliability benefit, the film retains the capacitance benefit by demonstrating an overall lower integrated *k* value as compared to the SiCOH *k* 2.55 dielectric. Figure 5.20 shows a STEM cross-sectional structure of 7 nm BEOL devices with three thin wires: dual damascene Cu in $k = 2.45$ porous SiCOH, 36 nm pitch with significant capacitance reduction. It is shown that excellent reliability results can be obtained for Cu interconnects with this OMCTS-based pSiCOH 2.45 at these small dimensions [59].

5.2.3 Advanced Dielectrics and Processes for Metal Interconnect

Flowable Gap Fill SiCOH

For low-*k* SiCOH film with good gap fill, flowable gap fill CVD of Lightly porous pSiCOH with $k \sim 2.75$ with

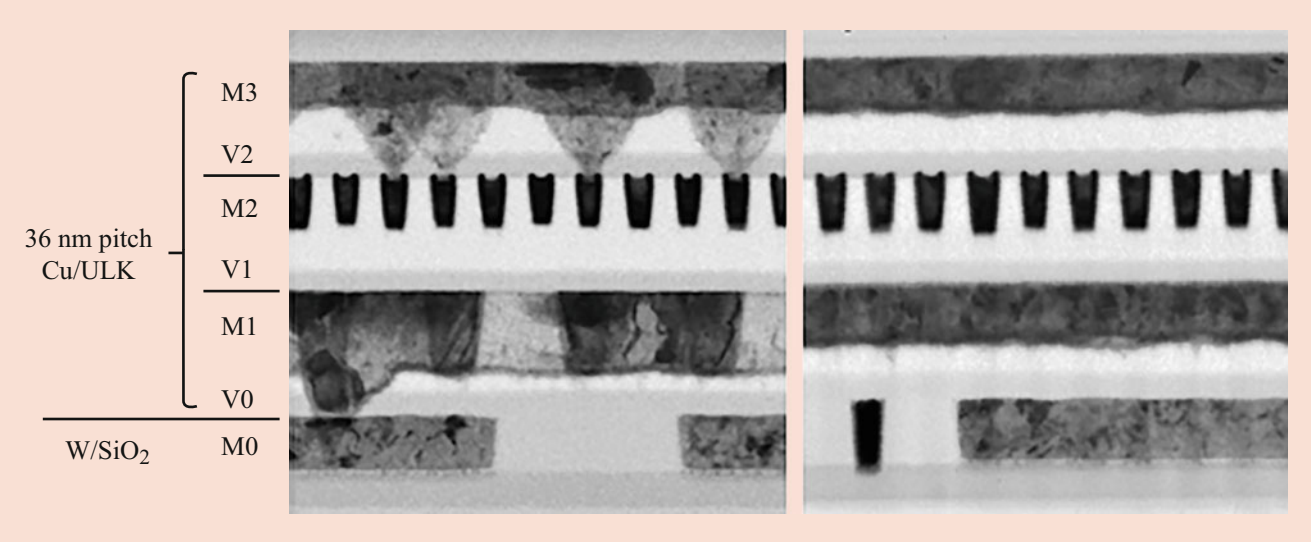

Fig. 5.20 Cross section of a 7-nm BEOL structure with 3 thin wires: dual damascene Cu in ILD $k = 2.45$ porous SiCOH, 36 nm pitch with significant capacitance reduction

excellent gap fill capability was developed for fully aligned via (FAV) structure application 5 nm BEOL and beyond [60]. Figure 5.21 shows typical good fill behavior of FCVD SiCOH 2.75 over high aspect ratio. The film was deposited using cyclic organosilicon precursor like OMCTS and linear precursor tetramethoxyl silane (TMOS) deposited at <100 °C to fill high aspect ratio gap and then UV cured at 400 °C to densify and to enhance cross-linking Si-CH2-Si and Si-O bonding in the structure to improve film's modulus. The UV cure also creates porosity in the film to reduce *k*. Post UV cure flowable low-*k* SiCOH 2.7 dielectrics has higher porosity and higher PID than standard plasma-deposited SiCOH 2.7. Table 5.4 shows the relative comparison between industry plasma CVD SiCOH 2.7 and 2.55 vs FCVD SiCOH 2.78. As deposited, the FCVD SiCOH film has relatively lower carbon concentration, higher porosity, and higher relative PID compared to plasma-deposited film than the sample *k* value. Furthermore, the as-deposited FCVD SiCOH 2.75 film is also inferior to plasma CVD SiCOH 2.7 in terms of dielectric reliability performance. However, the FCVD SiCOH film improves significantly with subsequent processing ion implant and laser annealing [61].

A recent study [61] showed that a UV cure-based silylation process can be implemented at post-etch/strip step to repair the processing damage of Cu/ULK (ultralow-*k* SiCOH ~2.6–2.7) interconnect. This will reduce post processing capacitance by 3.0% and 4.0% at 32 nm and 24 nm line widths, respectively. Also, TDDB lifetime improves by 5 orders of magnitude. The simple UV-based recovery process using in situ plasma preclean of Cu will restore some of the pristine ULK IMD properties and reduce the capacitance in pattern structures. The UV cure-based silylation process can also remove some volatile weakly bonded ULK impurities, smoothening the film's surface roughness, and enhance sur-

face hydrophobicity. This subsequently results in a strong improvement of TDDB and EM in the Cu/low-*k* interconnect structure. This UV-based low-*k* silylation recovery process can be implemented as an RC performance and reliability booster to the conventional damascene Cu/low-*k* integration scheme.

Pinch-Off Deposition Air Gap

Further capacitance reduction is therefore vitally important for BEOL device performance. To further reduce capacitance below SiCOH 2.4, other innovations in device structure and process integration such as air gap are surely needed [63–68]. For BEOL, air gap is one promising approach to reduce capacitance that has widely been published by IBM [63, 64] since early 2007. More significantly, this air gap technology may be the only road map ensuring that effective dielectric constants ≤ 2.0–2.2 can be achieved [69]. Examples of alternate schemes with better capacitance reductions by simpler processing steps have been reported [68]. Air gap technology has also reached manufacturing in the Intel 14 nm technology node [67]. Our recent work [70] presents an overview of material and process technology requirements for FEOL air spacer and BEOL air gap formation using a pinch-off deposition approach. These approaches utilize established dielectric materials and processes such as plasma CVD of SiN, SiCN, SiCOH, and pSiCOH in the formation of the air spacer/air gap. The selection of these dielectric materials and processes has a large impact in the void (gap) dimension and volume. The void dimension and volume in air gap/air spacer structures can be controlled with various dielectric deposition processes and materials to facilitate subsequent process fabrication steps and ultimately to build a robust device with substantial capacitance reduction. Figure 5.22 shows typical pinch-off plasma CVD

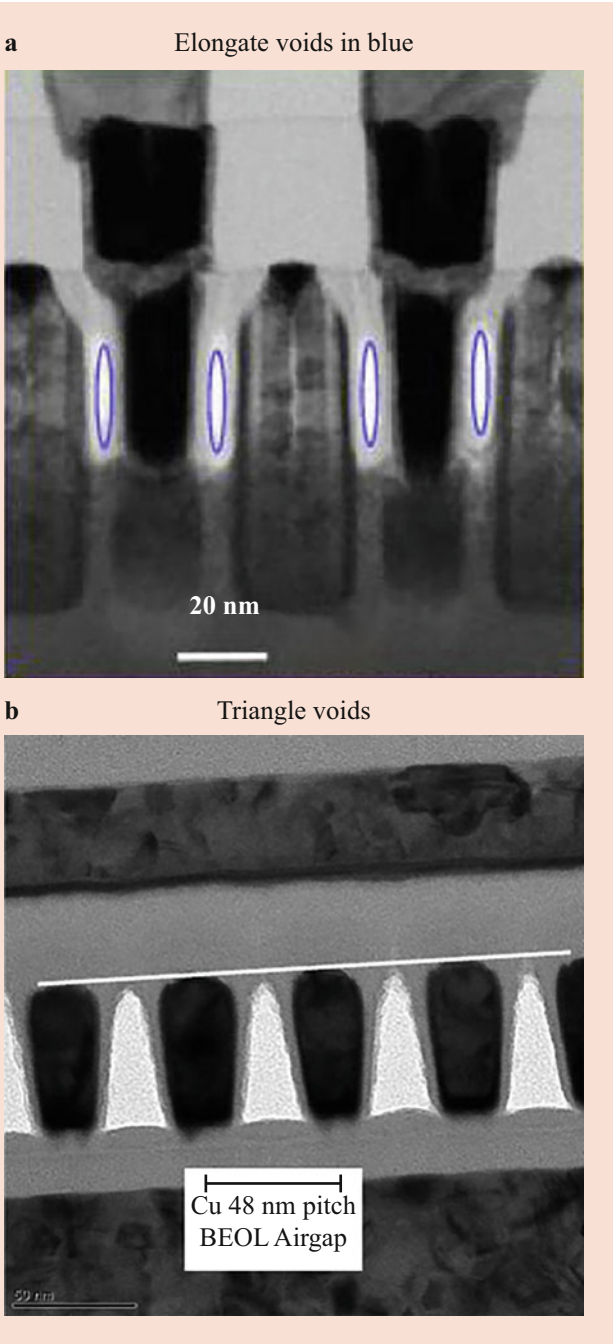

Fig. 5.22 (**a**) Typical pinch-off plasma CVD processes for elongated voids in FEOL gate region of devices and (**b**) triangle voids in BEOL Cu-low-*k* interconnect

processes for elongated voids in FEOL gate region devices (Fig. 5.22a) and triangle voids (Fig. 5.22b) in BEOL Cu low-*k* interconnect. The void's shape, volume, and dielectric material selections have significant impacts in the total effective capacitance of the devices. We successfully implemented a pinch-off deposition process with suitable device integration to produce significant capacitance reduction in both 10 nm FEOL FinFET air spacer and 48 nm pitch Cu-ULK BEOL structures. The capacitance reduction was obtained with improved device performance and without degradation

in reliability. Typical capacitance reductions can be tuned to 15–25%, depending on the air gap depth. For BEOL Cu low-*k* interconnect, a capacitance reduction of ~20% is achieved with no line resistance increase relative to the baseline ungapped process. Additionally, both TDDB and EM reliability are equivalent to those of ungapped controls.

Novel Low-*k* C-Rich SiCN Dielectrics

With device scaling reaching below sub-7 nm and beyond, Cu interconnect extendibility is reaching a limit [69, 70]. Reducing barrier-liner thickness to increase Cu volume for lower R degrades EM performance and dielectric TDDB. Similarly, using a lower dielectric constant *k* (lower capacitance) of pSiCOH below 2.4 material impacts TDDB performance [39–41]. Furthermore, mechanical considerations, plasma-induced damage (PID) integration challenges, pattern collapse, and reliability requirements of pSiCOH materials for future nano fabrication have been a great concern [71–74]. In a recent paper [75], we reported a new class of the plasma CVD of mechanically robust, low-*k* C-rich SiCN, and pSiCN dielectrics with excellent built-in Cu oxidation and diffusion barrier properties that have been developed and evaluated as potential alternative to low-*k* interlevel dielectrics for Cu interconnects [62]. The novel low-*k* dense C-rich SiCN ($k = 3.3$) and lightly porous C-rich SiCN ($k = 2.8$) films have high modulus (E ~> 15–30 GPa) and significantly lower plasma-induced damage (PID) as compared to our current advanced pSiCOH (k ~ 2.4–2.7) dielectrics as shown in Tables 5.5 and 5.6. The excellent Cu diffusion barrier properties of these SiCN dielectrics enable the use of thinner metallic Cu barriers resulting in larger Cu line's volume, reduced Cu metal resistance up to 30%, and overall RC in the sub-50 nm pitch interconnects without TDDB reliability penalty. The high modulus dielectrics also enable high aspect ratio sub-40 nm patterning without pattern collapse. Figure 5.23a–c show the typical dual damascene M2 level Cu-SiCN ($k = 3.3$) dielectric stacks and analysis; specifically (a) STEM of fabricated structure of "5 nm" BEOL metal 2 low-*k* C-rich SiCN-CuMn (0.5% Mn) interconnect with no metal liner. (b) SIMS analysis showing no Cu diffusion (no Cu detected) into C-rich SiCN and the formation of $MnSiO_x$ at interfaces. (c) EDX analysis confirms no Cu diffusion and no significant plasma damage to the dielectric. No copper is detected in the voltage sweep run, SIMS, and EDX analyses performed at

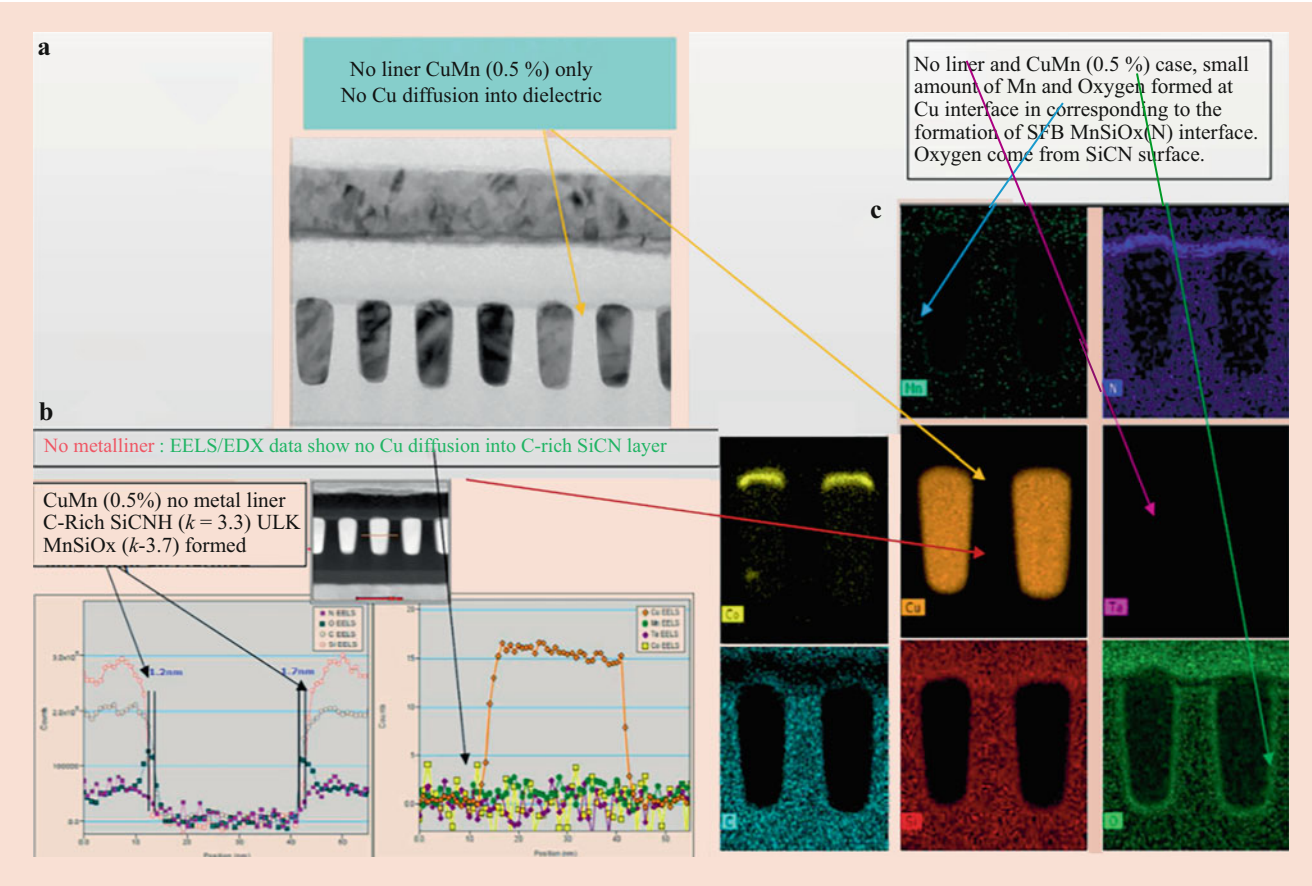

Fig. 5.23 (**a**) STEM of BEOL M2 low-*k*, C-Rich SiCN-CuMn interconnect with no metal liner. (**b**) SIMS analysis showing no Cu diffusion (no Cu detect) into C-Rich SiCN and MnSiOx at interfaces. (**c**) EDX analysis of X-section confirming no Cu diffusion or plasma damage even without metal liner

multiple sites on a wafer fabricated at 36 nm pitch BEOL. Figure 5.24 shows the 48 nm pitch Cu_SiCN3.3 TDDB (5 MV/cm, 125 °C) test result of the M2 structure, indicating robust TDDB breakdown performance even without metallic liner and with substantially thinner liners with thicknesses in the range of 2 and 6 nm. The TDDB data for pSiCOH $k = 2.55$ and $k = 2.45$ were also measured and used as references. No TDDB degradation (leakage performance or yield) as compared to standard pSiCOH dielectric is observed for SiCN with 10% smaller dielectrics spacing. For Cu and low-k dielectric extendibility to sub-5 nm dimension, these robust low-k SiCN dielectrics with ultrathin ≤2 nm metallic liner show promising potential as future dielectric materials for Cu and other metal interconnect.

5.2.4 Summary

We summarize various types of low-k interlevel dielectric materials development k implemented in various technology nodes at IBM development/manufacturing facilities over last 25 years in Table 5.5. This provides a simplified overview. Similar types of low-k interlevel dielectrics have also been used in semiconductor device fabrication over the years.

The search for extremely low-k dielectrics with robust performance properties for nano-device metal interconnects continues as devices reach the sub-5 nm dimension [68]. In a recent publication [76], it was reported that 3 nm thick boron nitride (BN) films deposited by inductive plasma CVD processing have ultralow κ values of 1.78 and 1.16 (close to that of air, $\kappa = 1$), at operation frequencies of 100 kHz and 1 MHz, respectively. The films are mechanically and electrically robust, with a breakdown strength of 7.3 megavolts per centimeter with good cobalt diffusion barrier properties. The measured extreme low-k value of ultrathin films generated some excitement in the low-k dielectric and nano-device community, but the low-k value needs to be confirmed by other measurement. Plasma CVD BN deposited on top of n-type silicon substrates is known to form p-n junctions and produce erroneous k measurements [77]. Our work in the 1990s showed that thick plasma-deposited boron nitride and silicon-boron nitride films are somewhat unsuitable for interlevel dielectric and are unlikely to be suitable for low-k interlevel dielectric for metal interconnect [77–79] due

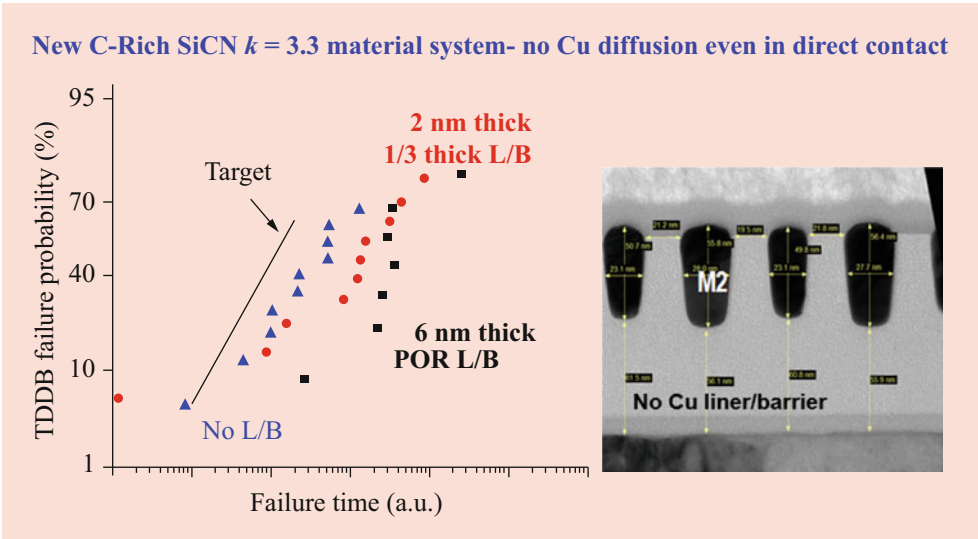

Fig. 5.24 Robust improvement in the Cu diffusion and oxidation barrier properties of the SiCN novel dielectric are demonstrated at sub-50 nm pitch TDDB of Cu (Mn)-SiCN interconnects. The TDDB performance exceeds the desired target over a substantially expanded range (2–6 nm) of metal liner/barrier (L/B) thicknesses

5.3 BEOL Thin-Film Metals

The initial development and continued scaling of copper damascene interconnects have been enabled by the concomitant development of suitable barrier, liner, and seed layers which enable the integration of copper wires into damascene features [80, 81]. When combined, these layers must satisfy multiple requirements: (1) They must provide sufficient adhesion of the copper wiring features to the dielectric, both under reliability and temperature stresses, as well as under the strong mechanical shear stresses which are experienced during chemical-mechanical polishing (CMP). (2) They must serve as diffusion barriers between the copper metal and the dielectric. This capability serves two functions: it prevents copper from diffusing into the dielectric, which would lead to dielectric breakdown or current leakage. It also prevents oxidizing species in the dielectric from migrating into copper, which would compromise conductivity and reliability. (3) They must serve as robust initiation (seed) layers for the electroplating processes which have been traditionally used to fill the wiring features in damascene interconnects. Wherever possible, the demands of scaling and process simplification make it preferable to select materials that can satisfy multiple demands at the same time. We shall review prior developments in this area, including more recent developments that have been driven by the demands of interconnect scaling.

5.3.1 Requirements for Barrier, Liner, and Seed Layers

Prior to the introduction of copper interconnects in the late 1990s, the commonly used metals for back-end-of-line (BEOL) conductors were aluminum for intralevel wires and tungsten for some interlevel via plug applications [82–85]. The development of dual damascene aluminum interconnects later obviated the need for tungsten vias. Both aluminum and tungsten typically used thin, conformal films of titanium (Ti) and/or titanium nitride (TiN) as liner layers, due to their adhesion properties and chemical compatibility with the integrated BEOL process flows.

The development of copper interconnects [86, 87] required an entirely new material set for barrier and liner layers. Titanium was fundamentally unusable as a liner due to its solubility in copper, which results in diffusion of Ti into copper wiring structures when the two metals are in contact. This leaching of Ti into the Cu conductor metal results in monotonic increases in wire resistance ("poisoning") with thermal cycling or current stress. In addition, Ti and TiN both form corrosion couples with copper with some commonly used chemical-mechanical polishing (CMP) slurries, making them unsuitable even in combination with other materials, where the Ti or TiN and Cu layers are not in direct contact.

Tantalum (Ta) and tantalum nitride (TaN) emerged as the leading candidates for use as Cu liners for multiple reasons [80, 81]. Of primary importance is that Ta is not soluble in Cu, so the resistance poisoning effect is absent. There are no corrosion reactions observed between Ta and Cu in the presence of CMP slurries or commonly used wet clean chemistries. The Cu diffusion barrier properties of Ta and TaN are well established, ensuring safe integration of Cu with dielectrics.

One salient concern in the initial development of copper interconnects was adhesion. TaN was seen to have excellent adhesion to silicon dioxide, but adhesion and wettability of Cu seed layers were relatively poor. Conversely, Cu wettability and adhesion on Ta is very good, but Ta adhesion on silicon dioxide was very poor in early studies.

An additional consideration in the selection of tantalum-based liners was the desire to replicate the current strapping redundancy seen with the combination of TiN liners and aluminum conductors that preceded copper. This capability

enables the liner to serve as a parallel conduction path in case of electromigration voiding in the conductor metal, so that the voided point exhibits increasing resistance as a warning of impending failure but does not become a catastrophic "hard" open. Such behavior can be important in signaling impending electromigration failures in applications where reliability is of paramount concern.

In cases where Ta or TaN layers are used separately, such parallel current strapping was not readily possible. Tantalum deposited in thin films deposited on silicon dioxide by magnetron sputtering typically nucleates in the metastable β-phase (tetragonal or hexagonal), with an effective resistivity typically in the range of 150–220 μΩ-cm. Tantalum nitride (TaN) as deposited by reactive magnetron sputtering normally has resistivities of 200 μΩ-cm up to 350 μΩ-cm, depending on the deposition conditions. By contrast, current redundancy for the liner layer typically requires an in-plane resistivity of <50 μΩ-cm, which is only achievable with the body-centered cubic (bcc) α-phase of Ta. This low-resistivity α-phase Ta is stable and naturally occurring but is quite difficult to form when sputtered as a thin film directly on silicon dioxide. Achieving α-Ta formation in thin films sputtered directly on silicon dioxide typically requires some combination of either high temperatures (>600 °C), incompatible with BEOL processing, or extremely low power, low-deposition rate process conditions which typically have poor throughput, uniformity, and step coverage.

One fortunate property of the TaN and Ta system during sputter deposition is that a bilayer deposition on silicon dioxide of TaN first followed by Ta on top results in the nucleation of α-Ta in the top layer under conventional magnetron conditions [80, 81]. When used as a liner for Cu interconnects, this bilayer of TaN on the bottom and Ta on the top thus places the low-resistivity (<50 μΩ-cm) α-Ta in direct interfacial contact with the Cu conductor, enabling the redundant current strapping capability for high-reliability applications. The Ta/Cu interface is also optimal for liner-conductor wettability and adhesion, while the TaN layer next to the silicon dioxide insulator is optimal for adhesion at that interface.

A further advantage of the TaN/Ta bilayer as a Cu liner is that TaN can be reactively sputtered in the same chamber as Ta, with the only difference in the process conditions being the simultaneous flowing of nitrogen and argon at the same time as sputter gasses. Once the TaN deposition is complete, the Ta can be deposited by shutting off the flow of the nitrogen and continuing the sputter process with argon only. In production magnetrons, the sputter yields and binding energies of TaN vs Ta are similar enough that the transition between TaN and Ta happens without hysteresis, i.e., the same target voltage is achieved regardless of whether the nitrogen flow is increasing or decreasing. This lack of hysteresis in the reactively sputtered TaN/Ta system means that the bilayer structure can be deposited in the same chamber repeatedly under production conditions, unlike other reactively sputtered liner metals, such as Ti and TiN. The α-Ta layer has been observed to be formed with only ~20 Å of TaN underneath. Moreover, very high step coverage can be obtained with TaN/Ta layers, owing to the low sticking coefficient and multiple-bounce kinematics inherent in the sputtered TaN and Ta depositions. Following its initial adoption into production use for copper interconnects, multiple generations of directional, ionized sputter sources for the TaN/Ta system have been developed by the semiconductor tooling industry. A summary of the advantages of the TaN/Ta liner system over other candidate materials is shown in Table 5.7 [80, 81].

The standard method of filling BEOL interconnect structures with copper has been electrolytic plating using copper sulfate chemistries with proprietary additives. The initiation of electrolytic copper plating requires a copper seed layer [86, 87]. High-quality, void-free filling of wiring structures requires the copper seed layer to be continuous over the field area (top surface of the wafer) and all along the sidewalls and bottoms of trench (horizontal, in-plane) and via (vertical level-to-level) structures. For dual damascene structures, the maximum aspect ratio (height/width) of the completed, planarized wiring structures is typically on the order of 2:1–4:1 and can be roughly twice has high for unplanarized structures during the barrier/seed layer deposition and plating steps. Directional sputtering of copper is needed to achieve sufficient seed layer coverage over all surfaces of unfilled structures. As a result, process and equipment development for copper sputtering has been a major focus in the semiconductor tooling and manufacturing industries since the inception of copper interconnects. At advanced ground rules, barrier and seed layer processes and the associated electroplating chemistries and waveforms often require co-optimization in order to achieve reliable, high-yielding copper interconnects. In the next section, we will discuss tooling and typical process flows for traditional copper barrier and seed layer deposition.

5.3.2 Sputter Deposition Tooling for Barrier, Liner, and Seed Layers

Sputter processing is one of the most widely used processes in thin-film fabrication. Sputter deposition is a method of depositing thin films onto a substrate by accelerating ionized gas atoms into a target made of source material for the film. The sputter gas is usually argon for its relatively high mass, low cost, and chemical inertness, but other noble gasses or reactive gasses such as nitrogen and oxygen are also used for specific applications. If the sputter gas ions have kinetic

energies in the correct range, atoms of the source material will be ejected from the target. The substrate is positioned so that the ejected target atoms are collected on it and then nucleate and coalesce into a thin-film layer of the target material. The same mechanism can be done in reverse, with ionized gas items being accelerated toward the substrate, resulting in ejected atoms from the substrate depositing onto the chamber shielding. This type of process is called sputter etching, and it can be used for surface cleaning and material removal. An in-depth discussion of the fundamentals of sputter processing is beyond the scope of this chapter, but the interested reader is referred to references [88–94] for a more thorough treatment of the subject matter. Sputter processing falls under the broader category of deposition methods known as physical vapor deposition ("PVD"), which can also encompass evaporation. In modern semiconductor fabrication, sputter processing is the only PVD method used in mass production, so the terms PVD and *sputtering* are effectively interchangeable in this context.

For deposition of metallic liner and seed layers for copper interconnects, modern semiconductor manufacturing relies on DC magnetron sputter chambers which process one wafer at a time. A simplified schematic is shown in Fig. 5.25 for illustration. The magnetron is a rotating mechanism which sweeps a powerful permanent magnet in regular orbits across the backside of the sputter target. Magnetrons are designed so that the magnetic field from the permanent magnet keeps the free electrons liberated during argon ionization confined

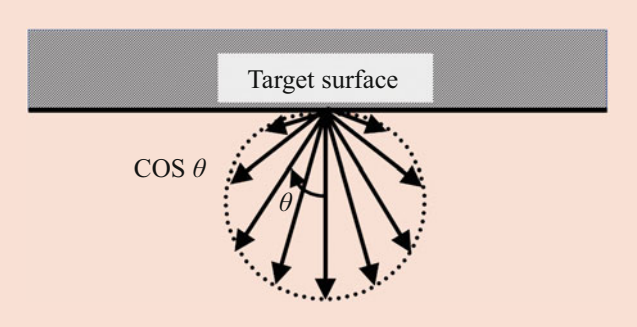

Fig. 5.26 Illustration of the cos θ emission distribution from the target surface. When sputter gas ions impact the target, atoms are ejected from the target in a spatially broad distribution of velocities, with the velocity being proportional to cos θ

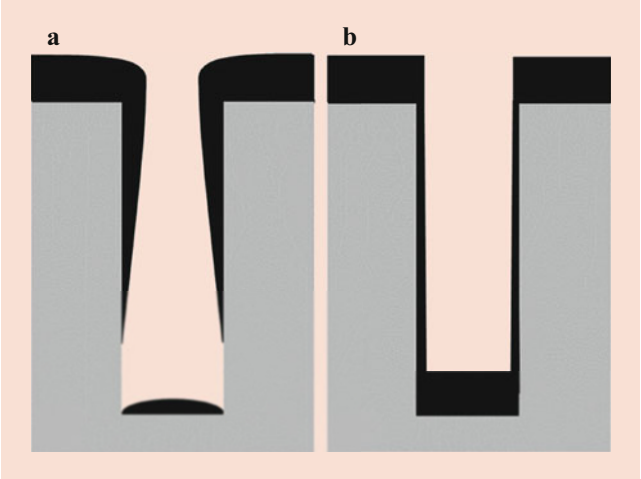

Fig. 5.27 Schematic illustration of sputter deposition coverage on a high aspect ratio feature (**a**) with an uncollimated flux (**b**) with collimation

near the target surface. With the magnetic field lines running parallel to the target surface, free electrons travel in cycloidal orbits along the field lines, due to the $E \times B$ drift force, and can ionize multiple sputter gas atoms by collisional ionization. This magnetic confinement enables the free electrons to make multiple orbits of the magnetron and thereby maintain a high plasma density and rapid sputter deposition rate.

When the sputter gas atoms are ionized, they are accelerated into the target by the naturally occurring plasma potential near the target surface (cathode fall), causing target atoms to be ejected. The atoms are ejected from the target in a spatially broad distribution of velocities, with the magnitude of the velocity being approximately proportional to cos θ, where θ is the angle of the atom's velocity relative to the normal from the target surface (see Fig. 5.26). The actual velocity distribution my deviate somewhat from a pure cos θ distribution, depending on the sputter gas energy and target material, but the overall result nevertheless is that sputter deposition usually results in a broadly distributed flux of metal atoms with weak directionality.

For applications where there is little or no topography on the substrate, a nondirectional flux of sputtered atoms is often perfectly acceptable and might even be desirable for depositing thicker layers at a rapid rate. However, barrier/liner/seed applications for copper interconnects typically require a very high degree of conformality on all the surfaces of damascene features, which will often have aspect ratios >4:1 during the metallization process steps. Minimum thickness requirements of ~15–20 Å are typical to ensure sufficient barrier coverage for films like TaN, Ta, and Cu seed. Given these demanding constraints, sputter deposition of barrier/liner/seed layers like TaN, Ta, and Cu typically requires a very high degree of directionality in order to guarantee conformal coverage of the layers.

The need for directional sputter deposition in barrier/liner/seed applications is illustrated schematically in Fig. 5.27a, b. As shown in Fig. 5.27a, for high aspect ratio damascene features with vertical sidewalls, the off-normal flux of sputtered atoms from uncollimated deposition results in significant buildup of sputtered material on the top corners of damascene features. The overhang from this thick accumulation of deposition at the corners ("bread loafing") results in shadowing of the bottom sidewalls of the features and minimal coverage on the bottom corners. This bread loafing phenomenon is more pronounced in sputtered materials with a high sticking coefficient, such as Cu, and is less pronounced in materials with a low sticking coefficient, such as Ta and TaN, which can undergo multiple bounces that result in more uniform coverage. In contrast, Fig. 5.27b illustrates the advantages of collimated sputter deposition for high aspect ratio features. The reduction of off-normal sputtered atom flux results in less overhang and shadowing of the sidewalls, enabling better coverage of the bottom surface, sidewalls, and corners.

Several methods have been developed and refined by the semiconductor tooling industry to enhance the directionality of sputter deposition for damascene liner applications. Figure 5.28 shows a generic magnetron diagram with uncollimated flux from the target. The simplest means of increasing the directionality of the sputtered atom flux is to increase the target-to-substrate spacing, a configuration sometimes referred to as "long throw" PVD. By moving the target and substrate further apart, the substrate subtends less solid angle relative to the target, which has the effect of filtering out off-axis sputtered atom flux. The remaining flux is therefore more directional than with a smaller target-substrate spacing. The use of "long throw" PVD has several limitations that limit its extendibility. As the target-substrate distance increases, the center-edge uniformity of the sputter deposition will be adversely affected, owing to the size limitations of

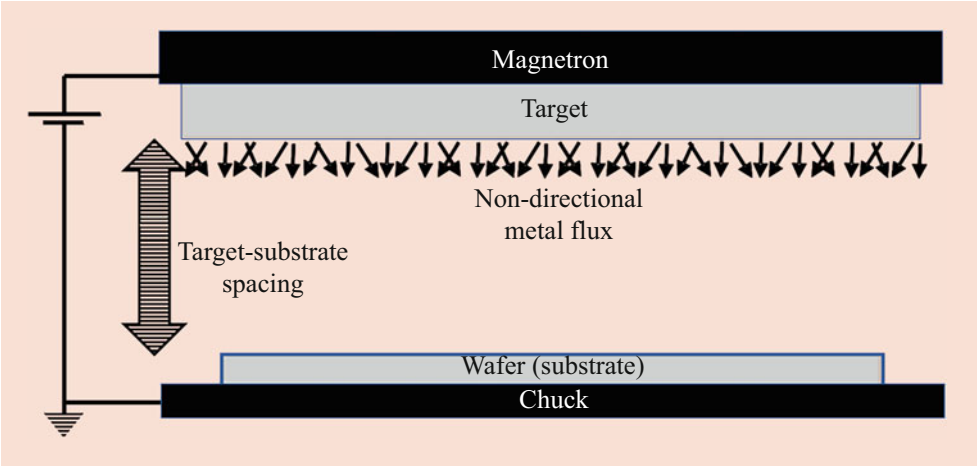

Fig. 5.28 Cross-sectional illustration of a sputter source illustrating the adjustment of target-substrate spacing to increase directionality through directional selection. At longer spacings, the wafer subtends a smaller solid angle of the target flux, resulting in a more directional deposition onto the wafer

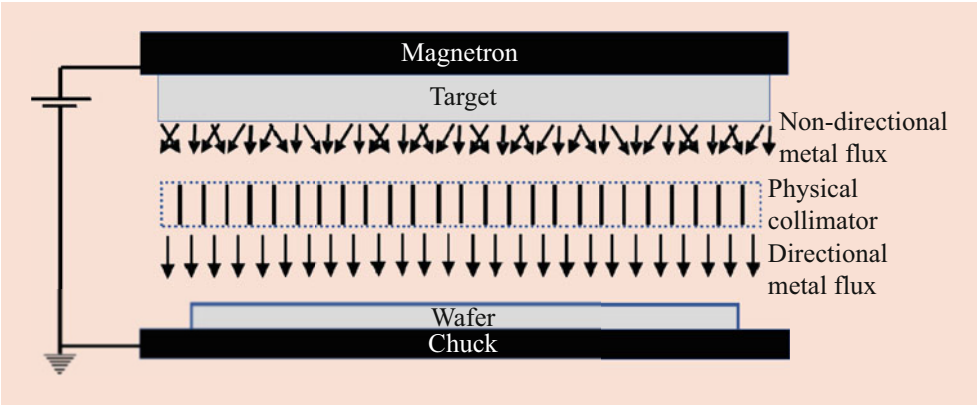

Fig. 5.29 Schematic illustration of a directional sputter deposition source using collimation. The collimator is positioned in between the target and the substrate and is typically a metal honeycomb structure fabricated from sheet aluminum or stainless steel

the target. Even if the target could be enlarged indefinitely, the normal operating pressure of modern PVD discharges is at minimum ~0.1 mTorr or higher. At these pressures, the mean free path for gas atom collisions is ~10–20 cm, so that scattering of the directional flux off the ambient sputter gas negates the collimation effect of the long throw geometry [91–93, 95, 96].

One method of filtering out off-normal sputtered atom flux that avoids the pitfalls of long throw PVD is to use a physical collimator in between the target and substrate [95–97]. A schematic diagram is shown in Fig. 5.29. A physical collimator is just a continuous sheet of tubes that span the sputter chamber below the target and physically filter out off-axis sputtered atoms while maintaining a close target-substrate spacing. In practice, the "tubes" are just an array of honeycomb-shaped structures fabricated from a sheet metal like stainless steel or aluminum. The collimation effect can be increased or decreased by adjusting the aspect ratio (height/diameter) of the collimator cells. Typical collimator heights might be on the order of 1–2 cm, with a lateral cell dimension of ~1 cm, resulting in an aspect ratio of 2:1. The effect of collimator aspect ratio of the angular filtering of sputtered flux is discussed in more detail in [90]. One disadvantage of physical collimators is that the off-axis flux deposits on the top and sidewalls of the collimator, creating a buildup of material over time that obstructs deposition and can also increase the effective aspect ratio of the collimator. This phenomenon results in a steady decline in deposition rate over time, which means that the deposition time must be continually adjusted upward so as to keep a constant deposition thickness on the substrate. Sputter tool vendors will typically have software applications to do the deposition time adjustment automatically once the deposition rate decline is calibrated. It is not unusual for collimators to be replaced as a preventive maintenance measure in the middle of the target and shielding life, while the rest of the shielding and the target continue to end-of-life after the collimator replacement. Collimators can also be subject to significant heating in high deposition rate applications, which can be mitigated by water cooling of the collimator holder.

While collimators are still used in some advanced PVD applications, the technique that offers the most control over liner and seed layer coverage on damascene features is ionized PVD [98–101]. A commonly used ionized PVD configuration in BEOL liner and seed layer deposition is shown schematically in Fig. 5.30. In this configuration, metal atoms are ejected from the target using a magnetron in the normal manner. Argon sputter gas flows are typically set to achieve

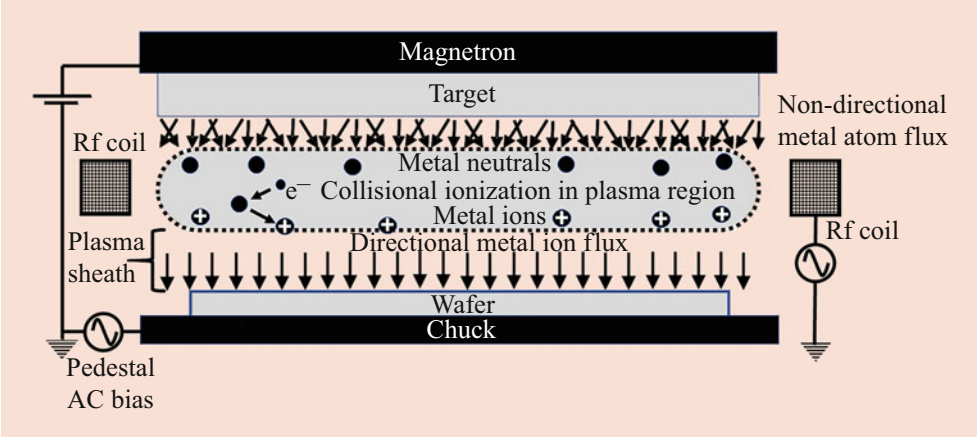

Fig. 5.30 Schematic illustration of a typical sputter source for ionized sputter deposition. The RF coil encircles the source and is used to create an inductively coupled plasma between the target and the substrate (wafer)

pressures in the range of ~1–10 mTorr. A secondary argon-ion plasma is ignited in the space between the target and the substrate, using radiofrequency coils driven at 13.56 MHz, to create an inductively coupled plasma with densities typically greater than 10^{11} cm^{-3} As the sputtered metal atoms traverse the secondary plasma region, they are thermalized by collisions with the argon sputter gas and ionized by collisions with free electrons in the plasma. The collisional ionization efficiency can be quite high, owing to the relatively low ionization energies of typical sputtered metals (<8 eV) relative to the ionization energy of the argon sputter gas (15.8 eV). Once the ionized metal atoms traverse the plasma region, their positive charge causes them to be accelerated toward the substrate. The acceleration of the ionized metal species in the plasma potential provides a strong collimation effect, which is usually augmented by an externally applied AC wafer bias to the substrate. This ionized collimation effect can be achieved with close target-substrate spacing and without interposing a physical collimator, enabling more control over uniformity and stability in deposition rate. Further enhancements to the ionized metal flux density and uniformity can be achieved with magnetic fields generated using electromagnets mounted external to the chamber.

It should be noted that commercially available PVD systems for liner and seed layer depositions will sometimes combine more than one of the collimation techniques discussed here. Additionally, other configurations for ionized PVD have been used commercially, though they are less common. Optimization of ionized PVD for advanced technology nodes is an area of continuous research and development for semiconductor tooling vendors.

5.3.3 Barrier/Liner/Seed Process Sequences and Enhancements

Now that we have reviewed standard techniques for directional deposition of BEOL copper barrier seed layers, we shall review how these techniques are typically used in deposition sequences for high-volume manufacturing. Figure 5.31a is a schematic illustration of a damascene interconnect structure which is incoming to barrier/liner/seed layer deposition. The trench structure is used for intralevel (within-level) signal and power transmission. The via performs the same functions for interlevel (between-level) signals and power transmission, as indicated by the exposed contact to the prior level metal.

In modern semiconductor manufacturing, the deposition of damascene barrier, liner, and seed layers for copper interconnects occurs in single-wafer process chambers which are clustered together on the same ultrahigh vacuum mainframe [92, 93]. Inside the tooling mainframe, wafers are moved from one single-wafer process chamber to another robotically, without breaking vacuum. After the wafer is introduced into the vacuum tool, the unfilled damascene structure (Fig. 5.31a) is subjected to a "degas" step for desorption of water and other oxidizing species which might have been absorbed into or on to the surfaces of the dielectric. Subsequently, the wafer will typically be moved to a preclean chamber for a reactive clean using a hydrogen plasma to reduce copper oxides on the exposed metal contact from the layer below. Historically, physical sputter etching using argon-ion plasmas has also been used for surface cleaning, but sputter etching is typically too damaging to low-*k* dielectrics to be used in technology nodes smaller than 45 nm.

Once the degas and surface cleaning steps are complete, the wafer is moved to the PVD TaN/Ta deposition chamber. Ionized PVD deposition, using a source like that depicted in Fig. 5.6, has been used for TaN and Ta barrier layers going back many technology nodes. The TaN layer is deposited first, as indicated in Fig. 5.31b, since it has the higher adhesion to the dielectric, has better barrier properties than Ta, and promotes nucleation of the low-resistivity alpha-phase Ta on top. The TaN layer is deposited reactively by flowing both argon and nitrogen gasses during the deposition. Once the TaN deposition is complete, the Ta deposition takes place by switching off the nitrogen flow so that a pure Ta layer is

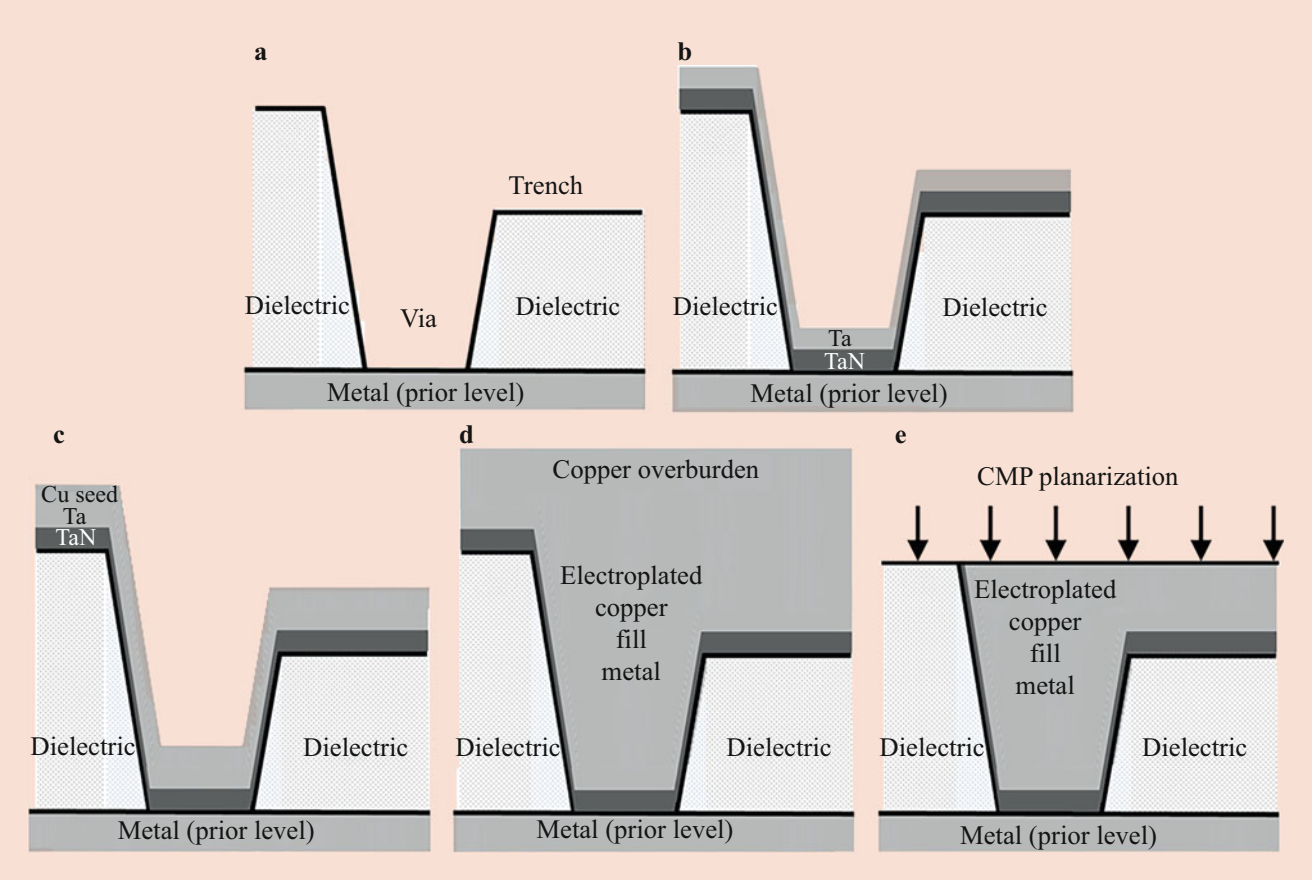

Fig. 5.31 (**a**–**e**) Typical deposition sequence for barrier/liner/seed process sequence used in copper damascene metallization, with subsequent plating (**d**) and CMP (**e**) steps added (see text)

deposited, using only argon as the sputter gas. The result is that the Ta liner layer is deposited conformally on top of the TaN barrier layer, as shown in Fig. 5.31c [80, 81, 102–108].

The final deposition process in this clustered sequence is the deposition of the copper seed layer, which is also done by ionized sputtering. The copper seed layer has critical requirements: it must be sufficiently thick so that even the thinnest areas of coverage (~20–30 Å inside small features) carry adequate plating current inside the feature and serve as a nucleation layer for electroplated fill. In the field area (top surface), it must be thick enough to distribute plating current evenly over the full surface area of the wafer from the wafer edges, where the plating current contact is made. Due to the higher sticking coefficient of copper, it is more prone to the "bread loafing" effect described earlier. Copper, like a handful of other metals such as silver and gold, is capable of sustaining a self-sputtering plasma without using argon as a sputter gas once the plasma has been ignited. This "self-ionized" sputtering has been used for copper seed layer deposition for several technology nodes [109–113]. In self-ionized sputtering, the plasma is typically ignited at low power with argon flowing, but the argon is shutoff once ignition is achieved. Copper atoms, which have an ionization potential (7.7 eV) roughly half that of argon (15.8 eV), have sufficiently high sputter yield (>2.0) that a self-ionized plasma of copper atoms can be sustained in the absence of argon sputter gas. In practice, a negligible argon flow will be present between the cooled wafer chuck to the wafer backside for temperature control. With self-ionized sputtering, the bias power applied to the wafer can be used to adjust the directionality and resputter properties of the copper atom flux at very low process pressures of <1 mTorr. Low bias powers will result in a less directional copper deposition which gives poor coverage in high aspect ratio features but a higher deposition rate on the top surface, similar to Fig. 5.27a. High bias powers will result in very directional deposition with high bottom surface coverage inside high aspect features, similar to Fig. 5.27b. Due to the high sputter yield of copper, the high bias powers come with the trade-off that high copper-ion energies can result in a net etching of copper on the top surface due to copper-on-copper collisions, which will resputter copper from the top surface onto the shielding. In

practice, self-ionized copper seed depositions typically use some combination of a low-bias initial step combined with a high-bias second step to achieve sufficient coverage both in the field area and inside high aspect ratio features.

The schematic illustration in Fig. 5.31c shows the result of the completed deposition sequence, with the TaN, Ta liners, and Cu seed layer coating the damascene feature without vacuum break. Once the wafer is vented to atmosphere, it will move to the electroplating sector to fill the structure with copper, with the PVD Cu seed layer deposited here serving as the plating initiation layer. Following Cu plating fill and overburden deposition (Fig. 5.31d) and CMP planarization (Fig. 5.31e), the finished damascene level is typically deposited with a CVD $SiC_xH_yN_z$ dielectric cap layer for hermeticity and is moved on for the next-level build.

Copper-Alloy Seed Layers

The process technologies described above have been scaled successfully from the introduction of copper interconnects at the 220 nm node down to nodes in the 45–28 nm range. At line widths in the range of 100 nm and smaller, a significant limitation on electromigration performance arises due to the need to suppress Cu atom diffusion along the top-surface interface between the copper and the CVD $SiC_xH_yN_z$ dielectric capping layer.

One advance that has been particularly successful in enabling scaling of Cu interconnects below the ~100 nm dimension is the introduction of Cu-alloy seed layers. With Cu-alloy seed layers, the conventional ultrapure Cu target (typically 99.99% pure or higher) is replaced with an alloy target containing a minority-alloy component, typically Mn or Al in a concentration range of <1%, with the remainder ultrapure Cu [114–122]. The minority alloy is selected for several key properties: it must have an energetically favorable reaction with oxygen so that its oxide forms more readily than does SiO_2. It must be soluble in copper, and it must diffuse readily through copper during standard BEOL process heating cycles. In addition, there must not be any traces of oxygen within the copper interconnects, such as those found with CVD or ALD films deposited using organometallic precursors. When these conditions are satisfied, the minority-alloy component will exhibit a "self-capping" behavior, in which the minority-alloy atoms diffuse through the copper and form a chemical bond with the cap during the cap deposition. This top-surface interfacial layer promotes adhesion between the dielectric cap and the top surface of the copper conductor and has been proven to boost electromigration performance by impeding copper diffusion along the copper-capping layer interface. A schematic illustration of the alloy seed self-capping process is shown in Fig. 5.32a–d. Images from TEM/EELS/EDX analysis which illustrate the self-capping phenomenon are shown in Fig. 5.33.

Wetting Layers for Copper Liner Applications

When first introduced into the semiconductor industry, copper interconnects relied on the PVD TaN and Ta barrier/liner layers described above. With the progression of copper interconnect scaling to feature dimensions smaller than 40 nm, the need for an enhanced liner that would enable copper gap fill at smaller dimensions has become critically important.

The most critical area for improvement for copper liners is the wettability of the copper seed on top of the liner layer. Wettability is the property of the liner surface that enables a copper seed layer to coalesce into a continuous film when deposited on top of the liner. A liner with improved wettability will enable the copper seed layer to coalesce into a continuous layer at a thinner copper thickness than would be the case with a liner with poorer wettability. Improved wettability liners will thus enable thinner copper seed layers to be deposited on small-dimensioned features, with concomitant reduction in seed layer overhang ("bread loafing") and improved feature fill with copper plating. Many everyday phenomena exhibit analogous behaviors, such as the dewetting of water on a hydrophobic surface (poor wettability). A common example is the "beading up" of water on a freshly waxed automobile finish. In contrast, good wettability is illustrated by the phenomenon of water flowing off a hydrophilic surface in continuous sheets, as in the case of an unwaxed automobile finish.

Research on BEOL liners with improved wettability relative to Ta dates back to the early 2000s. Fundamental studies of alternative candidates for copper liner applications have been conducted by Shimogaki et al. [123–125]. In these experiments, the surface wettability and adhesion strength of different copper/liner interfaces were measured by depositing thin copper layers on top of different liner films and assessing the agglomeration and dewetting behavior of the copper following thermal cycling. The wetting angles of the copper films on the different liner candidates were then measured using electron microscopy. The wetting angle data was used to extract the adhesion strength of the copper liner interface using the Young-Dupré equation. These studies found the adhesion strength of the Cu/Ru and Cu/Co interfaces to be in the range of 2.8–2.9 J/m^2, a significant improvement over the Cu/Ta interface adhesion strength of 2.0 J/m^2 [124]. Some correlation can be seen between higher Cu/liner adhesion and smaller lattice mismatch between the liner material and crystalline copper [123].

Cobalt and ruthenium have the additional advantages that they both are insoluble in copper and can be deposited using commercially available CVD (chemical vapor deposition) chemicals and tooling. The CVD deposition method is more conformal than the directional PVD deposition methods used to deposit TaN and Ta. They also have resistivities similar to alpha-Ta, although their poor barrier properties and adhesion

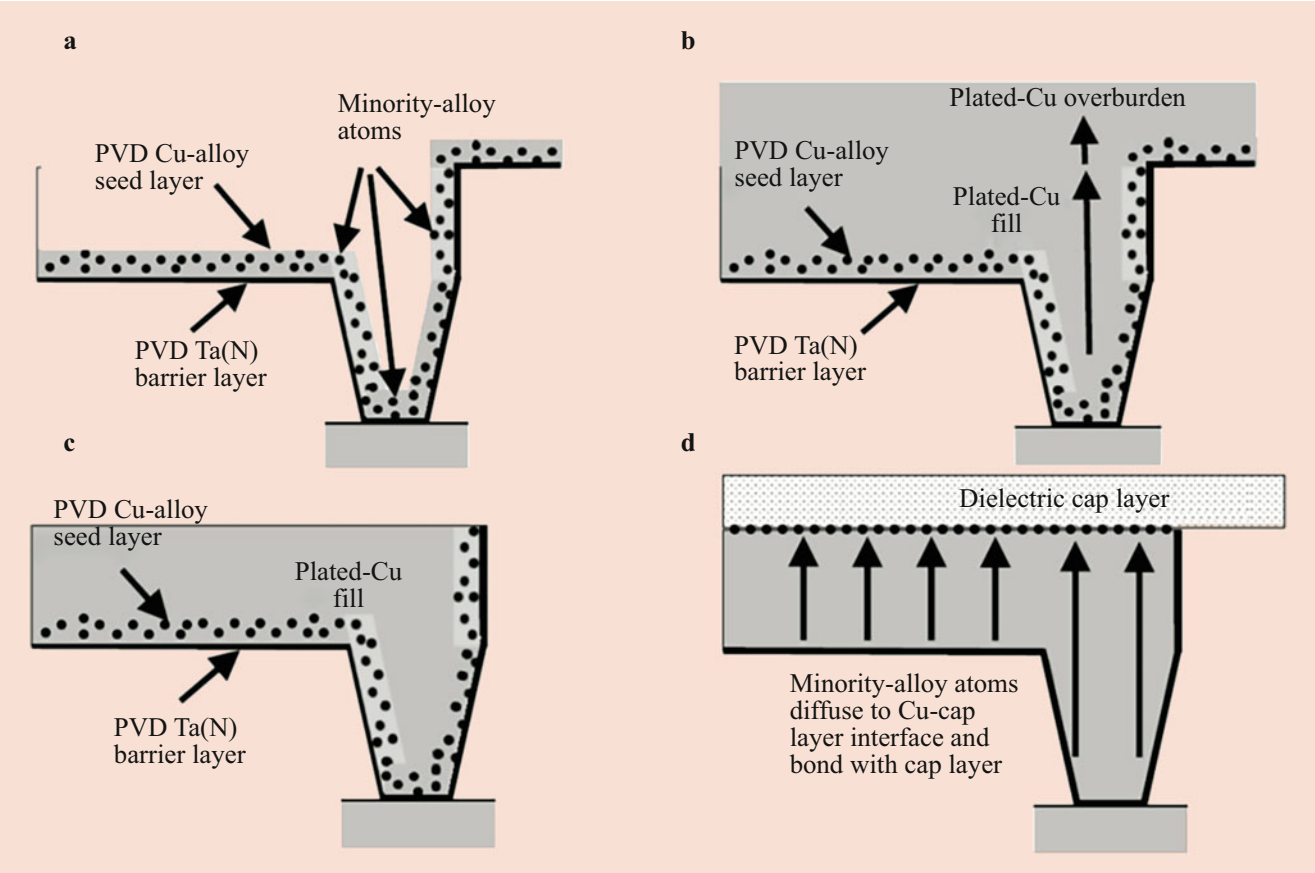

Fig. 5.32 (**a**–**d**) Schematic illustration of the self-capping effect used with alloy seed layers. The barrier/liner layers are not shown. Atoms from the minority alloy component (typically Al or Mn) are represented by the black dots (see text)

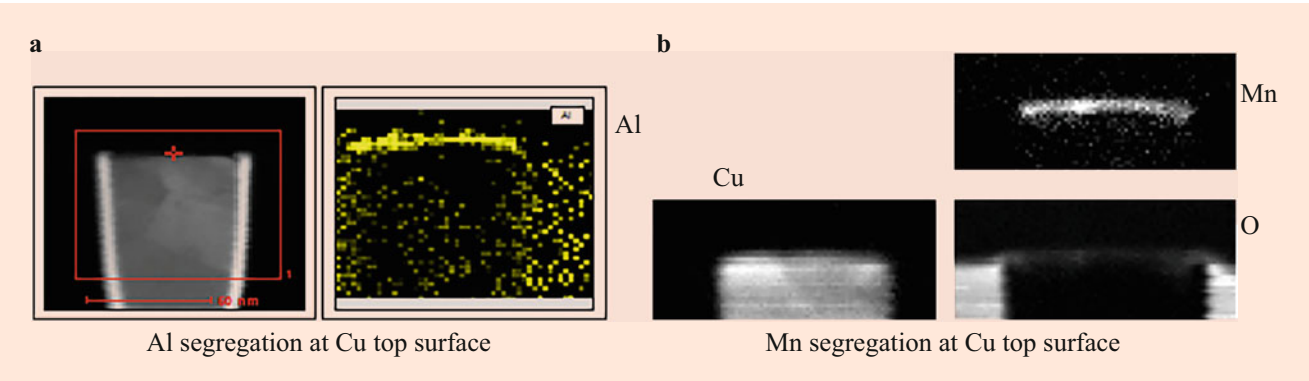

Fig. 5.33 TEM/EDX images of copper interconnect structures built using PVD CuAl (**a**) and PVD CuMn (**b**) alloy seed layers. The self-capping behavior of the alloy components is illustrated by the Al and Mn elemental maps. (Ref. [120], reprinted with permission)

to dielectrics generally make them inadequate as stand-alone barriers. Thus, a PVD and/or ALD TaN adhesion and barrier layer is needed between the liner and the dielectric, similar to the TaN/Ta bilayer discussed previously. Single-wafer chambers for CVD Co or Ru can be integrated onto the same vacuum cluster tooling as PVD Ta(N), PVD Cu, degas, and preclean chambers, so that integrated process flows which deposit a CVD Co or Ru liner in between a PVD TaN barrier and Cu seed layer can be run without breaking vacuum.

Development of integrated process flows using copper wetting layers has proceeded in parallel with the fundamental studies. Numerous studies of ruthenium liners have demonstrated improved copper feature fill, yield, and reliability at ground rules down to the 7 nm technology node and

below [126–138]. Initial studies of process flows using CVD Co liner layers began somewhat later [138–143] and have demonstrated similar yield and reliability improvements at advanced ground rules.

In terms of industry adoption in high-volume manufacturing, CVD Co wetting layers have had far more success than CVD Ru, for a combination of reasons. The Ru liner material, which is a "noble metal" in the platinum group, is difficult to polish in damascene process flows due to its chemical inertness. Cobalt liners can be polished quite easily with standard CMP slurries and are thus easier to integrate into existing copper process flows. While CVD Ru liners gained considerable initial attention due to the high Cu wettability and feature fill they displayed, the higher Cu surface mobility they show relative to Co liners results in generally poorer electromigration results when the two materials are compared directly. Some work on "Co-doped" Ru liners has attempted to address this discrepancy [144–146]. Finally, at advanced 7 nm ground rules, Cu interconnects using Co liners have been observed to have resistances ~10–15% lower than Cu interconnects using Ru liners. The resistance difference is attributed to differences in sidewall scattering behavior as well as different grain size distributions [147].

Due to the presence of oxygen compounds in the precursors for CVD Co and Ru liners, the use of Cu-alloy seed layers for self-capping and electromigration enhancement, as described previously, is ineffective [142, 143]. The residual oxygen in the CVD wetting layers neutralizes the self-capping effect of the minority-alloy components. As a result, one related advance that has been critical to the adoption of CVD Co liner wetting layers into high-volume manufacturing is the development of precursors for selective CVD Co deposition on copper surfaces. These precursors, which are different from those used for the (nonselective) CVD Co wetting layers discussed above, enable thin Co capping layers to be selectively deposited only on the exposed top surfaces of damascene Cu wires without any deposition on the surrounding dielectric. A schematic picture is shown in Fig. 5.34. In comparison to Fig. 5.31a–d, the PVD Ta liner is replaced with a nonselective CVD Co liner which serves as the wetting layer. Since the CVD Co's adhesion and barrier properties are not sufficient when the layer is used alone, the PVD TaN barrier layer is kept as the first layer next to the dielectric. In parallel to the PVD-only TaN/Ta/Cu sequence described previously, deposition of the CVD Co wetting layer and PVD Cu seed layer follows after the TaN barrier deposition in a clustered vacuum system. Electroplating is used to fill the feature with copper, and CMP is used to planarize the structure to the requisite trench height. Following planarization, the polished damascene layer is then placed in another clustered vacuum deposition system, where a reactive preclean is done to remove native copper oxide from the exposed metal, and the selective CVD Co cap

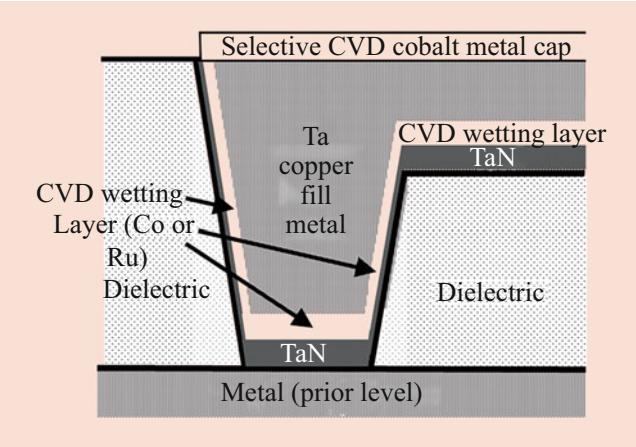

Fig. 5.34 Schematic illustration of an interconnect structure with a CVD wetting layer (Ru or Co) replacing the PVD Ta liner. The CVD wetting layer requires the deposition of a selective CVD Co metal cap in order meet electromigration requirements

layer, typically ~20–30 Å, is deposited on top of the exposed Cu wire in the same vacuum cluster tool. The result of this type of process flow is that the copper wiring structures are surrounded on all four sides by cobalt layers, either from the nonselective liner/wetting layer on the bottom and sidewalls or from the selective capping layer on top, as shown schematically in Fig. 5.34. This metallization scheme has shown 10–100× improvement in electromigration performance and up to 70% improvement in electromigration activation energy [142]. The cobalt liner/selective capping scheme has been widely adopted in the semiconductor industry wiring dimensions of 32 nm and below. The selective CVD Co cap layer integration will be discussed in more detail in section "Selective Cobalt/Dielectric Cap", in conjunction with advanced capping schemes.

Copper Reflow for Damascene Feature Fill

Further scaling of semiconductor interconnects has made electroplated fill more difficult for structures smaller than ~10–15 nm in size. This trend has driven the development of alternative feature fill methods using PVD Cu combined with reflow at elevated temperature.

A fundamental physical consideration with small damascene features is the minimum thickness of the barrier and liner layers relative to the feature dimensions. For TaN layers used as copper barriers, the minimum thickness necessary for the layer to serve as a barrier is typically of order 1.5–2.0 nm. Even for the most advanced ionized PVD deposition, the minimum thickness is typically achieved on the middle sidewalls: thicker nominal deposition on the field area (top surface) will be required to meet the minimum sidewall coverage. Wetting layers such as Ru or Co are normally deposited using CVD and have conformality approaching 100%. Nevertheless, they have similar minimum

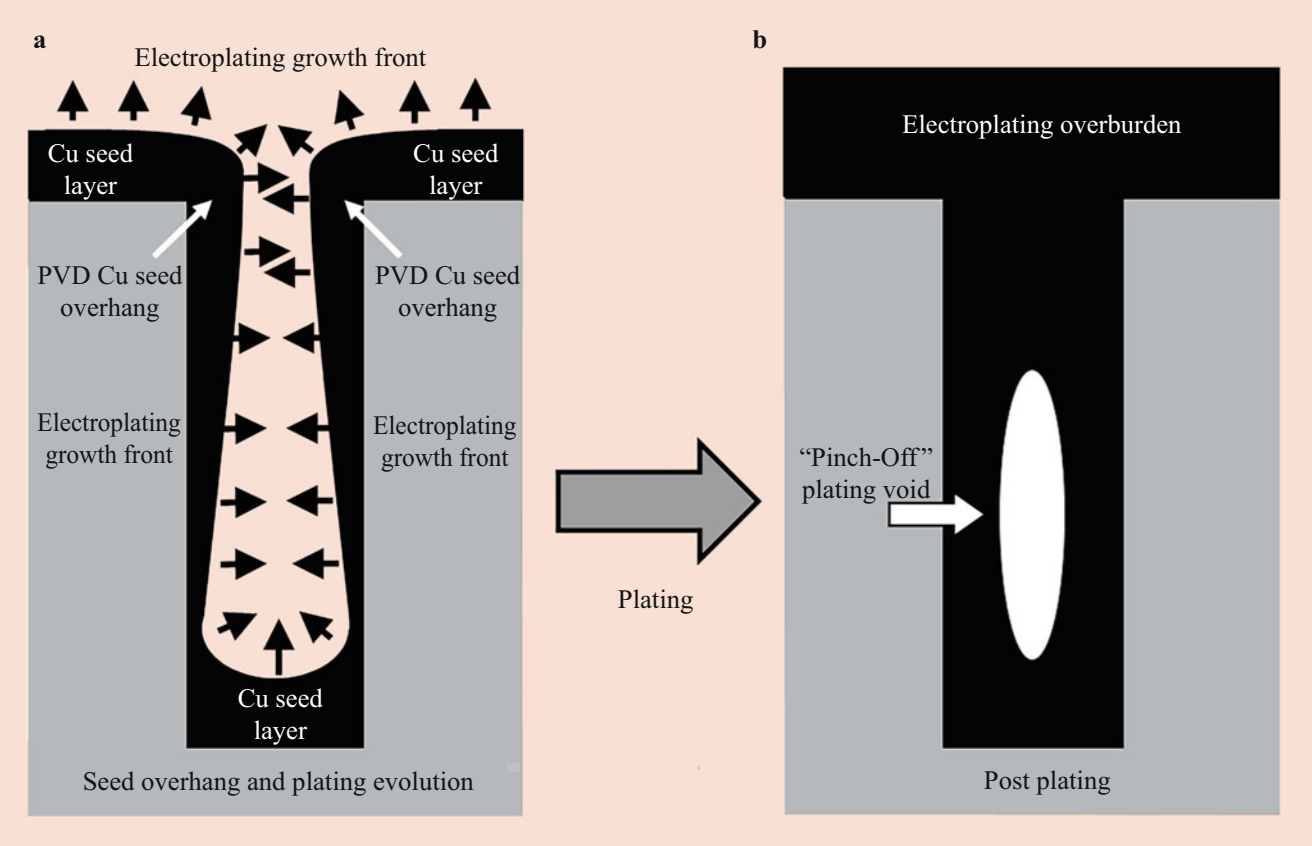

Fig. 5.35 Schematic illustration of Cu fill issues seen with features <20 nm in size. The barrier and liner layers are omitted for clarity. The encroachment of the PVD Cu seed layer makes electroplated feature fill unfeasible, due to the large overhang inherent in the deposition (**a**). Electroplated fill results in trapped voids inside the feature (**b**)

thickness requirements of approximately 2.0 nm. Sputter-deposited copper seed layers will typically require slightly higher minimum thicknesses of 2.0–3.0 nm, which is also typically achieved on the sidewalls. The resulting aggregate thickness of the combined barrier, liner/wetting layer, and seed layer will therefore be at least 5 nm at the very minimum point on the sidewalls and likely thicker. The problem this presents for trench or via features with minimum dimensions of <15 nm is readily apparent: with barrier, liner, and seed layer encroaching from opposite sides of the feature by at least 5 nm, the remaining space for mass transport of Cu into the feature through electroplating becomes vanishingly small at <5 nm. In addition, the effective aspect ratio of the feature will be increased dramatically by ~2× or more, due to the higher proportion of lateral encroachment from the sides relative to the bottom.

The previous example is idealized in that it does not consider the lack of conformality of the PVD TaN and PVD Cu layers. In particular, even the most advanced ionized PVD Cu seed layers are highly non-conformal, owing to the high sticking coefficient of Cu during sputter deposition. The resulting overhang ("bread loafing") effect discussed previously puts even more prohibitive constraints on the feature fill capabilities of PVD Cu seed and electroplating, as is illustrated schematically in Fig. 5.35a. The overhang of the Cu seed layer seen at the top of the feature accumulates heavily at the upper corners due to the high sticking coefficient during PVD Cu deposition, which results in a pronounced narrowing at the top of the feature opening. Once the electroplating process is initiated, this narrow top-corner opening becomes closed ("pinch-off"), since the copper plating growth from the feature bottom cannot advance quickly enough to fill the feature before the opposite sides at the top merge together. Furthermore, overhang at the top corners will result in shadowing of the bottom sidewalls during directional sputter deposition, making coverage in the bottom corners very thin. The thin coverage at the bottom sidewalls makes the seed layer vulnerable to etching or complete dissolution by standard sulfuric acid-based electroplating baths. As illustrated in Fig. 5.35b, the result is the formation of "pinch-off" voids deep inside the feature, which make it impossible to meet basic yield, performance, and reliability metrics.

An alternative means of filling damascene features smaller than ~20 nm with copper combines many of the methods

described previously, such as TaN barriers, CVD wetting layers, and self-ionized PVD copper, with the new technique of reflowing the PVD copper at elevated temperature. Reflow of PVD conductor metal was previously developed to fill damascene aluminum interconnects in the 1990s at feature sizes in the range of ~250 nm [83–85]. The introduction of copper interconnects in the late 1990s made electroplating the preferred feature fill method for many technology generations [85, 86]. With the introduction of reflow for copper interconnects, metal deposition schemes have come full circle.

The reflow of the PVD copper inside features <20 nm in size is accomplished either by adding radiant lamp heating capability to ionized PVD copper deposition chambers or by the use of a heated chuck, either in the PVD Cu deposition chamber or a separate high-temperature chamber [148–152]. A schematic illustration of a process sequence using ionized PVD and radiant lamp heating is shown in Fig. 5.36. Following deposition of TaN barrier and CVD wetting layers (not shown), a high aspect ratio feature is deposited with a layer of self-ionized PVD Cu. Subsequently, the wafer is heated using radiant lamps so that Cu atom surface mobility is increased, enabling diffusion of the copper surface layer atoms from the top and sidewalls of the feature down into the bottom. In the smallest features, the interfacial attraction between the wetting layer and the copper enhances feature fill from the bottom upward as a result of capillary action. By exploiting this capillary effect, PVD copper reflow is complementary to electroplating due to its superior capability to fill features that are too small to be filled by acid plating solutions. This sequence can be repeated in whole or in part, in order to enhance small-feature fill or to deposit a "touch-up" seed layer on the top surface. Wider features in the same patterning level, which are too large for the capillary action to be effective, can subsequently be filled using electroplating after the smallest features have been filled by PVD Cu reflow. Electroplating can also be used to give a thicker overburden for planarization by CMP. Similar process flows are possible using heated deposition chucks or separate anneal chambers instead of radiant lamps.

The requirements for successful PVD Cu reflow fill are generally more stringent than for copper seed and

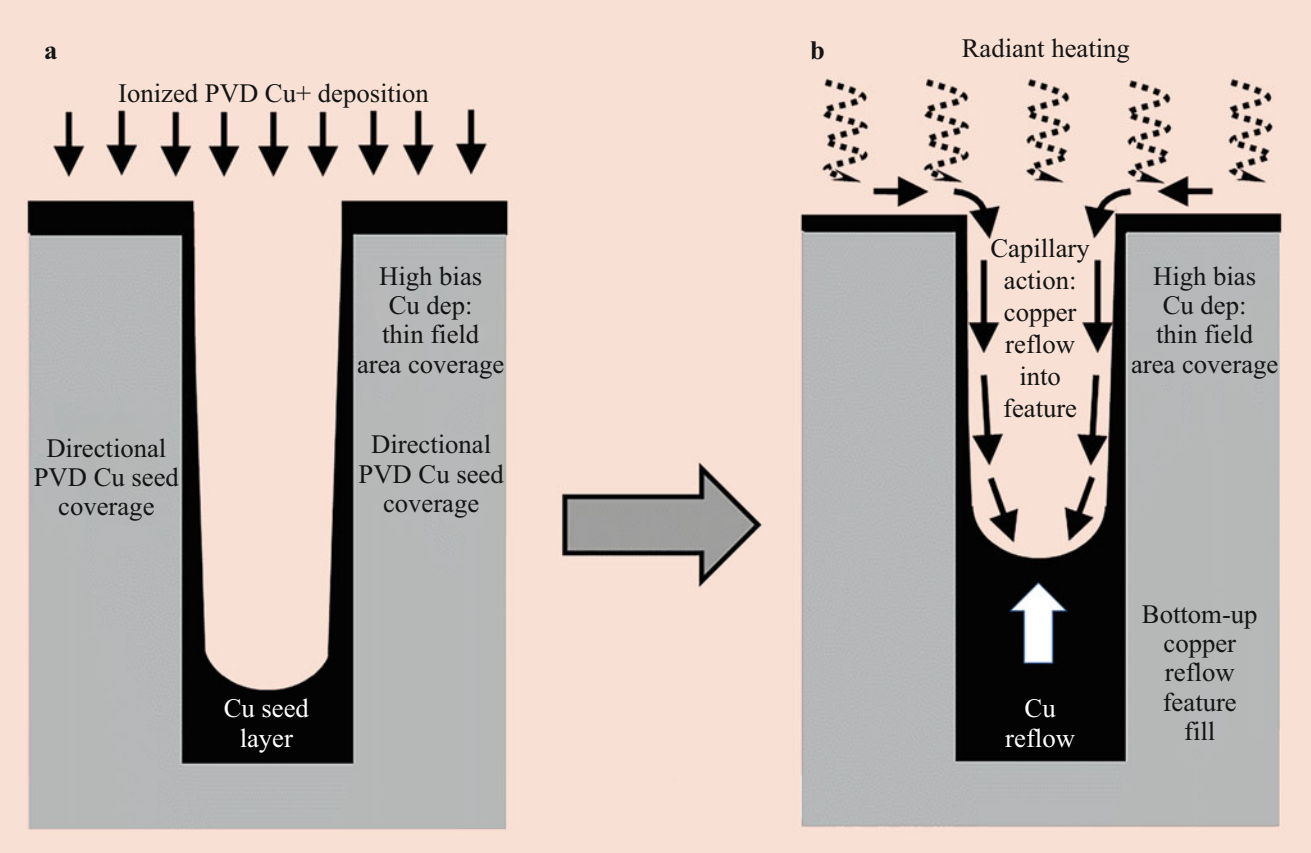

Fig. 5.36 Illustration of PVD Cu reflow fill of features <20 nm in size. The barrier and liner layers are omitted for clarity. By tuning the feature profile, top-surface coverage, and bottom coverage, a continuous film of Cu can be deposited with a larger volume of Cu inside the feature (**a**). Following radiant heating, capillary action and surface tension in the PVD Cu cause it to flow down into the feature, providing void-free fill that cannot be achieved with electroplating (**b**)

electroplating at larger dimensions. The process parameters for the PVD Cu deposition must be carefully tuned and optimized so that multiple conditions are satisfied: the thickness and volume of the top surface Cu must not be so thick as to cause Cu diffusion upward out of the feature and onto the top surface during the heating cycle, which would lead to Cu dewetting on the sidewalls and voiding. Alternatively, if self-ionized PVD Cu deposition is deposited at a bias power that is too high, the top surface layer can be partially sputtered away by Cu-Cu self-sputtering, which leads to mixing between the wetting layer and the Cu and to increased Cu resistance [150]. The proper balance between feature bottom coverage and top-surface coverage can typically be adjusted using the bias power on the self-ionized PVD Cu deposition. The reflow time and temperature cycle, which is typically at ~200–350 °C, must be optimized so that there is surface diffusion of the Cu down the sidewalls into the feature but must not be so extreme as to cause the Cu to dewet and agglomerate where coverage is thin. Similar precautions must be taken with trench and via profiles, to ensure continuous Cu sidewall coverage without dewetting or producing a discontinuity which would break the Cu surface tension and diffusion path down into the feature. Incoming feature profiles and sidewall angles must be engineered so that there are no undercuts or excessively steep sidewalls that would cause discontinuities in the PVD Cu coverage, which is generally line-of-sight.

Evaluations of copper fill using reflow have been published using 14 nm [129, 132, 133], 10 nm [135], and 7 nm technology ground rules [145, 146, 148–152], corresponding to nominal feature dimensions ranging from 32 nm down to 18 nm. These studies show improved fill capability, yield, and reliability reflow copper at these ground rules. Initial studies at 32 nm feature dimensions demonstrated the elimination of sidewall voids, tighter resistance distributions, and improved via-chain yields with reflow copper when compared against PVD seed/plating fill [150, 151]. One advantage of the reflow-type process is that the elevated temperature of the fill results in better annealing and larger grain sizes of the copper which lower the interconnect resistance and enhance electromigration performance. Studies at 7 nm used Kikuchi backscattering to demonstrate an overall upward shift in the grain size distribution of approximately 2× when compared with traditional seed layer-electroplating process flows. This grain size enhancement was also confirmed by electromigration studies which showed >10× longer fail times for the earliest fails and >2× longer fail times for the median points when reflow copper was benchmarked against seed layer-plating fill schemes [145, 146]. Reflow copper thus has potential to extend copper damascene technology beyond the limitations imposed by acid electroplating processing at feature sizes smaller than ~20–30 nm.

5.4 Dielectric Cap Deposition and Interconnect Capacitance

Figure 5.37 shows the results of modeling of the total capacitance vs cap dielectric constant and thickness for 14 nm node BEOL M2 interlevel metal structures with a fixed interlevel dielectric pSiCOH ($k \sim 2.55$) and constant Cu line dimensions. The modeling shows that both the dielectric constant (k) of the cap film and its thickness determine the capacitance increase of the interconnect.

At a fixed cap thickness of 20 nm, a ~20% decrease in total capacitance can be obtained when the k of the dielectric cap is lowered from 7 to 3. The decrease in capacitance with the reduction of cap thickness is much more significant for higher-k caps (e.g., $k = 5$ or 7) as compared to lower-k caps (e.g., $k = 3$ or 3.5). The modeling shows that the difference in capacitance is significant for thicker cap films (~3% @ 20 nm) even for small differences in dielectric constant (e.g., $k = 3$ and $k = 3.5$ curve). Figure 5.37 thus shows that thinner caps with lower dielectric constant are required to reduce the total capacitance of the device. However, a robust dielectric barrier film is required for fabrication of reliable device structures, and, as we will see later, thinning of the cap is limited by the requirements that it must satisfy. Therefore, the first approach used by industry to address the contribution of the cap to the RC delay of the BEOL was the reduction of the dielectric constant, k, of the cap.

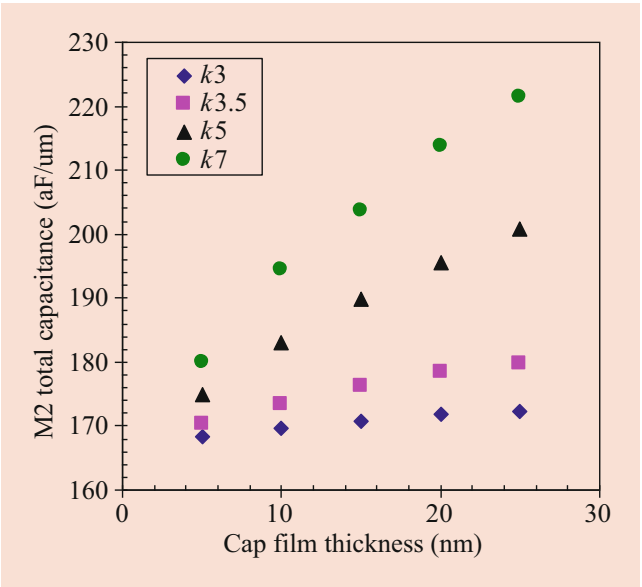

Fig. 5.37 Total capacitance as a function of the thickness of the dielectric cap and its dielectric constant. The modeling shows reduction in capacitance with thinner, lower k dielectric caps. (Ref. [54], reprinted with permission)

Table 5.8 Selected properties of dielectric caps – most caps have compressive stress, and some turn to tensile after post-UV, ultralow-*k* SiCOH cure

Cap	Description	Minimum thickness (nm)	*k*	Breakdown voltage (MV/cm)	Modulus (GPa)	Stress after UV (350C cure in Ar) (Mpa)
SiCNH	SiCNH	20	5.3	5	100	Tensile
Bilayer low-*k*	SiCNxH/C-rich SiCNyH	25–30	3.8	4.2	104	Low tensile
Bilayer nitride	SiNx/SiNy	10	6.8	7.5	150	Compressive
Trilayer	SiNx/SiNy/SiCNH	25–30	4.2	5	150	Compressive
Cyclic SiN	Multilayer SiN	12–20	6.1	8	160	Compressive
Cyclic SiCN	Multilayer SiCN	4	5.8	5	120	Compressive
Co/SiN	In situ clean/s-elective CVD Co/multilayer SiN	Co (1.8–2.4)/SiN (12–20)	6.1	8	NA	Compressive
AlO*x* /oxygen-doped carbide	Conformal AlOx + oxygen-doped SiC (ODC)	2–4 nm (AlO)x/ 3–5 nm (ODC)	4.5–6	5	>50	Compressive

Tensile stress is undesirable

5.4.1 SiN and SiCNH Caps

The first generation of dielectric cap that was integrated successfully with Cu metallization was SiN ($k \sim 7$) at 0.22 and 0.18 μm technology nodes [153, 154]. Conventional SiN film was a robust Cu cap, but with a relatively high dielectric constant.

The second-generation cap with lower-*k* value was SiCNH ($k \sim 5.3$) obtained by incorporation of carbon into the SiN. SiCNH cap was initially introduced at 130 and 90 nm technology nodes and has been used since for several technology generations [155]. The significant decrease of the dielectric constant from 7 to 5.3 reduced the cap's contribution to the total capacitance of the interconnect and the RC delay. Other properties of the SiCNH cap film are shown in Table 5.8.

Key Requirements for Dielectric Caps

While it is desirable to reduce the thickness of the dielectric cap as much as possible, this reduction is limited by the key requirements that a cap must satisfy. The cap has to:

1. Be a barrier to Cu diffusion into the dielectric.
2. Protect the Cu lines from corrosion during patterning steps in the fabrication of the device.
3. Act as an etch stop layer for via build and, in some cases, as stopping layer for planarization by chemical-mechanical polishing (CMP), balancing the stress at copper low-*k* interface [155].
4. Protect Cu from oxidation. During the fabrication process, the Cu lines covered by the cap are exposed to oxidizing plasmas during the deposition of SiCOH or pSiCOH ILD, and the cap has to prevent the oxidation of Cu.
5. Provide a hermetic seal and prevent humidity ingress to the Cu in the final device.

Finally, the breakdown voltage and current leakage of the cap should be maintained above minimal values and the mechanical properties of the cap should be maintained in order to withstand subsequent processing steps [156].

The requirements described above that must be satisfied by a dielectric cap induce challenges in the thinning of existing caps or the development of new ones. This is illustrated next by the description of the oxidation barrier test.

Effects of Reduction of SiCNH Thickness of Oxidation Barrier Properties

Caps of SiCNH in the thickness range of 35–40 nm were implemented at 90–45 nm technology nodes [157]. The thickness of the SiCNH cap film needs to be scaled down further for sub-30 nm devices in order to minimize the overall device capacitance. Various barrier performance tests along with evaluation of electrical properties were performed to evaluate the lower limit of acceptable cap thickness that will satisfy the requirements described above and it was found, as illustrated next, that material modifications are required to further scale the thickness of the SiCNH cap film below 20 nm [157].

An oxidation barrier test was performed on SiCNH films, 5-nm to 35-nm thick, and the results are shown in Fig. 5.38. The figure shows optical images of as-deposited SiCNH over Cu and after exposing the Cu covered by the SiCNH to the oxidation test (at 310 °C in air-ambient exposure for 24 h [39]). The first panel in Fig. 5.38a shows an optical image of the as-deposited SiCNH cap film on top of blanket Cu, while

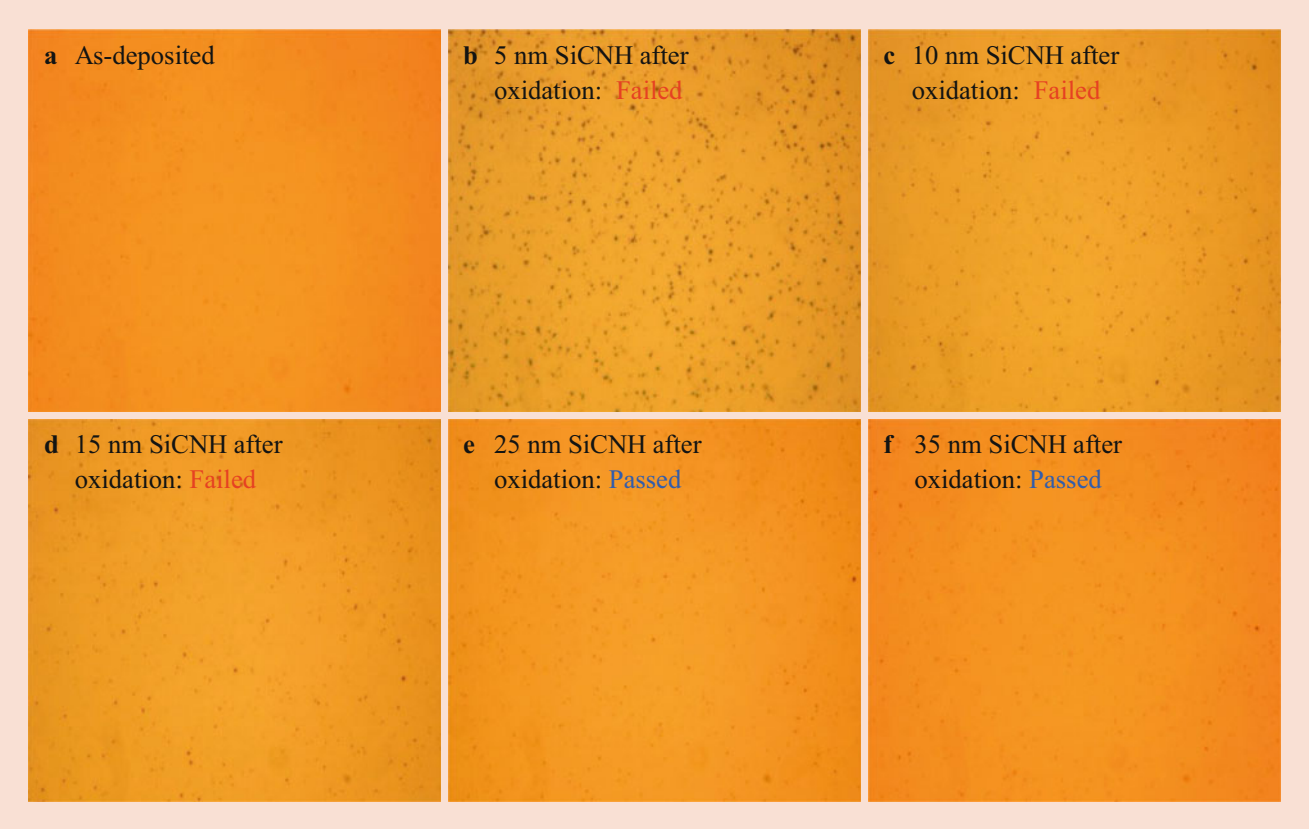

Fig. 5.38 (**a**–**f**) Top-view optical image of (**a**) as-deposited SiCNH on Cu, (**b**–**f**) 5–35 nm SiCNH on Cu post oxidation test (310 °C, 24 h, ambient air). Dark spots represent oxidized copper. (Ref. [54], republished with permission)

the other panels (Fig. 5.38b–f) show images of SiCNH cap films of different thickness on Cu after the oxidation anneal. The black dots visible in the optical images corresponding to 5, 10, and 15 nm caps indicate partially oxidized copper (CuOx) after the oxidation test. The amount of oxidized copper (density of black dots) decreases with the increase in cap thickness and for 25- and 35-nm-thick caps, no sign of copper oxidation was detected after the oxidation test. These results indicate that a thickness bigger than 15 nm is required for SiCNH to act as an oxidation barrier.

The scaling down of the cap thickness for reducing the RC delay is also limited by the cap's performance as a barrier to Cu diffusion. It was shown elsewhere [156–159] that the thickness range of SiCNH caps showing good oxidation barrier performance is also the thickness range satisfying the requirement for robust copper diffusion barrier. The Auger analysis has shown that, while the oxygen penetrates in the SiCNH cap to about 10 nm below the surface and the Cu diffuses into the cap by less than 10 nm during the oxidation test, the formation of Cu hillocks under thin caps is another factor imposing a lower limit on the thickness of a reliable SiCNH cap [157].

The breakdown and leakage of SiCNH also showed degradation with reduction of cap thickness from 35 nm to 20 nm and were further affected by exposure to UV. These observations indicate that minimum SiCNH thickness required for reliable device performance is about 20–25 nm [157]. Thinner caps are possible but require more complex advanced processing or multilayer deposition and treatment. Other properties of SiCNH caps such as modulus, breakdown voltage, and stress are summarized in Table 5.8.

5.4.2 Advanced Caps with Reduced *k* and/or Reduced Thickness

Bilayer Low-*k* Dielectric Cap (SiCNxH/SiCNyH)

The results discussed in the previous section indicate that new cap materials are required for further reduction of the BEOL capacitance. As shown in Fig. 5.37, one way to achieve the capacitance reduction is to decrease the k value of the cap. A new PECVD bilayer SiCNxH/SiCNyH dielectric cap film was developed to achieve this goal [158]. The two layers have different properties and the combined bilayer stack retains the benefits of both films. The first layer (SiCNxH) interfacing the copper has high nitrogen content and robust barrier properties, while the second layer (SiCNyH) is a film of lower nitrogen content, lower dielectric constant,

and good plasma etch selectivity. The difference in nitrogen content of the layers was obtained by changing the precursor chemistry used for depositing them. Silane + ammonia or trimethyl silane + ammonia mixtures were used to deposit the first nitrogen-rich layer. The chamber was then purged prior to introduction of a carbon-rich organosilicon precursor (dimethyl silacyclopentane) and ammonia for the deposition of the second carbon-rich layer [158].

The thickness of the two layers in the bilayer film can be adjusted to obtain robust cap performance at a low effective dielectric constant. The range of *k* values of the bilayer film obtained by varying the precursor flow rates and the thickness of the individual layers have been discussed elsewhere [156]. The two layers can be combined to obtain a reliable cap with a dielectric constant of the bilayer film of ~3.8, significantly lower than that of the SiCNH film discussed in the previous section (see bilayer low-*k* cap in Table 5.1). The barrier performance, electrical properties, and electromigration (EM) performance of this bilayer film have been found to be comparable with that of the single layer SiCNH, indicating that this capacitance reduction strategy has minimal impact on reliability [154, 158]. A scanning electron micrograph (X-STEM) of a cross section of a bilayer cap of total thickness of 26 nm is shown in the left panel in Fig. 5.39a.

With each technology node the layers of the metallization stack become thinner and the thickness of the cap needs to be reduced, especially in the thin wire levels. In this section, an alternate ultrathin bilayer cap film will be discussed. Reduction of the cap's thickness require better intrinsic cap properties compared with that of SiCNH, and this bilayer cap is therefore based on SiN.

The new bilayer cap film is deposited using silane and ammonia as precursors. The two layers in the bilayer film offer different properties and the combination of the two layers in a single stack offers additional advantages. In the SiN*x*/SiN*y* bilayer stack, the first silicon nitride, SiNx, layer is deposited at a low plasma power to minimize the damage to the pSiCOH ULK film. The second silicon nitride layer, SiNy, is a denser film deposited using same precursors but at a high RF power. This second layer is characterized by relatively high compressive stress, and hence the film stack retains compressive stress post exposure to UV cure [159].

The first layer interfacing the Cu is less dense and may not be a robust copper barrier. But this film protects the ULK surface from damage that could be created during the deposition of the dense second layer. Since the purpose of the first layer is to protect the ULK surface, an ultrathin (1–1.5 nm) first layer is enough to form a continuous film. The second layer provides the barrier properties, and a film thickness in the 7–10 nm range is required. This combined bilayer stack can provide robust barrier performance in the 8–12 nm thickness range [159]. The modulus of this bilayer SiN film (bilayer nitride cap in Table 5.8) is higher than that of the carbon containing SiCNH or the bilayer SiCNxH/SiCNyH cap films discussed in the previous section.

Trilayer Low-*k* Ultrathin Dielectric Cap (SiNx/SiNy/SiCNyH)

The bilayer SiCN*x*H/SiCN*y*H described above is a low-*k* dielectric cap showing robust barrier performance. However, upon exposure to UV used for the cure of the pSiCOH ILD, the bilayer cap film changes its stress from compressive to

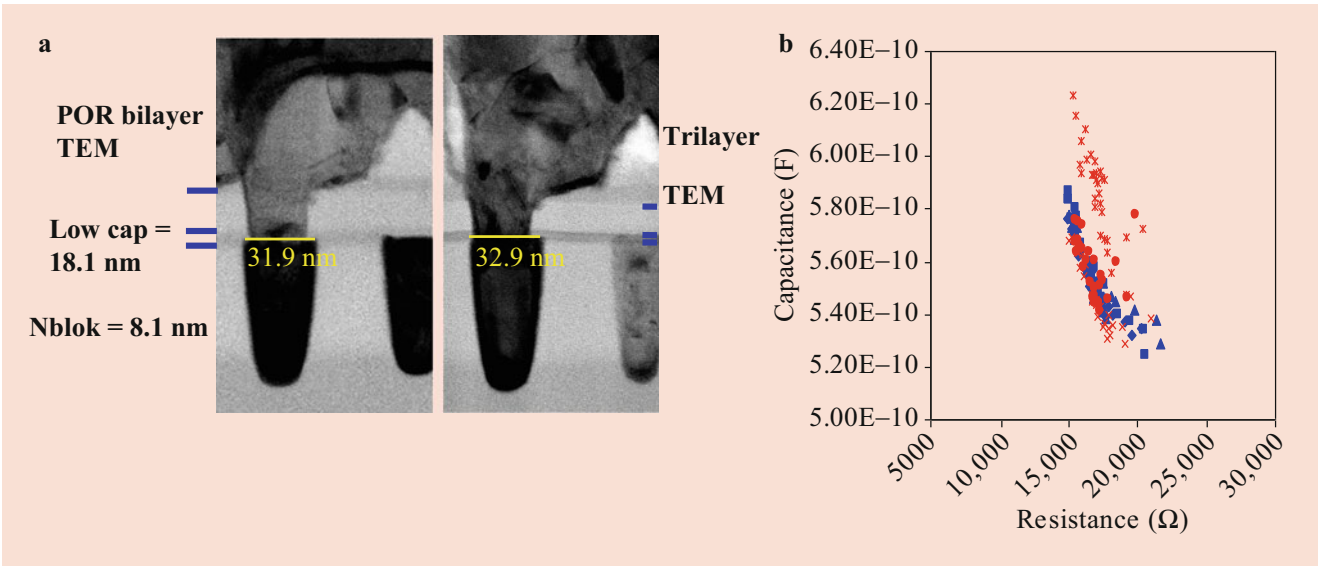

Fig. 5.39 Typical 20–26 nm thick low-*k* bilayer and trilayer caps on 32 nm Cu low-*k* interconnect structure. (**a**) Cross-sectional micrographs of bilayer (left) and trilayer (right) caps. (**b**) Capacitance versus resistance of ~20 nm trilayer cap (blue) and ~26.2 nm bilayer cap (red). A ~ 4% capacitance reduction was obtained with thinner trilayer cap as compared to the bilayer cap. (Ref. [54], republished with permission)

tensile. The stress of the as-deposited bilayer SiCNxH/SiCNyH is lower than that of the SiCNH film (Table 5.1), but both films become tensile after exposure to UV. This can lead to potential cracking in the BEOL structure, impacting the device reliability. The SiN*x*/SiN*y* bilayer film discussed above overcomes the stress change problem because it retains compressive stress post UV exposure. But this bilayer film is a silicon nitride cap; hence the dielectric constant of the cap is relatively high. In order to overcome these issues, a robust trilayer cap film, which retains compressive stress post UV cure of the pSiCOH, was developed with a dielectric constant of ∼4 (see trilayer cap in Table 5.1).

PECVD was used to deposit the three layers of the trilayer cap films in a sequential manner. Silane and ammonia were used for depositing the first two SiNx and SiNy layers of a total thickness of ∼4 nm. These layers were deposited at low and high RF plasma power to form a film with high, as-deposited, compressive stress (∼1200 MPa compressive). The third layer was deposited using trimethyl silane + ammonia as precursors. This is a carbon-rich layer with $k \sim 3.3$ and reduces the effective k value of the trilayer stack. The presence of the first two nitride layers provides high modulus to the composite cap.

The trilayer film provides excellent cracking resistance in BEOL ULK structures. The initial low power SiNx layer prevents damage to the pSiCOH surface. The right panel in Fig. 5.39a shows a cross-sectional scanning electron micrograph (X-STEM) of a typical 20 nm trilayer cap. The trilayer cap has low leakage and provides ∼4% decrease in capacitance as compared to the low-k bilayer SiCNxH/SiCNyH cap (Fig. 5.39b) [159].

Conformal Cyclic SiN

Dielectric films with high conformality are required for various applications for sub-20 nm technology nodes [160]. In the case of copper interconnects, the interface between copper and the cap plays a critical role in electromigration (EM) lifetime. Often, recesses can be seen in Cu lines near the corners after CMP, and such recesses can result in voids in the BEOL structure and affect EM lifetime. With increasing density of the interconnect structure, such recesses are expected to be more frequent. Thus, a newer conformal dielectric cap film is required to cover the copper lines without leaving any voids. In contrast to changing the deposition technique from PECVD to ALD or PEALD [160] as discussed by many in the industry, we describe a new cyclic conformal SiN cap prepared by PECVD. Such films can be deposited in existing PECVD cap tools without requiring significant investment in tool upgrades.

The new conformal SiN film is formed by using a cyclic deposition-plasma treatment process. The multilayer SiN film is formed by depositing ultrathin (∼2 nm) layers using mixtures of silane and ammonia. Each layer is deposited using a low-power RF plasma to improve the film's conformality and reduce damage to the pSiCOH ILD. After the deposition of each layer, a mild plasma nitridation is performed to densify the film. The process is repeated until the desired film thickness is achieved. The multilayer SiN is a highly conformal film that provides good step coverage with conformality of ∼70% or greater, as illustrated in Fig. 5.40.

The multilayer, cyclic SiN film has high breakdown voltage and low leakage currents, and ultrathin (10–14 nm) caps show robust copper oxidation barrier performance. The as-deposited films are compressive and remain compressive after exposure to UV irradiation. Other properties of this cap are summarized in Table 5.1. The conformal cyclic SiN shows higher modulus and breakdown in comparison to previously discussed dielectric caps and retains compressive stress post UV curing.

Selective Cobalt/Dielectric Cap

As was previously discussed in the thin-film metals Sect. 5.3.3, as the spacings between the Cu lines decrease with each technology node, there is a significant drop in EM reliability because of potential fast diffusion paths between the lines. This problem has become critical for sub-32 nm nodes. The interface between Cu and the dielectric cap plays a critical role in the EM performance. Weak adhesion between Cu and the dielectric cap makes the structure susceptible to EM induced mass flow [160, 161]. It was shown that the void growth rate under EM testing increases with decreasing interface de-bond energy between the copper and cap [161, 162]. The post-CMP recess observed in copper lines can aggravate this issue.

Metal capping layers have better adhesion to Cu wires, but any residual metal deposited on top of the ILD dielectric can cause the degradation of the time-dependent dielectric breakdown (TDDB). Furthermore, metal caps could interact with Cu and increase its resistivity, an issue that should be avoided to prevent an increase in RC. Different selective deposition methods have emerged to provide a selective metal cap solution for EM enhancement without TDDB degradation. One of the methods for selective metal capping is to use electroless deposition of Co cap [163]. The major issue with this approach is the contamination of the ILD from the plating bath, which can cause degradation in yield and potential impact on capacitance. In addition, the electroless-plating approach adds processing steps and increases wafer cost.

Alloy (doped) Cu seed layers [120, 164], using Mn or Al which is the preferred doping component, were covered previously in the metals section. The alloy self-capping technique is ineffective in the presence of CVD liner wetting layers such as Co or Ru, due to the presence of oxygen in the organometallic CVD liner precursors, which suppresses the

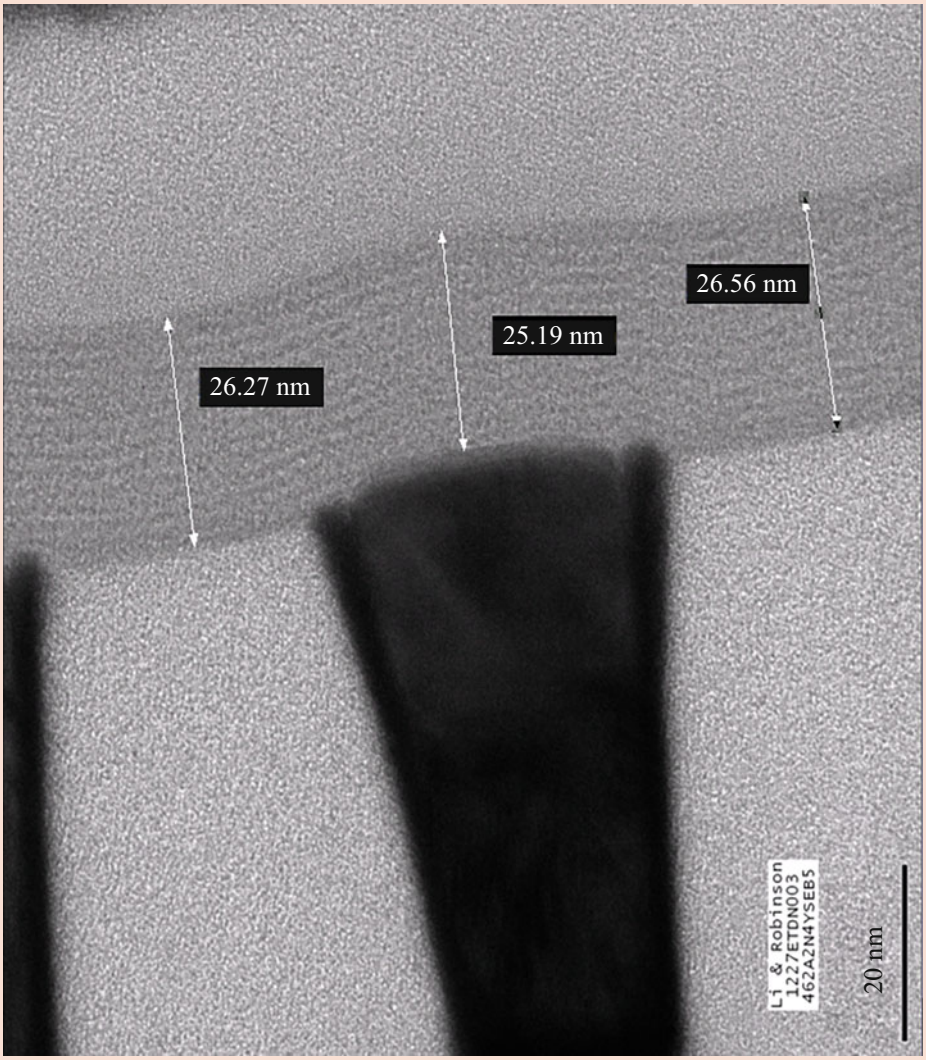

Fig. 5.40 Conformal cyclic SiN copper barrier film. The multilayer film with good conformality over copper recess. (Ref. [54], republished with permission)

cap layer bonding of the Mn or Al alloy components. They also have the drawback that un-segregated dopant (minority-alloy) atoms can stay in solution in the Cu wire and drive up resistance due to impurity scattering [120].

A more robust approach for improving EM is the use of a metal cap layer, e.g., Co, deposited on top of the metal lines using selective chemical vapor deposition (CVD). The deposition should be highly selective to enable the deposition of a sufficiently thick cap on Cu without metal deposition on the ILD dielectric. Such a process is described next.

A carbonyl-based precursor is used in the current selective CVD Co process [162, 164]. Prior to the deposition of Co, the copper surface is cleaned to remove any copper oxide and carbon residues. Co is deposited selectively only on Cu using a cyclic process where in each cycle the deposition of a thin Co layer is followed by a plasma treatment. The deposition rate drops with time in each cycle and the plasma treatment generates a fresh metal surface to restore the deposition rate. Co is not deposited on top of the oxygen rich pSiCOH. Figure 5.41 illustrates the selectivity of the Co process after the deposition of a 3 nm Co film.

Figure 5.41a–c show the EDX scans of Co liner and Co cap selectively deposited on top of Cu lines, TaN/Ta liner, and the conformal cyclic SiN cap, respectively. Co is identified only on top of the Cu but not outside it on the dielectric.

A similar, but nonselective, PECVD Co wetting layer, as described in the thin-film metals Sect. 5.3.3, was used to fabricate Co liners along the walls of the Cu lines and vias. Electromigration reliability was then evaluated for structures using an ultralow-$k \leq 2.55$ pSiCOH ILD and either dielectric caps, or selective Co plus dielectric cap, or a wrap-around Co structure where the Cu is encapsulated between Co cap and Co liner. The EM lifetime distribution for these structures is shown in Fig. 5.42. Electromigration testing was performed under a constant DC current density. In order to get any substantial fails on samples with Co cap, the testing

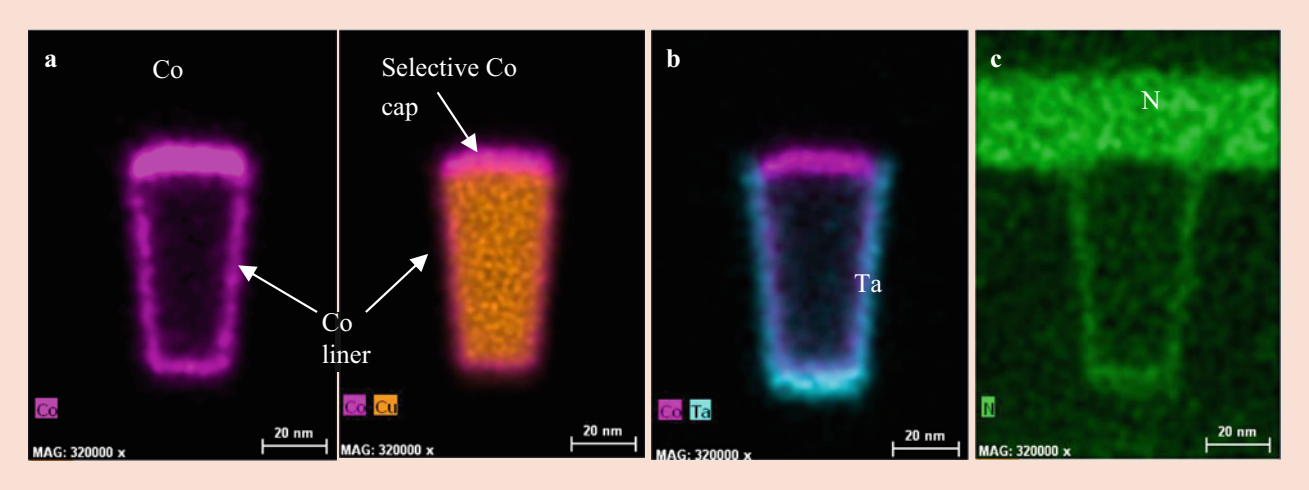

Fig. 5.41 EDX signal of (**a**) Co from selective cap and liner and Cu in the trench; (**b**) Ta from the barrier layer and Co from the selective cap; (**c**) N from dielectric cap and liner layer. Co selectively deposits on top of Cu and not on ILD or the Ta liner. A complete wrap around structure is achieved by using a Co cap and Co liner. (Ref. [54], republished with permission)

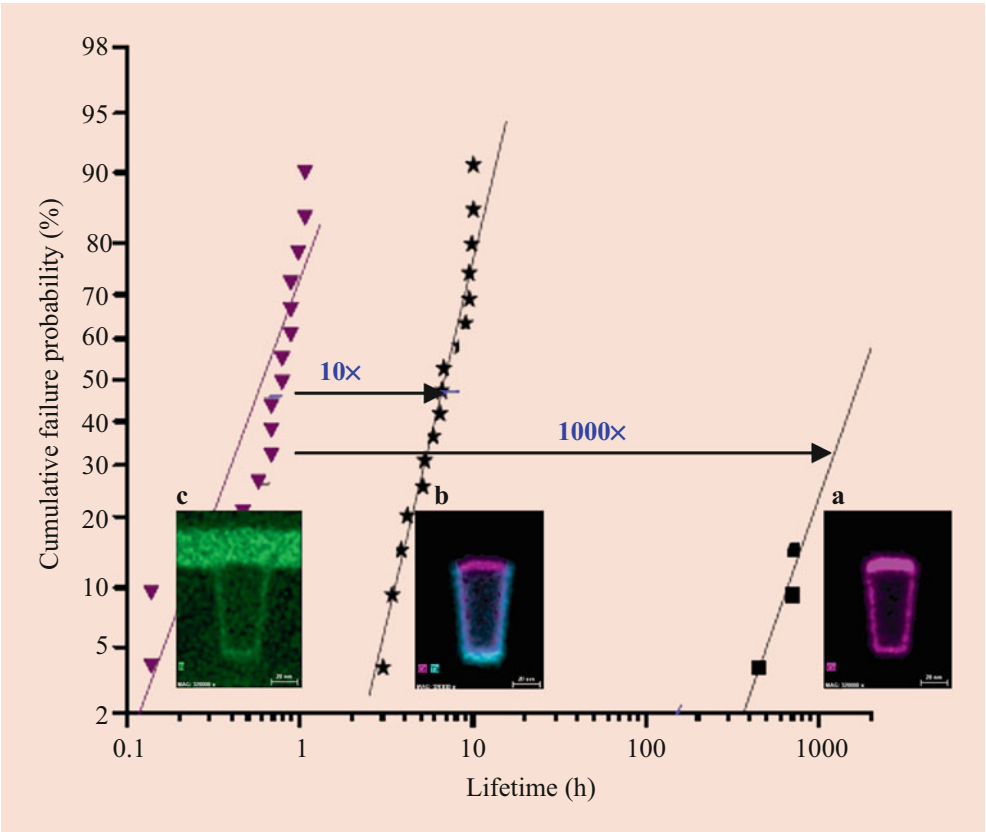

Fig. 5.42 Electromigration lifetime distribution with: (**a**) conformal cyclic SiN dielectric cap, (**b**) selective Co/conformal cyclic SiN cap, and (**c**) Co liner along with selective Co/conformal cyclic SiN cap. 10× improvement in lifetime is achieved with a metal only cap layer and ~1000× improvement is obtained with a Co cap and Co liner complete wrap-around structure as compared to dielectric only cap structure. (Ref. [54], republished with permission)

temperature was increased to 340 °C, i.e., 25–50 °C higher than the regular testing temperature. As shown in Fig. 5.42, the use of the CVD Co cap film improves the EM lifetime by ~10×, while the Co wraparound structure increases the EM lifetime by ~1000× compared to the structure with only dielectric cap.

Thin Co at the edges of Cu lines, with Cu recess at the corners is a weak point for Cu migration. As shown in Fig. 5.41b, Co cap aligns well with the Co liner but does not deposit on top of TaN/Ta liner. Thus, a preferred approach for obtaining the maximum EM benefit is to use a combination of Co liner with selective Co cap.

5.4.3 Integration of Advanced Selective Cobalt/Dielectric Cap

The results discussed above show a considerable improvement in device reliability with the selective metal cap process. It is important to understand the impact of any other parameters on device performance, especially if the selective Co cap deposition was followed with an in situ vs an ex situ dielectric capping process [165]. After the Cu lines are selectively capped with Co, there is still a need to deposit a dielectric barrier cap layer before depositing the ILD pSiCOH film. The dielectric barrier cap prevents the selective Co from oxidizing during the pSiCOH deposition. The dielectric cap can be deposited without a vacuum break after the deposition of the Co, in a chamber sharing the same platform as the CVD Co chamber (in situ), or can be deposited in a stand-alone tool, whereby the Co cap is exposed to air before the deposition of the dielectric cap (ex situ). In the ex situ process, the Co surface will be partially oxidized, and it will be difficult to reduce the Co oxide prior to dielectric cap deposition. Furthermore, a thicker Co cap film is required for an ex situ process to prevent the oxidation of Cu underlying the Co layer. In contrast, with an in situ process, the dielectric cap is deposited on Co without any intermediate oxidation of the Co or Cu. In this case, a thin continuous Co layer as low as 1.8 nm is sufficient to get the required EM benefits. A ~10× improvement in EM was observed with an in situ capping process [165] vs the ex situ process. Similar selective metal caps such as Mn [166] or Ru [167] have also been investigated. The combination of CVD Co liner and selective CVD Co cap has seen widespread adoption in advanced logic technologies at ground rules of 16 nm and below.

5.5 Summary

SiCNH and SiN*x* dielectrics have been used as cap materials for Cu/low-*k* interconnects in many device generations. The SiCNH cap has minimum thickness limit for performing as an oxidation barrier. Reduction in RC with aggressive interconnect scaling therefore required development of new, thinner, lower-*k* dielectric barrier films. This led to development of several multilayer caps with $k < 4.5$ and thinner 4–25 nm caps. Conformal dielectric cap film was developed to provide good coverage of recesses in copper lines. In addition, a selective Co cap process was developed to further improve the EM performance in recent years together with various dielectric cap listed in Table 5.8 [166–169].

There are good etch stops such as AlO*x*/oxygen-doped SiC (ODC) [168] that have also been used as excellent stops in manufacturing sub-20 nm node devices. Aluminum oxide films characterized by a dielectric constant (k) of less than 7 (such as between about 4 and 6) and having a density of at least about 2.5 g/cm^3 (such as about 3.0–3.2 g/cm^3) are deposited on partially fabricated semiconductor devices over both metal and dielectric to serve as etch stop layers. The films are deposited using a deposition method that does not lead to oxidative damage of the metal. The deposition involves reacting an aluminum-containing precursor (e.g., a trialkylaluminum or other cyclic aluminum oxide compound). A second layer of oxygen-doped silicon carbide (ODC) was deposited on top to act as a secondary oxidation barrier. This composited AlO*x*/ODC cap/etch stop has excellent etch stop properties and is currently the leading cap being used in tight metal pitch levels by leading semiconductor manufacturers, for sub-20 nm BEOL device fabrication in addition to the standard SiN, SiCN, and cyclic SiN/SiCN cap listed in Table 5.8. These are the most common dielectric caps that are being used at various levels as oxidation barriers and etch stops in semiconductor fabrication.

There are also many other promising caps and etch stops such as high-*k* dielectric HfOx, SiC, SiCNO, and others that have been described in detail with various references in recent cap review [170]. However, those caps tend to have limited use and generally tailor to specific application. In the near future, lower-*k* metal oxide etch stop such as MnOx and MnSiOx ($k \sim 3.7$) together with ODC with thickness in 1–3 nm range should be explored as alternate device-compatible etch stop/cap for sub-5 nm Cu interconnect device fabrication in air gap [170] or ultrathin cap/liner [171, 172]. When other low-diffusivity metals such as Co or Ru are used in interconnect, the need for good etch stop and oxidation barrier cap with excellent electrical and mechanical properties is still highly critical to achieve desirable performances and improve reliability in future nano-electronic devices.

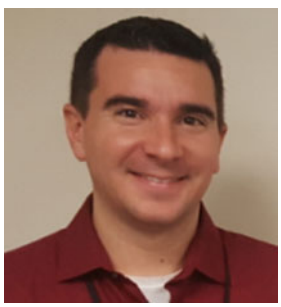
Shyng-Tsong Chen received his Ph.D. in physics from the Massachusetts Institute of Technology (MIT) in 1985. He has over 35 years of semiconductor research and development experience at IBM and is a technical lead in BEOL integration.



Nicholas A. Lanzillo received his Ph.D. in physics from Rensselaer Polytechnic Institute in Troy, NY, in 2014. He is currently a Research Staff Member in IBM Research Division in Albany, NY. His research interests include advanced interconnect technology development, design technology co-optimization (DTCO), and quantum computing.

Son Van Nguyen is a Research Staff member at IBM research in Albany, New York, USA. Dr. Nguyen research is focused on electronic materials including ultralow dielectrics and copper interconnects for future high-performance nano-electronic logic and memory devices with 250+ patents and 170 publications. Dr. Nguyen received a Ph.D. in Solid State Chemistry at Brown University in 1981 and worked at Exxon Research, Applied Materials, and IBM last 40 years.

Takeshi Nogami is Principal Research Staff member of IBM Research in Albany, NY. He received BE, ME, and Ph.D. in chemical engineering from the University of Tokyo, Tokyo, Japan. He worked for Toshiba, Kawasaki Steel, AMD, and Sony Corp. prior to joining IBM in 2006. He has been working on copper interconnect technology. He holds over 120 US patents.

Andrew H. Simon received his A.B. in physics from Princeton University and his Ph.D. in physics from the University of Illinois at Urbana-Champaign. He is currently a Senior Technical Staff Member in IBM Research Division in Albany, NY. He has over 30 years of experience in semiconductor research, development, and manufacturing, primarily in metal processes for advanced logic.

Wet Chemical Processes for BEOL Technology

Abstract

This chapter covers wet processes for logic back-end-of-the-line interconnect technology – namely, wet cleans and wet etching (Sect. 6.1), electroplating (Sect. 6.2), and chemical mechanical planarization (Sect. 6.3). Each section details the introduction of the process and equipment used in 300-mm semiconductor industry from the beginning of Cu era. All the critical components of the process and equipment are described followed by the experimental results and discussion for each of the application. In wet cleans and wet etching section, applications like post-etch residue clean, backside clean, and hardmask wet etch are covered. Plating section includes copper electroplating of damascene and dual damascene structures. In chemical mechanical planarization section, metal – copper, tantalum, tantalum nitride, and cobalt – polishing and planarization, and post-cleaning applications are covered.

Keywords

Wet clean · Wet etch · Corrosion · Copper · Electroplating · Electrodeposition · Plating · BEOL · Damascene · Interconnect · Chemical mechanical planarization · Slurry · Planarization · Topography · Polish · Brush clean

6.1 Wet Cleaning/Etching for Cu Interconnects

In fabrication of Cu interconnects, wet cleans are integrated in every module to meet the defectivity requirement that is essential to wafer electrical yield and reliability. Wet cleans are primarily used in Cu interconnects for surface cleaning and etching materials. In general, "wet clean" is applied on the wafer to:

(a) Remove organic and metallic particles or contaminants [1, 2]
(b) Remove unreacted residues or particles after film deposition [3]
(c) Remove plasma reactive ion etch (PRIE) residues after plasma etching step [4]
(d) Remove organic and metallic contaminants on backside or bevel of the wafer [5–9]

M. Rudan et al. (eds.), *Springer Handbook of Semiconductor Devices*, https://doi.org/10.1007/978-3-030-79827-7_6

On the other hand, "wet etch" is applied to:

(a) Remove sacrificial materials – dielectrics, metals, organic layers, silicon antireflective coating, and metal nitrides [10]
(b) Partially etch or recess a material to a target thickness – dielectrics, metals, and semiconductor materials [11]

In both cases, wet chemical solution which is a mixture of chemical components is the core of this process. Both aqueous and non-aqueous solutions are used in semiconductor industry. Standard wet clean solutions used in Cu interconnects include, but not limited to, dilute hydrofluoric acid (dHF), standard clean 1 (SC1), standard clean 2 (SC2), ultra-dilute sulfuric peroxide (uDSP) mixture, and chrome phos. These solutions are applied at temperatures ranging from room temperature to 70 °C. Starting from 14 nm technology, formulated vendor cleans were introduced both for cleaning and etching materials. In this chapter, advancement of wet cleans in Cu interconnects is discussed.

6.1.1 Wet Clean Tooling

Before going into the details of wet chemistries that are used in Cu interconnects, an understanding of equipment is needed to describe how a wet clean is performed. There are two major types of equipment for wet cleans. First one is a batch tool, where a boat of wafers is immersed in the target chemistry to perform the cleaning. A 200-mm wafer wet processing was by immersion batch process which continued into early 300-mm wafer process. As technology advanced, additional defectivity reduction requirements from wet clean triggered equipment to move from batch to single wafer processing. The immediate benefit is isolating device side process fluids without exposure to entrained particles from the backside. In the interest of Cu interconnects, the below section is dedicated to single wafer wet clean equipment.

Figure 6.1 shows a scheme of a single wafer wet clean equipment. Key components in single wafer wet clean tool are shortly described in the following:

Chemical solutions are procured in bulk 55 gallon drums and are situated in sub-fab to supply to the tool level via supply pump. These chemistries are supplied at room temperature and fed either into a day tank or onboard chemical mix tank (30–50 L capacity). In some cases, 5 gallon carboy is also used as the feed.

Chemical mix tank is where all the chemical components are mixed. In an example of aqueous chemistry, targeted chemicals are mixed with deionized (DI) water in the chemical mix tank at the targeted ratios. After mixing is complete, mixture is heated to target temperature. Chemical recirculates between the chemical mix tank and chamber in a loop, chemical mix loop, with an extension at the chamber to dispense chemistry through nozzle on a scan arm, as shown in Fig. 6.1.

Scan arm consists of several channels extending to nozzles that dispense onto the wafer. Through each channel one of (a) formulated chemical mixture (b) DI water, (c) isopropanol or (d) nitrogen is dispensed onto the wafer. There can be multiple scan arms within a chamber.

Chuck pins are used to hold the wafer both in stationary position and rotating movement. They are in contact at the bevel of wafer extending up to 4 mm of the wafer edge.

In wet clean tool, *drain cup* is used to direct the post-process chemical into specific drain. Drain options include acid waste, base waste, solvent, and fluoride. Depending on the chemical compositions, these drains are selected in the recipe steps to direct each chemical for downstream treatment before disposal.

Wet clean process recipe on the tool can be broadly divided into four steps. First step involves preparation of the chemical in the chamber. In this step, the chemical is dispensed from nozzle to drain directly for few seconds to ensure that a fresh chemistry is ready to be dispensed on the wafer. During this step, scan arm is in home position, i.e., not on top of the wafer. In the second step, scan arm position comes onto the top of the wafer, and the chemical mix is dispensed onto the wafer to perform the targeted cleaning or etching. During this step, wafer is continuously rotated at rpm varying from 300 to 1500. There are substeps within second step, which involve change in rotation speed and change in scan arm position to optimize the uniformity and particle removal efficiency across the wafer. In the third step, dispense liquid is switched from chemical mixture to DI water. During this step, wafer continues to rotate, and DI water replaces the chemical mixture on the wafer and rinses off any residual chemical from the wafer. The final and fourth step is wafer drying step. In this step, wafer is dried using nitrogen flow or a combination of isopropanol and nitrogen flow. During all the four steps, wafer is continuously rotated, and at the end of fourth step, wafer rotation slows down to zero.

6.1.2 Wet Clean or Wet Etch Applications

Wet clean innovation and development for Cu interconnects have been driven by the advancements in patterning, materials, continuous scaling of the critical dimensions, and the requirement of defectivity levels to sub-100 nm size. Cu interconnect cleans are mainly divided into (a) post-film deposition clean, (b) pre-lithography backside clean, (c) patterning and hardmask open clean, (d) post-via etch clean, and (e) hardmask wet etch.

(a) Post-film Deposition Clean

Each interconnect level begins with deposition of several films including dielectric cap, interlevel dielectric (ILD),

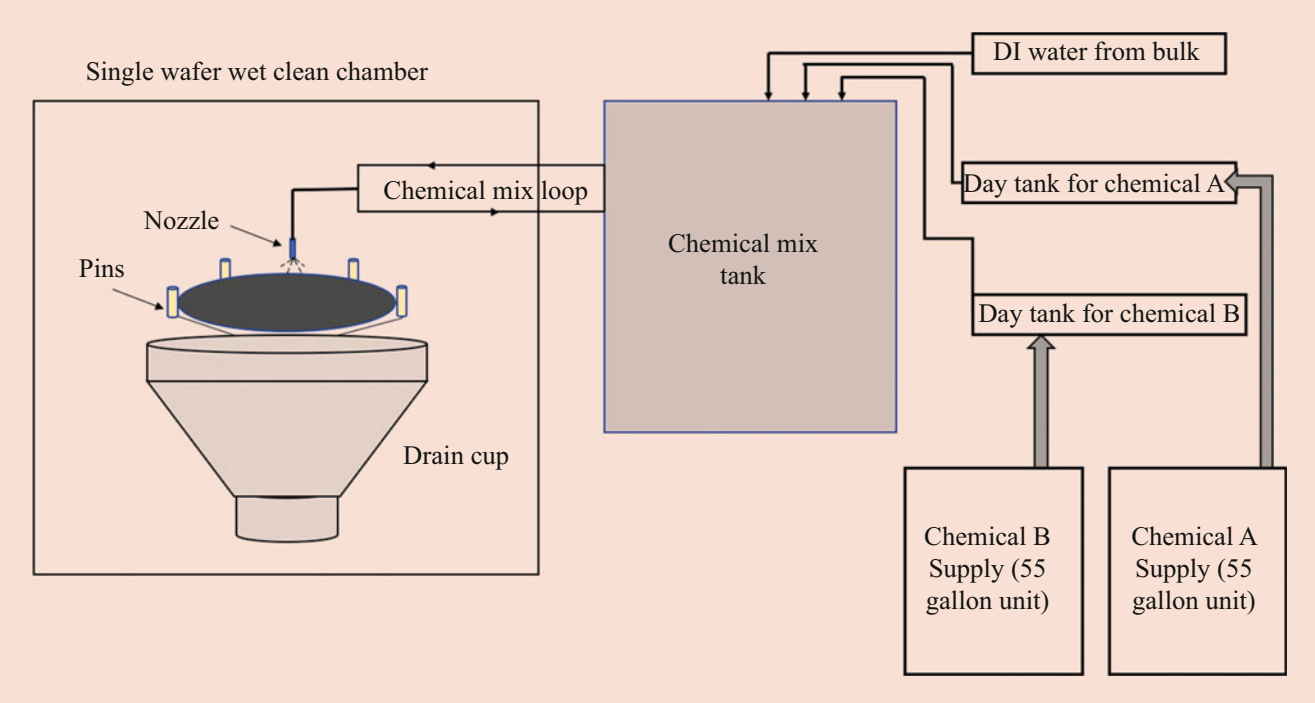

Fig. 6.1 Schematic of a single wafer wet clean tool

silicon dioxide, silicon nitride, and titanium nitride. Usually after dielectric film deposition, unreacted species remain on surface as particles. These particles appear as embedded defects in downstream processing and negatively impact patterning process. Wet cleans are applied on these films to remove these unreacted species or particles. These cleans need to be chemically mild to avoid any chemical etch or damage to the films. Known solutions include SC1, brush clean, or DI water spray.

(b) Pre-lithography Backside Clean

After coating lithography films including organic planarization layer (OPL), silicon antireflective coating, and photo resist, backside cleans are performed to remove backside particles to eliminate any hotspots during lithography exposure. The main sources of these particles are from wafer handling and chucks from the upstream tooling. Particles are mostly composed of carbon, oxygen, and silicon. Figure 6.2 shows the evaluation of backside cleans for this step. DIW brush clean is commonly used at this step and is efficient at removing particles as shown in Fig. 6.2. Brush assists in scrubbing off particles, and DIW liquid carries them away in solution. The unremoved defects are mostly chuck marks. With the advanced development of backside chambers by equipment vendors, DIW with high N_2 flow is used as an alternative to brush clean, and when this is combined with chemicals like dilute HF and SC1, it is shown to provide similar results as brush clean (Fig. 6.2). In addition, backside cleans have been implemented at other steps in the process including post-dielectric deposition, post-plasma etch, and post-metal liner deposition [9]. These cleans reduce the defectivity on backside and eliminate the possibility of particles falling onto topside of the wafer in foups.

(c) Patterning and Hardmask Open Cleans

Optical 193 nm lithography is shown to have difficulty in resolving features below 80-nm pitch structures in a single exposure. Several patterning methods such as double patterning – litho-etch litho-etch (LELE) – sidewall image transfer (SIT), self-aligned double patterning (SADP), and triple patterning, litho-etch litho-etch litho-etch (LELELE), were used to extend 193 nm lithography down to 48-nm pitch structures [12]. Wet cleans play an important role to clean the residues during these patterning steps and remove sacrificial layers. As an example, SIT patterning scheme is shown in Fig. 6.3.

In this case, OPL was used as mandrel material, silicon dioxide as spacer material, and TiN as hardmask (HM) material. Wet cleans are performed during this patterning (a) after mandrel etch and (b) after spacer etch back. Here, the wet clean is intended to clean post-etch residues around the mandrel material and spacer materials and on TiN HM. The key requirement of this wet clean is to not etch/attack any of the materials exposed. Dilute HF (dHF) wet clean works

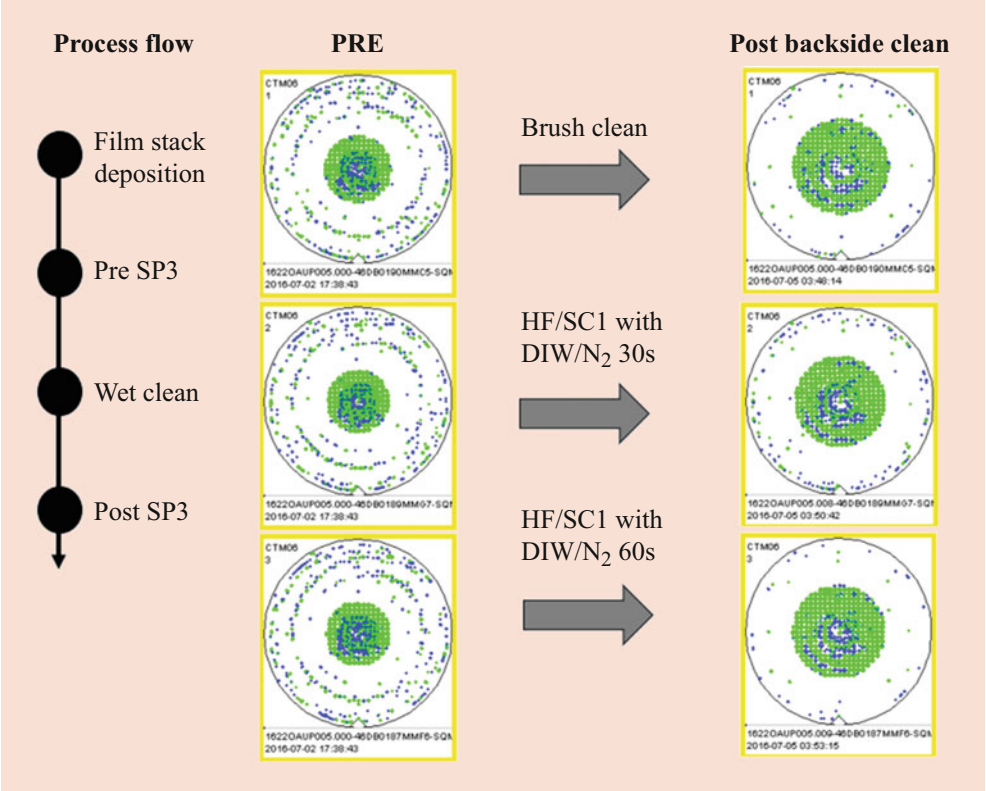

Fig. 6.2 Evaluation of backside cleans at pre-lithography step

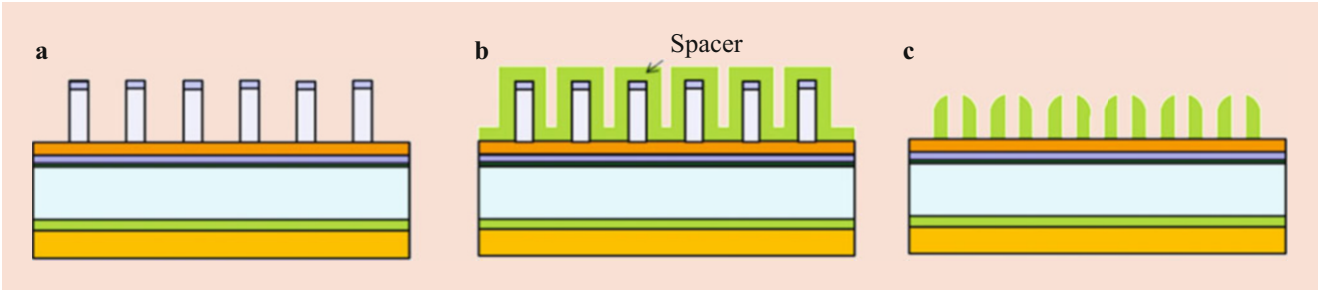

Fig. 6.3 SIT patterning module: (**a**) post-mandrel etch clean, (**b**) post-spacer deposition, and (**c**) post-spacer etch back/mandrel removal and wet clean to remove etch residues

well for both applications in removing the post-etch residues. Concentration of dHF is varied between 300:1 and 1300:1 – DIW:49% HF and temperatures between room temperature and 60 °C were evaluated for this step [14]. dHF etch rate of oxide at these concentrations is <1 Å, and that is enough to remove few monolayers of oxide/native oxide on the surface of the exposed materials. Removal of these films results in undercut and lift-off of the post-etch residues that are on the surface. One of the challenges with silicon dioxide as spacer materials is the potential undercut at the spacer and hardmask interface from dHF wet clean. This undercut at the interface results in spacer flopover. Alternatively, chemistries such as ultra-dilute sulfuric peroxide (uDSP), dilute SC1, and formulated chemistries were also proven to efficiently clean the post-etch residues. Figure 6.4 shows the impact of wet clean after spacer etch back on electrical resistance and yield. When there was "no clean" after spacer etch, very high line resistance and ISOVIA resistance were observed. This indicates shallow trench or smaller trench CD due to blockage of the trench pattern from residues after spacer etch back. In all the other cases where clean was applied, very high yields were observed with dHF split showing the best distribution.

At 7-nm technology node and 36 nm pitch, EUV lithography was introduced as a single patterning method to direct print lines [15]. The single patterning method simplifies the patterning stack in terms of wet cleans, and the first post-plasma etch clean is applied after hardmask open (HMO)

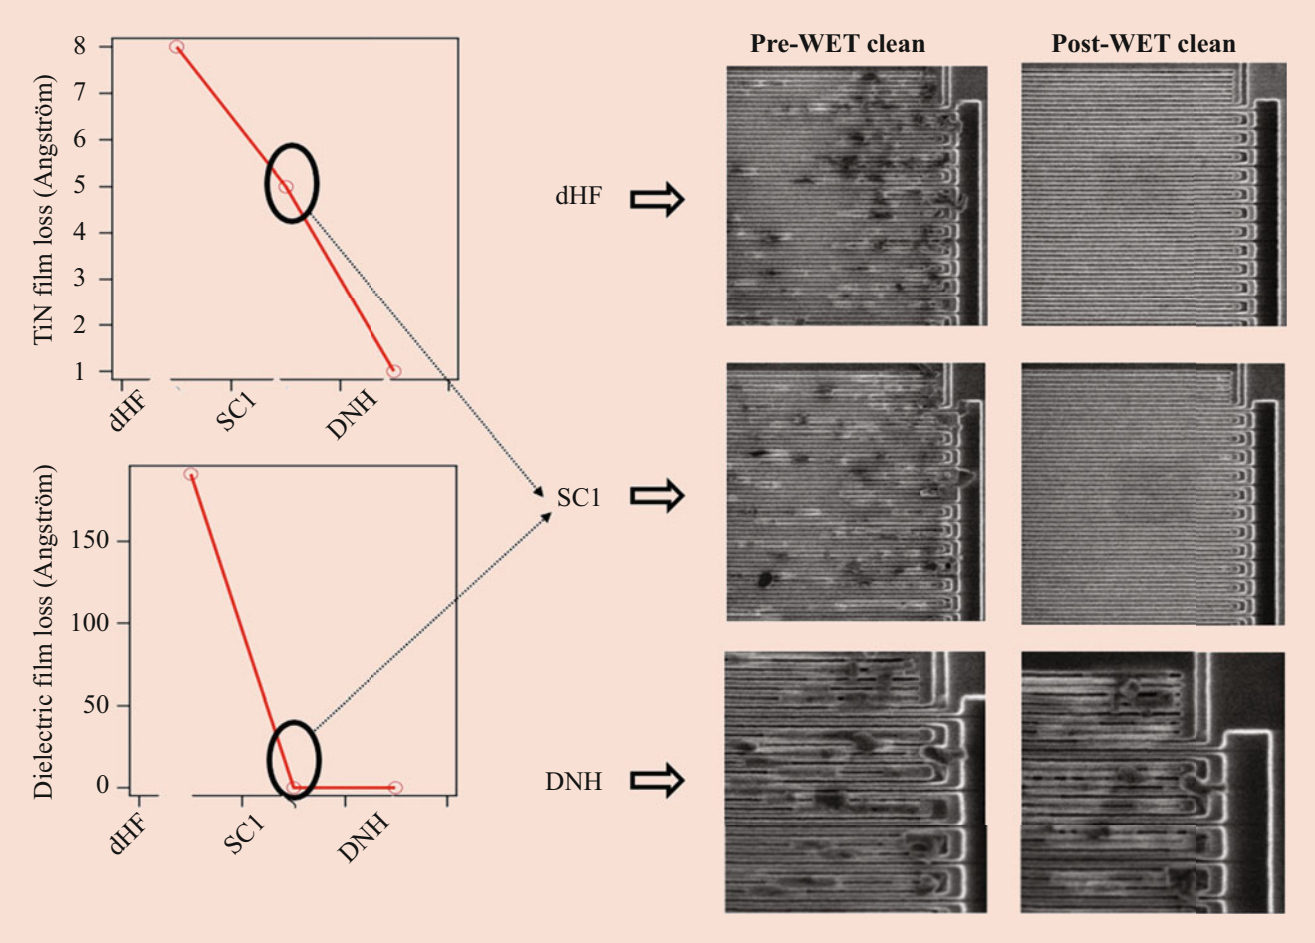

Fig. 6.6 Wet clean evaluation for EUV HMO application

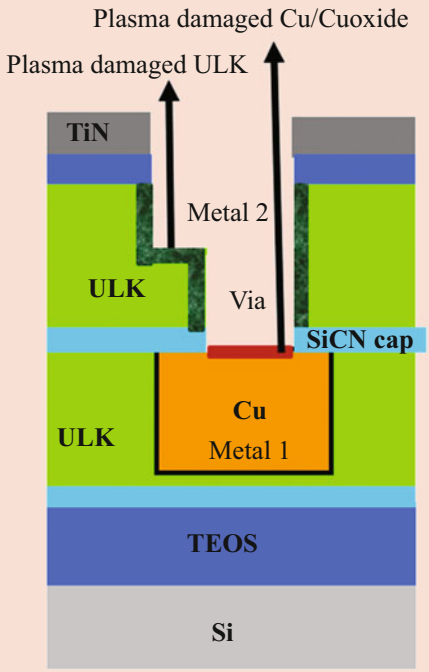
step. Incomplete residue removal blocks downstream trench and via etch and results in an electrical open. On the other hand, TiN undercut can result in increased or nonuniform CD of trench, and in the worst case, it will lift off TiN resulting in an electrical short to the neighboring line. Figure 6.5 shows the pre- and post-HMO wet clean. The post-wet clean cartoon is an example of chemistry where there is active undercut into the dielectric hardmask. dHF for this application cleans residues efficiently, but as can be seen in Fig. 6.5c, there is clear undercut underneath TiN. The undercut is a result of active etching of the exposed dielectric film underneath TiN. In some cases, even though the pristine dielectric material does not etch in wet chemistry, a plasma-modified material can have active etch rat. As an alternative wet clean, SC1 chemistry for this application shows no undercut in Fig. 6.5d.

Figure 6.6 shows the TiN and dielectric wet etch rate with various wet cleans and top-down scanning electron microscope (SEM) images before and after wet clean. To test the effectiveness of wet clean in removing post-etch residuals, an aggressive polymerizing etch chemistry was applied at HMO step. As expected, a high number of post-etch residues were seen on the trench macro. In comparison to dHF, SC1 and dilute ammonia wet clean (DNH) show lower TiN removal. Mostly the removed film removal here is the titanium oxynitride (TiO_xN_y). dHF completely removes TiO_xN_y, ~8 Å, whereas SC1 removes it partially, and no etch rate was observed with DNH. For the dielectric etch rate, dHF showed the highest etch rate of >150 Å, and no etch rate was observed for both PAM and DNH. The observed high etch rate of dHF is the root cause of the undercut. In terms of post-etch polymer residual removal, both dHF and SC1 showed 100% removal as shown in Fig. 6.6 TDSEM. In contrast, DNH did not remove the residues. So, while both SC1 and DNH are attractive in having low etch rates of dielectric, only SC1 is effective in completely removing the residues. Both the ability of breaking down the residues by peroxide in SC1 and partial removal of TiO_xN_y provide optimal wet clean solution for this application.

(d) Post-via Etch Cleans

The next wet clean in BEOL module after HMO cleans is post-via etch clean. With interconnect scaling, trench (line) and via resistance increase are expected due to reduced Cu



Element	Target
Cu loss	Total Cu loss after damage removal <5 Å per cleaning cycle
Dielectric (ULK and Cap) compatibility	ULK loss including damage removal <5 Å No impact on ULK properties (n and k) Dielectric cap loss <5 Å
Cleaning of Cu residues	No Cu void at the via bottom
Critical dimension (CD)	CD growth <1 nm
Reliability	No degradation
Defectivity	Less than 50 adders at 30 nm
Pattern collapse	No collapse for aspect ratios upto 10:1

Fig. 6.7 Schematic of post-via etch structure and material removal targets for wet clean

volume. For trench there is no metal-to-metal interface at the bottom, but for via, there is additional interface resistance between via and the line below. To meet the via resistance targets, this interface must be free of metal oxides or post-plasma etch residues.

For via etch, fluorine-based reactive ion etch (RIE) gases with the combination of CO/CO_2 ash are used. After finishing the plasma etch, carbon-fluorine-hydrogen (CxFyHz)-based post-etch residues (PER) are present on the exposed structures. A wet clean is essential here to remove dry etch polymer residues, remove plasma etch damage on Cu, and retain critical dimension (CD) by not etching all exposed materials like metal nitride hardmask, sacrificial hardmask, ultralow-k (ULK) , SiCN dielectric cap, Cu, barrier/liner - TaN, Ta, Co, Ru, etc. [16–18]. Also, pattern collapse needs to be prevented on the narrow structures with aspect ratios >6:1, and particle performance needs to be <50 @ 30 nm. As shown in Fig. 6.7, there is plasma damage on the sidewall of ULK and top of exposed Cu surface. Plasma from RIE depletes carbon in the outermost layer of ULK resulting in more like a silicon oxide film. This makes the damaged ULK more susceptible for wet removal in chemistries like dHF. Plasma-damaged Cu was shown to contain oxygen, fluorine, and carbon on the top surface. Table in Fig. 6.7 summarizes the key requirements of wet clean.

In the literature, cleaning formulations were published for post-via etch clean that include dilute hydrofluoric acid solutions, semi-aqueous fluoride solutions, hydroxylamine, and solvent-based chemistries that may also contain tetramethylammonium hydroxide and ammonium fluoride [19–23]. Among these wet cleans, TMAH-based cleans are known to negatively impact CD by removing excessive dielectric [24]. While organic solvent-based chemistries were also considered for this application, they are not preferred over aqueous commodity chemicals due to cost and environment health and safety (EHS) concerns.

Dilute-HF(dHF) solutions with and without the addition of organic acids are proven effective for post-via etch clean application while meeting the critical requirements listed in Fig. 6.7 [16, 18]. These solutions are cost-effective and applied at very dilute concentrations to clean the post-etch residues. They are efficient in removing Cu oxide and have shown to have varying control of damaged low-*k* dielectric films (CDO) removal. In the following, the main challenges with dHF-based chemistries and known methods to address those are summarized.

- **Dissolved oxygen**: The dissolved oxygen in the solution enables continuous etch of Cu by the sequence of oxidizing Cu into Cu oxide and dissolving Cu oxides. This is anisotropic etch at the via bottom that leads to undesirable voids during downstream metallization and electromigration degradation. To address this concern, oxygen levels were reduced both in liquid and the environment of the chamber by purging nitrogen [25]. In dHF solution, oxygen concentration reduction from 7 ppm to <30 ppb was reported by purging N_2 in the liquid. N_2 purge solutions are referred as deoxygenated solutions. Cu etch

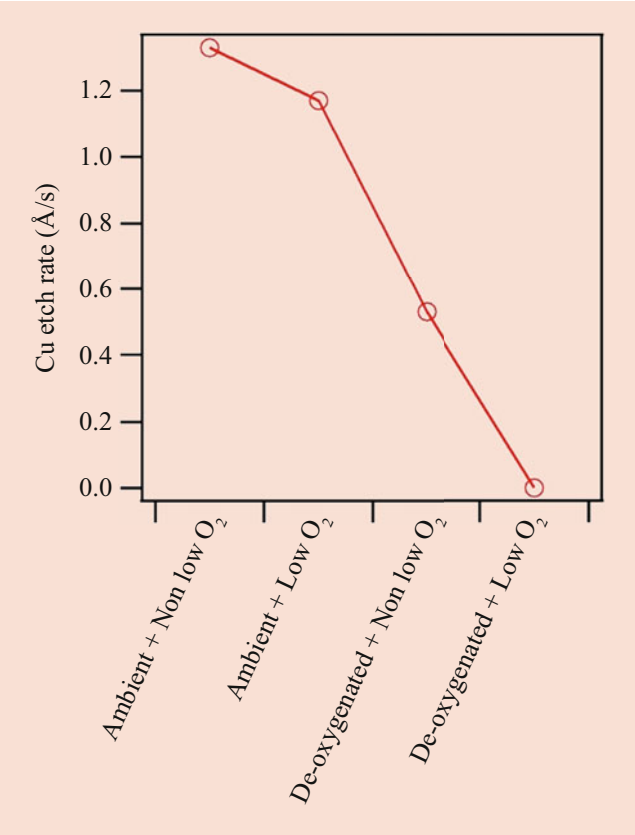


Fig. 6.8 Copper etch rate (Å/s) under varying chamber and liquid dHF conditions [25]

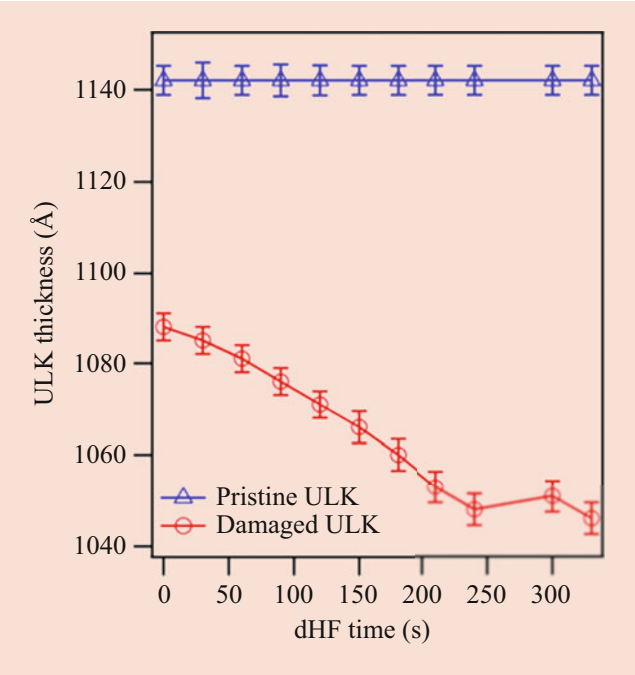

Fig. 6.9 ULK thickness loss as function of dHF time

rates under ambient and deoxygenated dHF solutions with and without low O_2 chamber conditions for as-deposited (electroplated) Cu films are shown in Fig. 6.8 [25]. The etch rates were measured using x-ray fluorescence (XRF) technique. Copper etch rate of 1.3 Å/s was measured for the non-deoxygenated solution and non-low O_2 chamber condition. Reducing the oxygen level below 30 ppb in the low O_2 chamber slightly decreased the etch rate to 1.1 Å/s. Deoxygenating the solution with N_2 purging significantly reduced the Cu etch rate ($\sim 3\times$). Deoxygenated dHF solution and low O_2 chamber condition showed the lowest Cu etch rate of ~0.1 Å/s. The importance of both deoxygenation and low O_2 chamber environment is required to control copper etch rate during the post-via etch cleaning steps, which is critical to avoid any excessive Cu etch at the via bottom.

- **Excessive ULK removal**: It is important to control the amount of damaged ULK removal to avoid increase in critical dimension (CD) and undesirable profiles for metallization. For this reason, dHF concentration must be ultra-dilute (>1000:1 H_2O:HF). Figure 6.9 shows negligible etching of non-damaged or pristine ULK film in dHF-based (0.05 wt% HF) solutions even in prolonged treatment time of up to 3 min [25]. In the case of a damaged ULK film (simulating via sidewall by exposing ULK to partial plasma etch), an etch rate of 0.1 Å/s was observed. This example shows that the amount of damaged ULK removal can be controlled both by concentration of HF and wet clean process time.

(e) Hardmask Wet Etch

In BEOL, a metallic hardmask, titanium (Ti), or titanium nitride (TiN) is commonly used as a patterning for Trench-First-Metal-Hard-Mask (TFMHM) scheme, achieving smaller dimensions and high aspect ratios during etch processes [27–29]. For BEOL pitch of ≥64 nm pitch, post-via etch clean is immediately followed by metallization of barrier/liner/Cu to fill the trenches and vias. However, void-free metallization became challenging for sub-64-nm pitch structures due to the incoming profile after post-via etch wet clean [29]. Figure 6.10a shows the TEM cross section of 48-nm pitch (23-nm metal CD) trench structures with ultralow-k (ULK), dielectric hardmask (HM), and metal HM in the stack [28]. In this example, titanium nitride (TiN) is used as metal HM. The re-entrant profile and undercut under at the interface of dielectric HM and ULK are the main reasons for the voids observed during metallization as shown in cross section, Fig. 6.10b, and top down of scanning electron microscope image, Fig. 6.10c.

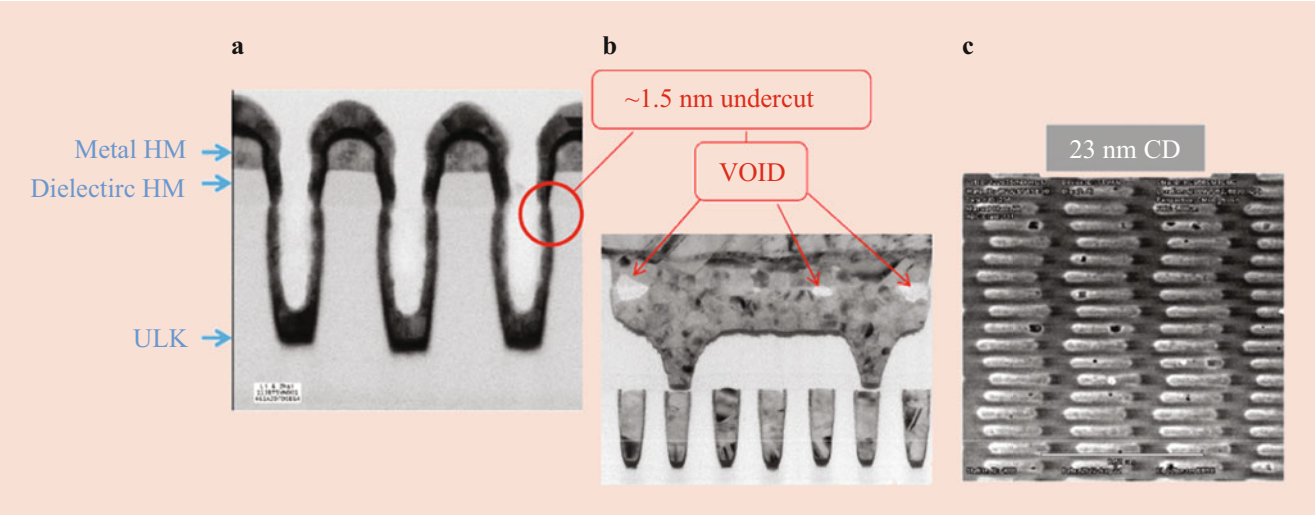

Fig. 6.10 (**a**) TEM cross section pre-metallization, (**b**) TEM cross section post-metallization, and (**c**) SEM top-down image post-CMP

To address the gap fill challenge, MHM needs to be removed before the metallization. Hence, it is essential to remove MHM selective to ILD materials, metals including Cu, Co, and TaN. To enable this, plasma dry etch or wet etch solutions were evaluated in industry [30]. Plasma dry removal of TiN was not successful due to the excessive damage of ULK that results in poor time-dependent dielectric breakdown (TDDB) in reliability test. Wet etch is very attractive for this application as ULK damage can be minimized. However, none of the commodity chemicals can be directly applied here due to low etch rate or incompatibility with the exposed materials. For example, dHF solutions do not have appreciable TiN etch rate, and concentrated or extensive exposure of dHF solutions leads to ULK damage as described in post-via etch clean section. On the other hand, chemistries like SC1 and SC2 are capable of etching TiN but are not compatible to the metals (Cu, Co) that are exposed at the bottom of the via. Due to these challenges, this application required development of a "custom chemical mixture."

At metal levels > M1, TiN HM wet etch needs to be compatible to M1-level Cu that is exposed at the bottom of the via like shown in Fig. 6.7. Several vendors developed custom chemical solutions for this application [31, 32], and in general the chemical mixture includes four key components mixed with DI water:

- Oxidizer – to oxidize TiN
- Corrosion inhibitor – to passivate metal (in some cases dielectric too)
- pH-adjusting agent – to adjust pH
- Chelating agent – to complex metal ions and form stable soluble compound

In addition to the four key components mentioned above, other chemical additives are added at very low concentration (<5%) for further stabilization and improved compatibility with exposed materials. For oxidizer, hydrogen peroxide is proven for this application with the following reaction with Ti^{3+}-forming soluble Ti^{4+} compounds in water [33]:

$$Ti^{3+} + 3/2\ H_2O_2 + 4OH^- = [TiO_2(OH)_3]^- + 2H_2O$$

For TiN wet etch, higher temperature gives faster TiN etch rate as TiN etching follows Arrhenius temperature behavior. For every 10 °C increase in temperature, the etch rate almost doubles. The pH of the mix solution is preferred to be in the range of 6–9 due to required compatibility with ULK films and better stability of H_2O_2. Corrosion inhibitor is added to passivate Cu and Co metals that are exposed at the bottom of via. Typically, in these solutions, Cu and Co etch rates are <2 Å/min compared to TiN etch rate of ~120 Å/min at 65 °C. At the same conditions, no etch rates were observed for pristine and damaged ULK. In contrast to the top-down SEM and TEM cross-sectional images shown in Figs. 6.10 and 6.11 shows void-free gap fill when TiN HM is removed with a wet etch. This was a clear technology enabler at 48 nm pitch, and a new wet step is introduced in manufacturing.

Figure 6.12 shows summary of two products evaluation for TiN HM removal. Product A clearly shows later attack of Co at the bottom of via, and product B was optimized with corrosion inhibitor for Co and shown to have good compatibility with Co. Retention of Co cap is critical for electromigration.

Finally, reliability evaluations with and without TiN wet removal were summarized in Fig. 6.13. Three times improvement was observed in upstream electromigration, and no degradation was observed in TDDB. This result indicates minimal to no damage to ULK with TiN wet removal

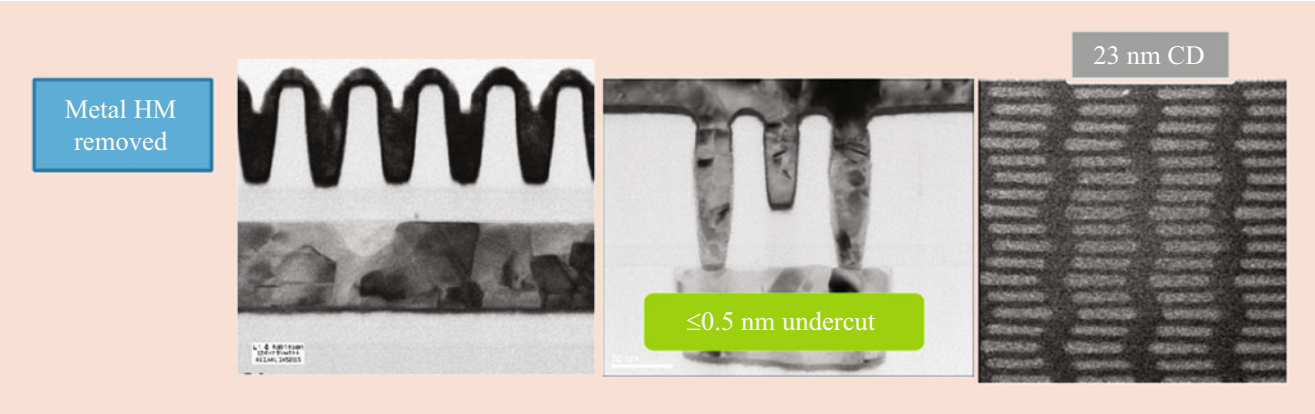

Fig. 6.11 TEM cross-sectional of (**a**) line (**b**) via and (**c**) top-down SEM images of 48-nm pitch structures with TiN HM removed prior to metallization

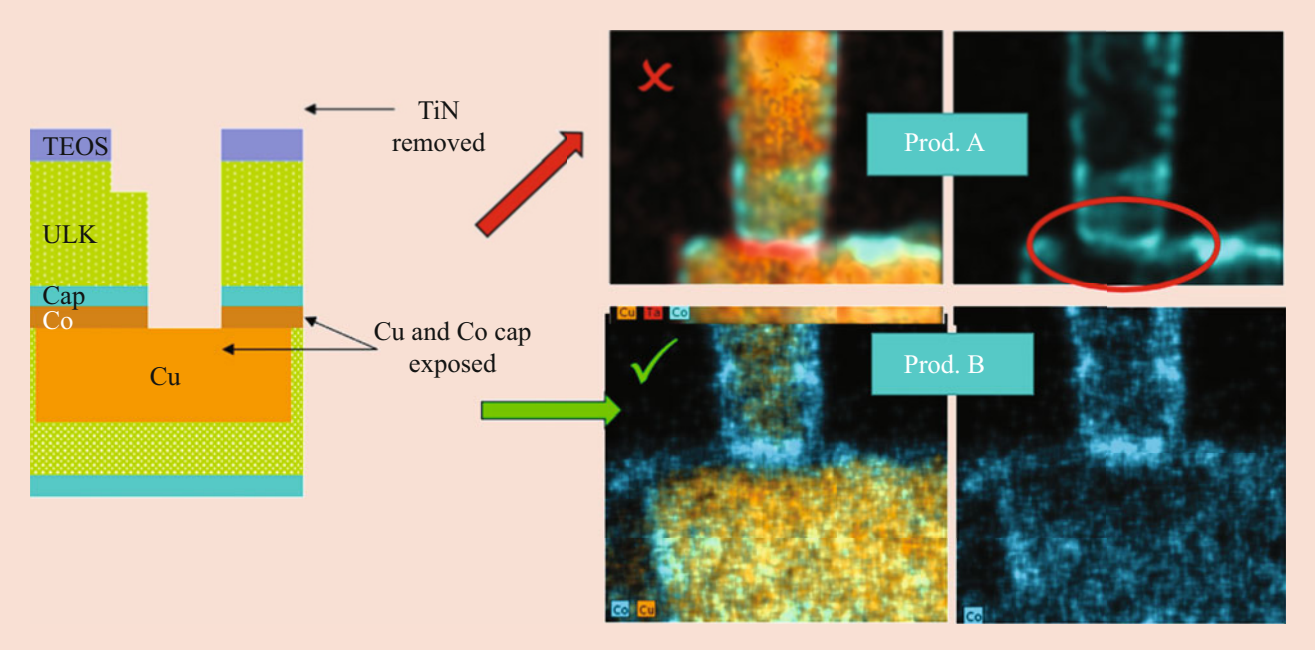

Fig. 6.12 Importance of corrosion inhibitor in TiN removal chemistry and in its role of protecting Co at via bottom. Product A is without corrosion inhibitor, and product B is with corrosion inhibitor

chemistry and gap-fill improvement due to metallization friendly profile.

In summary, wet cleans are widespread in every module of the fabrication of BEOL copper interconnects. The applications have extended from a mere particle clean with SC1/SC2/dHF to specialized custom chemical mixtures to clean and wet etch various materials. Single wafer tools made it possible to achieve defects <50 nm and excellent across wafer temperature and uniformity control. Additional chamber developments controlling oxygen concentration in chamber to sub-100 ppb levels enabled minimal metal corrosion in advanced interconnect features for post-via etch cleans. Metal hardmask wet etch opened gates for several formulated chemistries from vendors and is now implemented in manufacturing for ≤14 nm technologies. As traditional technology node scaling becomes increasingly difficult, wet clean and wet etch needs continue to increase to enable novel integration schemes.

6.2 Cu Electroplating

A brief survey of the literature shows that copper and copper electroplating have been active areas of material research for about the last 20 years, no doubt driven by the adoption of electroplating as an enabling copper interconnect process in the late 1990s. This is reflected qualitatively in the literature trends; an internet search shows that the number

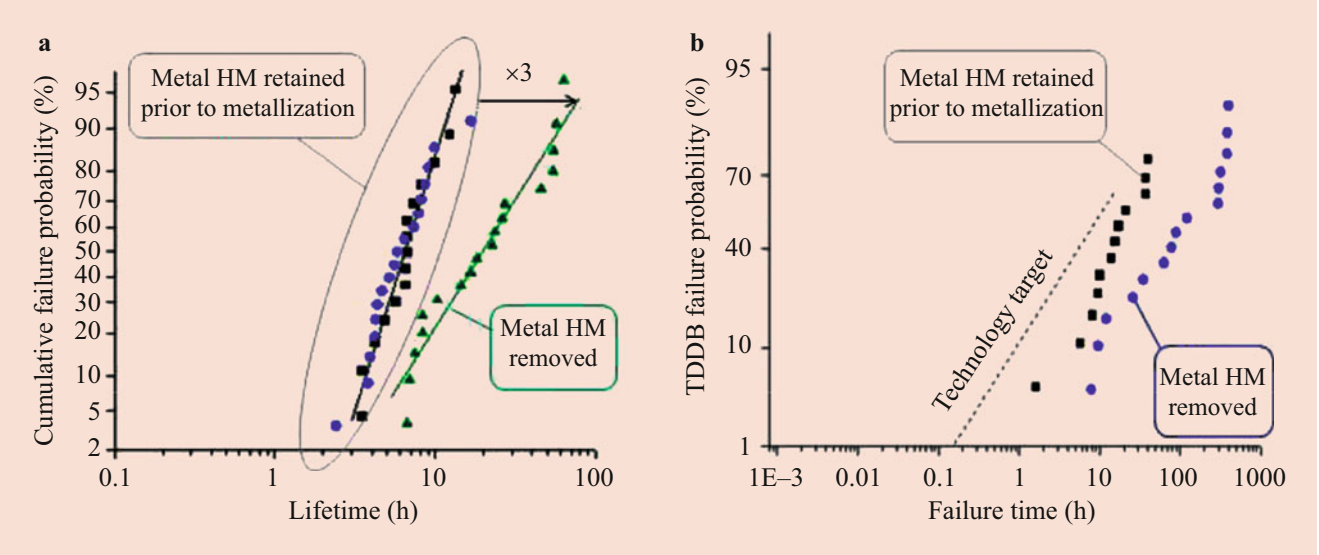

Fig. 6.13 Electromigration and TDDB summary with and without TiN HM wet removal. (**a**) 3× improvement on upstream electromigration. (**b**) No TDDB degradation

of publications with occurrences of "copper electroplating" from 2011 to 2015 was over ten times greater than that between 1991 and 1995 (just prior to the announcement of electroplated Cu interconnects). Although research interest in copper electroplating may be starting to plateau somewhat (the period between 2016 and 2020 appears on track to finish with less literature occurrences of copper electroplating than the prior 5-year period), technological challenges in the field of plating for BEOL are in contrast increasing rapidly. Small BEOL feature sizes at advanced nodes complicate extending conventional electroplated Cu interconnect approaches, with new copper fill techniques and new interconnect metals being considered as alternatives at small dimensions [34, 35]. In this chapter section, we will give some background on the initial electroplated copper interconnect work, describe the basic mechanism of how Cu is plated in interconnect features void free (and associated models), cover some of the relationships between electroplating processes and interconnect performance, and then discuss some future electroplating challenges for both copper and some new possible interconnect metals. We note that several excellent reviews on the application of copper electroplating in BEOL processing are available [36–42]. We build here upon this previous work with more recent data, attempting to emphasize the influence of electroplating process and chemistry on 300-mm wafer BEOL yield and reliability where possible, using internal results as well as some selected from the literature.

6.2.1 Background

The electrodeposition or "electroplating" of metals has found use in numerous industrially important applications to produce protective, functional, or decorative metal coatings and fully formed objects [43–46]. Among these applications are several related to microelectronics and semiconductor technology [47, 48]. Compared to other film deposition methods, key advantages of electrodeposition include the ability to produce relatively thick, sound, high-purity metal and alloy films with tailored properties in nonplanar geometries. Since many metals and alloys can be electrodeposited at or near room temperature with relatively low-cost and straightforward chemistries and equipment, these processes can be successfully scaled up and implemented in high-volume manufacturing. Examples include several decades of copper, nickel, and chromium plating in the automotive industry as a metal finishing treatment for bulk metal parts [43, 45]; multiple generations of copper, nickel, gold, and solder alloy plating for microelectronic packaging since the 1970s [49–52]; and more recently for about the past 20 years superconformal copper electroplating in semiconductor fabs worldwide for on-chip BEOL interconnects [53].

Some of the history behind how electroplating was selected as the preferred Cu interconnect fabrication process at IBM is described in references [37] and [53]. Multiple Cu deposition approaches were evaluated besides electroplating, including electroless, chemical vapor deposition (CVD), and a few different types of physical vapor deposition (PVD). Electroplating was the only deposition technique at that time that could "superfill" Damascene features with copper, i.e., fill faster at the feature bottom than at the feature top and sidewalls, enabling a void and seam-free copper interconnect. The superfilling effect is shown in Fig. 6.14, where the bottom-up copper fill of the high aspect ratio feature is evident. Without a significant local deposition rate difference

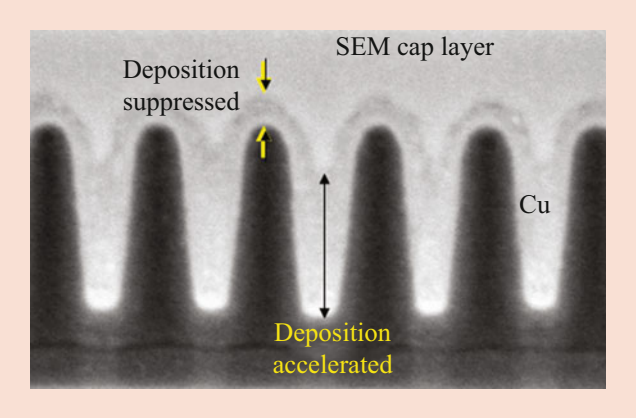

Fig. 6.14 Superfilling effect shown by scanning electron microscopy (SEM). Electroplated copper (dark gray) fills the features etched into the dielectric (black). The thickness deposited into the etched areas is higher than that outside the features, enabling void-free fill. The light gray layer at the top of the micrograph is an SEM encapsulation layer

between the feature bottom and sidewalls, a seam or void would be visible (see, e.g., Reference [39]). We distinguish true superfilling from the phenomenon of "geometric leveling"; in the latter case, certain conformal fill processes appear to be bottom-up due to the feature geometry (this typically occurs for geometries with much lower aspect ratio than conventional BEOL features; see references [54–57] for a discussion of this effect). Since these plated interconnects had the best characteristics, work continued on integrating electroplated copper in the BEOL. We should note that some of these initially unsuccessful, alternative deposition methods from copper interconnects' early days have attracted interest again as the conventional electroplated copper fill approach encounters scaling difficulties (this will be discussed later in this section).

6.2.2 Cu Plating Chemistries

Current BEOL Cu plating baths are sulfate based, with copper sulfate providing the metal species to be electrochemically reduced and sulfuric acid the electrolyte conductivity (there is also typically a small amount of chloride ions, historically added to promote copper anode corrosion, but also helping in the function of the organic additives [58–60]). These sulfate baths displaced older chemistries where a complexing agent such as cyanide or pyrophosphate was employed to promote a good copper electrodeposit morphology and to prevent poor plated adhesion from a copper "displacement" reaction on less noble substrates (such as zinc, steel, etc.). References [43] and [51] discuss the limitations of these older copper chemistries and why they fell out of favor. Good quality copper plating from the new sulfate baths (sometimes referred to as "acid copper plating") would not be possible without organic additive systems that were developed in the 1970s that enabled low resistivity, ductile copper [61–63]. Once work using these baths for copper interconnect plating started, it was discovered that these organic additives are also critical for copper superfilling.

Typically, three types of additives are used in copper baths for interconnect plating [38, 39, 41]. The first type, known as suppressors (or less commonly "carriers"), are polymers usually employed at fairly high concentrations such that they are not very sensitive to mixing or transport conditions [38, 39] and strongly inhibit copper electrodeposition when chloride ions are present. The second type, accelerators, are sulfur-containing molecules that strongly adsorb on the copper surface, displacing the suppressor and hence increasing the local Cu deposition rate relative to the fully suppressed state. Levelers, the third class of additive, are usually aromatic nitrogen-containing molecules (Janus Green B is one model leveler) employed at low concentrations and also deposition-inhibiting species. Being dilute, they are more sensitive to transport or mixing conditions and thus act to smooth or level out any protrusions in the substrate surface (see references [54–57] for a discussion of this mechanism). One should note that to achieve superfill, only the first two additive types are necessary, suggesting that the interaction between the suppressor and accelerator is the most important aspect in the superfill mechanism [38, 64, 65].

The impact of the suppressor and accelerator on copper deposition kinetics (in other words, how easily the cupric ions in solution are reduced to copper metal) is shown schematically in Fig. 6.15 for a copper substrate (leveler effects on copper kinetics won't be discussed here, but the reader is referred to references [66, 67] for a discussion of this topic; levelers will be discussed later with respect to their impact on electrodeposited copper surface topography and potential for disrupting copper superfilling). Curve A represents the cathodic current density (shown on the y-axis and proportional to the copper deposition rate through Faraday's law) as a function of the electrode potential (the x-axis) when no additives are present. The isolated electrodeposited Cu crystallites obtained in the absence of additives are shown qualitatively also [68, 69]. As stronger cathodic potentials are applied, the current density rapidly increases once the copper reduction potential is attained. After adding a suppressor to the bath, a similar cathodic potential sweep results in curve B; deposition current does not start to increase until the electrode is much more cathodically polarized, reflecting a suppression or inhibition of the copper electrodeposition reaction. The adsorption of the suppressor on active growth sites to inhibit Cu deposition is shown qualitatively as well. For both curves A and B, the observed current density is identical for both the forward and reverse potential scans, suggesting that the copper deposition kinetics are essentially reversible with and without suppressor. Finally, curve C shows the impact of the addition of an accelerator species to a

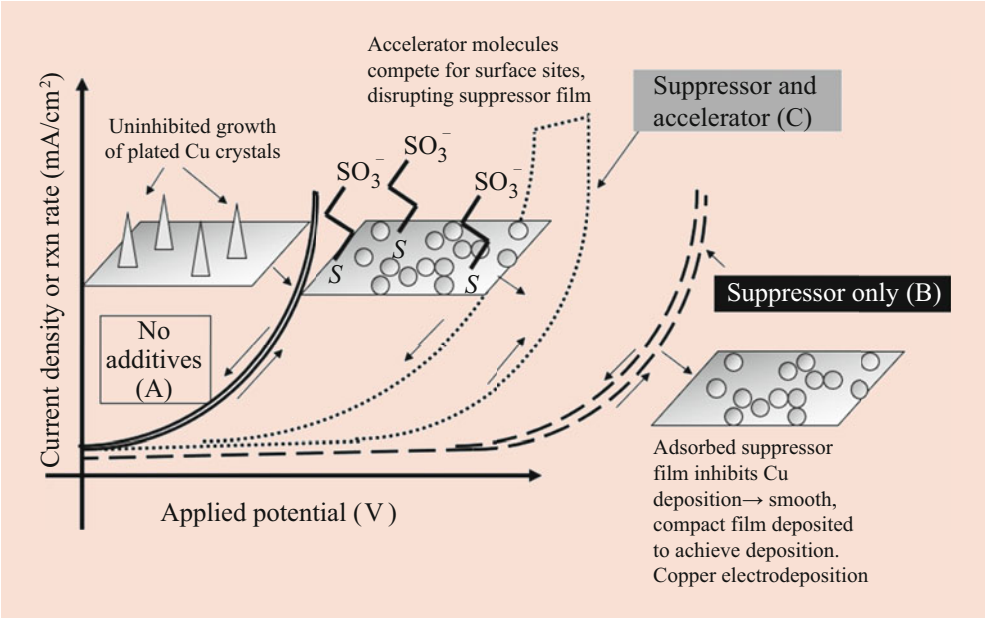

Fig. 6.15 Schematic polarization curves for an acid-sulfate copper bath, with additives as indicated. In the case of no additives (A), isolated uninhibited deposited crystals emerge. When a suppressor is added in (B), copper deposition is inhibited, requiring larger applied overpotentials to achieve deposition. Copper electrodeposit morphology is improved, with a denser film resulting. No polarization hysteresis occurs. When an accelerator and suppressor are used together (C), hysteresis for the copper deposition polarization results

bath with suppressor. As expected for the accelerator, the Cu deposition reaction is less polarized, with a given potential having a higher current density (or deposition rate) as compared to the fully suppressed condition exhibited by curve B (the displacement of the suppressor by the accelerator molecule is shown qualitatively also). Another characteristic appearing with the introduction of the accelerator to the suppressor-containing chemistry is the hysteretic nature of the polarization curve, i.e., deposition currents are higher on the return scan as compared to the forward one. This hysteresis shows that when an accelerated (or high deposition rate) state is achieved, it tends to persist with these additives. Physically, this could be understood as a tendency for the accelerator to remain adsorbed on the copper surface and allow copper deposition to freely occur once the suppressor has been displaced. Reid provides a more detailed discussion of these aspects in Reference [39]. These additive characteristics are the basis of most superfill models in that a locally high copper deposition rate at the feature bottom and/or a highly suppressed one at the feature top leads to a bottom-up Cu fill (superfilling).

Many models have been developed to explain copper superfilling; earlier models emphasized the inhibition of copper electrodeposition at the feature top [36, 70], while later ones focused on a locally higher accelerator coverage at the feature bottom to explain the bottom-up fill effect [41, 64, 65]. Since these later models were consistent with the observation of copper superfill in the absence of leveling additives (and also with the experimental observation of "bumps," or regions of locally high Cu thickness just over Damascene trench features after superfilling [64]), they have become generally accepted. Figure 6.16 shows schematically how a locally high accelerator concentration may occur at the feature bottom due to changes in the copper surface curvature as metal is deposited. Simply put, as copper deposition occurs, the two surfaces from the two trench bottom corners meet, forming a copper surface of very pronounced curvature. The additives that were initially distributed uniformly across the copper surface become packed together as the two deposition fronts from the trench bottom meet. Since the suppressor is usually present at a fairly high concentration with its inhibiting effect saturated, no additional suppression in the copper growth rate occurs with the increased copper surface curvature. But the accelerator is added in a concentration range where higher surface coverage results in an increased copper deposition rate; thus, the "crowding" of accelerator at the feature bottom leads to a faster local plating rate. Though this type of mechanism is more or less accepted, other copper superfill models emphasizing additional aspects have continued to be proposed [71–73]. While the exact mechanism of additive superfilling is still studied and debated, a number of effective additive packages for copper superfilling have been commercially available since electroplated copper interconnects became mainstream in the late 1990s [41, 74–77]; these initial additive sets have evolved over the years to maintain good copper gap fill in the face of shrinking BEOL feature dimensions and increasingly limited PVD copper seed coverage.

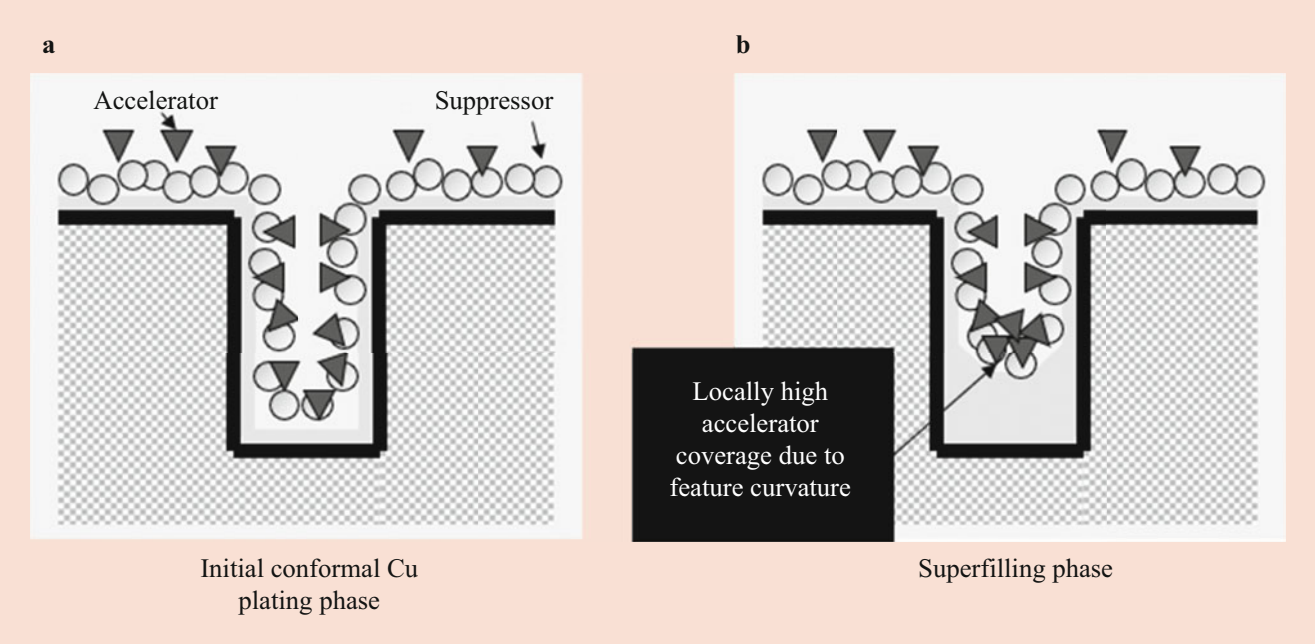

Fig. 6.16 Schematic illustration of the superfilling mechanism. Initially (**a**), additives are adsorbed uniformly across the copper surface. As filling proceeds and the copper bottom surface curvature changes (**b**), the additives become locally concentrated

It should be noted that superfilling is not unique to copper. Damascene features have been superfilled with other electrodeposited metals such as silver, gold, nickel, and cobalt [78–82]. Some of these metals could be of interest as potential replacements for copper as it becomes more difficult to scale to smaller feature sizes (this will be discussed later).

6.2.3 Tooling for Copper Electroplating

The superfilling characteristics of copper plating chemistries discussed in the preceding section could not be leveraged for BEOL interconnect fabrication without appropriate equipment for handling, immersing, electroplating, rinsing, and then drying a copper-seeded silicon wafer [38, 40, 42, 83]. Such equipment is known in the industry as a "tool." With current state of the art technology interconnect sizes approaching just 20 nm in width (and even smaller ones in development), the Damascene features are fully filled in less than a second or two of plating [42]. It is interesting to compare this to fill times for one of the early copper interconnect technologies where features were only partially filled after 20 seconds even with a current density (i.e., deposition rate) much higher than that typically used today [84]. In just under a second or so, today's copper plating tools must fully immerse a wafer in the electrolyte without entrapping any air bubbles or wetting defects, distribute the additives in the bath uniformly across the wafer surface, and allow them to adsorb, all the while carefully controlling the potential or current between the copper-seeded wafer (acting as the cathode) and the copper anode to protect the PVD copper seed from corrosion (most typically by dissolved oxygen in the bath), nucleate plated copper on the seed, and initiate copper fill. Since they have the smallest copper volume, the narrowest (and hence most challenging) Damascene features are the first to fill, usually within a second or less. This process is shown schematically in Fig. 6.17 (of course, commercially available plating equipment for the semiconductor industry is much more sophisticated than the sketch here). A description of a more advanced wafer entry waveform is in reference [85]. Another process aspect that has been engineered over the years is the wafer-scale plated copper uniformity, both in the initial stages of the fill (to have uniform plated copper nucleation and fill rate across the wafers) and the final wafer thickness distribution (to facilitate the subsequent planarization of the plated copper overburden) [42].

For high-volume production, the tool must process a considerable number of wafers each day; as a result, any aging or breakdown of the plating chemistry from this heavy use must be minimized to maintain good quality copper gap fill. A tool may have many hardware features to ensure good quality copper fill and keep defectivity low over time during production (most of these are proprietary and hence can't be discussed here), but among them perhaps the most important is an analysis and dosing system to maintain the additive chemistry within control limits. Since the additives impact the copper deposition kinetics, electrochemical methods are convenient to measure the concentrations of the various

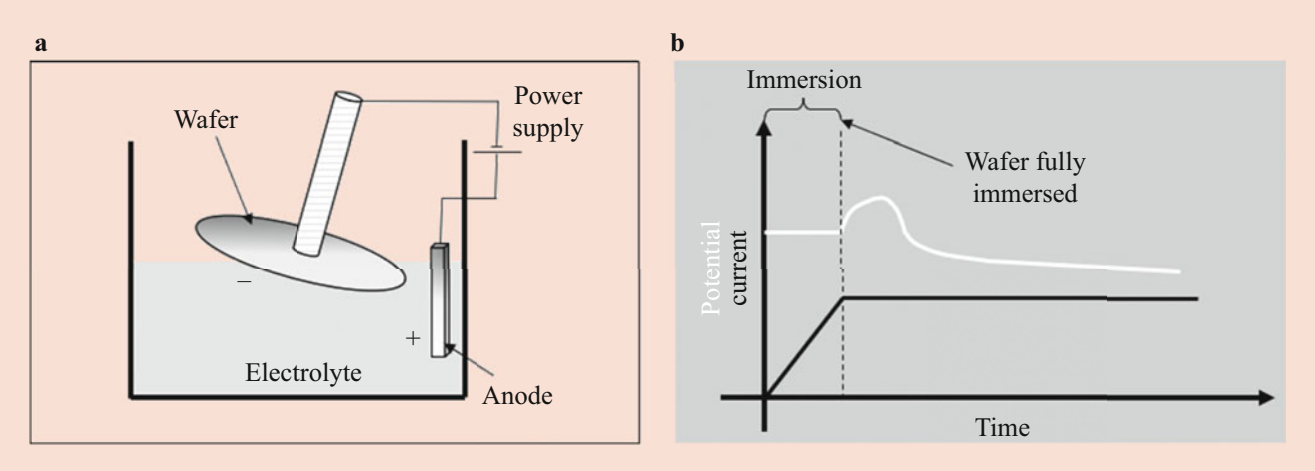

Fig. 6.17 Simplified sketch of electroplating equipment (**a**) and waveform control (**b**). A power supply controls the potential and current between the wafer (the cathode) and an anode. The waveform manipulation is synchronized with the mechanical movement and immersion of the wafer into the electrolyte so as to provide optimal filling

organic species in the bath (the inorganic species can be measured electrochemically or with other techniques) [86, 87]. Typically, the analysis method is validated by testing a known standard solution periodically.

6.2.4 Copper Electroplating, BEOL Yield, and Reliability

Since successful plated copper fill of Damascene structures relies on a continuous coating of PVD Cu seed, both copper plating and seed must be developed in tandem for a given feature geometry. If the feature geometry or seed process changes (e.g., an intentional change due to a new integration requirement or an unintentional one from a process drift), the copper plating process often must be re-optimized. The relative quality of the copper metallization is typically gauged while the wafers are still in the fab (through in-line electrical testing of test macro-yield and defectivity inspections) [88–91] as well as during post-fab characterization (usually reliability and quality assurance testing) [92]. Yield can be very sensitive to voiding originating from either the barrier/seed or plating process, while electromigration reliability tends to be more strongly influenced by interfacial adhesion quality and thus more dependent on the barrier/seed process.

An example of the interplay between seed and plating processes is shown in Fig. 6.18. The current flowing through a dual-Damascene viachain (with a metal line and via critical dimension or "CD" of about 33 nm) is shown for wafers processed with three different copper additive chemistries (all had the same inorganic makeup but with additive sets provided by different vendors); two different liner/seed processes were used for each chemistry. A viachain is a convenient macro to evaluate metallization fill quality as one defect will cause a break in the metal chain, resulting in a blockage of current flow. Metallization with more defectivity will thus have a lower viachain current. If the structures are exposed to thermal budget, smaller defects will often coalesce into larger voids and further impede the current flow, allowing enhanced sensitivity to defect characterization by this method. For the plot on the left, it is obvious that all chemistries perform well with liner/seed process 2, while for liner/seed process 1, they are all worse, with similarly low yields. By applying a long thermal budget (similar to what the structures would be exposed to by being built up and packaged), all wafers suffer some yield degradation, but chemistry B appears to be a bit better than the others for wafers with liner/seed process 2 (as expected, liner/seed process 1 shows further yield degradation with more temperature exposure). It is only possible to distinguish between chemistry performance with the more optimized liner/seed process, and only then after applying some thermal budget to induce some yield loss. These differences in chemistry could be related to differences to the additive molecules themselves or their relative concentrations (in this example, the vendor-recommended concentrations were used). Although most vendor additives are from the same general class of compounds, subtle differences may exist that can lead to large differences in Damascene fill performance; see, for example, articles by Reid and coworkers on suppressor and leveler additive effects [39, 42, 93].

Even for a single additive chemistry, the concentrations of the additives and other inorganic species can be important in achieving good parametric yield. Figure 6.19 shows viachain currents for both short and long via chains having about 28-nm metal CD processed with the same additive chemistry but with changes in concentrations for some of the constituents. All conditions perform well for the short viachain

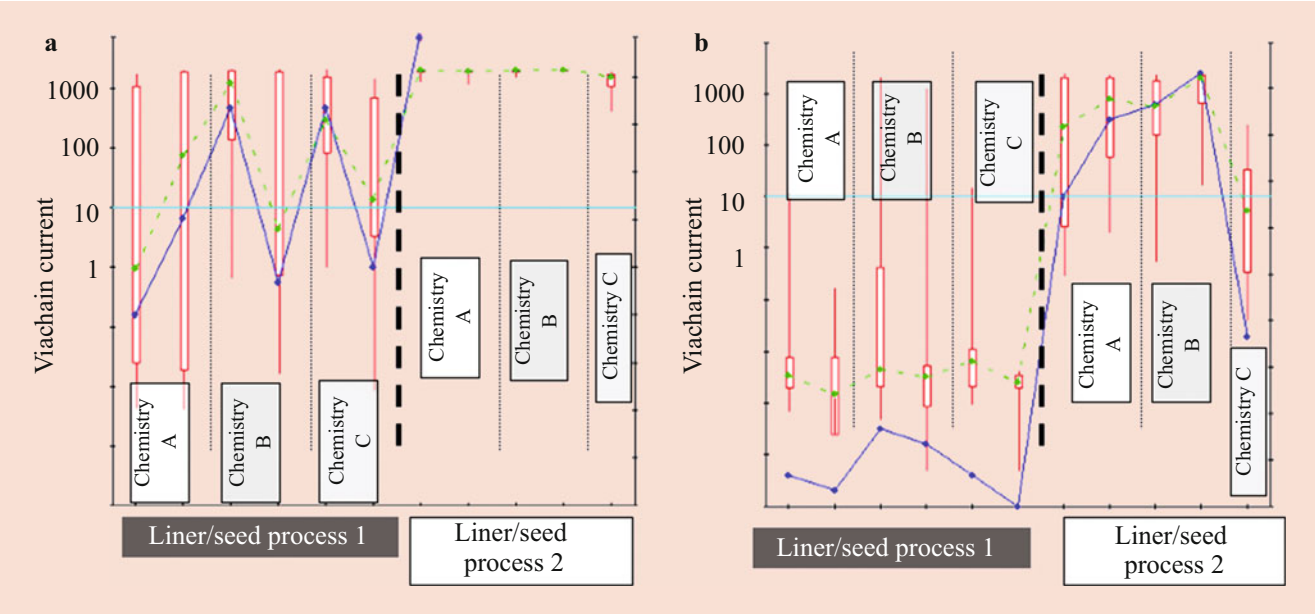

Fig. 6.18 Viachain test current for various chemistries and liner/seed processes as shown (higher currents suggest better quality fill). (**a**) at-level test. (**b**) post high temperature anneal test data. The top and bottom of the whiskers in the plot represent 5% and 95% of the data population, respectively, while the top and bottom of the box represent 25% and 75% of the data population, respectively. The point in the middle of the box is the median value. Each set of data values is taken from a number of chips on a single 300 mm wafer. Both liner/seed and plating chemistry affect copper fill quality

macro, but for the longer chain (which is more sensitive to defects), some differences are apparent. The reference split (marked "A") is a concentration set for this additive package that was widely used for some time in the industry. Split condition "B," with a significantly higher accelerator concentration than split "A," has much better yield, with about 50% and 30% of tested chips having the expected target current value for these conditions, respectively. Split "C" shows that an adjustment to the chloride ion concentration with the same accelerator content as in "B" gives a further yield improvement to about 80%. The last experimental condition in the plot is for a bath identical to that in split "A" but freshly made up (the one used for split "A" had been in use for some time in a fab). The improvement from the chloride ion level adjustment could be related to some interaction with the suppressor [58–60] resulting in faster superfill and/or better plated copper nucleation on thin PVD copper seed. The similar performance of a fresh bath and one in use (with otherwise identical chemical makeups) suggests that the lower yield for this chemistry is unrelated to any bath aging effects.

As alluded to in Fig. 6.19, in some cases, adjusting accelerator concentration can result in a copper fill improvement. Another example of this is shown in Fig. 6.20 by post-CMP top-down scanning electron microscopy (SEM) , where ~23-nm CD metal structures are processed with various accelerator concentrations (all other processing conditions were kept constant). Clearly, copper fill is significantly improved once a threshold accelerator concentration is surpassed for this chemistry and test structure. The mechanism for this improvement is not clear but, as described above for the case of improved copper fill and chloride ion concentration, could be related to a faster superfill and/or improved plated copper nucleation. Since most suppressors are present in concentrations such that their inhibiting effect is saturated, it is perhaps not too surprising that Damascene copper fill is more sensitive to accelerator concentration.

Although higher accelerator concentrations can potentially offer some copper fill improvement, some complications may occur with this approach. Figure 6.21 shows the copper mounding mentioned previously that develops in areas with high feature pattern density and how employing a leveler can lessen this effect (the beneficial impact of a leveler on CMP is discussed in references [94] and [95]). For a given accelerator concentration, a leveler can mitigate plated copper topography, but mounding can reappear as more accelerator is used. Figures 6.21 and 6.22 shows the shorts leakage for a comb-serpentine macro as the accelerator concentration is increased; shorts current gradually increases until the accelerator is ~3 times its initial concentration, when it rises significantly. Adding more leveler can suppress the increased mounding observed at higher accelerator concentrations (far right split on plot A), but as shown in part B, excessive leveler concentrations can also degrade viachain yield. These results are consistent with similar experimental work in reference [93]. The fill degradation is likely due

to an interference of the leveler molecule with the superfill mechanism (Zhou and Reid discuss leveler effects on copper Damascene fill in detail) [93].

As Damascene copper additive packages have matured over the years with improvements in fill performance from new additives becoming more modest, other avenues for engineering copper plating processes have been explored. One such approach is using a low cupric ion concentration plating chemistry. Historically, a bath with a low copper content was not often discussed as a tactic for improving plated copper fill; given their limited deposition rates, such electrolytes likely did not seem like a preferred option for the thick copper overburdens required to fully fill the Damascene features on early BEOL technologies. Zhou and Reid discuss improved fill on 48-nm CD features with low copper baths, along with likely mechanisms based on electrochemical measurements [96]. In their study, low copper baths showed enhanced deposition polarization, higher plated copper nucleation densities, and better solubility and wetting of the suppressor [96]. Another recent study shows improvement for low copper baths on 24-nm dual-Damascene features with PVD Cu seed and a CVD Co liner [97]. Figure 6.23 shows electrical data for a 15,000 link viachain, ISOVIA, and wire resistance macros for a reference chemistry with 40 g/L copper and a low copper one. Test data for these structures is shown after they received more thermal budget to simulate the build of the upper-level BEOL wiring. It is clear that the low copper bath has lower ISOVIA and wire resistances as well as a higher viachain current, suggesting better metal fill quality (the authors state the wire resistance improvement for the low copper bath could be related to line height variations due to CMP differences, but it is pointed out that the ISOVIA and viachain macros are not influenced by CMP and are likely better due to a low copper fill benefit).

Besides chemistry modifications to improve fill, modifications to waveform can be beneficial. Ahmed and coworkers employed an optimized entry waveform to repair a marginal copper seed on sub-50 nm structures, showing improved post-CMP defectivity, via opens, and electromigration (due to elimination of early fails) thanks to improved plated copper nucleation [85]. Jing and coworkers showed defectivity improvements by optimizing entry conditions and waveform for 28- and 32-nm technology node BEOL structures [98, 99]. Since plating wafer entry conditions and waveforms can be replicated by competitors without much difficulty, details on such process parameters and their favorable impacts are not widely discussed in the literature by chip manufacturers.

6.2.5 Extendibility of Copper Electroplating: Future Perspectives

The original approach of using PVD barrier and copper seed layers followed by electroplating was successfully employed with relatively minor adjustments for the first few copper BEOL technology generations. As interconnect dimensions decreased, much effort was spent in reducing the thicknesses of these barrier and seed layers (as well as improving their conformality) to provide as wide a gap opening as possible for the subsequent plated fill step. Similarly, copper electroplating chemistries and waveforms were optimized to tolerate narrow gap openings to maintain good plated fill when appreciable barrier and seed scaling were no longer feasible. It was recognized that this conventional metallization approach would eventually have difficulties extending to small feature sizes due to a couple of fundamental issues. The first limitation is a loss of copper diffusion barrier performance once the barrier layer is thinned below some threshold thickness (typically considered to be below 5 nm or so based on blanket wafer measurements [100, 101]). The second limitation is the oxidation of thin copper seed; since in some narrow features the seed can be as thin as a few nm, a significant fraction of seed can be oxidized [102], resulting in a fill void (copper oxide is not stable in the acidic plating electrolyte and readily dissolves) [103]. This challenge of achieving adequate barrier/seed coverage while maintaining

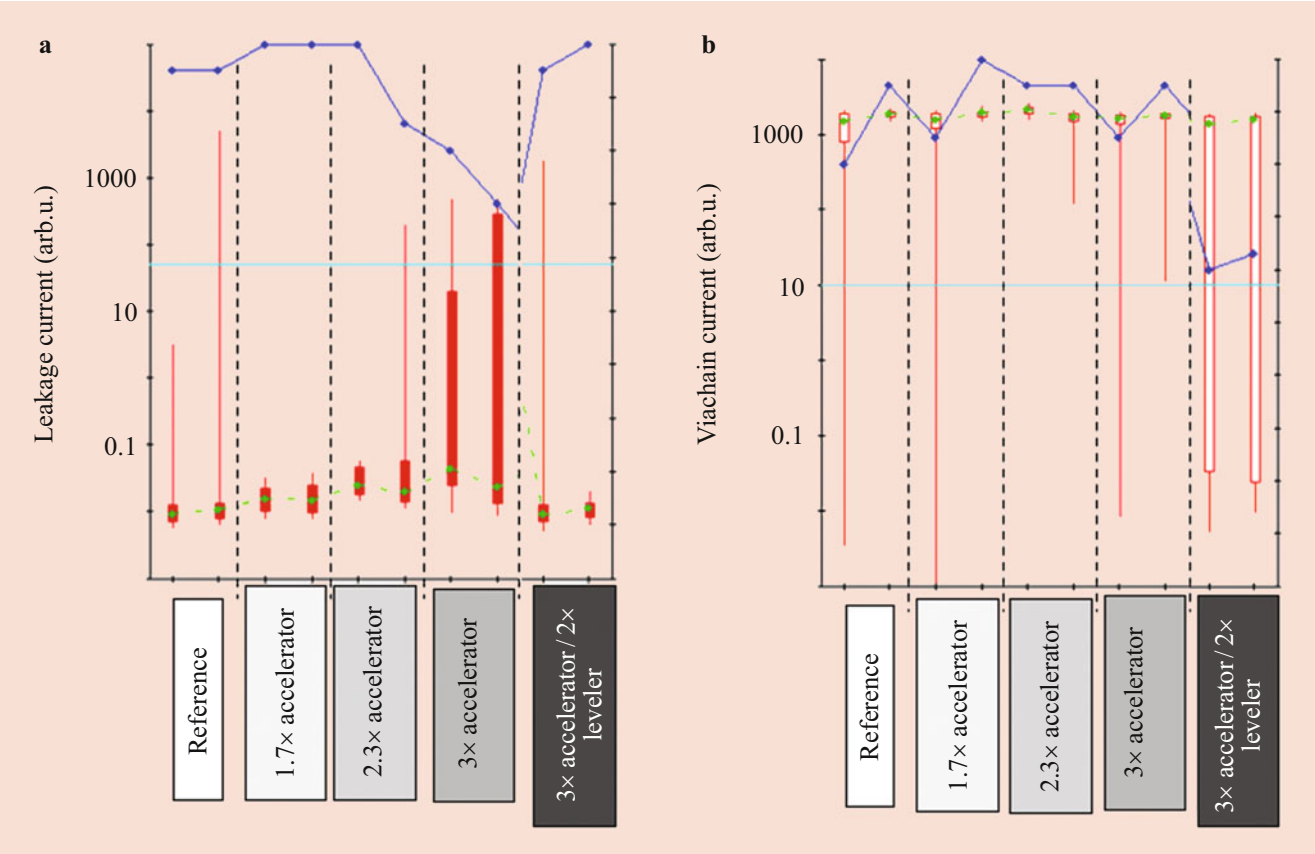

Fig. 6.22 (**a**) Shorts leakage for comb-serpentine macro with accelerator conditions as listed. As accelerator increases, shorts current rises once a threshold is passed. Adding more leveler restores shorts leakage to low levels. (**b**) Viachain currents for conditions as in (**a**). The increased leveler additive lowers viachain yield. Chart symbols depicting the data distribution are as described in Fig. 6.17. SEM cross section post-plating with and without leveling additive. (Reproduced with permission from Kelly et al. [94]. Copyright © 2013 Elsevier Masson SAS. All rights reserved)

a sufficient gap opening for plating is illustrated in Fig. 6.24. Dark-field transmission electron micrographs and associated energy dispersive x-ray (EDX) images for Co are shown for BEOL trench features just after copper plating with thick and thin PVD copper seed layers in Figs. A and B, respectively. A CVD Co liner, used in each case, can serve as an indication of the sidewall copper seed coverage quality as any exposed Co is attacked by the copper plating bath [97]. In Fig. 6.24a, a clear, uniform Co liner signal is visible with no evidence of any voiding at the sidewall interfaces, indicating good copper seed coverage. But a center void suggests that the gap opening is not large enough for defect-free copper feature fill. If the copper seed layer is thinned to enlarge the gap opening for better plated copper fill (shown in Fig. 6.24b), the center defect is eliminated, but sidewall voiding in the dark-field image and Co liner loss (note the nonuniform intensity of the Co liner signal) is evident (poor adhesion at the copper-barrier interface will significantly degrade reliability performance).

As a result of these expected difficulties in extending the Damascene copper seed and electroplating approach to future technology nodes, various BEOL metallization alternatives have been researched extensively for several years. A comprehensive review of these process alternatives is beyond the scope here, but some background will be given along with selected references for the ones that have attracted the most interest. To the authors' best knowledge, none of these approaches discussed below have been implemented in high-volume production at the time of this writing. For some of these schemes, some time has passed since any significant research activity has occurred (presumably due to the realization that some challenges inherent in a given approach were intractable), while for others some work is still ongoing.

One of the first alternative approaches considered was employing an additional copper plating step (sometimes using a copper plating bath with a neutral to alkaline pH) to "repair" any defects in the PVD copper seed before the conventional plated copper superfill step [104–106]. In some cases, fill could be improved on defective seeds with this approach. The most likely reasons this approach was not widely adopted are (1) the need for an additional copper plating step, ex-

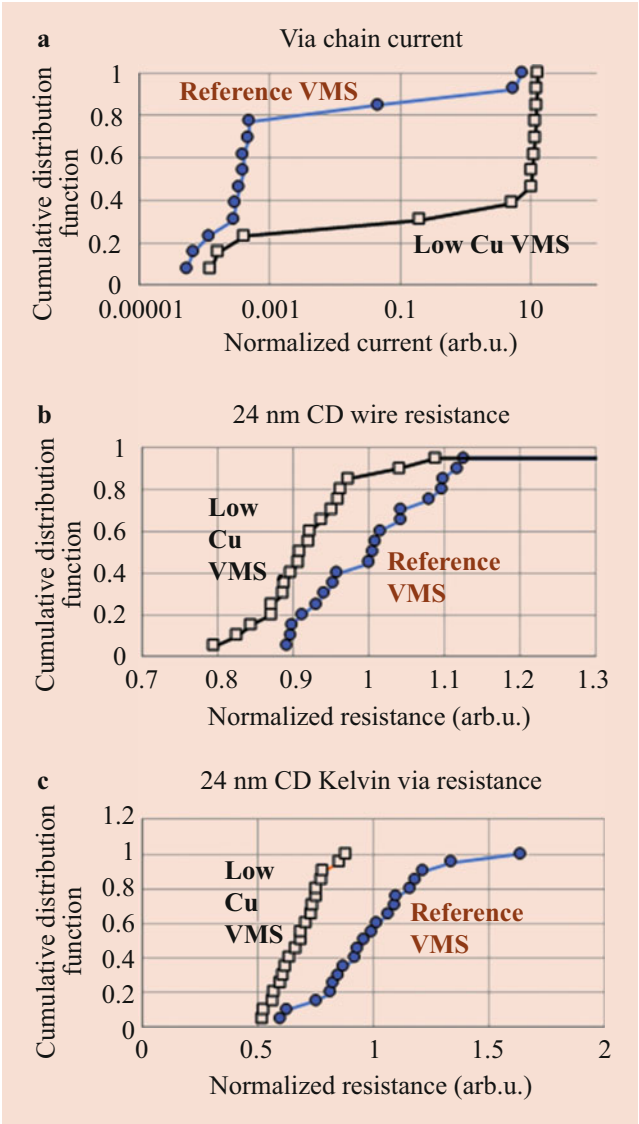

Fig. 6.23 Normalized viachain current (**a**), wire resistance (**b**), and ISOVIA resistance (**c**), expressed as a cumulative distribution plots. Low copper baths show better viachain yield and lower ISOVIA resistance. (Reproduced with permission from Reference [97])

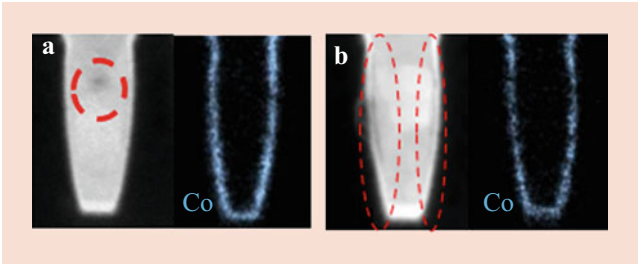

Fig. 6.24 (**a**) Dark-field scanning transmission electron microscope (DFSTEM) micrograph of trench feature with Co liner and thick Cu seed post-plating. While a center fill defect is present, no delamination is observed in the sidewall metal interfaces. The corresponding Co EDX map has a uniform intensity, suggesting that the liner is intact. (Reproduced with permission from Reference [97])

acerbating pinch-off issues during superfill of narrow CD features, and (2) compromised reliability from a defective seed (although these baths can nucleate on thin seeds and/or exposed barrier and improve Cu fill, adhesion may still be compromised from an oxidized liner and/or barrier). Another early alternative metallization approach involved dispensing with the PVD copper seed altogether and plating directly on a CVD or ALD liner such as Ru or Co (that have higher conformality due to the CVD process), alleviating pinch-off constraints due to the PVD copper seed [107–117]. The main challenges with these "direct plating" approaches are (1) high incoming substrate resistance due to lack of PVD copper seed and (2) obtaining good adhesion at the copper/liner interface (see Reference [101] where electromigration results are given for direct plated copper on Ru). Since the liner is air-exposed, its native oxide can complicate achieving copper/liner adhesion quality sufficient to pass reliability as in the case of seed repair. For Ru substrates, there is an additional challenge of CMP with a noble metal liner [118]. Another approach that has been evaluated is via prefill, [119–122] where a metal (typically Co) is selectively deposited (usually electroless deposition, but other techniques have been demonstrated as in reference [122]) in the via only on top of the exposed underlying metal level; the subsequent line metallization level is then fabricated in the conventional way. Since the barrier metal is moved from the via bottom to the via top for this method, a via resistance benefit is expected due to the larger area of the barrier layer. Other benefits include a relaxed aspect ratio for copper plating and a less difficult geometry for liner/seed when the overlying line level is metallized. Challenges for this technique likely involve obtaining good selectivity for the metal deposition and achieving good reliability (the selectively deposited metal is not encapsulated in a diffusion barrier, so it must not move into the dielectric or contain any diffusing species). The last alternative copper interconnect approach discussed here is the "reflow" technique, where the copper electroplating step is only used to provide the bulk metal overburden as the finer features are filled with copper PVD and a subsequent anneal [35, 123–127]. Since the entire metallization process (including the copper feature fill) is carried out without breaking vacuum, the copper seed oxidation issue is overcome, and good interconnect reliability can be achieved. The main challenges with this approach are throughput (although thick PVD metal layers are not required, the subsequent annealing for the reflow can slow the process) and the filling of complex dual-Damascene geometries by reflow in high-volume production (fill is not truly bottom-up and instead relies on the movement or "wetting" of the PVD copper across the substrate with temperature).

Finally, as interconnect dimensions shrink, other metals are being considered to replace copper due to its high line resistance at small interconnect CDs [128]. For a metal to be a good narrow CD interconnect candidate, it must (1) require only a thin or no barrier layer (to minimize the cross-sectional area of the typically more resistive barrier material), (2) possess favorable electron scattering properties at small dimensions [128], and (3) be compatible with conventional BEOL integration. It was mentioned previously that superfilling has been demonstrated for other metal systems; the one metal of this group whose use as an interconnect in a high-volume silicon technology has been disclosed in the literature is electroplated cobalt [34, 129]. These publications cite a lower via resistance as well as better electromigration performance as compared to copper (line resistance was not mentioned in these references). As future BEOL technologies are developed and new challenges emerge, it is possible that other plated metal systems could be researched and implemented as interconnects.

In summary: electroplating has been an essential process step in the fabrication of BEOL copper interconnects for over 20 years. The unique superfill capability of copper plating baths is made possible by organic additives that promote enhanced local deposition rates at the feature bottom, a phenomenon whose mechanism has been studied extensively. Incremental improvements in copper electroplating chemistries and waveforms (along with the barrier, liner, and seed layer processes on which plating depends) have reliably enabled the scaling of BEOL wiring dimensions from the submicron regime all the way down to just over 20 nm in width. As traditional technology node scaling becomes increasingly difficult, more exploratory metal fill processes (including metals besides copper) are being considered to meet the new challenges presented at these advanced nodes. With the potential for manufacturable, void-free fill of high aspect ratio features for a variety of metals, plating processes will likely continue to play a significant role in future BEOL interconnect fabrication.

6.3 Chemical Mechanical Planarization

As described earlier in this chapter, semiconductor devices are layered structures created through repetition of a small number of highly evolved process steps. Before the introduction of chemical mechanical planarization (CMP), the basic steps in semiconductor fabrication comprised of (1) deposition of a material layer, (2) deposition and lithographic patterning of masking layers to protect some areas of this material layer, and (3) a subsequent etching process to remove the unprotected first material, transferring this pattern into the structure below. This process would be repeated many times to create the semiconductor device and subsequent layers for contact to the device and on-chip interconnect wiring. However, each cycle of deposition and material removal would generate nonuniform topography in the wafer surface. This approach became a limiting factor for lithography since the topography exceeded the acceptable depth of focus (DOF) [130]. In 1983, a new process was invented which can accomplish material and topography removal to achieve a planar surface [131, 132]. This process of CMP was quickly adopted and allowed separation of duties in the process flow of semiconductor fabrication: RIE material removal for creation of patterned trenches and CMP to eliminate topography and remove unwanted overburden of deposited material. Initially applied to dielectric planarization steps such as the shallow trench isolation (STI) process [133], CMP has been an enabling technology for semiconductor manufacturing and is utilized for more than 14 interconnect levels in the 7 nm product [134].

6.3.1 CMP Tool Description

CMP Tool

CMP is a geometrically selective process for material removal; the highest points of topography are removed at a faster rate as compared to the low-lying areas. This planarizing effect is achieved by the combined action of an abrasive slurry and a moving polishing pad pressed against the wafer surface [135]. The CMP tool and process are depicted schematically in Fig. 6.25. The polishing pad is mounted face up on a rotating platen, and slurry is dispensed from above onto the pad surface. The wafer is held face down in a wafer carrier. During polishing, the wafer is rotated and pressed against the polishing pad. After completion of polishing, water is dispensed onto the platen to rinse slurry from the pad and wafer. The wafer is then removed from the platen and transported to cleaning and drying processes. To maintain consistent properties of the pad surface, a pad conditioner is pressed against the moving pad. The conditioner may be a

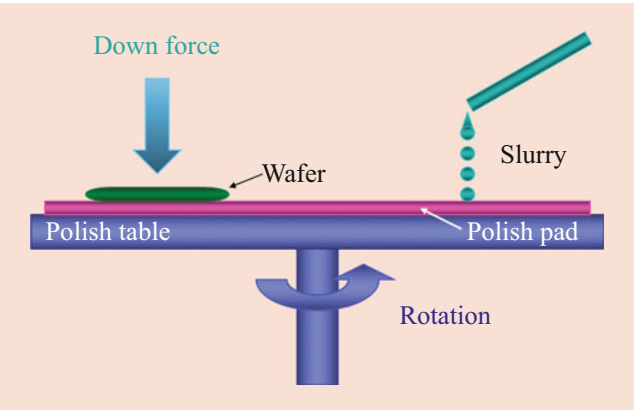

Fig. 6.25 Schematic diagram of the CMP tool and process

hard abrasive such as a diamond disc or a brush containing polymeric fibers. Conditioning may be applied during or before wafer polishing to prepare the pad surface.

CMP is fundamentally a local phenomenon; a successful CMP process requires the precise control of local chemical and mechanical conditions at the surface of the wafer. To achieve the required wafer-level uniformity, these local conditions must be reproduced across all areas of the wafer. Many mechanical approaches have been tried to achieve the required wafer-level uniformity in planarity [135]. Over time a common approach has evolved utilizing a rotating polishing platen and wafer carrier. Converging on a common approach has allowed the CMP industry to achieve a high level of tool and process optimization while reducing cost [136].

CMP Pad

The CMP pad covers the surface of the platen and is attached through an adhesive backing. The platen is typically more than twice the diameter of a wafer and has internal passages for flow of a liquid to control temperature. The pad is a consumable item; at the end of usable life, it is peeled off, and a new pad is installed. The hardness of the pad surface provides primary control of the planarizing effect of the CMP process. Pads of varying hardness or flexibility are available to suit the needs of different CMP processes. The use of a "hard" pad results in better planarity, but higher levels of defects while use of a "soft" pad result in better defectivity and higher topography. To achieve better planarity and better defectivity, a pad stack containing a softer sub-pad is often used underneath a hard pad. Modern pads with composite materials that incorporate the properties of conventional hard pads while providing better defectivity have become available in recent years.

The top portion of the pad often contains a pattern of grooves to aid in distribution of slurry as the pad passes under the wafer. The pad material is typically a urethane polymer and contains a distribution of pores. During polishing, these pores serve as local reservoirs for slurry to maintain the polish rate and uniformity of the CMP process. Key CMP parameters such as removal rates, planarity, and defectivity depend on the performance of the pads, and these parameters can vary over the lifetime of the pad. In addition, pad-to-pad (within batch) and batch-to-batch variations in pad performance have been observed in manufacturing. The pad manufacturing is a very complex process, and manufacturers have made tremendous progress in their methods for process control over the past decade. Still, pads are a major contributor of CMP process-related variabilities in semiconductor manufacturing.

(i) Pad Conditioner

A consistent pad surface must be maintained to achieve adequate and repeatable removal rate of material from the wafer [137]. An abrasive pad conditioner is used to remove spent slurry abrasives and restore the pad surface to a repeatable condition. This also removes polishing debris, exposes new pores, and creates asperities in the pad surface which are local high points [138]. The abrasive material used is typically diamond, but conditioning may be effected by using a brush for some softer pad materials. During CMP these asperities create local regions of high pressure and are necessary for maintaining adequate polish rate. Without conditioning, the CMP pad will typically "glaze over," and rate will drop significantly. As noted above, conditioning may be applied prior to polishing a wafer or in situ during polishing.

(ii) Wafer Carrier

The wafer carrier has evolved into a sophisticated component of the CMP process. In a basic sense, the carrier holds the wafer face down against the polishing pad. A retaining ring is employed around the circumference of the wafer to resist the sheer forces of the CMP process, preventing the wafer from sliding out of the carrier. The carrier also serves to provide local control of the downforce for annular regions or "pressure zones" of the wafer. The local force is typically applied through pressurized air to the backside of the wafer through an elastomeric membrane [136, 139]. The pressure can be varied for individual annular regions to control local polish rate. This downforce control is essential for achieving uniform material removal across the wafer. Modern wafer carriers currently comprise as many as eight pressure zones. Typically, the force of the retaining ring applied to the pad can also be controlled. This "active" retaining ring is useful for further control of wafer-level uniformity of removal rate, particularly near the edge of the wafer.

(iii) Wafer Cleaning

During polishing, the wafer is exposed to chemicals and abrasive particles from the CMP slurry. After polishing, the wafer must be cleaned and dried. The surface of the exposed materials on the wafer such as copper must also be protected from atmospheric corrosion or chemical attack and remain stable until the deposition of a capping layer to seal the copper surface. To accomplish this, water is typically dispensed onto the CMP pad after completion of polish to dilute and rinse away the slurry chemicals and abrasive particles. In place of water, this pad rinse may be accomplished with a solution formulated to promote cleaning and passivation of the wafer surface. The wafer is then transported through a series of one or more cleaning steps. The wafer may be immersed in a tank of cleaning solution with megasonic energy applied to facilitate removal of slurry particles from the surface. To achieve effective removal of slurry particles, it is necessary to employ a mechanical brushing action as well [140–142]. This brushing is accomplished using soft,

hydrophilic PVA (polyvinyl alcohol) brushes, usually in conjunction with a cleaning solution. The brushes are typically cylindrical in shape and pressed against the wafer surface while both brushes and wafer are rotated [143]. The wafer is processed through one or more stages of brush cleaning; each stage can be accomplished in separate modules of the CMP tool. An alternative approach for brush cleaning employs PVA material which is rotated and swept like a phonograph needle across the wafer surface in the presence of wafer or cleaning chemical.

(iv) Wafer Drying

The final step in CMP processing is drying of the wafer. Originally wafer drying was accomplished through spin drying whereby the wafer is rotated at high speed and water is flung off the surface by centrifugal force and the remaining traces are removed by evaporation. However, the defectivity requirements for modern semiconductor products cannot be met through spin drying alone. Evaporating water, even water of high purity, tends to leave "water mark" defects on the wafer surface. For this reason, wafers are now typically dried through the use of the Marangoni effect [144, 145]. In this method, the wet wafer is passed through a zone of saturated gaseous isopropyl alcohol (IPA). As the leading edge of the wafer is wetted by alcohol, a surface tension gradient is created. Through this Marangoni effect, water on the wafer surface is drawn away from the leading edge, and the remaining IPA evaporates readily, leaving a clean, dry wafer surface.

6.3.2 CMP Process Description

As the name implies, *both* mechanical and chemical forces are necessary to accomplish the CMP process. Chemicals present in the CMP slurry create a modified surface layer of the material, and the mechanical action of the CMP pad with slurry particles removes this modified layer. It is important to stress that CMP does not proceed by direct mechanical abrasion; only the material which has been chemically modified will be removed [146]. The mechanism described enables CMP to achieve a smooth, scratch-free surface. CMP processes can typically achieve surface finishes of less than 0.5-nm RMS roughness.

To understand the fundamentals of the CMP process, it is useful to begin with the Preston equation, which was developed in 1927 to describe the mechanism for lapping or polishing glass [147]:

$$r = kPv \tag{6.1}$$

where r is the material removal rate, P is the force applied normal to the surface, v is the differential speed, and k is the Preston coefficient. The differential speed pertains to the pad moving against the wafer surface. For many CMP processes, the Preston equation serves as a useful model; we find that removal rate varies linearly with the Pv term. As an example, we can consider a CMP process for removing SiO_2 whereby the slurry has a basic pH and the abrasive particles are silica (SiO_2). In this case, the SiO_2 surface of the wafer is partially hydrolyzed by hydroxyl ions in the slurry. This "softened" SiO_2 layer is then removed by action of the CMP pad and abrasive particles. This paves the way for further hydrolysis of the SiO_2 surface which is again removed by mechanical action. In practice these phenomena occur simultaneously during CMP to produce a steady state of material removal. This simple CMP model, comprising an abrasive and a chemical medium that "softens" the wafer surface, is applicable to many semiconductor applications where the goal is to reduce the thickness of a single material. Systems behaving this way will tend to reduce topography and planarize the surface of this material, since the local pressure and thus the Pv product will be larger on points of higher topography. The effectiveness of reducing topography can be expressed as planarization efficiency E_p, given by:

$$E_p = 1 - \frac{E_u}{E_d} \tag{6.2}$$

where E_d is the removal rate on a raised area of topography and E_u is the removal rate on an area of recessed topography.

Many CMP applications require the exposure of more than one material on the wafer to the CMP process. In these cases, it is necessary to control the relative removal rates of individual materials. For example, CMP is often used to remove an overburden of material which has been deposited to fill a trench formed in a layer of another material. In this case, a high removal rate is desired for the overburden material, while a low removal rate is desired for the underlying layer. This difference in removal rate is referred to as *selectivity* (S) and is given by the equation:

$$S = \frac{R_A}{R_B} \tag{6.3}$$

with R_A, R_B the removal rates for materials A and B, respectively. An example of this process is CMP for shallow trench isolation (STI) [148], where an SiO_2 overburden is removed with the goal of stopping on silicon nitride. In this type of application, the object is for the SiO_2 fill material in the trench to be coplanar with the surrounding SiN as shown in Fig. 6.26.

Polishing must proceed long enough to ensure complete removal of overburden over the entire wafer. To ensure this, all areas of the wafer will experience some "overpolish" or

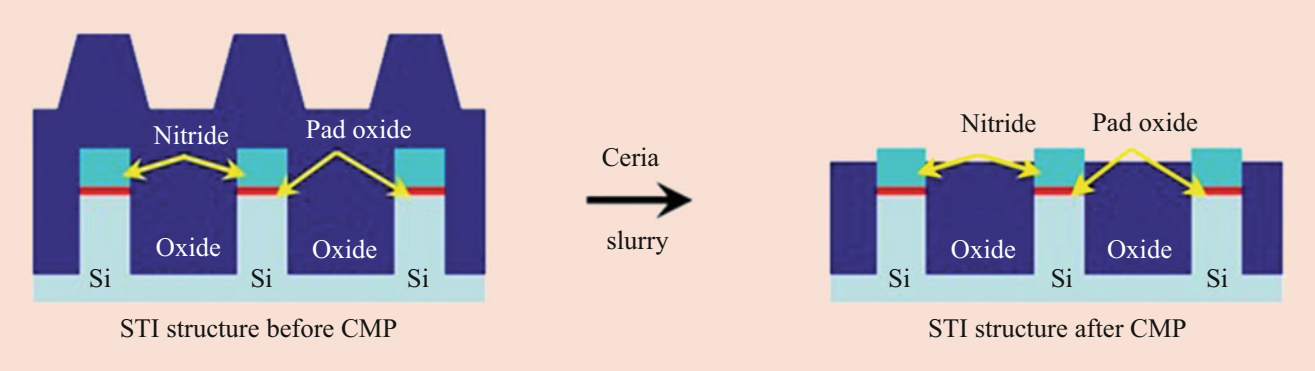

Fig. 6.26 Schematic diagram of the STI CMP process

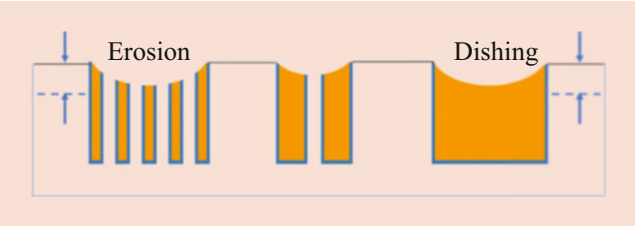

Fig. 6.27 Dishing and erosion from copper CMP

continued polishing after overburden has been removed in some areas. During overpolish, we do not want to create a recess in the filled trench structure. Here, the "Prestonian behavior" of CMP is useful for minimizing the topography of the final surface. Once a recess begins to develop in the trench region, the pad acts as a beam across this area, exerting a lower local pressure (the *Pv* product is locally reduced). If CMP continues, the recess will tend to reach a limiting value which is dependent on the stiffness of the polishing pad and the process selectivity for the materials present. The post-CMP recess in an individual trench is defined as "dishing" (Fig. 6.27). Wider trenches tend to dish more since the beam (polishing pad) will deflect more over this larger span. Planarization will also be affected by the number and placement of multiple trench features with respect to each other. If several trenches are arranged in near proximity, the relative area of low polish rate "stopping" material between the trenches is decreased. The stopping material between the trenches will experience higher mechanical Pv conditions, and local polish rate will increase. As a result, the entire region will polish faster and will become recessed. This recessing of patterned regions is referred to as erosion (Fig. 6.27).

Varied trench widths and pattern densities are necessary in circuit design but present challenges for the CMP process. To some extent, the circuit pattern can be modified to improve overall planarization. Ideally, we would maintain a uniform density of trench widths and density of pattern across all areas of the chip. In practice there are limitations to achieving this through circuit layout, so it has become common practice to further improve pattern factor by the addition of non-active "dummy" fill features [149]. For copper CMP processes for interconnects, it is typical to define an acceptable range of pattern densities and to use a dummy fill technique to achieve densities with that range. Similarly, trench features tend to dish more as width increases. If a circuit requires wide trench features, dishing can be reduced by the addition of small areas of stopping material within the trenches. As an example, large copper shapes may be necessary for electrical test probing or for lithographic alignment marks. Small dielectric "cheese" features can be added within these shapes to reduce copper dishing.

6.3.3 Copper CMP

The schematic diagram of the Cu BEOL fabrication process is shown in Fig. 6.28.

Copper interconnect "wires" are fabricated through a series of steps which are repeated to create each wiring level of a multilevel structure. In simple terms, (i) a trench pattern is formed in a stack of dielectric layers through lithography and RIE, (ii) TaN/Ta barrier, Cu seed layer, and Cu conductor metal layers are deposited over the patterned dielectric to fill these trenches, and (iii) the Cu overburden, TaN/Ta barrier, and a portion of the underlying patterned dielectric are removed through CMP. To meet the requirements of the semiconductor circuit, the resultant wires must be within a specified range of resistance per unit length. To achieve the target wire resistance, the unit processes used to form these wires must provide adequate control of the wire dimensions. Lithography and RIE are responsible for controlling the width and depth of the lines, while CMP is responsible for the height of the lines through control of material removal.

To achieve the required control of line height, copper CMP is typically accomplished in two steps: (i) a highly selective removal of copper overburden stopping on the barrier metal

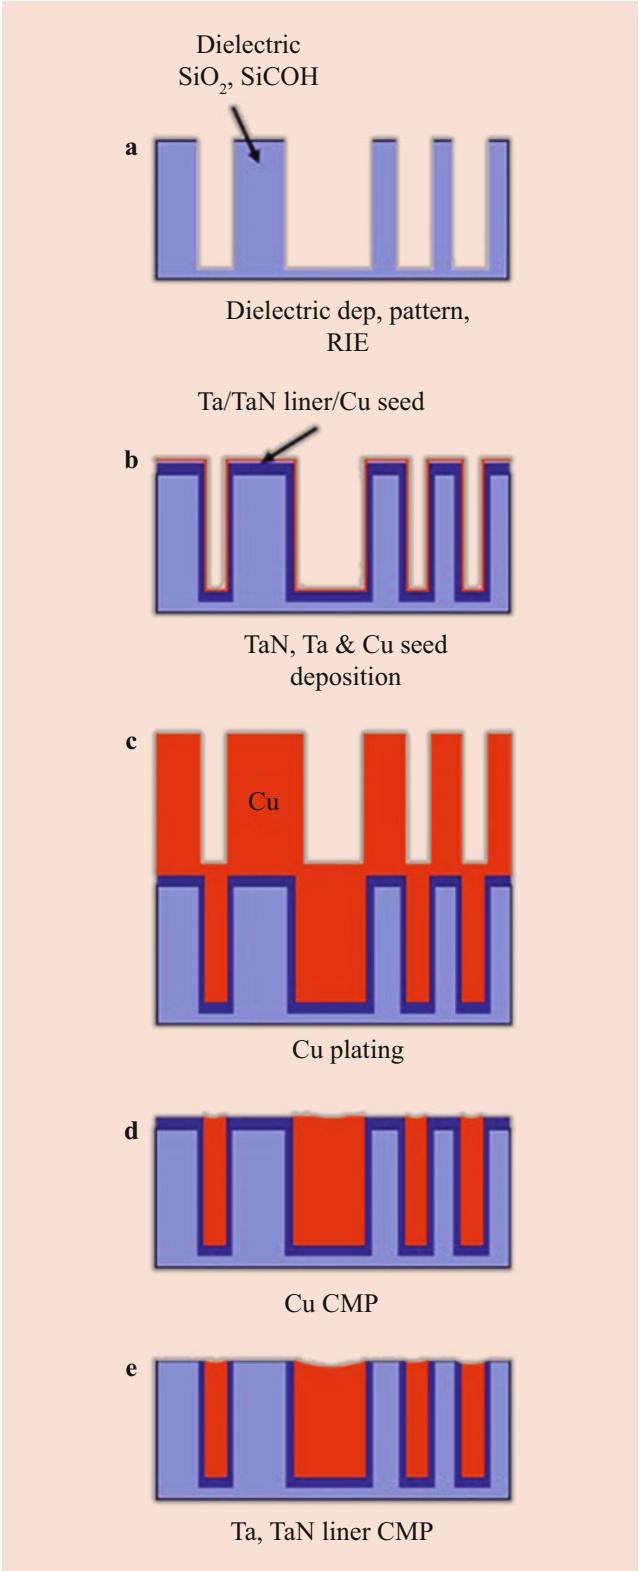

Fig. 6.28 Schematic diagram of the Cu BEOL CMP process (**a**) Dielectric deposition and patterning (**b**) Barrier and copper seed deposition (**c**) Copper plating (**d**) CMP of copper overburden (**e**) CMP of barrier metal

followed by (ii) a low selectivity removal of liner/barrier metal, dielectric, and trench copper to achieve target line height and a planar final surface.

Step 1: Copper CMP – Removal of Copper Overburden

The control of material removal rate across varying line widths and pattern densities is the primary challenge in achieving line height targets. For copper interconnect CMP, the chemical difference between the copper overburden and the underlying barrier and dielectric lends itself nicely to a two-CMP-step approach to achieving target line height. The first CMP step, bulk removal of Cu overburden, exploits this chemical difference to achieve a high selectivity to the barrier material. By stopping on barrier, the task of overburden removal is accomplished with little or no pattern-dependent erosion of the underlying structure. The resultant top surface of barrier becomes a consistent starting point for the subsequent nonselective barrier CMP step. In addition to stopping on barrier, the bulk Cu CMP process must also provide minimal or no dishing across the range of line widths present. The design of a copper slurry to meet these requirements requires understanding and control of surface chemistry during the polishing process.

The planarization mechanism for the bulk copper CMP process is depicted in the schematic diagram shown in Fig. 6.29.

The typical components of a bulk copper slurry are (i) oxidizer, (ii) inhibitor, (iii) abrasive, (iv) surfactants, and (v) polyelectrolytes and similar materials to prevent the adhesion of abrasive particles, pad debris, and other materials to the polished surface. Understanding of the role of each on the kinetics of the CMP process is critical for the development and optimization of the slurry composition.

Oxidizer The oxidizer provides chemical driving force for the dissolution of copper. The oxidizer removes electrons from copper metal forming Cu^{2+} ions which are soluble in the slurry.

$$Cu^0 \rightarrow Cu^{2+} + 2e^-$$

The oxidizer must provide the chemical potential to remove electrons from copper. In addition, it must be stable in the slurry and not react with other slurry components except as required during the CMP process. A common oxidizer for bulk copper is hydrogen peroxide.

Copper Inhibitor To achieve planarization, the reaction between Cu and oxidizer must not proceed without the action of the CMP pad and abrasive. In other words, removal of

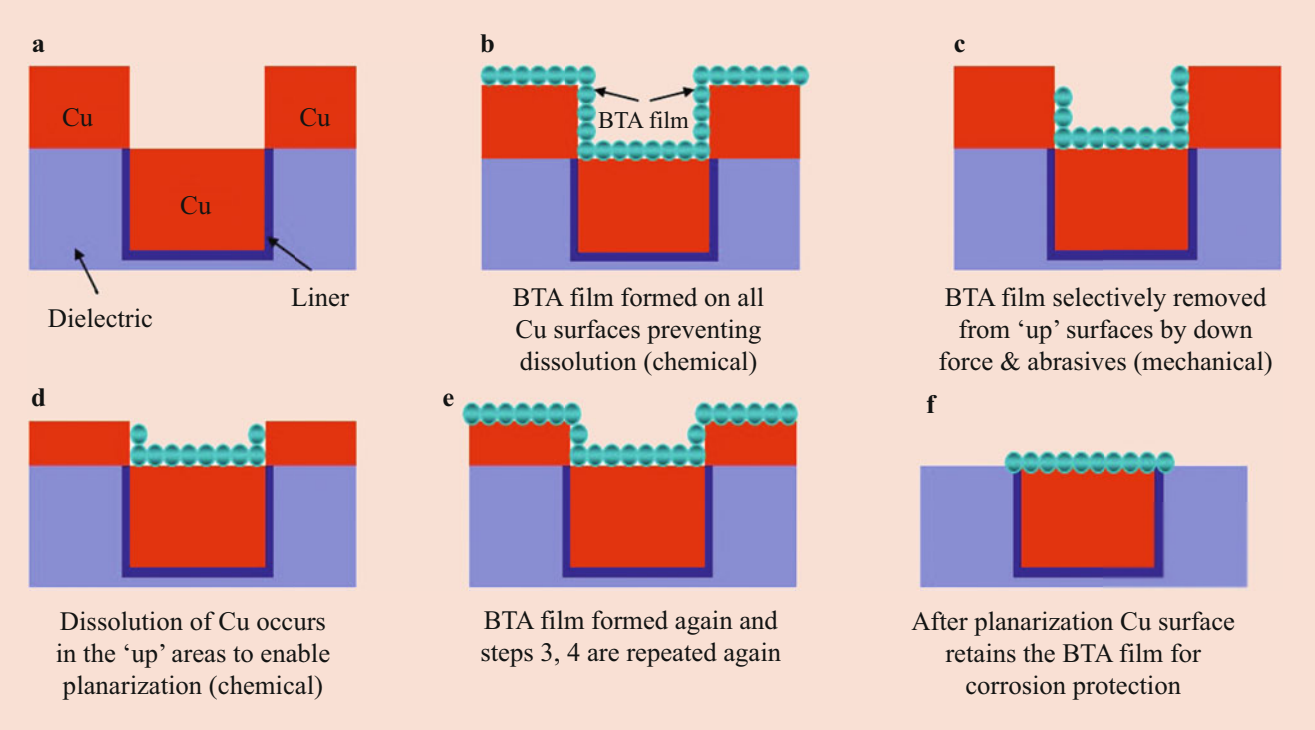

Fig. 6.29 Schematic diagram of the Cu planarization processa. (**a**) Wafer surface with plated copper overburden (**b**) Copper surface exposed to CMP slurry, with adsorbed BTA film (**c**) Copper surface with BTA film removed from "high" areas, due to mechanical action of pad and slurry (**d**) Dissolution of exposed copper in high areas (**e**) Reformation of BTA film due to exposure to slurry (**f**) Planarized structure after removal of copper overburden

copper under "static" conditions must be prevented. This is accomplished by using an inhibiting agent, a molecule which specifically adsorbs on copper to form a film which blocks the oxidizer from coming into contact and reacting with the copper surface. Multiple classes of molecules can adsorb strongly enough on copper to achieve this purpose; among these are sulfur compounds and heterocyclic compounds of nitrogen such as triazoles [150]. Benzotriazole (BTA) is a well-known copper inhibitor which has been employed effectively in copper slurries. BTA is strongly adsorbed onto the copper surface, particularly under acidic conditions [151], and readily forms a protecting film. Depending on the BTA concentration and chemical composition of the slurry, a thicker BTA film can be formed. The adsorbed BTA molecules can interact with each other to form a durable, compact film. Figure 6.30 illustrates the behavior of the BTA inhibitor in suppressing the dissolution of copper during CMP.

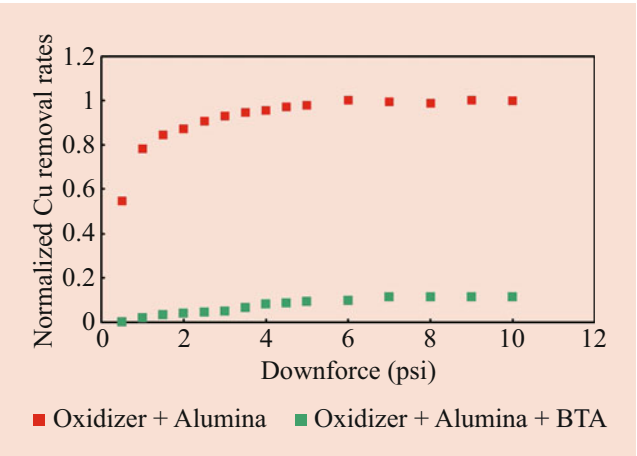

Fig. 6.30 Normalized Cu removal rates vs. applied pressure (down force) in the absence and presence of BTA

Abrasive The abrasive is comprised of highly engineered particles, typically oxides of silicon or aluminum. Particle size can be as small as 25 nm but can range up several hundred nm. Best polishing performance is achieved through well-controlled distribution of particle size and shape. The industry trend is toward solution-grown, (colloidally grown) abrasive particles for leading edge semiconductor technology nodes with stringent planarization and defect requirements.

During polish, mechanical force is transferred through the pad, and the slurry particles are pressed and moving against the wafer surface. If a particle impacts the surface with sufficient force, it can disrupt the inhibitor film and allow local dissolution of copper. After dissolution, the freshly exposed

copper surface is chemically active, and the inhibitor can readily reform the surface film. Due to the mechanical action of the pad, areas of raised topography on the wafer experience a higher local pressure and a larger number of *Pv* film-disrupting impacts as compared to areas which are not raised. These effects promote high planarization efficiency since raised areas will experience a significantly higher removal rate for copper.

Additives for inhibitor film modification Copper slurries offered by industry vendors have evolved dramatically as interconnects have scaled from 180 nm to 7 nm and beyond. This evolution has been necessary to meet increasing planarization and defectivity demands for each new node. Controlling the properties of the adsorbed inhibitor film is essential to meeting these requirements. Some of the factors which must be considered in manipulation of this film are:

- Chemical nature of inhibitor: Choice of adsorbing molecule determines strength of adsorbate to copper surface interaction.
- Concentration of inhibitor: Affects fraction of copper surface covered by inhibitor molecule.
- Manipulation of inhibitor film properties: Addition of other species which compete for adsorption onto copper surface allows tuning of chemical and mechanical properties of the film.

Surfactant molecules can compete with the BTA film and modify the overall film properties. Typical anionic surfactants such as sodium alkyl sulfates form a surface film by physical adsorption as opposed to the strongly adsorbed compact BTA film. Thus, the surfactant film can influence the Cu removal rate by competitive adsorption and BTA film modification as illustrated in Fig. 6.31. The result is an increase in removal rate for a system with surfactant as compared to a system with BTA alone.

A more detailed explanation of this behavior can be found through adsorption theory. Surfactant molecules adsorb onto the Cu surface by physical adsorption. This type of physical surface adsorption can be described by the Langmuir isotherm, as shown below:

$$\beta C = \frac{\Theta}{1-\Theta} \tag{6.4}$$

The coverage of the copper surface by surfactant can be expressed as βC, where β represents the free energy of adsorption of the molecule, C is the concentration of the surfactant, and Θ is the fraction of area covered. The Langmuir adsorption isotherm describes the physical adsorption with no mutual interactions between adsorbed molecules.

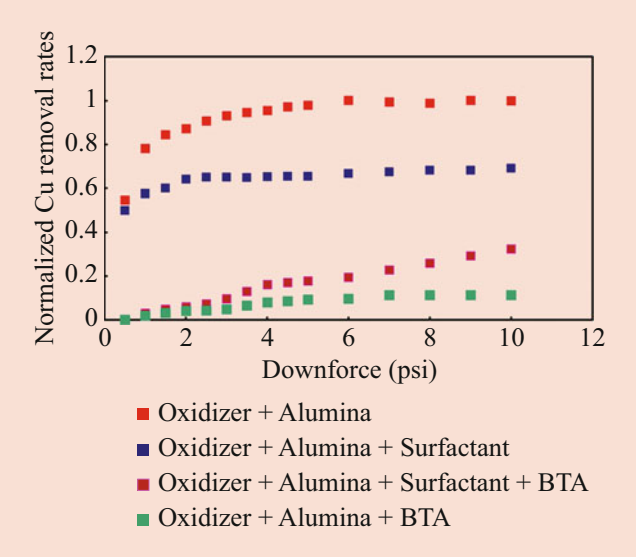

Fig. 6.31 Normalized Cu removal rates vs. applied pressure (down force) in the presence and absence of BTA and the surfactant

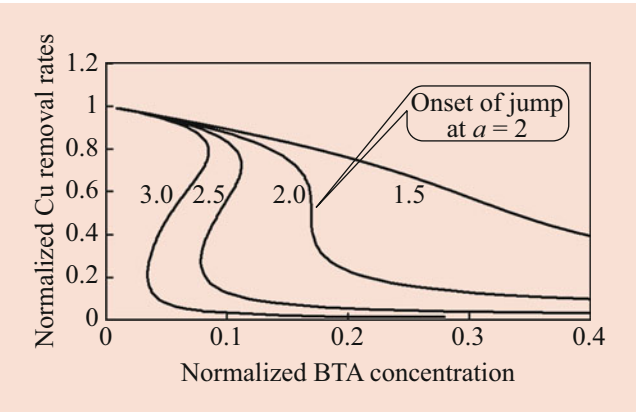

Fig. 6.32 Normalized Cu removal rates vs. normalized BTA concentrations, showing inflection at $a > 2$

The Frumkin isotherm also describes the surface coverage βC of an adsorbate, with parameter a introduced to account for adsorbate-to-adsorbate interaction as shown below:

$$\beta C = \frac{\Theta}{1-\Theta} \exp\left(-2a\Theta\right) \tag{6.5}$$

Values of a greater than 2 indicate a strong, compact surface film. BTA molecules are known to interact or bond to one another once they are adsorbed on the copper surface. Figure 6.32 describes the normalized copper removal rate predicted as a function of BTA concentration. Per the Langmuir isotherm, for values of a greater than 2, there is a discontinuity in film coverage with BTA concentration, resulting in a dramatic decrease in removal rate vs. BTA concentration.

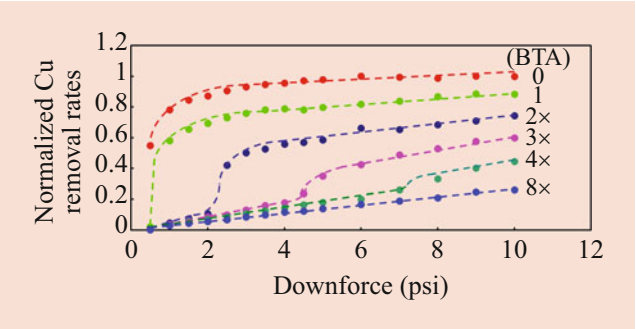

Fig. 6.33 Normalized Cu removal rates vs. applied pressure (down force) at various BTA concentrations

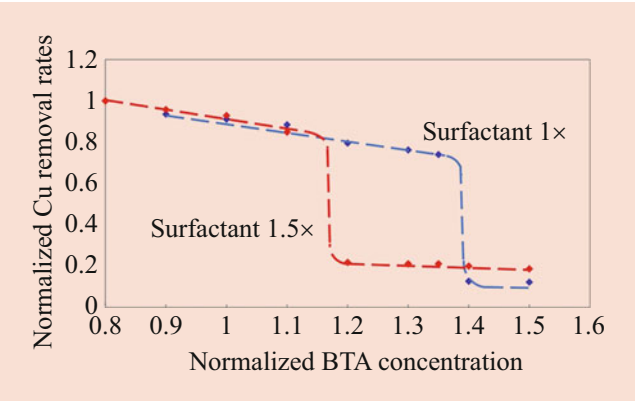

Fig. 6.34 Normalized Cu removal rates vs. normalized BTA concentrations at various surfactant concentrations

The applied downforce is also a factor in the stability of the BTA film during polishing. Consistent with this model, a jump CMP polish rate is observed as a function of downforce (Fig. 6.33). The understanding and control of these relationships are useful in optimizing slurry formulations and tuning copper CMP processes for specific applications. High and low areas experience different local downforce (Fig. 6.29). Enhanced planarization efficiency and reduced copper dishing can be achieved by establishing film conditions that magnify the removal rate differences between the high and low areas of topography.

The inhibiting film behavior and the resulting downforce transition can further be tuned through the introduction of a second adsorbing species. For an inhibiting system based on BTA, if a second species is introduced which adsorbs onto copper, it will take the place of some BTA molecules and interrupt some of the BTA-to-BTA bonding. The result is a less compact film; in this way tuning of the system can be accomplished through adjusting the concentrations of both adsorbing species (Fig. 6.34).

To meet the requirements of semiconductor fabrication, the amount of copper removed in the CMP process must be carefully controlled at all locations on the wafer. To achieve this, film thickness measurement during CMP is important. For measurement of copper, induced current sensors can be embedded in the platen under the polishing pad [156]. As a sensor passes under the wafer, a current is induced which is used to determine metal film thickness as a function of wafer radius. This thickness information can be used to control the pressure zones in the wafer carrier to maintain uniform metal removal across the wafer. This measurement can also be used for determining the approximate endpoint of the metal polishing step. The signal strength for induced current diminishes with metal thickness; therefore the exact point of metal clearing is difficult to detect. The *presence* of a metal film at various radii on the wafer can be detected by reflection of a signal from a laser embedded in the platen. While this reflectivity measurement cannot measure the thickness of metal, it can be used in conjunction with the induced current technique to more accurately detect the point of metal clearing. In the bulk copper CMP step, it is important that virtually all copper to be removed above the barrier film since the copper polish rate of the subsequent barrier CMP step is relatively low and the barrier CMP process is not tuned to remove remaining bulk copper. Using the endpointing techniques described above, it is possible to detect the point of bulk copper overburden removal. However, copper overburden does not clear simultaneously in all areas within a die; varying pattern density and the presence of topography from previously built layers will cause some local regions to clear later than others. Also, even with optimization of wafer-level removal uniformity, some regions of the wafer may clear later than other regions. For these reasons, the bulk copper CMP process is typically not stopped immediately at the detection of endpoint. A period of continued copper polish or "overpolish" is used to ensure that copper is removed from all areas of the wafer and all areas with the die. The polish conditions may be adjusted during the overpolish period. For example, downforce may be reduced to control dishing and erosion. The duration of the overpolish step can be for a few seconds or longer than 1 min, depending on the interconnect structure and level being polished. In setting up a new copper CMP process, it is useful to inspect the wafer surface after the bulk CMP process step through optical and SEM methods to determine optimum overpolish time and ensure complete removal of copper.

Step 2: Barrier CMP – Removal of Barrier and Setting Copper Line Height

To reiterate, the *overall* copper CMP process must achieve electrically separated copper conductors with a consistent line heights, independent of pattern density and with a minimum of defects. The first step, bulk copper removal, was described above and relies on high selectivity and high planarization efficiency to achieve removal of copper overbur-

den with minimal loss of barrier metal. Typically, a relatively hard pad is used to maximize planarization and to minimize removal differences due to pattern density. Some introduction of defects (from hard pad) can be tolerated at the bulk copper CMP step in the interest of planarization, since the barrier layer and some dielectric will be removed in Step 2 and minor defects may be removed.

The second step, barrier CMP, must meet numerous, interrelated, and often conflicting requirements:

1. Nonselective removal of barrier metal, remaining hardmask (if present), and a specified amount of dielectric.
2. Achievement of final CMP topography within specified limits to enable subsequent lithography and further downstream processing. This includes correction of topography generated in Step 1 due to copper dishing.
3. Setting of copper line height across all pattern densities to meet circuit design requirements.
4. Achievement of low defectivity for outgoing wafer surface including removal of defects if present from Step 1 overburden removal.

Barrier slurry formulation In concept, a slurry for barrier CMP needs to be nonselective or have equal polish rates for barrier, copper, dielectric, and hardmask if present. In practice, this is a complex challenge, since the chemical reactivity of copper (a metal) is different from the barrier (a semi-metallic material) and the dielectric (a ceramic). For copper removal, an oxidizer/inhibitor system can be employed, similar to that used for the bulk copper slurry. The oxidizer is typically hydrogen peroxide, and a film formed by a copper inhibitor provides self-limiting behavior that aids in controlling topography generated in areas where copper is removed. For dielectric removal, silica abrasive is typically used. Silica generally follows the polishing mechanism described for oxide CMP earlier in this chapter; the silica particle interacts with the partially hydrolyzed dielectric surface. This "softened" dielectric is removed in the interaction, and then further hydrolysis can occur at that site. The polish rate for a low k dielectric is typically lower than for silicon dioxide. This is thought to be due to the presence of carbon which renders the material more hydrophobic and less prone to hydrolysis.

A polishing system built solely upon these mechanisms for copper and dielectric cannot be readily optimized for the variety of pattern densities normally found in interconnect circuits. For dense regions of copper lines, the copper mechanism dominates; the small areas of dielectric between these lines receive relatively more mechanical force and polish quickly. Polishing in these regions will ultimately be controlled by the copper inhibitor film mechanism. However, for areas sparsely populated with copper lines, polishing of the dielectric will dominate, and simple "Prestonian" polish behavior is obeyed. The polish rate will vary according to the amount of dielectric area present (Fig. 6.35). The difference in these mechanisms creates differences in overall removal rate (and resulting copper line height) for different pattern densities.

To manage this, a self-balancing system is needed which can accommodate both copper-rich and dielectric-rich areas of the pattern. To achieve control of polish rate in dielectric-rich regions, an inhibitor molecule can be employed which adsorbs on dielectric. Similar to the action of BTA on copper, this inhibitor allows removal on raised areas of dielectric and decreases removal rate in recessed areas. One such group of molecules are polyelectrolytes which have been shown to enhance planarization in barrier slurries.

Tantalum nitride is the typical barrier used for most copper interconnect products. The barrier film thickness is typically less than 10% of trench width; therefore, tuning of the barrier material polish rate is not as critical as tuning of copper and dielectric polish rate. Once the horizontal barrier film is removed from the dielectric surface, planarization is domi-

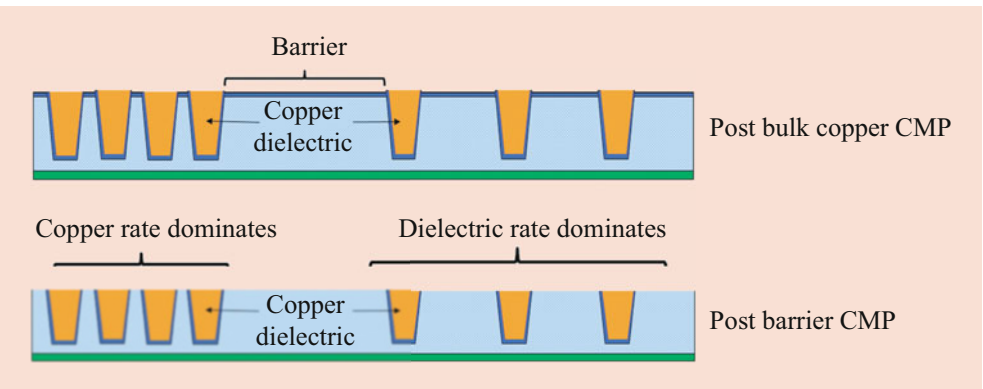

Fig. 6.35 Polish rate behavior of barrier CMP process for dense and sparse patterned areas

nated by the materials present in larger areal fractions: copper and dielectric. TaN can be polished by silica abrasive alone but will typically have a removal rate of less than one half that of dielectric. The presence of oxidizer can enhance TaN removal rate to be approximately equal to dielectric rate. The mechanism here is thought to be surface oxidation of TaN to Ta oxide. The thin surface oxide layer is then removed in a mechanism analogous to the polishing of SiO_2. In support of this mechanism, a peak in TaN removal rate is observed with increasing oxidizer. For oxidized concentrations beyond this peak, TaN becomes passivated; the growth rate of oxide exceeds the ability of the abrasive to remove it, and polish rate decreases.

Process Control for Barrier Polish

Control of the barrier CMP process is critical in meeting the copper line height specifications. These translate directly to resistance distribution for the interconnect circuits. As described above, control of topography and pattern density variations can be accomplished through a properly formulated barrier slurry. Unlike the bulk copper polish step, barrier CMP is a blind polish; there is no "stop layer" to provide a built-in means of controlling the total amount of material removed. Additionally, the induced current and laser methods used for control of bulk copper polish are not readily applied to the barrier CMP process. For these reasons, barrier CMP may be controlled by time (duration of polish). It then follows that consistency of removal rate and control of within wafer removal uniformity are critical. Wafer and platen rotation speed and wafer carrier zone pressures must be carefully optimized for within wafer uniformity. To provide better control over total material removal, optical critical dimension (OCD) measurement capability is often incorporated in the CMP tool to measure copper line height. This measurement is performed after CMP once the wafer is clean and dry but before the wafer is returned to the cassette. This capability can be used for automated process control (APC) in a production environment. The line thickness result from onboard OCD can be used to adjust the polish time for subsequent wafers. With wafers loaded throughout the tool, a few wafers may be polished before the result can be used for polish time adjustment. After that, OCD feedback from selected wafers can be used to continually adjust polish time for subsequent lots. A measurement of copper line height in situ during barrier polish would be very valuable for controlling removal uniformity through carrier zone pressures and for endpointing. CMP tool vendors are working on development of in situ measurement techniques including optical and induced current sensors for measurement of metal thickness. Further progress toward effective in situ measurement for barrier polish is expected.

6.3.4 Control of CMP Defects

The chemical and mechanical forces present in the CMP process provide the potential for generating defects in the interconnect structure. These defects can degrade chip yield, performance, and reliability. This section describes the typical defects observed from CMP and approaches to mitigate these. Figure 6.36 illustrates some examples of defects which can be caused by copper CMP.

Scratches

Scratches are created when foreign particles, other than normal slurry particles, are present between the pad and wafer surface. In general, a harder pad will generate more and deeper scratches than a softer pad. As a trade-off, a softer pad will be less efficient at planarization and will have a shorter useful life. Due to the relative softness of copper and low k dielectric materials, a very soft pad is typically used for barrier polish; pad life for these is much lower than for the harder pads used in bulk copper polish. To control scratching, it is important to maintain clean conditions at the wafer-to-pad interface and to prevent the introduction of unwanted solid material. Care must be taken when handling and installing polishing pads and whenever work is being done in or near the polishing module. Slurry blending and delivery systems must be designed to prevent agglomeration of abrasive particles. These systems should contain filters which are properly sized to catch unwanted particles and should be replaced at proper intervals. Scratches can also occur from particles or material generated within the CMP process. If delamination occurs, where pieces of solid material break loose from the wafer itself, scratches will typically result. Particular attention must be paid to the die patterns at the extreme edge of the wafer and the wafer bevel. The upstream processes which form the underlying patterned layers do not all terminate at the same location at the wafer edge. Locally, there can be missing or poorly adhered areas which can break free and cause scratches. Similarly, the unpatterned bevel area at the wafer edge can be a source of residues from previous processing that can break free and cause scratches in CMP. Typically, wafer bevel cleaning is used in a manufacturing fab to remove these residues periodically in the flow of processing.

Delamination Delamination is caused by an interface failure in the wafer structure during CMP. A portion of material can break away and, as mentioned above, will often cause scratches. While this occurs during the CMP process, the root cause of delamination is a weak interface in the underlying structure. The tensile strength of materials and interface adhesion in an interconnect structure

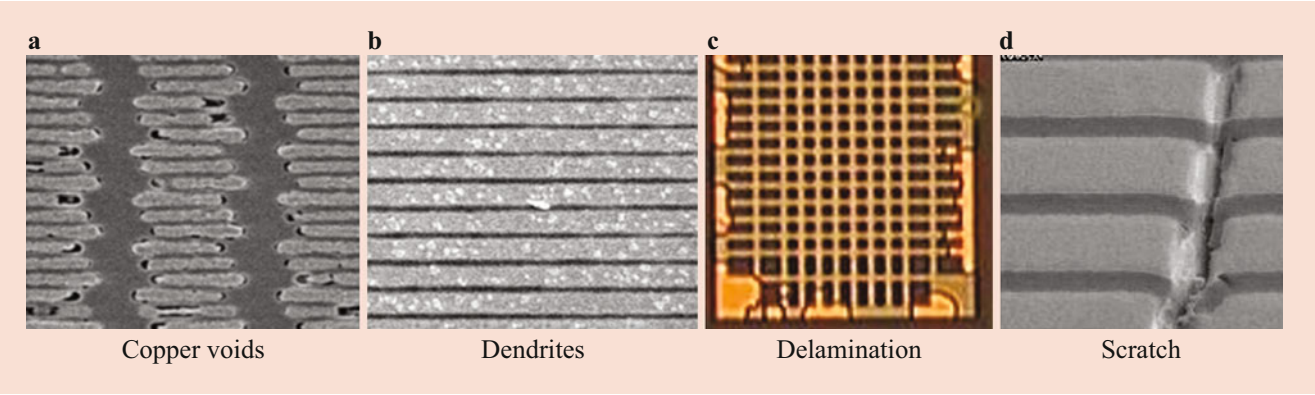

Fig. 6.36 Typical defects which can be caused by the copper CMP process. (**a**) Copper voids (**b**) Dendrites (**c**) Delamination (**e**) Scratches

should far exceed the mechanical forces generated in CMP. When delamination is observed, the integrity of underlying materials and interfaces must be improved.

Metal voids Bulk copper and barrier slurries are available from numerous commercial sources. These are highly developed to achieve copper removal and planarization without "attack" or uncontrolled local dissolution of the metal. If post-CMP metal voids are observed using a proven, qualified CMP process, the root cause may lie in the upstream metallization processes. It is essential that the post-RIE trench profile, barrier/seed deposition, and plating processes are co-optimized to provide robust, void-free metal fill with strong metal to dielectric interfaces. If metallization is marginal, voids may be observed post-CMP, even though they are not detectable post-copper plating.

Dendrites After CMP, the copper surface may react with ambient oxygen. The resulting copper oxide product can grow unevenly, taking the shape of small bumps on the copper lines or growths with various other shapes. If not suppressed, these "dendrites" can grow to bridge across one or more copper lines and cause circuit shorting [152–154]. The continued industry trend of scaling interconnects, including reduced interconnect pitch and lower k dielectrics, has exacerbated the tendency to grow dendrites. Following CMP, a dielectric capping film is deposited on the copper surface which serves as a hermetic seal to prevent further oxidation of copper. In practice, there will be some delay period between copper CMP and deposition of this cap. In a production environment, the wafers must be able to wait for a few hours before capping without significant dendrite growth. It has been shown that exclusion of moisture and oxygen by storage of wafers in dry nitrogen can significantly delay the growth of dendrites until capping is performed [153]. In addition, an important factor in dendrite suppression is passivation of the copper surface in the post-CMP cleaning process. An inhibiting film is present on the wafer surface after the barrier CMP step. This film serves to protect copper from oxidation during post-CMP rinse and wafer transport to the brush clean module. In the brush clean process, this inhibiting film is removed and replaced with a uniform passivating layer, typically copper oxide with other adsorbed inhibiting species. These commercially available brush clean chemistries are typically very alkaline; they are carefully formulated to achieve effective passivation of the copper surface. The selection of this cleaning solution and optimization of the overall brush clean process are therefore essential to achieving a usable post-CMP queue time to capping.

6.3.5 Copper CMP for Alternative Barrier/Seed Systems

Filling of trenches with copper has been a challenge with pitch scaling. To assist in copper fill, additional "seed assist" materials such as cobalt or ruthenium may be employed between the barrier and copper seed [155]. The implementation of a new material in the interconnect structure requires careful selection of barrier slurry and optimization of CMP process conditions [156]. CMP processes are dependent on the redox reactions which enable the dissolution of copper and barrier metals. The electrochemical potential driving these reactions is a function of the metals present; the introduction of an additional metal layer will shift this potential and change the behavior of the CMP process.

Ru Liner CMP

Considering the electromotive series, ruthenium is more noble than copper. During CMP the potential of copper is shifted toward the anodic direction in the presence of Ru.

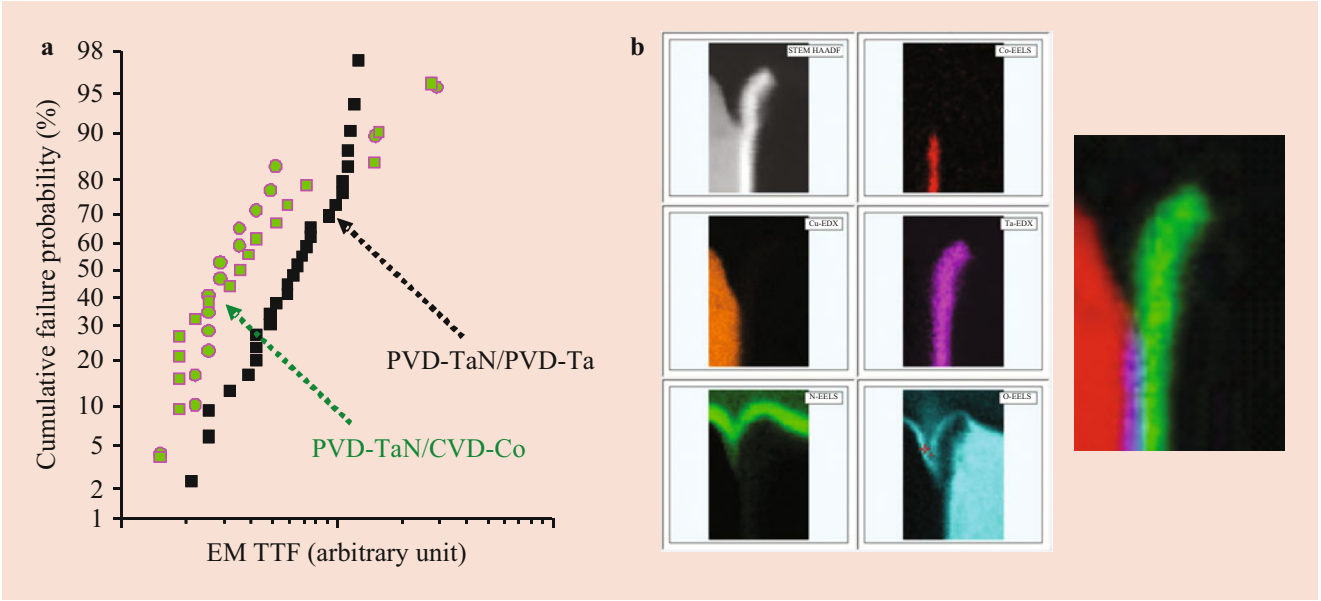

Fig. 6.37 EM lifetime degradation with TaN/Co liner (**a**) and STEM/EDX map showing Co divot defect formation (**b**)

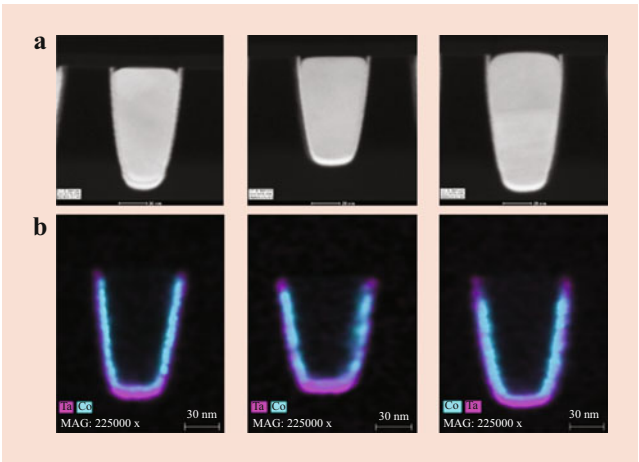

Fig. 6.38 STEM images (**a**) and EDX/EELS maps (**b**) with different wet process chemistries. No difference in imaged divot size is seen among different samples (**a**), while large differences in the depth of the Co recess (slit) are still detected by EDX/EELS mapping (**b**)

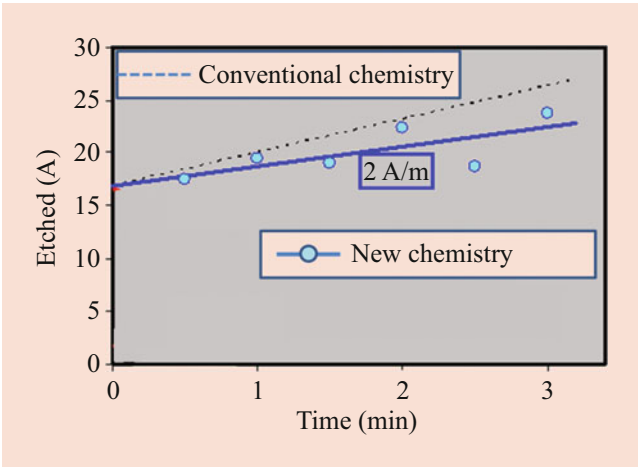

Fig. 6.39 Co etching rate reduction through modification of post-CMP clean chemistry

Using a copper CMP process designed for a conventional TaN barrier system, there is typically a higher rate of dissolution for copper when Ru is present. Subsequently, the top surface of the copper lines becomes recessed with a concave shape. This is in contrast with the flat or slightly convex copper shape usually observed for TaN liner alone. Also, polish rates for ruthenium are typically very low. This difficulty in removing the Ru film translates to a strong dependence on the fraction of Ru area present, i.e., on pattern density. The result can be a significant difference in post-CMP line height between different circuits within the same die.

Co Liner CMP

Unlike ruthenium, cobalt is *less* noble than copper. Once again, the barrier slurry and overall CMP process need to be specifically optimized for cobalt. If a TaN barrier CMP process is applied to a structure containing a cobalt wetting layer, cobalt can dissolve preferentially to copper. In this case, the top surface of copper lines may tend toward a more convex shape as the cobalt is lost at the interface to dielectric. In some cases, this cobalt loss can create deep divots or sidewall voids at the interface to dielectric [157].

Figure 6.37a shows an EM comparison between Cu lines with TaN/Ta liner vs. TaN/CVD-Co liner. For the Co liner structure, post-CMP trench top corners have divot defects, as shown in the STEM/EDX images in Fig. 6.37b [158]. Such

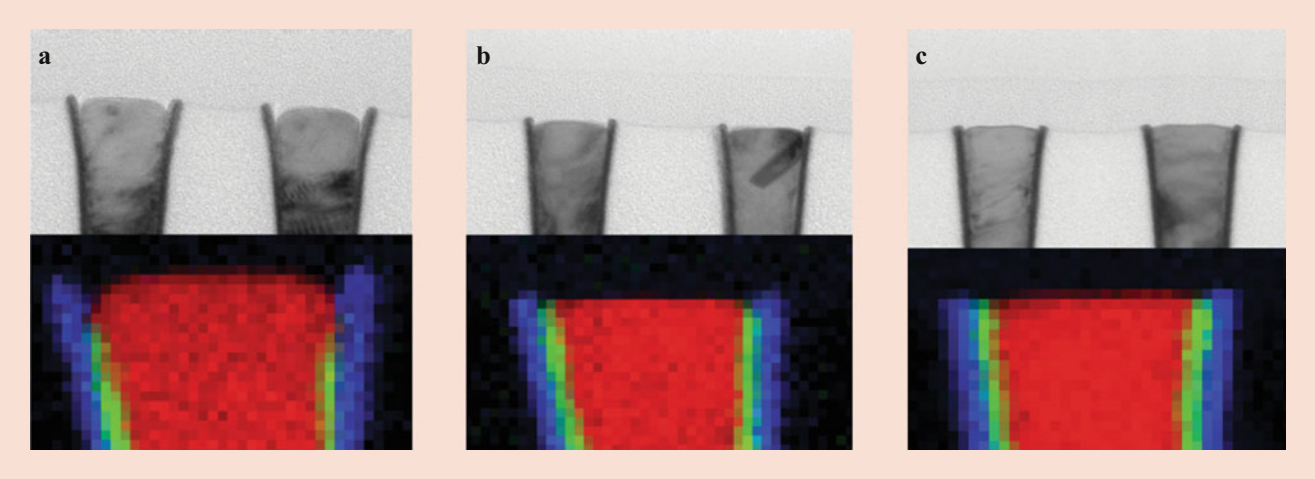

Fig. 6.40 Cross sections and EELS mapping of copper interconnects with Co seed assist layer. Red = copper signal, Blue = Ta signal, Green = cobalt signal. (**a**) Post CMP cleaning with chemistry developed for "normal" TaN/Ta barrier without Co layer. Divot is present at top corner of line due to loss of cobalt. (**b**) Same CMP process with addition of special inhibitor rinse on CMP pad after barrier CMP, divot is reduced. (**c**) Same CMP process as in a., but brush clean chemistry optimized for cobalt seed assist layer

divots can be the source of EM void nucleation sites; the recessed Cu surface where the cap dielectric cannot cover causes reduced EM lifetimes as shown in Fig. 6.37a.

Careful optimization of all CMP processing steps is necessary to effectively minimize these divot voids. Studies showed that even when no difference in imaged divot size is seen among different samples (Fig. 6.38a), large differences in the depth of the Co recess (slit) are still detected by EDX/EELS mapping (Fig. 6.38b) [158]. It was reported [159] that alkaline barrier slurries and reduced hydrogen peroxide concentration may help to suppress divot formation.

The post-CMP clean process must also be optimized to prevent unwanted dissolution of cobalt. Figure 6.39 illustrates the relative cobalt etching rates between a standard post-CMP clean chemistry and a chemistry modified with an inhibitor specifically for cobalt. This new chemistry was shown to reduce the formation of Co divots from the CMP process [158].

Figure 6.40 shows the EDX/EELS maps of the wire top corners for chips A, B, and C which are TaN/Co/Cu wires processed with different post-CMP clean chemistries. Figure 6.41 illustrates the EM performance for these structures. A clear correspondence between the EM performance and the divot suppression is evident, illustrating the need for specific optimization of post-CMP cleaning for cobalt liners.

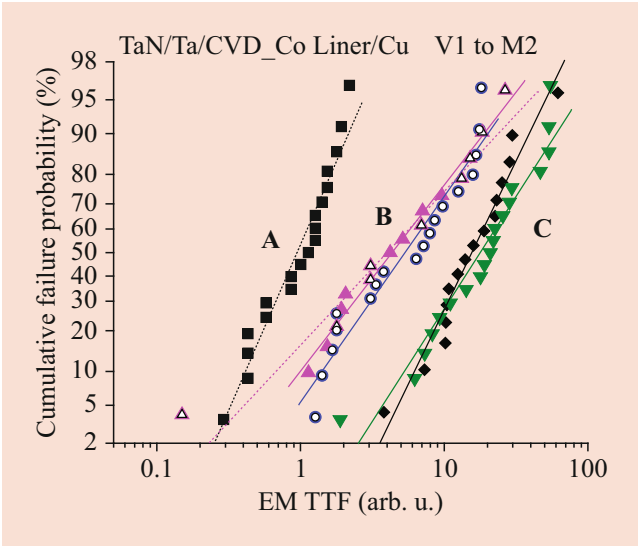

Fig. 6.41 EM lifetime dependence on divot formation. Each structure was processed with a different post-CMP clean chemistry as in Fig. 6.40

6.3.6 Summary

Since the dawn of copper interconnects, CMP has been fundamental to the fabrication process flow. Minimum conductor line widths which were initially 0.18 μm have been reduced to 18 nm and below! The CMP process will continue to be scalable through the understanding and control of the mechanical and chemical parameters described in this chapter. Slurry and post-CMP clean chemical formulations must be carefully tuned to the materials present to achieve the required control over conductor line height with low defectivity. The evolution of CMP process tools continues to improve control over mechanical parameters, while improvements in CMP endpointing techniques and automated process control will help to advance interconnect manufacturing.

Abstract

Moore's law has for more than five decades been the roadmap guiding the semiconductor industry. While originally driven by lithography advancements and material innovation, since the 22 nm/14 nm node, new device architectures like FinFET have been introduced to tackle the increasing challenges related to power efficiency, performance, area scaling, and cost. With the introduction of FinFET, design-technology co-optimization also gained a lot of importance. More than ever, the industry is looking for that magic device concept to continue CMOS scaling beyond the 3 nm technology node. Gate-all-around devices, coming in different flavors (nanowires or nanosheets), have been proposed as possible candidates for keeping leakage under control. These architectures can be seen as an evolutionary step from FinFET. More disruptive is the introduction of high-mobility channel materials like (Si)Ge. While many hurdles have been overcome, especially the lower bandgap and thus higher leakage are still a concern. Next, going 3D seems a straightforward way to continue area scaling. Based on the gate-all-around integration scheme, complementary FET (CFET) where nMOS and pMOS are stacked on top of each other shows potential for not only area scaling but also power-performance improvements, but it comes at the cost of a more complex integration scheme. Finally, as the industry will move more toward heterogeneous integration, sequential 3D, allowing for fine-grained connections between the different layers of active devices, will be key in enabling these more complex systems.

7.1 Introduction

In his famous paper "Cramming more components onto integrated circuits" [1], Gordon Moore laid out the guidelines of today's nano-electronics industry. Based on only a few data points, he predicted that the number of transistors would double every year with innovations in lithography as the main driving force to enable transistor scaling. This was later adjusted to every 18 months and even 2 years. For more than five decades, the semiconductor industry has been very successful in following this Moore's law, using the scaling guidelines, set out by R. Dennard et al. in 1974 [2] as, with every new technology node, the following advantages can be expected: 50% area reduction, 30% cost reduction, 20% power reduction, and 25% performance increase (at reduced V_{DD}). This metric, known as PPAC (power-performance-area-cost), has become very important in recent years to assess the viability of new technology nodes. As Moore's law

is a law of economics in nature, transistor scaling can only be maintained if the benefits outweigh the manufacturing efforts and costs that come along with the increased complexity of scaling.

Scaling was "business as usual" until the 90 nm technology node. Three scaling scenarios can be distinguished: constant voltage scaling, constant field scaling, and general scaling. Constant voltage scaling was done mostly in the 1980s and the early days of scaling. It was a pure geometrical process where the increasing electric field in the devices was disregarded. This resulted in excessive power dissipation and reliability issues. Constant field scaling, where all dimensions and voltages were scaled with the same factor, was rediscovered in the 1990s and used to mitigate the increasing problems with power density and hot carrier degradation. But it had some drawbacks: the performance improvement was reduced as compared to the constant voltage scaling scenario, and with scaling of the supply voltage V_{DD}, the threshold voltage V_T needed to be scaled accordingly which started to become an issue. Finally, general scaling where the dimensions of the basic building block, the MOSFET, are scaled down with a factor α ($\alpha = 1/\sqrt{2} \sim 0.7$) and the voltages with a different factor k is probably the most relevant for today's CMOS technology. Ion implantation, silicidation, chemical mechanical polishing (CMP), and the use of Cu in the back-end (BEOL) were successfully introduced along the way to improve the performance of the devices and to keep the leakage under control.

Scaling limits can basically be divided into three categories: wiring, lithography and more general patterning, and the limitations set by the device physics itself. The 90 nm technology node was a first breaking point. Boosting the device performance and keeping the unwanted short channel effects (SCE) under control was mostly done by scaling the gate oxide thickness t_{ox} of the transistor. By then, the nitrided gate oxide SiON had reached a physical thickness of only 1.2–1.3 nm. The gate leakage density, however, had increased to 100 A/cm^2 [3] as the quantum mechanical tunneling limit was reached and further scaling of the gate dielectric seemed impossible. Other ways needed to be found to improve the device performance. Strain engineering was introduced to boost the performance as t_{ox} was no longer scaled down. Channel strain engineering by either source/drain (S/D) boosters like SiGe for pMOS or strained contact etch stop layers (CESL) for nMOS were very effective in increasing the mobility and thus the on-current of the device I_{ON} [4, 5]. Figure 7.1 also shows that around the 90 nm node, scaling of the gate length started to slow down, allowing the reduction of SCE without impacting the density scaling, as for the latter, the reduction of the gate length L_G is not the key metric, but rather the scaling of the metal pitch and the contacted poly or gate pitch (CPP or CGP; this is the gate-to-gate pitch where the contact is placed in between as shown in the top-view schematic of Fig. 7.2). Scaling of both parameters by a factor 0.7 provide the required 50% area reduction with every technology node. Nowadays, gate length scaling is merely a consequence of CPP scaling as depicted in Fig. 7.3. At 90 nm, the CPP was roughly 300 nm, allowing for some room to relax the gate length from that node on since gate oxide scaling stopped.

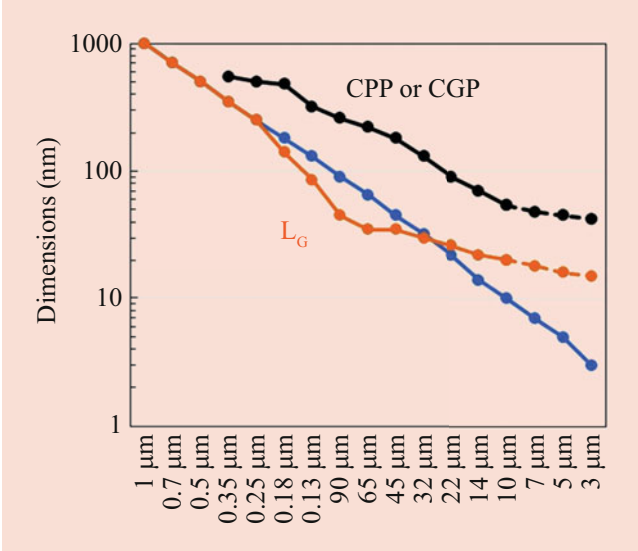

Fig. 7.1 Gate length and contacted poly pitch or gate pitch (CPP or CGP) as function of technology node; the blue line indicates the technology node while the orange line the gate length and the black line the CPP or CGP

Finally, at the 45 nm technology node, metal gate and high-k dielectrics were introduced replacing the traditional poly/SiON gate stack in MOSFETs and allowing further gate dielectric scaling. The next major innovation was introduced at 22 nm: the FinFET [6]. The advantage of this multi-gate device architecture is its better gate control and better immunity to SCE which reduces the subthreshold leakage significantly. This fully depleted device is to some extent very similar to the planar fully depleted silicon-on-insulator (FDSOI) device, where scaling of the channel thickness on the buried oxide (BOX) is used to keep the SCE under control. In FinFET, the gate is wrapped around the up-standing thin channel or fin (Fig. 7.4). The height of that fin FH is an important design parameter that, different from FDSOI, allows to increase the current drivability without having an impact on the active footprint of the device.

The use of fully depleted devices (FinFET and also FDSOI) is key to allow further scaling of the gate pitch and as such implicitly the scaling of the L_G and V_{DD}. The supply voltage V_{DD} of the transistors had been bottomed out at around 1 V at the 32 nm node, even though dissipated power density had gone up to 100 W/cm^2, basically reaching a limit where innovations in packaging and cooling would be needed to guarantee reliable operation of the integrated circuits.

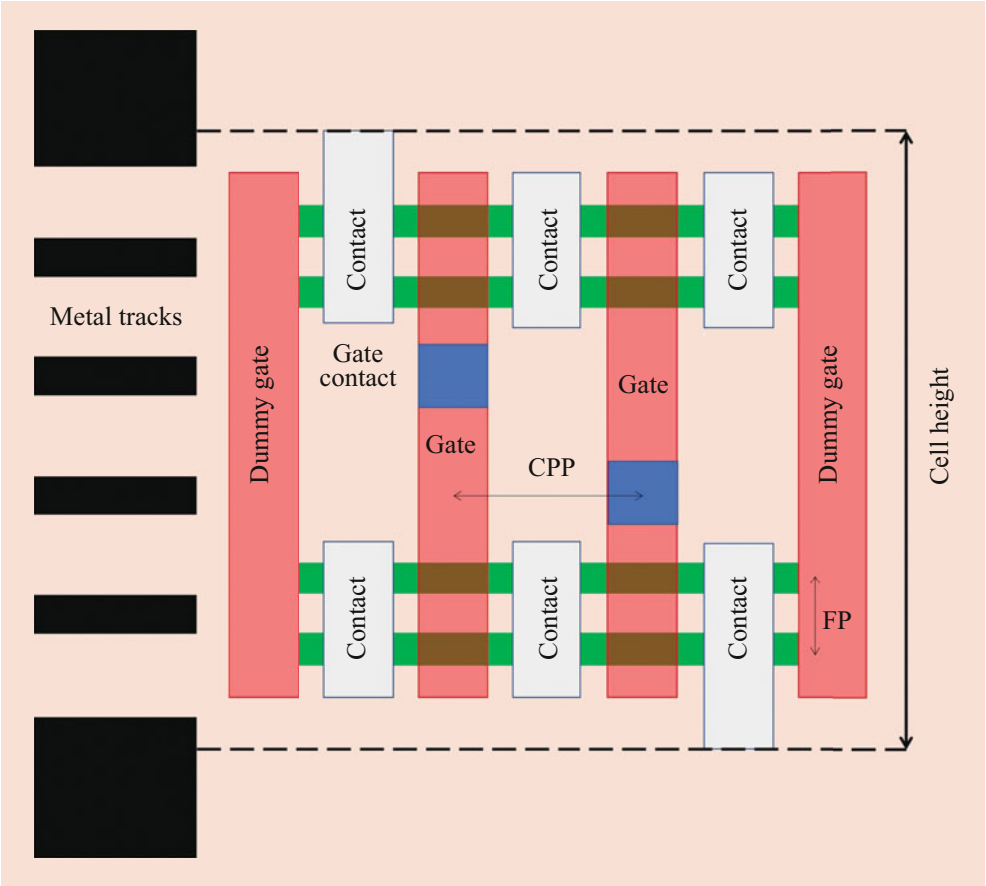

Fig. 7.2 Schematic presentation of the contacted poly pitch (CPP), fin pitch (FP), and metal track, key features enabling area scaling; in this case, the top view of a 6-track (6T) FinFET standard cell layout with four internal tracks for signal routing and the outer V_{SS}/V_{DD} power lines is shown. The device depicted in this figure has two fins per device; the dummy gates are used to ensure that the performance of all devices, center and edge, closely match

The reduced subthreshold swing and thus lower threshold voltage V_T of the FinFET allow to keep the gate overdrive constant while reducing the V_{DD} without compromising the switching speed. State-of-the-art FinFET technologies nowadays show very well-controlled subthreshold swings (~65 mV/dec) down to gate lengths of 20 nm [6].

7.2 From Pure Dimensional Scaling to Design-Technology Co-optimization

The FinFET introduced new features and degrees of freedom that allowed the designers to further reduce the area. The width of the transistor is defined as $W_{eff} = n(2FH + FW)$ where n is the number of fins, FH the fin height, and FW the fin width. While the fin width is largely defined by the gate length and the SCE control, reduction of the fin pitch FP and number of fins n allow to further reduce the active footprint of the device. However, challenges in patterning and device performance no longer allow for aggressive scaling of CPP and metal pitch (MP) (Figs. 7.3 and 7.5), putting a lot more emphasis on the area reduction at standard cell level and block level. While area scaling was before merely a matter of scaling of the basic transistor dimensions, for technology nodes 14 nm and beyond, it has become a matter of standard cell scaling (SDC), entering the area of design-technology co-optimization (DTCO) [7]. Increase of the density is achieved by CPP and cell height reduction which is expressed in the number of metal tracks that are needed to access the standard cell. In the example depicted in Fig. 7.2, the track height is 6 (6T). Reduction of the cell height is achieved by reduction of the number of fins (fin depopulation) and reduction of the number metal tracks by innovations like buried power rail where the power lines (V_{SS} and V_{DD}) are embedded or buried in the isolation and as such partly taken out of the footprint (Fig. 7.6). Buried rail is one of the scaling boosters, special process, and/or layout constructs to facilitate area scaling.

In Fig. 7.7, it is shown that while the CPP and FP are no longer scaling with $\sqrt{2}$, the cell height is. One of the concerns in this scenario is the increasing complexity that the scaling

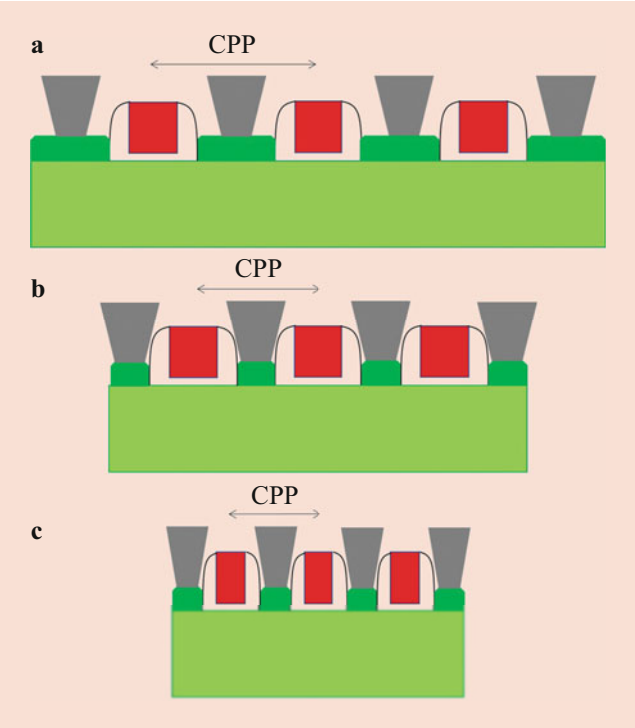

Fig. 7.3 Scaling of the CPP and its impact on gate length, contact area, and spacer scaling; in the case of (**a**) and (**b**), CPP can be scaled down without affecting L_G, spacer, and contact; case (**c**) requires the scaling of gate length, spacer, and contact to allow for further reduction of CPP

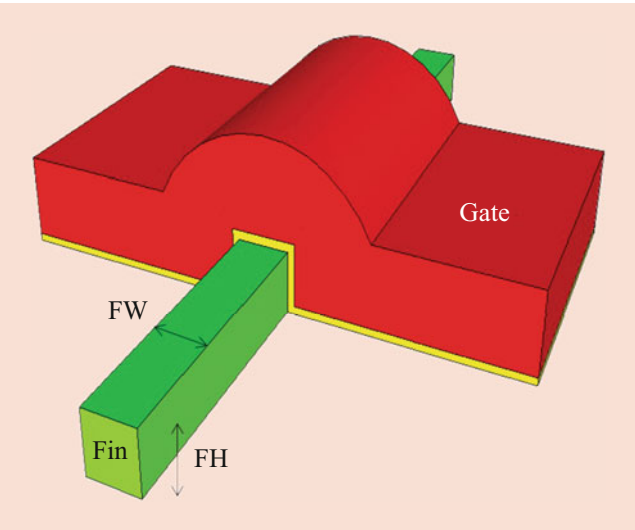

Fig. 7.4 Schematic presentation of a FinFET device indicating the most relevant features FH = fin height and FW = fin width; the current flows in both the sidewalls of the fin and the top of the fin

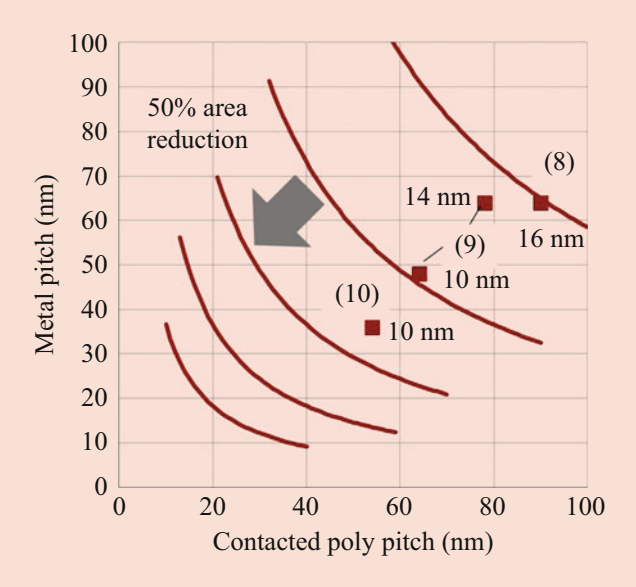

Fig. 7.5 CMOS scaling by contacted poly pitch CPP and metal pitch MP [8, 9]; lines are isolines of constant area; data points of published commercial technologies have been added

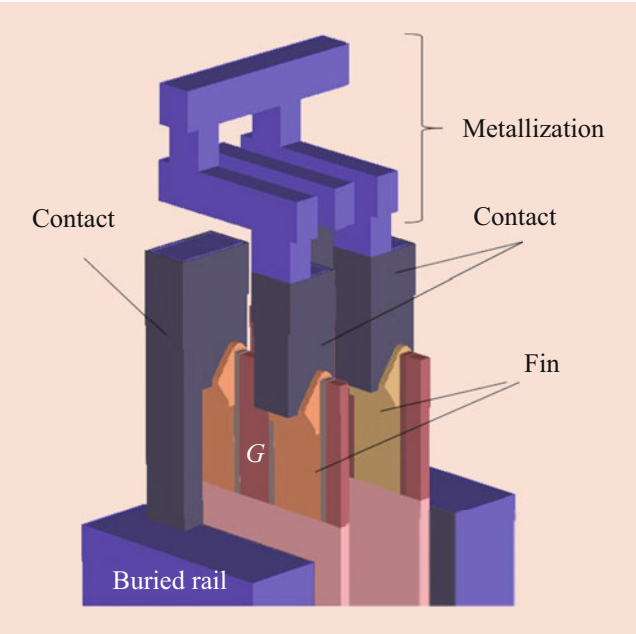

Fig. 7.6 Schematic presentation of the buried power rail [7]

boosters bring and with the trend toward fin depopulation the increase in variability. Moreover, to compensate for the loss in drive current, the fin height needs to increase leading to increased parasitics and challenges to process and integrate these high aspect ratio fins. Fin width control and fin collapse are only a few of the problems that one needs to deal with in this case. Figure 7.7 clearly shows a slow-down in CPP scaling, and this is related to the patterning challenges but more so the device performance. L_G, spacer, and contact are all competing for the limited available area. Reduction of L_G gives room to increase the spacer and contact area but leads to problems in short channel control and thus leakage. Gate-all-around or nanosheet devices are considered here as a possible solution, and this will be discussed in the next section. Reduction of the spacer leads to increase

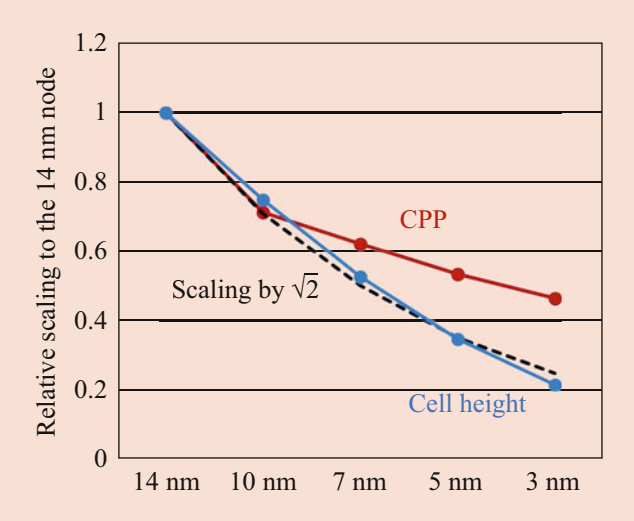

Fig. 7.7 Scaling trends for the contacted poly pitch (CPP) and cell height as referenced to the 14 nm technology node

of the parasitic overlap capacitances. This can be improved by changing the spacer material from nitride ($k \sim 7.2$) to low-k materials like silicon oxycarbide (SiCO) and airgap or partial airgap spacers ($k < 4$). This is again not without challenges both in integration (material conformality, etch selectivity, robustness to cleans, etc.) and at reliability level. Significant reduction of the contact area has led to contact resistance requirements well below 1×10^{-9} Ωcm^2 [11]. This can be achieved by increasing the active doping level in the semiconductor on the one hand (in situ P-doped Si for nMOS and B- and/or Ga-doped SiGe for pMOS) and, on the other hand, choosing the proper contact material. For the latter, direct contacting using Ti is used. While typically no silicidation anneal is performed at contact level, a TiSi alloy is by definition formed at the interface during subsequent processing.

It was reported that in the case of highly n-type doped Si, the contact resistivity tends to saturate at ~2e–10 Ωcm^2 [12], and the electron injection becomes independent of the barrier height between the semiconductor and metal. It is primarily limited by the intrinsic transmission probability of electrons being injected from the metal into the semiconductor, which depends on the Fermi level of the metal and the effective masses of both the semiconductor and the metal, favoring metals with a high effective mass.

Figure 7.8 shows the performance improvement over several technology nodes. While clear performance improvement of more than 20% at constant power could be achieved down to the 5 nm node, the performance increase at the 3 nm node hardly reaches 5–10%. In the best case, a 2-fin transistor was assumed with 30 nm fin height, which offers this power-performance improvement at the cost of larger area (5.5T cell height vs. 4.5T cell height in the case of a 1-fin scenario). The other option with a 1-fin transistor with 50 nm fin height allows for further area scaling but at the expense of lower drive current. At the 3 nm technology node, it is not straightforward anymore to achieve both area scaling and power-performance improvement with the FinFET device architecture. Therefore, there is a lot of interest to look at gate-all-around devices to improve these trade-offs.

7.3 Gate-All-Around Devices: The Evolutionary Path from FinFET

While industry will continue to scale the FinFET architecture further, with a clear trend toward higher aspect ratio for the fin and overall standard cell scaling by reducing the cell track height, likely new device architectures will be needed to keep the subthreshold swing and thus leakage under control for the 3 nm technology node and beyond. In that respect, lateral nanowires (in general called gate-all-around (GAA) devices) have emerged as possible successors of the FinFET device architecture, offering improvement in both power consumption and performance over FinFET at extremely scaled dimensions. Figure 7.9 shows a simulation study comparing the subthreshold swing SS_{SAT} in saturation ($V_{DD} = 0.7$ V) for FinFET devices with different fin widths. As the gate length for the 3 nm technology node will need to be scaled down to 14–15 nm, control of the subthreshold swing ($SS_{SAT} < 75$ mV/dec) becomes challenging, driving the required fin width down to 5 nm. Moving to nanowire devices at 14 nm L_G, however, allows to reduce the SS_{SAT} further and to use more relaxed dimensions as compared to the FinFET case. This is interesting as degraded mobility has been reported for ultra-scaled device dimensions [13]. Next to that, vertical stacking of several nanowires is considered as a way to increase drivability without impacting the active footprint.

These devices can be seen as an evolutionary step from FinFET, having many modules and the overall integration scheme in common as shown in Fig. 7.10. The main differences are related to the starting channel stack, consisting of a multi-stack of thin Si/SiGe layers and the selective removal of either SiGe or Si at the replacement metal gate (RMG) module to form Si or SiGe wires [15, 16]. Process innovations like reduction of the shallow trench isolation (STI) thermal budget and introduction of a SiN liner in the STI module are key to improve the shape controllability and the electrical performance of the devices.

Recent publications have also shown that possible variations of the GAA architecture like nanosheets where elongated thin film slabs (Fig. 7.11) are stacked on top of each other can be very interesting options to keep both electrostatics under control and increase current drivability [17]. Nanosheet devices offer higher W_{eff} per

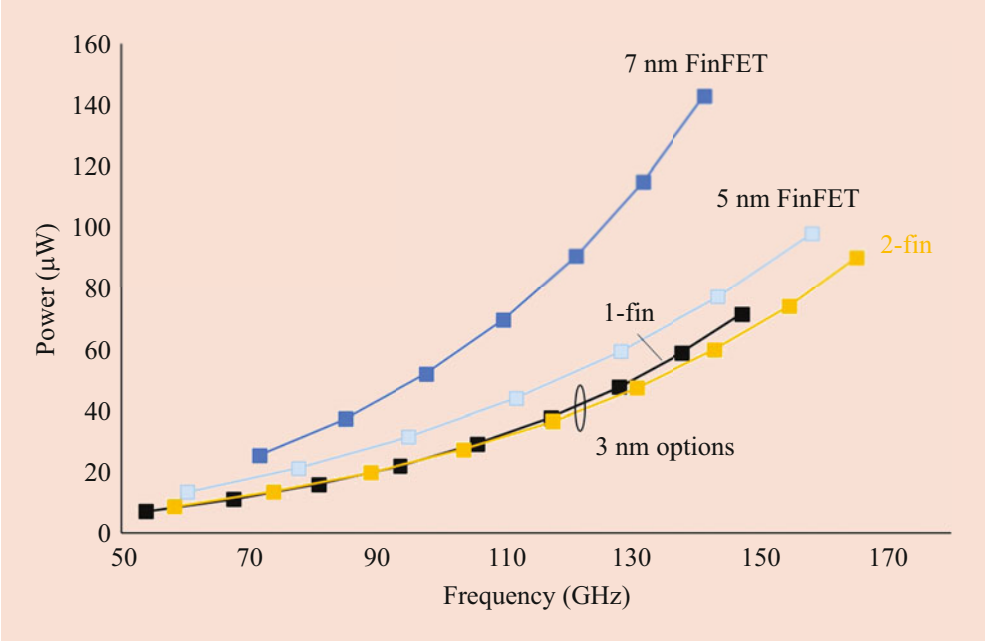

Fig. 7.8 Power versus performance comparing different FinFET technology nodes; the different points represent sweeps at different V_{DD} conditions (starting from $V_{DD} = 0.5$ V, in steps of 50 mV); the 7 nm and 5 nm FinFET devices have two fins

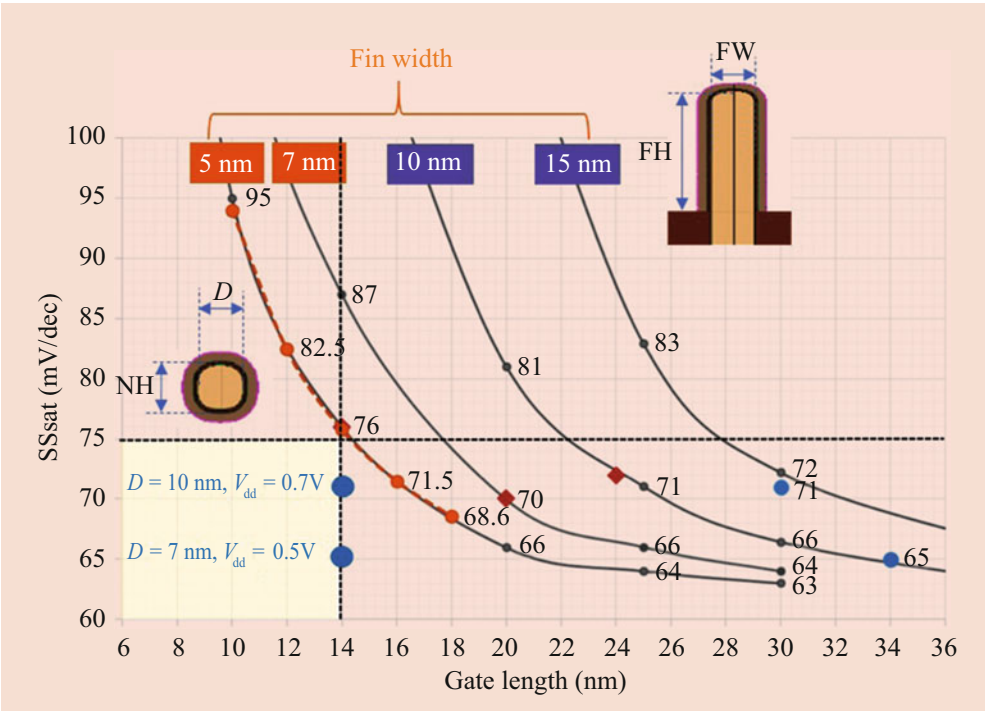

Fig. 7.9 SS at $V_{DD} = 0.7$ V as function of gate length comparing FinFET and GAA or nanowire (NW) devices; especially at shorter gate lengths, the GAA structure outperforms FinFET enabling reduced subthreshold swings; FH fin height, NH nanowire height, D diameter. (©2017 IEEE, reprinted with permission from Ref. [14])

given footprint with a less complex patterning strategy as compared to FinFET where double and quadruple patterning are required to achieve the fin width (~5 nm) and fin pitch FP requirements (~21 nm) for a 3 nm technology. One of the concerns with nanosheets is the possible degradation in electrostatics, but in [17], good short channel control was shown down to $L_G = 12$ nm at a CPP of 44/48 nm. Next to that, higher W_{eff} implies a higher parasitic capacitance, and impact on the dynamic power needs to be considered.

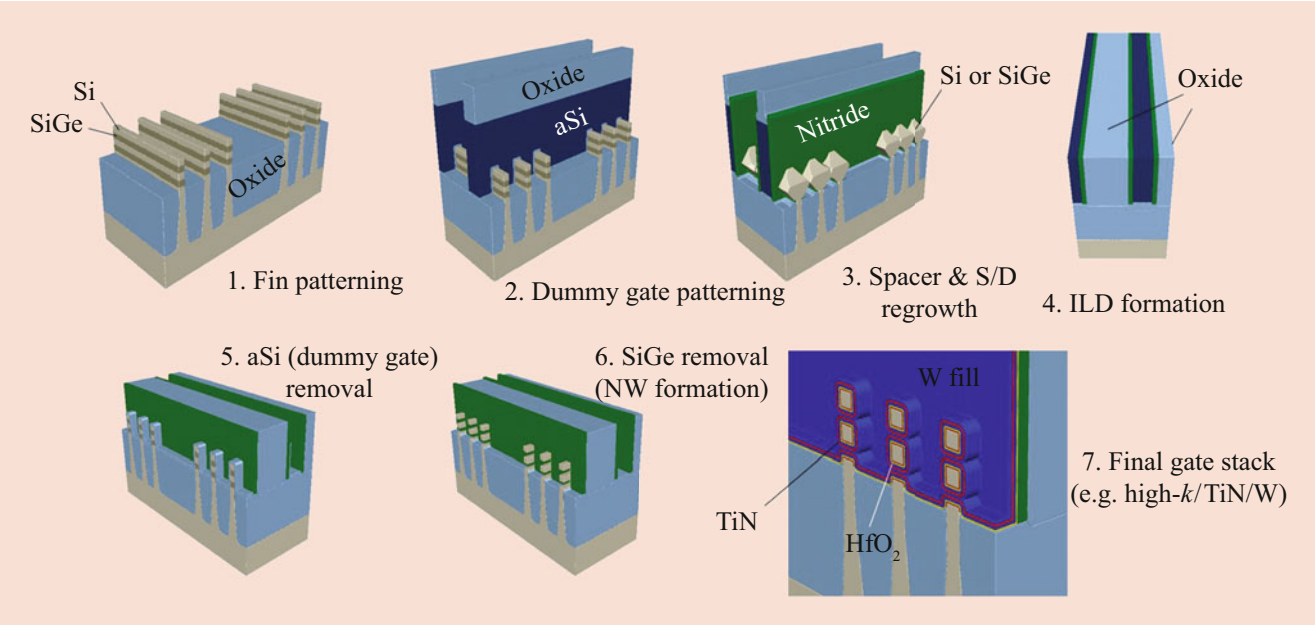

Fig. 7.10 Schematic presentation of the gate-all-around flow, which is based on a typical replacement metal gate (RMG) FinFET flow; the flow is shown up to RMG; starting with fin patterning, dummy gate patterning, spacer formation and S/D regrowth, interlayer dielectric (ILD) deposition and CMP, dummy gate removal, SiGe removal, and final gate stack formation. (©2017 IEEE, reprinted with permission from Ref. [14])

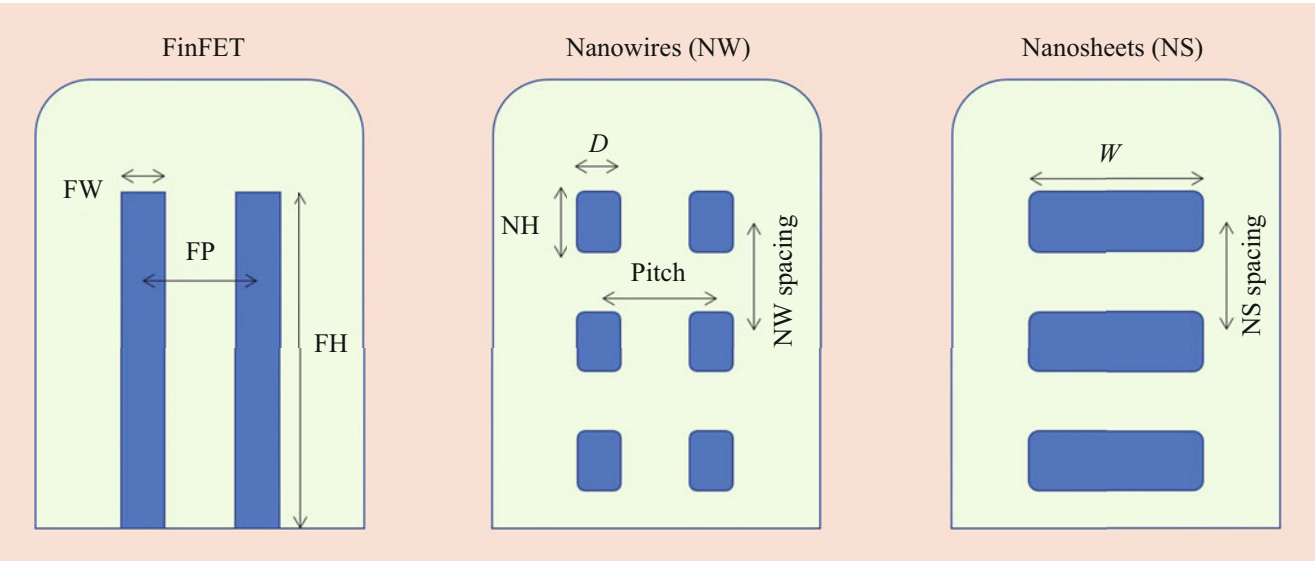

Fig. 7.11 Schematic presentation of FinFET device, a nanowire, and nanosheet device, indicating the most relevant geometrical parameters

In [18], a study is presented looking at the feasibility of 4.5T standard cells using nanosheet devices. The cell layout and parasitics set quite stringent requirements on the nanosheet geometry limiting the design space. Best performance and trade-off were achieved with three sheets with a 21 nm width and tight vertical pitch between the sheets (<14 nm). In that case, the nanosheet 4.5T cell outperforms the 5.5T (2-fin) and 4.5T (1-fin) FinFET cells but needs careful optimization of the intra-cell and inter-cell connections. The devices are most efficient with low fan-out and reduced wire length.

Further improvements come again from device scaling boosters like contact resistivity reduction down to 0.5e–9 Ωcm^2, the use of low-k spacers, and strain engineering (e.g., use of strain relaxed buffers (SRB) and SiGe channel for pMOS). Different from FinFET, the additional complexity

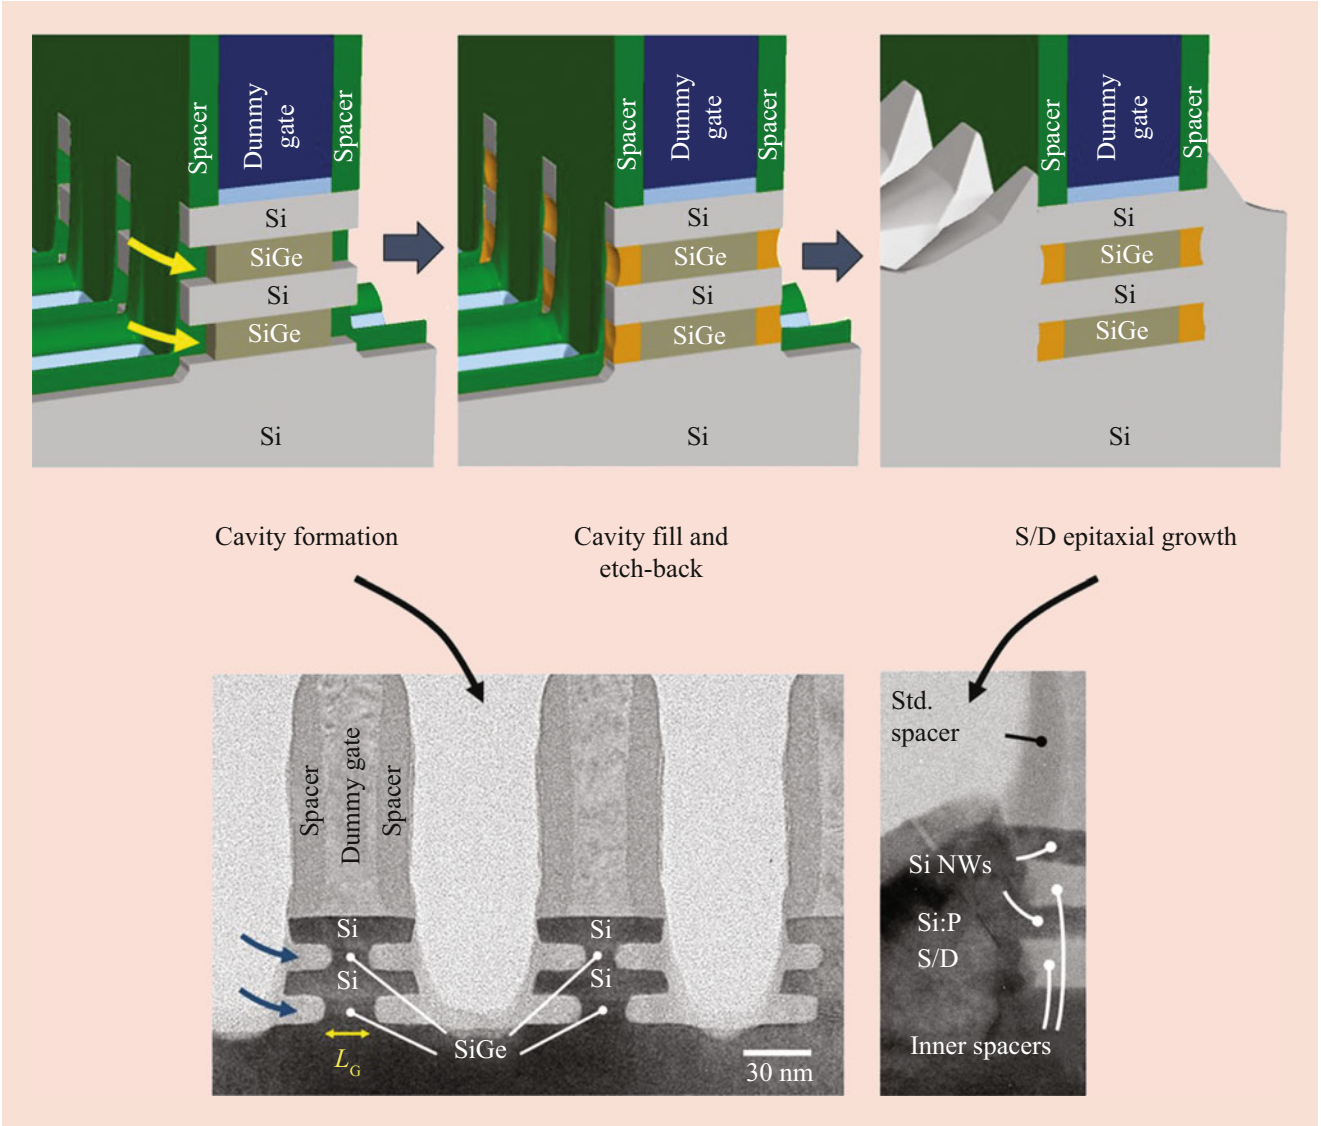

Fig. 7.12 Schematic presentation of the internal spacer formation (in orange) and transmission electron microscopy (TEM) pictures after cavity formation and S/D regrowth. (©2017 IEEE, reprinted with permission from Ref. [20])

for GAA devices in general lies in the use of internal spacers [19, 20] to reduce the parasitic capacitance and improve the ring-oscillator performance. There are several ways of introducing this internal spacer. The most attractive process scheme introduces, after source/drain (S/D) etch-back, a cavity by selectively etching the SiGe dummy layers, still present at that point in the flow, then filling the cavity with the spacer material and etching it back, and finally growing the source and drain areas (P-doped Si in the case of nMOS; B-doped SiGe in the case of pMOS) (Fig. 7.12).

In [19], it is also shown that the use of S/D stressors like SiGe for pMOS can still introduce a significant amount of strain in the nanowire channels. This has also been confirmed in [21] for Ge nanowire devices fabricated on a 70% SiGe SRB. While the Ge wire is relaxed after S/D etch-back, the Ge S/D regrowth on the SRB recovers the strain, and it has also been confirmed that the strain is maintained after wire release and gate stack formation.

Figure 7.13 shows the power-performance trade-off for the different FinFET technology nodes again. In this case, the 3 nm option with nanosheet devices ($W = 21$ nm, 4.5T) has been added. The latter option delivers the best power-performance at reduced area, meeting the requirements for the 3 nm technology node. While on paper this seems the most feasible route to continue scaling, it will require the introduction of all possible device boosters like low-k spacers (incl. internal spacers), contact resistivity below 1×10^{-9} Ωcm^2, S/D strain engineering, and innovations in local interconnects like the introduction of Co or Ru replacing the typical tungsten-based interconnects [10],

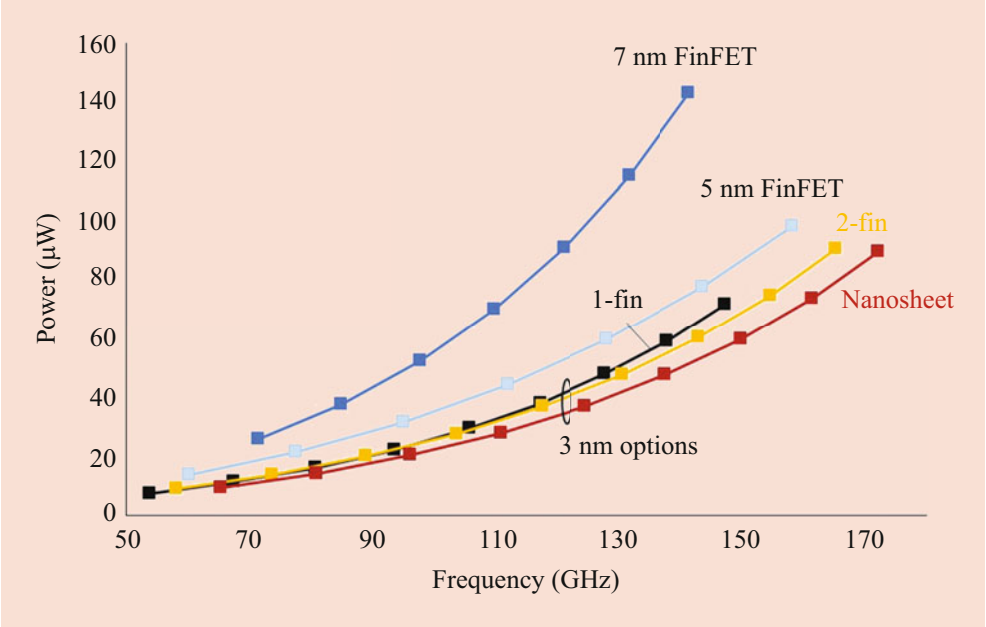

Fig. 7.13 Power versus performance comparing the different FinFET technology nodes and a nanosheet case (4.5T) for the 3 nm technology node; the different points represent sweeps at different V_{DD} conditions (starting from $V_{DD} = 0.5$ V, in steps of 50 mV); the 7 nm and 5 nm FinFET devices have two fins

going hand-in-hand with cell scaling boosters like buried rail and gate over active contact. Next to that, optimizations at the process module level are needed to further improve the shape controllability by modification of the STI, patterning of the multi-stack (Si/SiGe and increased aspect ratio), and improved etch selectivity at the wire release. Furthermore, conformal gate stack solutions that address the tight vertical pitch between the sheets for V_T setting and tuning will be needed. Reducing the vertical pitch means that less area is available to put the high-k dielectrics and the work-function metal layers, and this issue is even more problematic for vertically stacked GAA devices as compared to FinFET [16].

Alternatively, vertical devices are being considered. Vertical transistors (VFET) allow to form GAA structures and truly make use of the third dimension. They have been already successfully introduced for memory applications cfr. 3D NAND. What is quite interesting is that for these devices, the gate length can be decoupled from the CPP and, in principle, this allows further increase of the density. However, challenges in connectivity show that mostly regular designs like SRAM [22] could benefit from the vertical architecture, especially when several layers of VFET devices can be stacked (Fig. 7.14). Overall challenges for VFET are related to the disruptive integration, connectivity, and reduced current drivability due to problems related to the alignment of the gate to the source and drain areas [23] and also contacting of the source and drain, which make them in effect asymmetric devices. So far this architecture is not considered as a possible option to continue CMOS scaling, but needs to be seen rather in the context of heterogeneous integration where one could consider a VFET SRAM co-integrated with FinFET or GAA devices for the enablement of the standard cells (random logic). This can be done using 3D stacking or even co-integrated in the same plane/substrate.

7.4 High-Mobility Materials

New materials in which carriers can travel at much higher velocity than silicon can be solutions to the power density and switching speed dilemma. They allow to reduce the power supply voltage without impacting the device performance and as such would lead to a better power-performance trade-off. However, to be economically viable, these new materials should be introduced on a Si platform, and more specifically, they will need to be compatible with a FinFET or GAA-based technology. Figure 7.15 shows the bulk hole and electron mobility of different semiconductor materials as function of the material bandgap.

III–V materials like InSb, InAs, InP, and GaAs typically have high bulk electron mobilities, while the highest hole mobility can be achieved in Ge. Therefore, research during the last decade was focused on the use of InGaAs materials for nMOS and Ge for pMOS. Ge can also be considered for nMOS, thereby allowing a full Ge CMOS solution [24]. However, gate stack [25] and junction/contact engineering [26] have been identified as the major roadblocks for Ge nMOS, and overall literature shows that Ge n-FinFET is a

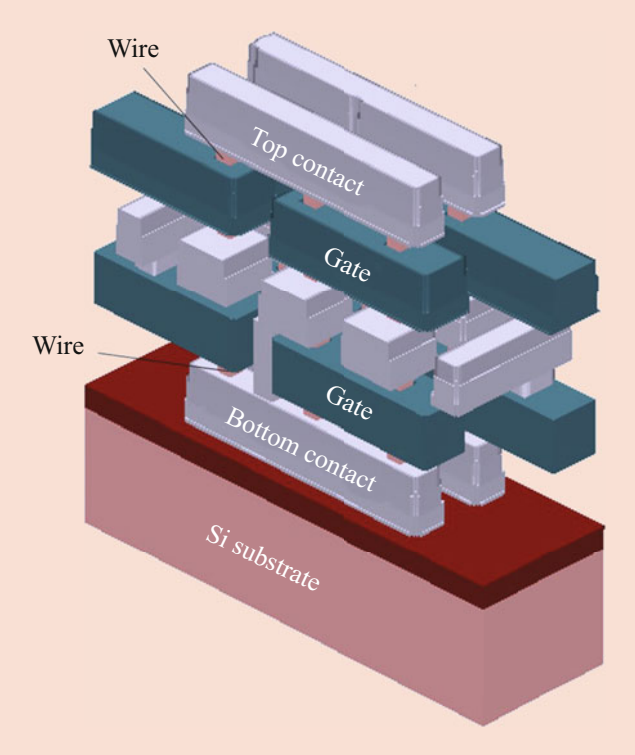

Fig. 7.14 Schematic view of an SRAM using two layers of stacked vertical devices

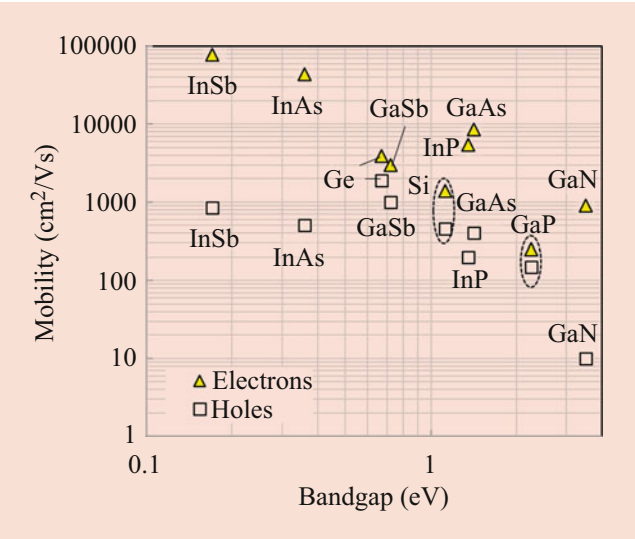

Fig. 7.15 Electron and hole mobility as function of bandgap for different semiconductor materials

rather weak device [27], for now unable to compete with strained Si. Next to the higher mobility and injection velocity, these materials, especially the III–V compound semiconductors, are interesting for the design of heterostructures. These heterostructures allow to fabricate quantum well (QW) devices with increased electrostatic control and more complex architectures like tunnel FET (TFETs) [28].

While high mobility is basically an indicator of high on-state current, the material bandgap shows how far the supply voltage can be scaled down. High bandgap materials typically need a high gate voltage (and thus V_T) to switch the transistor on, and as such, this does not allow reducing the supply voltage V_{DD}. On the other hand, low bandgap materials suffer from high off-state leakage currents as both band-to-band tunneling (BTBT) currents and thermionic emission currents are increased [29]. As such, trade-offs will be needed, and different technology flavors will require different channel materials. High-mobility channels are usually considered for high-performance (HP) applications, while Si devices will be required for low power, thereby highlighting the need for integration on a Si-based platform.

The major challenge related to the integration of these high-mobility materials is the large lattice mismatch (4% for Ge, 8% in the case of $In_{0.53}Ga_{0.47}As$), which introduces a large number of defects in the semiconductor layers. Typically wafer-scale hetero-epitaxy relies on the growth of thick metamorphic buffer layers [30] to achieve lowly defective channel layers, which is expensive and often complicates the integration of different materials on the same wafer. Patterned selective area growth (SAG) is a more appealing route to provide a direct and potentially more flexible means to integrate disparate materials. One such technique is the well-known aspect ratio trapping (ART) method [31], which relies on trapping of defects at the bottom of a high aspect ratio trench. However, reduction of defects along the trench still requires careful optimization of the epitaxial process, e.g., it was found (Fig. 7.16) that the starting Si interface in the trench (e.g., (111) V-groove) and the shape/roughness of the trench profile play an important role in achieving very low defective SAG [32], which was demonstrated for both III–V and Ge. Further reduction of the defectivity has been shown by combining defect trapping and epitaxial lateral overgrowth. In [33], the use of the latter approach, called nano-ridges, has also been successfully demonstrated for the integration of III–V lasers for photonics applications (Fig. 7.17).

Finally, III–V GAA [34] and Ge GAA [21, 35] devices have been demonstrated using either the buffer or the SAG approach (Fig. 7.18). The formation of high-mobility GAA devices, just like in the case of Si GAA devices, relies on the epitaxial growth of a multi-stack of a sacrificial layer and the final channel material. In the case of InGaAs, the sacrificial material is InP that can be selectively removed to InGaAs at the RMG level by HCl. For Ge GAA, SiGe (Ge concentration >50%) is used, but different from Si, the challenge lies in finding a chemistry that can remove the SiGe layer selective to Ge. In [35], a clear improvement in electrostatics for the Ge GAA devices has been shown over Ge FinFET. In the case of III–V, GAA structures allow to leave the channel n-type, thereby forming a junction-less device where the leakage

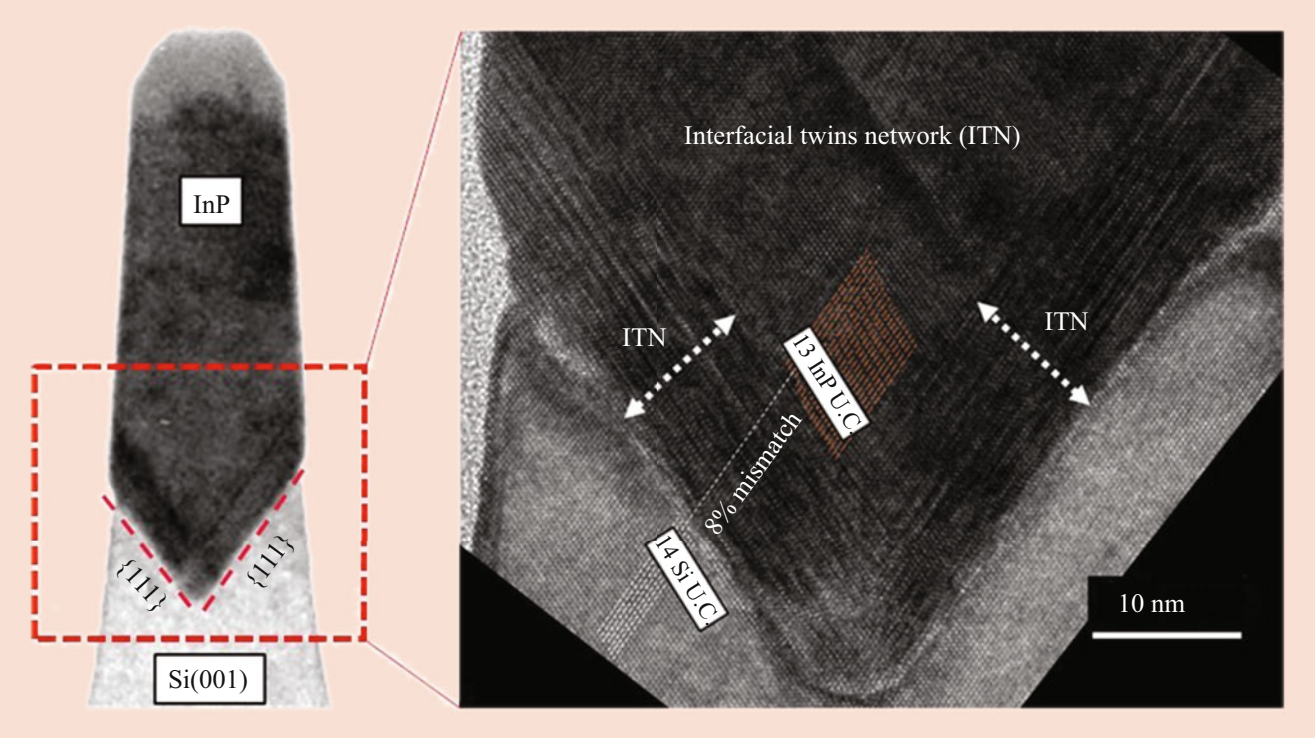

Fig. 7.16 TEM picture of the InP/Si interface where the InP has been selectively grown in the trench; a 10 nm interfacial twin network (ITN) is visible at the interface with the Si accounting for the 8% mismatch between the two materials [32]

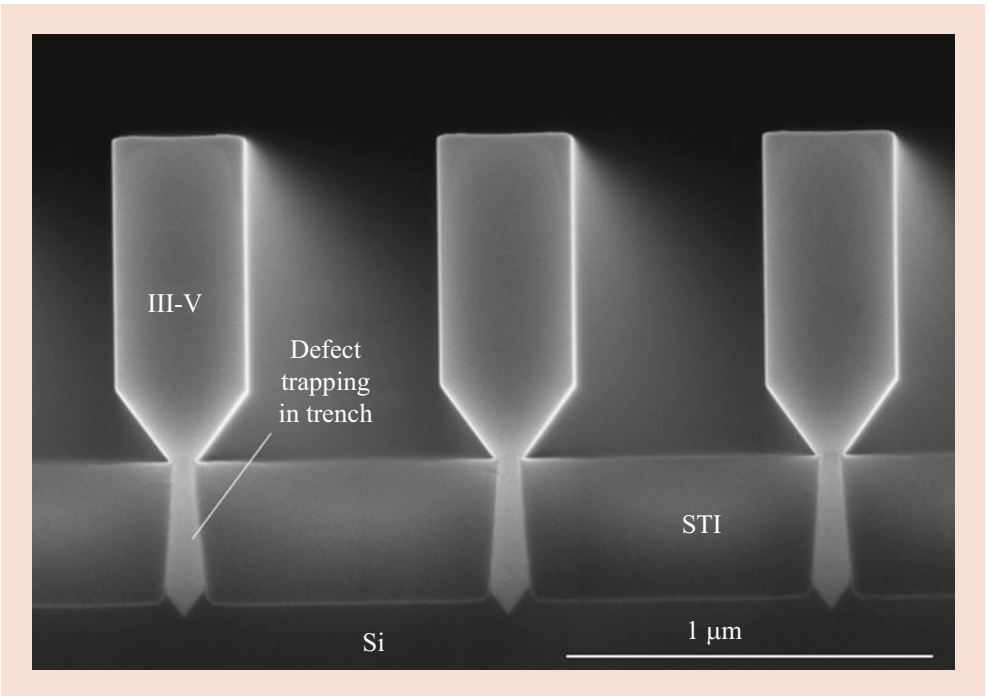

Fig. 7.17 SEM picture of the III–V nano-ridges grown on a 300 mm Si substrate; for this technology, the optimization of the growth conditions and the exploitation of the difference in growth rate on the different facets play an important role

can be suppressed. This cannot be achieved in a FinFET, even in an InGaAs/InP quantum well structure where the conduction band offset ΔE_c between the different materials allows to confine the carriers in the channel. Simulations have

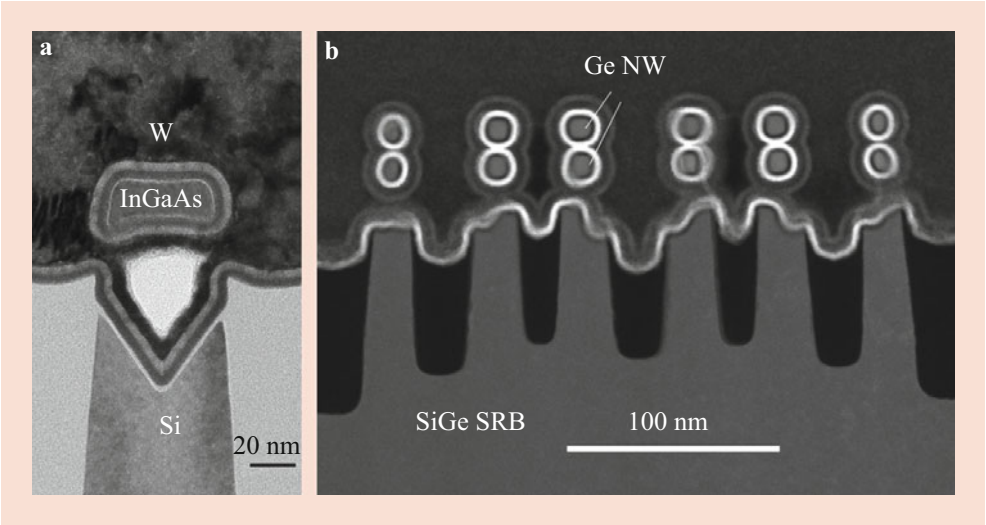

Fig. 7.18 TEM picture of III–V nanosheet devices (**a**) [34] and high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) of a vertically stacked Ge GAA device (**b**) [21]

shown that the 260 meV conduction band offset is not enough to fully suppress the leakage path, especially when the InP cannot be highly p-type doped, and that a combination of InGaAs with InAlAs is more beneficial ($\Delta E_c \sim 460$ meV). The latter material, however, poses many challenges in epitaxial growth, related to both the quality of the material and selectivity.

The difficulty in InGaAs is achieving a p-type doping in the channel to fabricate an nMOS device. Dopants like Zn and Be either are not compatible with front-end-of-line (FEOL) processing or are toxic, while Mg is a good candidate but requires a high number of dopants to be incorporated which deteriorates the quality of the material and the mobility of the devices [36].

Just as the case for Si devices, device scaling boosters like low-k spacers and contact resistivity reduction will need to be introduced to achieve the targets for the 3 nm technology node and beyond. For Ge pMOS, Ga-doped source/drain are quite interesting as about one order of magnitude higher dopant activation can be achieved over B-doped Ge. Even more interesting is that this can be achieved at low temperatures (~400 °C), thereby limiting the diffusion and being fully compatible with the low-T processing required for Ge [37]. Lowering the contact resistivity in InGaAs is more complicated. Only few data points show resistivity values below 1×10^{-8} Ω.cm^2 [38, 39] using InAs as contact material rather than InGaAs because of the Fermi level position in the conduction band. Most metal organic chemical vapor deposition (MOCVD)-grown InGaAs materials suffer from low dopant activation levels ($\sim 5 \times 10^{19}$ cm^{-3}), thereby limiting the contact resistivity levels to $\sim 5 \times 10^{-8}$ Ω.cm^2.

Another challenge related to high-mobility materials is the passivation of the Ge or III–V/high-κ interface which is much more challenging than for Si. Interface engineering and reduction of trapping in the gate dielectric are key to realize a reliable and scaled gate stack. In the case of Ge, the use of Si cap passivation has been very successful in improving the bias temperature instability (BTI) performance [40]. This can be attributed to the fact that only a part or small amount of the oxide traps in the high-κ layer is accessible by the carriers in the channel in the case of relaxed and strained Ge channels as compared to Si. For InGaAs, a large defect peak is observed close to the valence band edge, and a smaller peak exists at mid gap [41]. This can lead to degradation of the subthreshold swing and higher off-state leakage, while Fermi-level pinning in the conduction band severely degrades the on-state performance of the devices. Moreover, the interaction of the carriers with fast border traps or near interface traps can lead to frequency dispersion in both the CV and the MOSFET transconductance curves, leading to significant hysteresis. Recently [42], much progress has been made to find a scalable and reliable gate stack on InGaAs. The solution lies in finding a suitable (low defective) interfacial layer (IL) which reduces the interface traps (D_{IT}) and thus improves mobility, and dipole engineering, by, e.g., using $LaSiO_x$, which allows to decouple the channel carriers from the defects in the HfO_2 layer, thereby significantly improving the BTI behavior.

While much progress has been made in integrating III–V materials on Si in the last decade, there is more and more a consensus that these materials are more suited for particular applications like RF and photonics rather than replacing the channel material in ultra-scaled CMOS technologies. A DTCO assessment shows that while these devices are able to outperform strained Si at relaxed dimensions and reduced V_{DD}, when aggressively scaled down, the advantage becomes

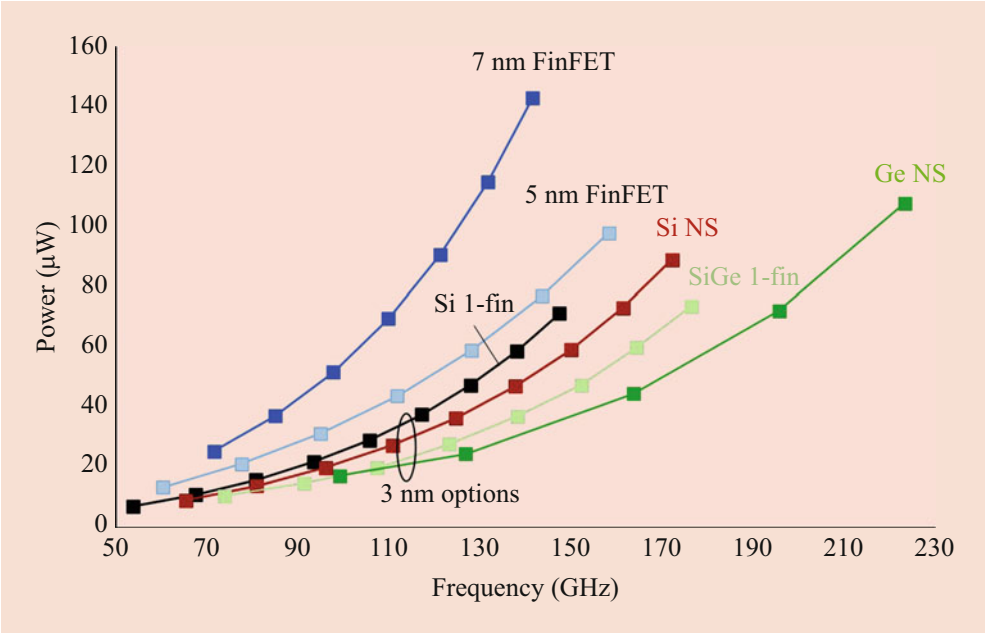

Fig. 7.19 Power versus performance (of a ring oscillator) comparing Si FinFET and Si nanosheets for the 3 nm technology node to a full Ge CMOS nanosheet case and a 1-fin Si/SiGe combination on SRB; the different points represent sweeps at different V_{DD} conditions (starting from $V_{DD} = 0.5$ V, in steps of 50 mV)

less obvious. Moreover, being able to decrease the contact resistivity below 5×10^{-9} Ω.cm^2 and to lower the trap level in the gate stack and the bulk material are key requirements for the comparable performance to Si.

The story for Ge is slightly different. Assuming that a full Ge CMOS solution is possible, 50% higher on-current can be achieved as compared to Si, especially in a GAA structure integrated on a SiGe SRB [43]. Especially the use of Ge nanosheets is interesting and allows even to relax the contact resistivity requirements over Si nanosheet devices. However, the major roadblock for Ge devices remains its high leakage current due to its low bandgap and the enablement of a well-performing nMOS device. The former implies that Ge devices need to be co-integrated with Si devices to enable the low-power device flavors. This can be done by either monolithic integration in the same plane or, even more interesting, using a 3D integration scheme like sequential 3D where the low-T Ge processing is favorable for putting the Ge devices in the top tier.

Alternatively, SiGe has been considered as a pMOS channel material [44]. The higher bandgap allows to target low-power applications while improving mobility and even more importantly the possibility to shift the V_T, enabling a single work function (WF) approach for both Si nMOS and SiGe pMOS and improving the BTI performance [45]. When integrated on a SiGe SRB, a combination of tensile strained Si for nMOS and compressively strained SiGe is possible when the Ge concentration of the pMOS SiGe is higher than the Ge concentration of the SRB [46]. Figure 7.19 shows that the Si and SiGe FinFET devices (on SRB) show better power-performance than Si FinFET. Similar to Ge, the fabrication of a scalable gate stack with low defectivity is, besides the integration of SiGe on a Si platform, one of the key challenges for the introduction of SiGe channels.

7.5 Going 3D: CFET and Sequential 3D Integration

7.5.1 Complementary FET or CFET

One way to continue area scaling is the use of 3D integration. There are different ways of 3D integration: complementary FET (CFET), sequential 3D, through-silicon via (TSV), wafer-to-wafer (W2W) bonding, die-to-wafer (D2W) bonding, or die-to-die (D2D) bonding.

The latter four approaches rely on parallel processing of the different wafers or dies which can contain different devices and technologies and address different functionalities of the system. The density of the interconnections is in these cases not very high and typically allows to connect only at block or (sub)system level. CFET and sequential 3D, however, allow to connect transistors and standard cells over different tiers. However, this comes at the cost of integration complexity.

The CFET is stacking of either nMOS on top of pMOS or vice versa using an integration flow based on GAA integration or even sequential 3D integration (Fig. 7.20). DTCO

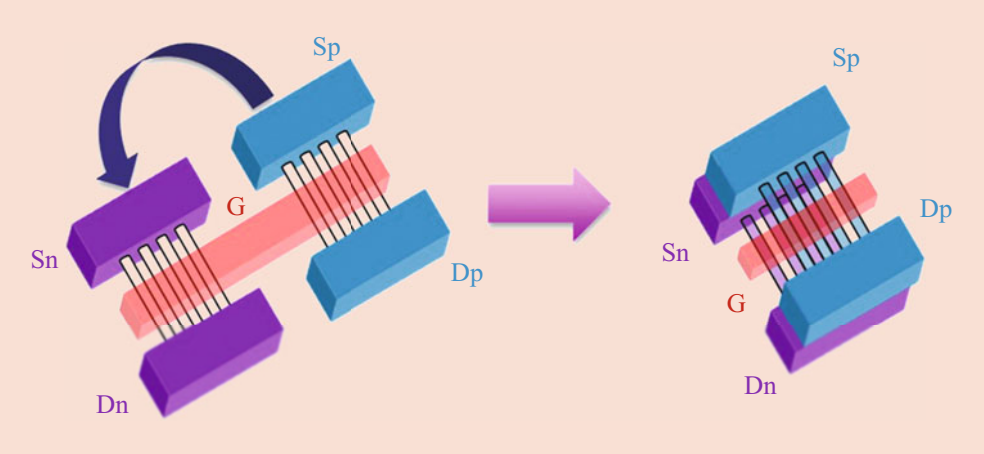

Fig. 7.20 Schematic representation of a CFET device; basically, the nMOS and pMOS devices using a common gate are folded on top of each other; Sp and Sn represent the pMOS and nMOS source, respectively, and Dp and Dn the drain of the pMOS and nMOS, while the gate is common

assessment of this approach has shown a 50% area improvement for both standard cells and SRAM [47], and TCAD simulation predicts that this approach can outperform FinFET and meet the 3 nm technology requirements for speed and power. The area gain is not primarily given by simply stacking the devices but in the first instance by the simplification of the terminals. The complementary nature of CMOS requires pull-up and pull-down networks controlled by common input gates, which the CFET structure uses in its advantage.

The CFET flow can follow a GAA integration flow up to the S/D contact. To separate the top device from the bottom device, the top structure needs to be sealed during S/D growth and bottom contacting. In subsequent processing, the same needs to be done for the top device, while the bottom device is covered with a dielectric layer.

The approach allows to combine different architectures for nMOS and pMOS, e.g., a bulk FinFET bottom pMOS with a GAA top nMOS or a nanosheet top device with a bottom nanosheet device when fabricated on a silicon-on-insulator (SOI) substrate. The top device, however, will always be in essence a GAA structure (nanowire, horizontal or vertical nanosheet).

While the CFET structure brings obvious gains in density scaling and has the potential to improve power and performance, the challenges lie in optimization of the deep vias, highlighting the need for advanced middle-of-line (MOL) integration schemes using, e.g., Ru as an interconnect metal.

7.5.2 Sequential 3D Integration

Sequential 3D integration [48] involves the vertical integration of sequentially processed device layers as shown in Fig. 7.21. After the processing of the bottom-tier devices, the substrate layer for the second tier is transferred, and the process flow continues with the processing of the second-tier devices. Different from the other 3D technologies, where the different tiers are processed in parallel, this integration allows for fine alignment of the top-tier devices to the bottom tier using advanced lithography. As such, a higher density of interconnects can be achieved between the different tiers.

This integration scheme comes in three different flavors. Firstly, in transistor-level stacking (T-S3D), the CMOS level is split into different tiers of pMOS and nMOS. In principle, this is an alternative way of fabricating CFET. The two tiers can be Si devices or use different channel materials. This is especially interesting when one wants to combine, e.g., Ge pMOS devices with Si nMOS devices, materials that have different thermal budget needs. Secondly, in CMOS-level stacking (C-S3D), the 2D standard cells are placed in the different tiers. This means that both tiers require CMOS processing. And thirdly, the partitioning can be done at block level to separate different functional blocks in different tiers, e.g., digital logic and analog and I/O devices or memory blocks and logic. This is referred to as hybrid (or heterogeneous) stacking (H-S3D) where apart from CMOS devices, different flavors of technologies can be combined.

The benefits of the three different flavors of the sequential 3D integration technology have been analyzed through a power-performance-area-cost assessment at 5 nm and 3 nm technology nodes [50, 51] and compared to the respective standard 2D cases where the devices are processed in the same plane. For the hybrid case (H-S3D), the logic and memory part were scaled to the 3 nm node in the bottom tier, and the remaining part (analog and I/O) was assumed to be manufactured in an older 28 nm technology node and put in the top tier. For this particular case, the non-scalable analog and I/O part takes up 30% of the overall circuit area.

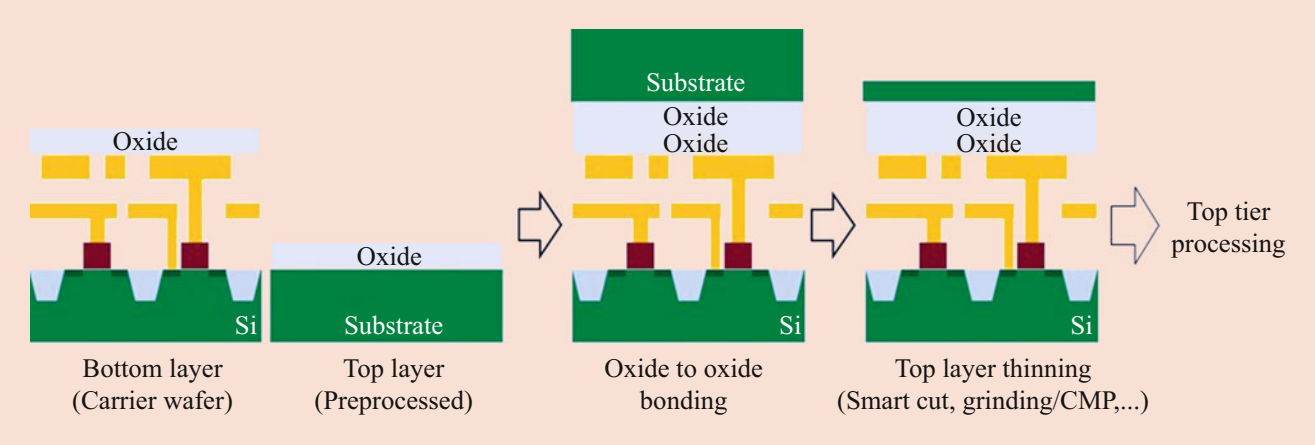

Fig. 7.21 Schematic presentation of sequential 3D processing; in this case, the Si layer for the second tier is transferred using bonding and substrate removal. (©2017 IEEE, reprinted with permission from Ref. [49])

For the T-S3D and the C-S3D cases, little to no cost reduction is obtained compared to the traditional 2D 5 nm and 3 nm implementations (Fig. 7.22). This is mainly due to extra process steps, such as the layer transfer, that significantly add to the cost. Also, depending on the implementation, some of the modules need to be processed twice (e.g., active area patterning, gate patterning, etc.), and this considerably adds to the processing cost of the dies. Next to that, a 50% area shrink is not straightforward to achieve. There is a fundamental limit to the minimum number of tracks needed to enable the cell: at least three to four tracks are required in order to interconnect the transistors (drain/source and gate/gate) and deliver power to the devices. As a consequence, a 50% area gain cannot be achieved for the T-S3D and C-S3D flavors.

Next to possible benefits in area and cost, reduction in RC delay is often seen as one of the advantages of sequential 3D integration. It is expected that stacking of the transistors or cells can relax the cross section of the wires, to some extent. The cell-level S3D case indeed turns out to be beneficial in terms of RC delay, but the results are very much dependent on the process assumptions. When the top tier is as performant as the bottom tier, and the metallization between the two tiers is Cu-based, a 25% reduction in RC delay is expected for the S3D case compared with a 2D implementation. However, due to thermal budget constraints, the performance of the bottom-tier metallization might be degraded as compared to the top tier, especially when Cu cannot be used, and in this case, the reduction in RC delay might be only 15% or even less.

The results of the previously described analysis very much depend on the process assumptions and the technology nodes considered. In [50], the devices are advanced FinFET technologies and mainly FEOL dominated, i.e., heavily dependent on the parasitics in the front-end. With further scaling, devices might become more BEOL dominated, having an increasingly larger RC delay. In this case, due to the gains in RC delay, even for the non-ideal case, the sequential 3D integration at transistor level and cell level might turn out more beneficial over the 2D cases.

T-S3D and C-S3D still are targeted toward overall CMOS scaling. However, applications like 5G, Internet-of-Things (IoT), machine learning (ML), and the increasing demand for data storage will require the enablement of systems with a variety of functionalities. The concept "one device fits all" is increasingly difficult to maintain. For example, while FinFETs are excellent logic devices, their increased parasitics (e.g., increased gate resistance) make them less suitable for high-speed applications, where planar technologies (bulk and FDSOI) outperform the most advanced FinFET technologies from f_t/f_{max} point of view. Hybrid scaling is gaining increasing interest where different technologies come together, leveraging new materials and devices, to enhance and optimize the overall system. This co-integration can be achieved either on the same substrate or through 3D stacking, where sequential 3D brings added value in realizing fine-grained interconnects. This will require system-technology co-optimization (STCO) where optimization is done across many different levels, from process unit steps and integration up to the application level.

A first example was described in [50], combining a 3 nm bottom tier with a 28 nm top tier (H-S3D). For this case, a 33% reduction in die cost was obtained compared to a 5 nm 2D system-on-chip (SoC) implementation (with a 125 mm^2 die size). In the 2D implementation, all devices of the circuit would be fabricated and optimized in the same advanced technology (e.g., 3 nm FinFET technology). With H-S3D, the analog and I/O part can now be moved to a different tier and fabricated with older technologies. This clearly makes the processing less complex and costly. The same holds for the interconnect schemes. The wiring that interconnects the transistors of the scalable parts can be optimized separately from

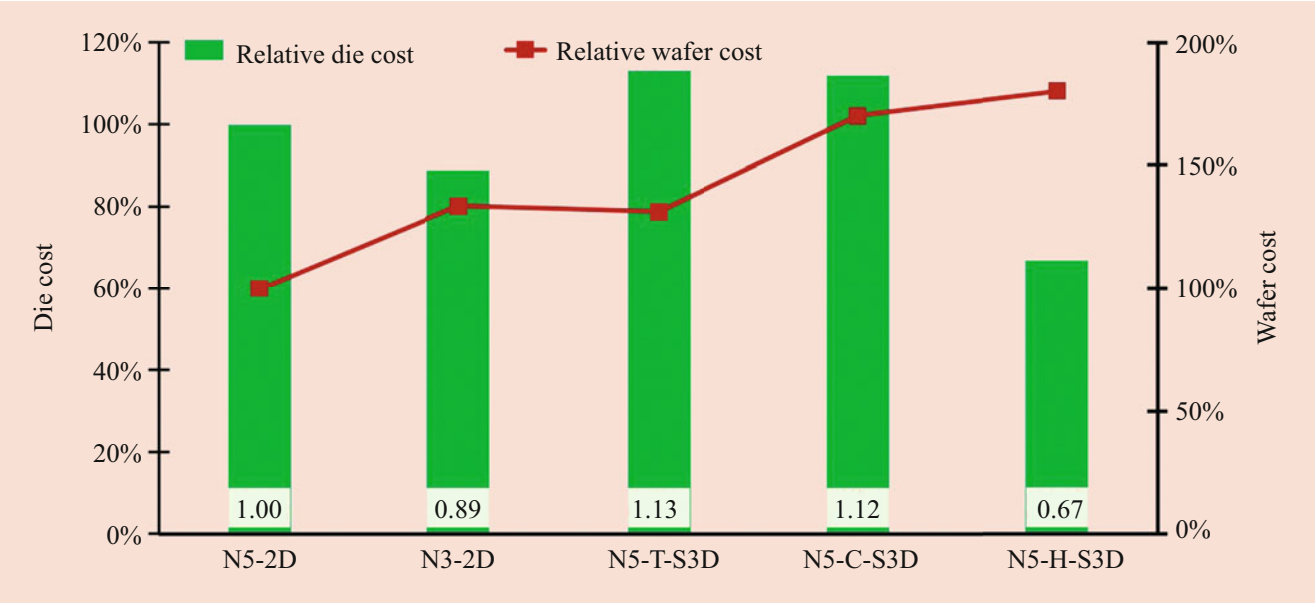

Fig. 7.22 Die cost for different sequential 3D implementations. N5-2D and N3-2D are the 5 nm and 3 nm 2D implementations, respectively; T-S3D, C-S3D, and H-S3D are sequential 3D implementations at transistor, cell, and IP block (hybrid) level, respectively. (©2017 IEEE, reprinted with permission from Ref. [50])

the interconnects of the other tier, and the connection between them can be realized through a regular, dense interconnect scheme, not necessarily in the most advanced technology.

While especially hybrid scaling looks to be an interesting case for sequential 3D integration, there are a number of challenges related to this integration scheme. Layer transfer and the thermal budget constraints are the most pertinent ones. For the layer transfer, approaches based on polycrystalline material deposition and recrystallization or selective epitaxial overgrowth from a seed window have been proposed before in literature. The first approach requires the use of a dedicated ns laser anneal for the recrystallization as the thermal diffusion to the underlying device layer needs to be limited as much as possible. Moreover, the quality of the material after recrystallization is questionable. The selective epitaxial overgrowth approach suffers from limited density, high thermal budget, poor control of thickness, and material defectivity close to the seed windows. The most interesting relies on layer transfer based on wafer-to-wafer bonding (oxide-to-oxide or SiCN-to-SiCN [52]) is an attractive approach. It can be enabled at low temperature (400 °C) and leads to defect-free material with very tight control of the thickness uniformity. As donor wafers, either SOI wafers can be used where the BOX can act as a stopping layer during substrate removal, or a modified SmartCut™ process can be used to transfer only part of the engineered substrate. The latter has the advantage that the donor wafer can be reused several times, making this a more cost-effective process. Stacked planar devices [53] as well as high-density FinFETs [54] have been demonstrated using this bonding approach, as is shown in Fig. 7.23.

The concerns related to thermal budget are twofold: the top-tier device integration needs to avoid high-temperature process steps to reduce possible impact on the bottom-tier devices, while the temperature robustness of the bottom tier needs to be improved to withstand the additional thermal budget coming from the top tier. The process steps with the highest thermal budget for a standard transistor fabrication are typically the anneals (>1000 °C) used for dopant activation, the selective source/drain epitaxial growth (pre-bake ~800 °C and growth ~750 °C) for thin film devices, and, in the case of RMG processing, the dummy a-Si gate deposition (~600–700 °C) and the anneal to improve reliability performance when high-k dielectrics are used (~800–900 °C).

There are a number of integration and device approaches that can be considered to tackle the concerns mentioned above. Junction-less devices have been considered in [53, 54] for the top-tier devices. In this case, the implantation and dopant activation can be done before the layer transfer, while the use of laser anneal, similar to the recrystallization scheme, is a viable alternative to activate the dopants after the layer transfer while limiting the thermal diffusion [55].

Depending on the technology that is envisioned for the bottom- and top-tier devices, there might be a clear concern about the gate stack stability, especially when a gate last process is needed. The issues regarding the gate stack are twofold. For the bottom-tier devices, a thermally stable gate stack is required in order to sustain the total thermal budget

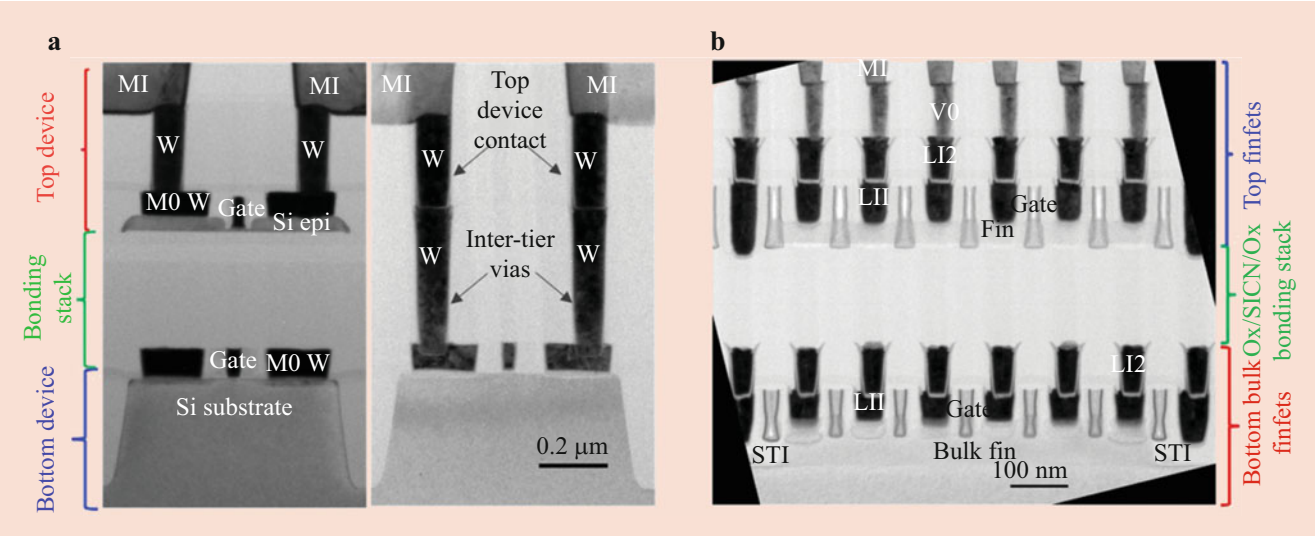

Fig. 7.23 TEM picture of stacked planar devices (**a**), also showing the connections (inter-tier vias) to the bottom tier devices; (**b**), the TEM picture showing the top SOI-based FinFETs stacked on bulk FinFET devices, FP = 45 nm and CPP = 110 nm. (©2018 IEEE, reprinted with permission from Refs. [53, 54])

of the top-tier device processing, which can consist of long anneals at low temperature. The non-ideal thermal budget may lead to shifts of the metal gate work function, metal diffusion in the gate stack, equivalent oxide thickness (EOT) increase, and degraded reliability. The use of proper diffusion barriers is needed to ensure a stable gate stack. In [56], it is shown that when carefully optimized, a limited top-tier thermal budget (in this case 520 °C 2 h) can be as efficient as a dedicated reliability anneal.

For the top-tier devices, low thermal budget processing is required to avoid degrading the bottom devices. But this low-temperature processing typically results in gate stack reliability issues for the top-tier transistor as is shown in Fig. 7.24. When compared to the same high-k/metal gate stack including a reliability anneal, the behavior of the low-temperature gate stacks is much degraded and fails to meet the BTI targets for both nMOS and pMOS.

In [56], two strategies were proposed to improve the reliability performance of the top-tier devices: the use of junction-less devices leads to a lower electric field, thereby reducing the density of charging oxide traps and improving the performance as indicated in Fig. 7.25. This improvement is more pronounced as the doping level in the devices is increased. While there is a clear benefit for device reliability, a trade-off will be needed as the increased doping level leads to reduced mobility and increased variability at the same time. A second approach relates to dipole engineering where a thin layer is introduced between the interfacial SiO_2 and HfO_2 to induce an interfacial dipole which modulates the effective work function and beneficially decouples the high-k defect levels from the channel Fermi level (Fig. 7.26). For nMOS, $LaSiO_x$ is used, while for pMOS, Al_2O_3 can be used. The latter only works in combination with a thin interfacial oxide.

While there are still many challenges ahead to make this a cost-effective integration approach, sequential 3D is gaining more and more attention in the context of heterogeneous integration these days.

7.6 Conclusions

While the industry is moving to the 7 nm and 5 nm technology nodes, the increased pressure on Moore's law is becoming clear. Increased complexity in patterning and process steps, difficulties in scaling of the transistor dimensions, and keeping power dissipation and parasitics under control are the grand challenges that FinFET scaling will be facing in the coming years, moving to 3 nm and beyond. Gate-all-around devices, in the form of either nanowires or nanosheets, can in principle extend the device scaling, but challenges especially in contact resistance and parasitic capacitance reduction will need to be overcome. Replacing the Si channel by higher-mobility materials, especially SiGe and Ge, is at least on paper an interesting scaling booster but addresses only part of the overall system requirements. Ge devices can outperform their Si counterparts but pose a problem for the leakage reduction, where co-integration with Si is a must for the low-power applications. Moreover, to be considered as an interesting option, a full Ge CMOS technology needs to be enabled. Many challenges in gate stack and contact/junction engineering need to be overcome to improve the Ge nMOS device. In that respect, SiGe channel can be seen as a good compromise.

[49, 56]

For long, III–V materials have also been considered as replacement of the Si channel, boosting the performance and allowing further V_{DD} scaling. Today, however, there is a clear consensus that these materials lose a lot of their benefits when scaled down below 10–15 nm, to the extent that these devices, even in the most ideal case, do not outperform Si. Nonetheless, these materials are gaining again a lot of interest in the context of photonic applications (III–V laser integration) and RF applications, addressing several challenges of next generation of mobile communication 5G.

Finally, 3D stacking, with several possible implementations, will be key for heterogeneous integration where scaling will be taken at an even higher level of abstraction. The benefits for standard device scaling are not always so straightforward, and while CFET, largely based on a gate-all-around integration flow, seems an interesting candidate to continue 50% area scaling with clear power-performance improvements, the complexity in enabling the different device connections will need to be closely studied in the coming years.

Abstract

The chapter provides an overview of recent advances in lithography for the production of integrated circuits (ICs). In the first section of the chapter, a brief introduction about lithography basics such as image formation, image resolution in projection systems, and resolution enhancement techniques is provided. In the following section, advanced lithography based on ArF 193 nm deep-UV (DUV) sources is discussed thoroughly, including photoresist requirements and characteristics, plasma etching selectivity, and the multiple patterning techniques commonly adopted for resolution enhancement in these processes. After mentioning some non-optical lithographic methods such as electron beam lithography and nanoimprint lithography, which are mainly employed for mask fabrication or niche applications, a detailed discussion is dedicated to extreme ultraviolet lithography (EUVL), which represents the technology of choice for the future and promises to be able to support a further scaling of ICs' critical size, as required by Moore's law. In particular, the evolution of EUVL laser sources based on Sn plasmas over the years is described, and their role in the diffusion of the technology is discussed. The requirements of EUVL resist are also described along with the role of stochastics, which are especially relevant for this technology because of the lower number of photons involved in resist exposure compared to the former DUV technology. In the end of the chapter, the mechanisms related to EUVL resist development are analyzed, including energy deposition, acid generation, and polymer deprotection.

8.1 Lithography Basics

Moore's law, which defines the path for the development of microelectronics, foresees a continuous shrinking of the minimum feature size of integrated circuits (ICs). Such dimensional scaling has a direct impact on requirements of the photolithographic processes. The advanced lithographic systems used nowadays permit to pattern deep-submicrometric geometries in ultraviolet (UV)-sensitive resist layers after exposure in a projection system and subsequent development of the exposed resist.

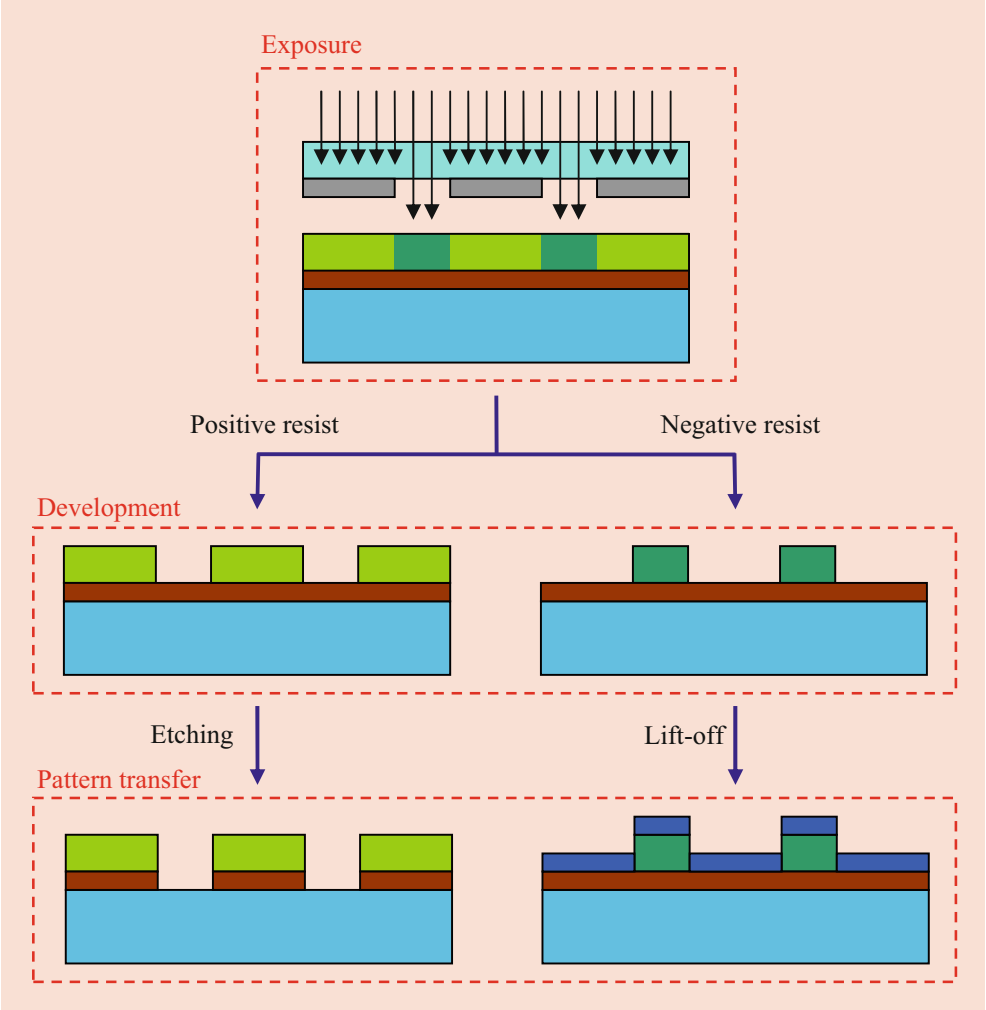

Fig. 8.1 Basic steps of photolithographic patterning procedure

The basic principle of photolithography is simple. A layer of photosensitive material is deposited on the wafer and afterward exposed to light through a patterned optical photomask (or reticle), in which some areas are transparent and other ones opaque. The absorption of light on the exposed parts of the resist layer induces chemical modifications in the material that are exploited to selectively remove exposed (positive resist) or unexposed (negative resist) parts. This selective removal procedure is performed by means of specific chemical solutions named resist developers and is called development. In positive resists, the unexposed material is insoluble in the developer and becomes soluble after being exposed to the light; in negative resists, instead, the material is natively soluble in the developer and becomes insoluble with the exposure. After the development procedure, some parts of the wafer will be still covered by photoresist, whereas other ones will be stripped. In this way, the pattern created on the photoresist can be transferred onto the wafer either using a selective etch that is slow enough on the resist to reach a target depth on the stripped areas without completely uncovering the protected regions (subtractive pattern transfer) or employing the resist as a stencil for a selective deposition (lift-off) process (additive pattern transfer), as illustrated in Fig. 8.1.

The performance of a resist material can be evaluated by measuring its exposure response curve, which is a linear-logarithmic plot reporting the resist thickness remaining after development normalized to the initial thickness (p) versus the exposure dose (D) used in the process.

The contrast parameter is calculated as shown in Fig. 8.2 for positive and negative photoresist and is related to the slope of the linearly variable part of the exposure curve. The resolution that can be achieved with a specific resist is related to contrast, since higher resolution is possible on resists with larger contrast parameter.

The way in which the reticle for selective exposure of the resist, named mask, is utilized in the exposure process distinguishes the two main types of lithography. In contact

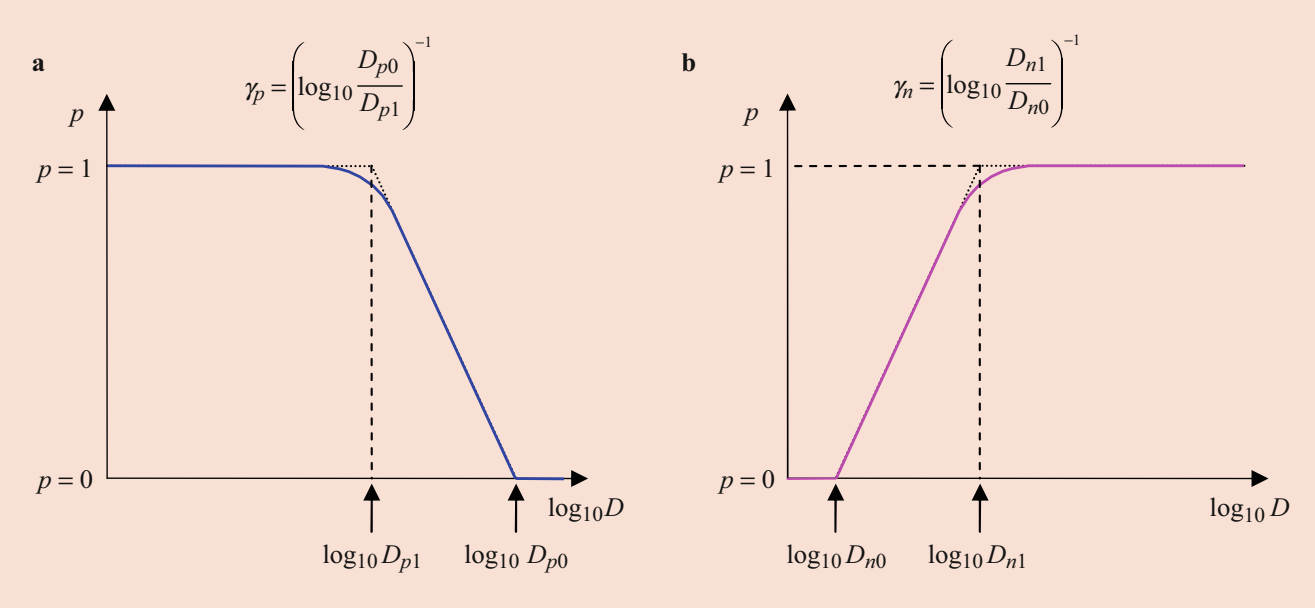

Fig. 8.2 Calculation of contrast parameter (γ) for positive (**a**) and negative (**b**) resist

lithography, the mask is a slab of glass or quartz, on which an opaque pattern is produced using a thin chrome layer. The mask is used during resist exposure after being placed in contact with the resist layer with the chrome-covered face downward. In order to achieve the highest possible resolution, the contact between the mask and the wafer must be performed in such a way that no space remains between them (hard contact), avoiding undesired light diffraction effects that may alter the pattern geometry.

The other possible method to perform the exposure employs the mask to project its transmission pattern onto the resist layer by means of an optical projection system that decreases the original size of the designed geometries in the focal plane, thus increasing the resolution.

With this method, the projected shadow of the mask on the wafer is generally small, and consequently a stepping or step and scanning system is normally needed to replicate the mask geometry several times on the wafer until a full exposure of the wafer is obtained. However, the advantages that projection systems provide in terms of resolution are so significant that contact lithography, which was utilized in the early phases of the development of the technique, has been now completely abandoned in massive IC production in favor of projection lithography. Since scanners used in projection lithography operate by repeating the projection of the mask several times on the wafer after stepping a predefined distance between two adjacent patterns, they are commonly named either step-and-repeat systems (i.e., steppers) or step-and-scan systems (i.e., scanners).

8.1.1 Image Formation in Lithography

Three fundamental methods can be adopted to transfer the image of the pattern from the mask to the photoresist layer (Fig. 8.3): contact, proximity, and projection lithography.

Projection lithography is preferred for production, whereas contact and proximity lithography are often employed in research because they are simpler methods that can be implemented with cheaper equipment.

A key issue in image formation is the achievable resolution (or half-pitch) that can be obtained on the resist after exposure. Since the photoresist needs to receive a sufficient radiation dose in order to change its solubility properties and form the pattern correctly, the light distribution on the resist during exposure needs to be examined carefully in order to evaluate the minimum feature that can be patterned on the resist and the precision of the patterned geometries.

The distribution of light on the resist during exposure is influenced by optical effects such as light diffraction, as a consequence of which the light energy dose on the resist becomes blurred and leads to limitations in patterning accuracy (Fig. 8.4).

The effect of light diffraction on image blurring is schematically represented in Fig. 8.5. For contact and proximity lithography, image blurring is determined by near-field (Fresnel) diffraction, whereas in projection lithography, far-field (Fraunhofer) diffraction is dominant.

The optical resolution of a projection lithography system can be calculated accounting for diffraction through the Airy

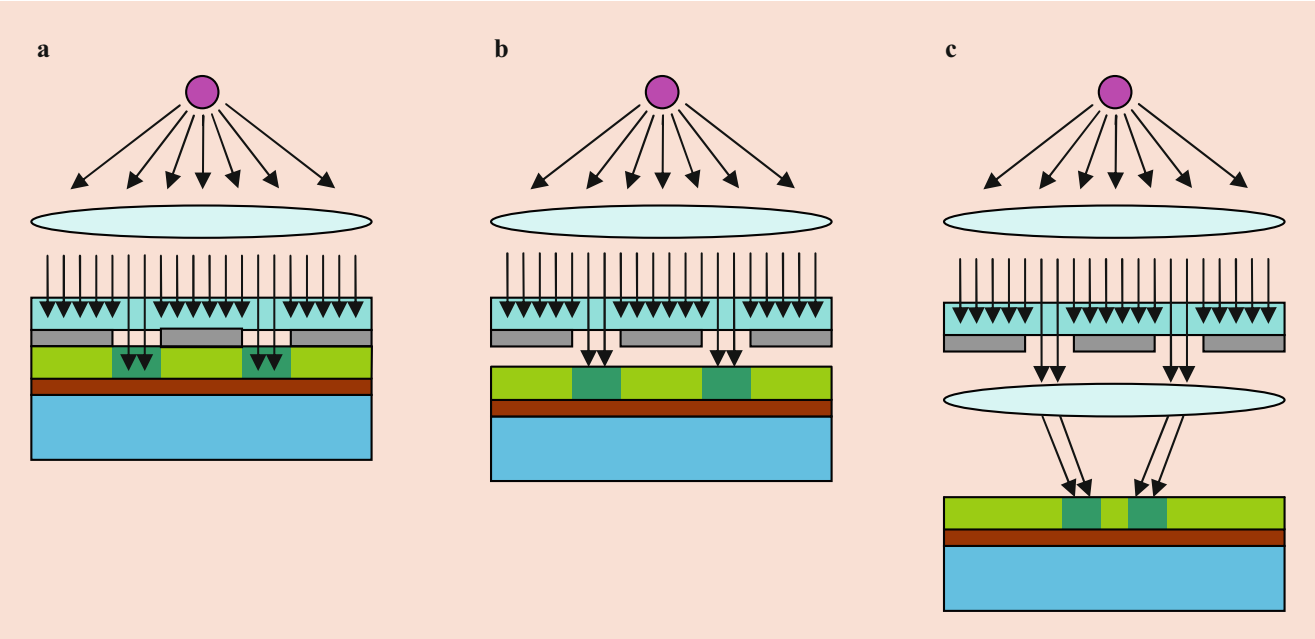

Fig. 8.3 Image formation in contact (**a**), proximity (**b**), and projection (**c**) lithography

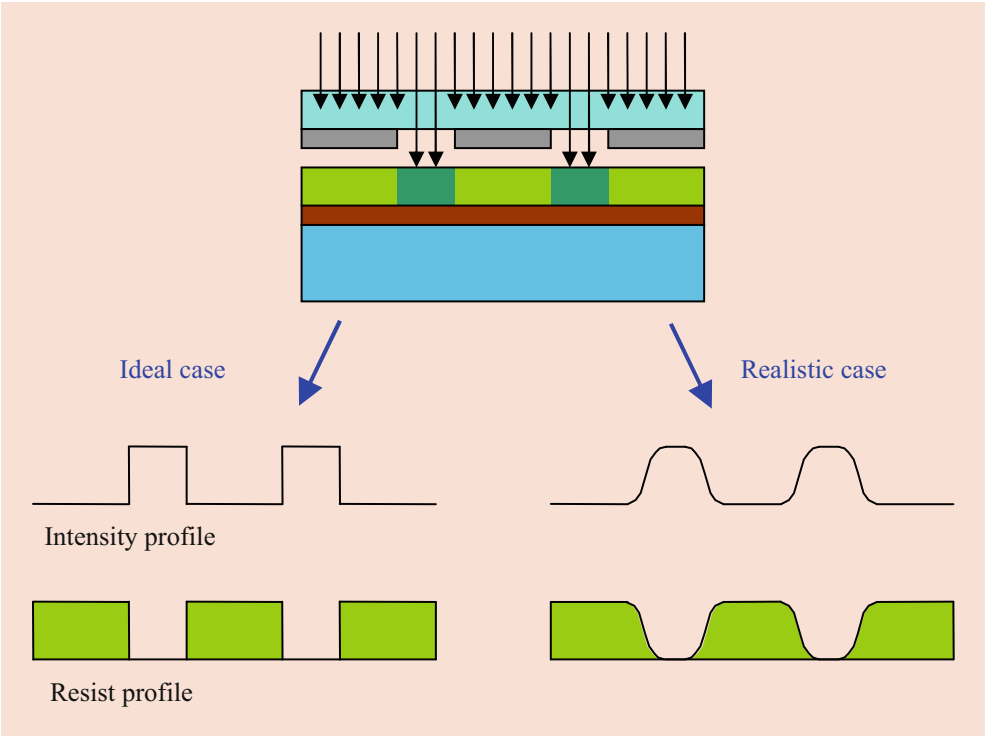

Fig. 8.4 Image and resist profile blurring due to non-ideal effects in lithography

principle, according to which a light point source after projection on the resist plane gives rise to an Airy circular pattern (Fig. 8.6). The diameter of the main lobe of the pattern is 1.22 $\lambda f/d$, with λ light wavelength and f and d focal length and diameter of the focusing lens, respectively.

The size of the Airy diffraction pattern can be taken as a measure to estimate the resolution in projection lithography, according to the Rayleigh principle (Fig. 8.6c). The Rayleigh principle estimates the minimum distance between two point sources (A and B, corresponding to the blue and red traces in

the figure) that can be resolved on the projection plane of the lithographic system as the distance at which the maximum of the Airy pattern generated by point source B is located on the first zero of the Airy pattern generated by point source A.

Through geometrical considerations, it is possible to calculate the resolution on the image plane (R) as:

$$R = 1.22\frac{\lambda f}{d} = 1.22\frac{\lambda f}{n\,(2f\sin\vartheta)} = 0.61\frac{\lambda}{\mathrm{NA}} \tag{8.1}$$

with

$$\mathrm{NA} = n\sin\vartheta \tag{8.2}$$

being n the refraction index of the lens and ϑ half of the acceptance cone angle of the projection system.

The Rayleigh criterion (8.1) can be generalized for lithography by estimating the minimum feature size that can be effectively exposed on the resist layer (MF) as:

$$\mathrm{MF} = k_1\frac{\lambda}{\mathrm{NA}} \tag{8.3}$$

with λ optical wavelength of the light source used in the equipment, NA numerical aperture of the optical projection system, and k_1 a process-dependent parameter.

Equation (8.3) puts into evidence the dependency of the lithographic resolution on the wavelength of the projection system and explains why the need for a continuous im-

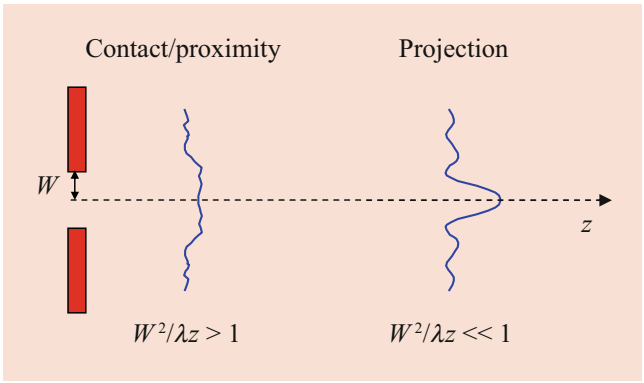

Fig. 8.5 Effect of light diffraction on image formation in lithography

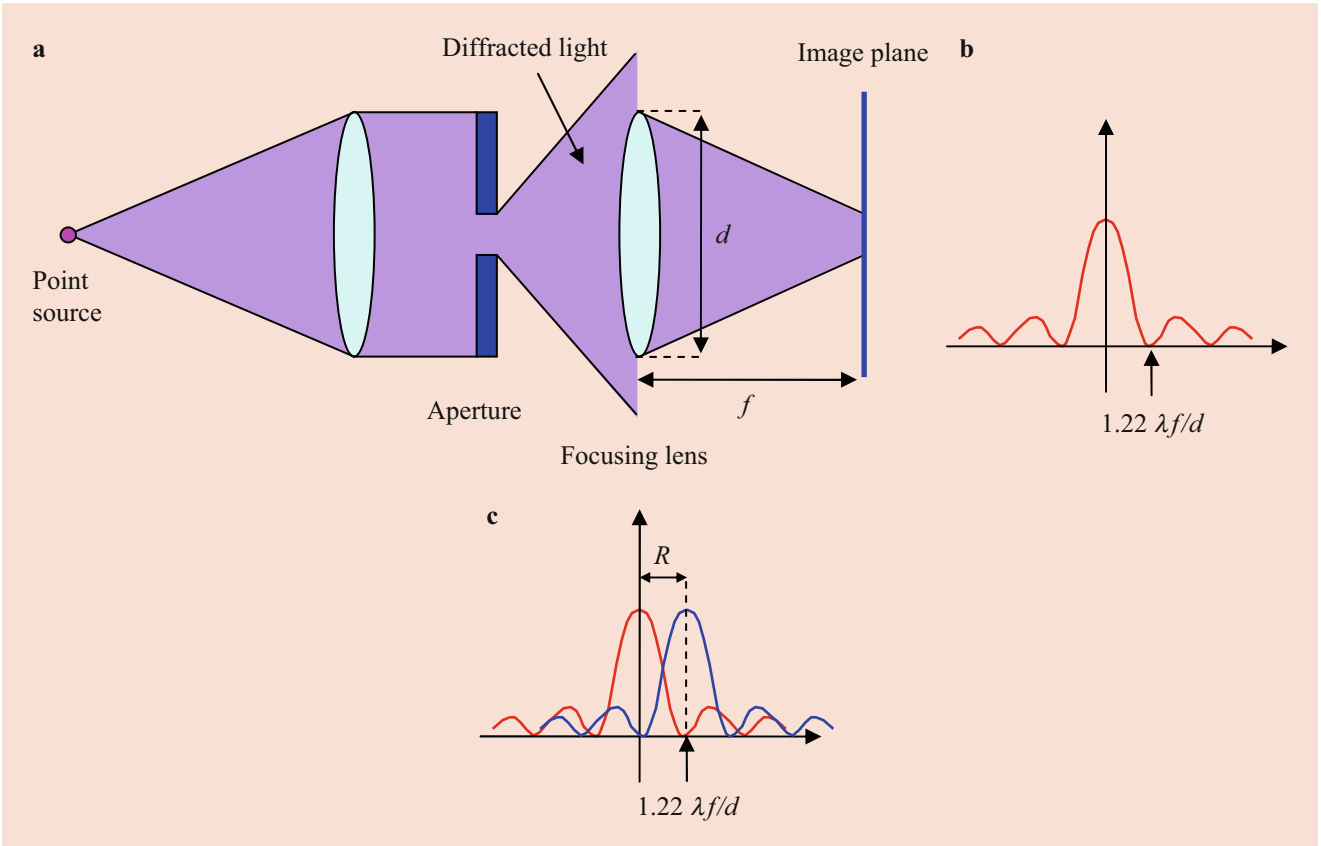

Fig. 8.6 Airy diffraction pattern (**b**) of a light point source (**a**) in projection lithography and Rayleigh resolution criterion for two point sources on the image plane (**c**)

provement of resolution in lithography has determined a constant decrease of the wavelength of the light used for resist exposition over the years and a continuous increase in the NA.

The first lithographic systems used for IC production employed light in the near-UV (NUV) region, produced by Hg lamps. Such lamps were able to emit spectral lines at the wavelengths of 436 (g-line), 405 (h-line), and 365 (i-line) nm, all of which could be used for lithography. Later on, new sources operating in the deep-UV (DUV) region were adopted, with typical wavelengths of 248 and 193 nm. The latest scanners went one step further and are now using a wavelength of about 13 nm, which is commonly referred to as extreme UV (EUV).

Due to the growing throughput requirements of the IC industries, light sources with increasing intensity were desired, in order to decrease the exposure time of the resist and enable the processing of a larger number of wafers per hour (WPH) in the system. Hg lamps were soon considered too weak in intensity for this purpose, and in the next generation of lithography equipment, excimer KrF lasers at 248 nm able to produce DUV radiation with higher intensity were adopted, in order to enhance the process throughput and resolution.

For DUV lithography, fluorine (F_2), krypton fluoride (KrF), and argon fluoride (ArF) lasers, with emission at 157, 248, and 193 nm, respectively, were investigated. Among them, the most successful ones were the KrF and ArF sources, which are still used nowadays for massive IC production in scanner projection systems. KrF-based systems were first utilized for the CMOS 0.25 μm node development and, later on, also adopted for the 0.13 μm node. Subsequently, ArF steppers were preferred to set up the production lines needed for massive IC fabrication with critical lengths of 110, 90, and 65 nm. ArF technology was even pushed beyond and employed in the development of the 45 nm node, thanks to the improvement in numerical aperture of projection systems that proved to be possible with special arrangements such as liquid immersion lithography. At the moment, ArF-based lithography with multiple patterning is the best available option for leading edge lithographic processes down to critical lengths of 22 nm.

As can be seen in Eq. (8.1), the NA of the lithographic system can be an important parameter to enhance resolution, since a better resolution of the lithographic process is expected by increasing the numerical aperture of the projection system. This happens because in a system with high NA, a larger number of diffraction orders are projected on the image plane, increasing the contrast of the pattern image and its intensity.

Considering a lens that is employed in the projection system, its numerical aperture (NA) depends on the index of refraction n of the medium in which the lens operates, according to Eq. (8.2). As can be seen from this formula, a high numerical aperture permits us to exploit a large optical acceptance angle in the optical system. This means that even light rays with relatively large inclination with respect to the lens axis can enter the optical system and contribute to the exposure process. Equation (8.2) also puts into evidence the fact that the numerical aperture of the lens can be readily improved without changing the lens material or design, but simply changing the refraction index of the medium in which the lens operates. In the first projection systems, the equipment operated in air, and consequently the refraction index that had to be used in Eq. (8.2) to calculate the NA was 1.

8.1.2 Resolution Enhancement Techniques

Several resolution enhancement techniques (RET) have been proposed through the years to improve resolution in lithography, such as immersion lithography, off-axis illumination, mask correction methods, and multiple patterning.

Immersion Lithography

In order to improve numerical aperture and take advantage of the term at the denominator of Eq. (8.3), immersion projection lithography was proposed. In this kind of equipment, the projection system is completely filled with an ultrapure liquid, which presents a much higher refraction index than air, such as water. In this way, the image formation of the exposure beam is better, and the resolution of the lithographic process is improved, because the numerical aperture of the system is enhanced according to Eq. (8.2).

In equipment with high NA, such as immersion lithographic systems, another important parameter that has to be considered to evaluate the performance of the process is the depth of focus (DoF). The DoF represents the maximum tolerance of the focal plane distance variation from the mask that can be accepted without appreciable problems on the focusing of the projected image in the resist. This parameter is important because it directly impacts the maximum thickness of the resist film that can be used in the lithographic process and the accuracy required for the wafer placement on the focal plane of the projection system.

Using the Rayleigh principle as in Eq. (8.3), the DoF may be expressed as:

$$\mathrm{DoF} = k_2 \frac{\lambda}{\mathrm{NA}^2} \tag{8.4}$$

in which λ is the operating wavelength of the tool and k_2 an empirical parameter derived from a fit with measured data.

Equation (8.4) shows that the DoF increases linearly with the operation wavelength of the lithographic system and quadratically with the inverse of the NA. Considering the

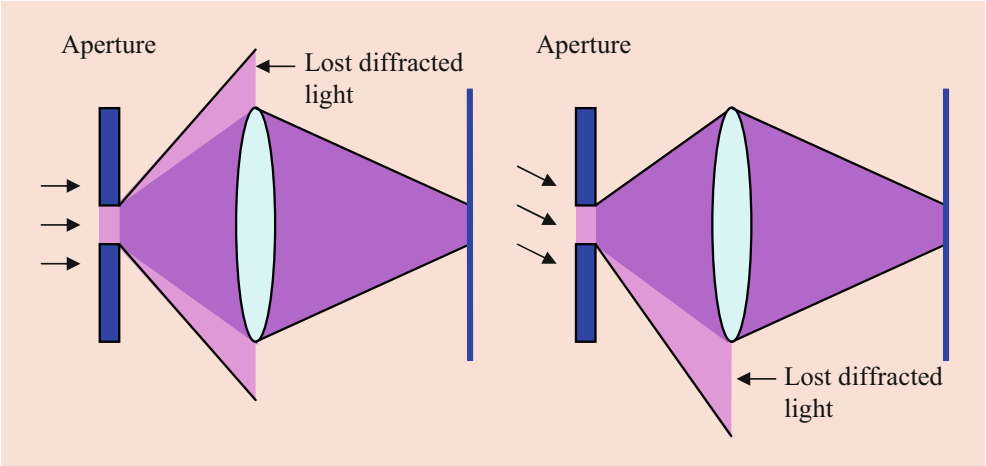

Fig. 8.7 Off-axis illumination principle

trends toward wavelength reduction and numerical aperture enhancement in projection systems to achieve higher resolution, it is worth noticing that both strategies tend to decrease the DoF, leading to more critical requirements on sample planarization, placement, and resist thickness in the process.

Off-Axis Illumination

Off-axis illumination allows to capture higher orders of diffracted light in the projected image, as shown in Fig. 8.7, and consequently improve resolution. Off-axis illumination can be implemented in different ways. Two widely employed techniques are annular and quadrupole off-axis illumination. Quadrupole off-axis illumination is more effective on line/space patterns than on isolated features but is orientation dependent. Annular off-axis illumination is less effective in general but has the advantage of being orientation independent.

Mask Correction Methods

When the patterning performed is in the subwavelength regime, as it happens when using DUV for the production of the more challenging technology nodes, special techniques must be used in order to enhance the masks. One example of RET based on mask correction is optical proximity correction (OPC), which consists of a computer-simulated modification of the mask geometry that can compensate the distortion of the projected pattern coming from the fact that its geometrical dimensions are smaller than the operating wavelength of the lithographic system [1]. Typical examples of these subwavelength pattern transfer effects that may be compensated with OPC are the corner rounding, the shortening of the lines close to their terminations, and the line width changes produced in densely or coarsely patterned areas of the mask.

Another type of RET is the use of phase-shift masks (PSM), a method that can improve the resolution of the pattern by exploiting interference effects induced on the UV light through its transmission across the mask material. In order to obtain this effect, the mask material is designed in such a way that a controllable phase shift can be produced on the transmitted light in different points of the mask, in order to obtain the desired interference effects on the resist [2].

Generally speaking, these mask improvement methods are often named source and mask optimization (SMO) methods, and their scope is obtaining an optimized projected image by modifying the shape of the mask geometries, taking into account the effect of all the diffraction orders collected by the projection system [3]. The final target of these optimization techniques is increasing the process window and improving the resolution of the projected image. Since the diffracted orders of the light source depend on its shape and on the inclination of the laser beam, a joint optimization of the mask geometries and of the source characteristics can be carried out in order to achieve the best result. This joint optimization of the mask and the light source has originated the denomination of the SMO methods. Due to the complexity of task, such optimizations are normally performed by running specific algorithms with a computer routine.

Beyond the modification of the mask geometries, RET techniques may also involve the introduction in the mask of additional features beyond those necessary for the design of the IC that are again used to compensate the negative influence of diffraction effects on image formation. This is particularly important when the mask includes sparse pattern on which the effect of light diffraction may be more difficult to compensate compared to dense patterns. Such additional features that are introduced are not meant to be reproduced on the projected image but are only used for compensation of the diffraction effects on the sparse pattern. They are named sub-

resolution assist features (SRAF) because they are normally designed with a size that is smaller than the resolution of the process. Peculiar examples of SRAFs are scattering bars and inverse scattering bars [4].

Multiple Patterning
When all the other RET techniques fail, multiple patterning can be applied to scale the feature size of lithography below the intrinsic limitations of the process. Different multiple patterning methods exist, and all of them involve the execution of more than one lithographic step, sometimes in combination with other additional processes. A more extended discussion of multiple patterning can be found in the next section devoted to ArF lithography.

8.2 Advanced Lithography Based on ArF 193 nm DUV Sources

In equipment based on ArF laser sources, the NA has been increased through the adoption of water immersion technology from 0.6 to 1.35. The development of the immersion lithography technique allowed to push the application of ArF 193 nm systems to the manufacturing of ICs with critical length scaled down to 45 nm.

Given the negative impact on the DoF that derives from the enhancement of NA, as discussed before, the resist thickness in high-NA ArF projection systems is severely limited, and consequently the resist selectivity to plasma etching processes becomes critical. Moreover, liquid immersion lithography also leads to other special requirements for the process, for instance, the need to develop photoresists that can be utilized in water or in another liquid environment, since all the projection system (including the wafer) needs to be immersed in the same liquid in order to operate correctly.

8.2.1 Resist Thickness and Plasma Etching Selectivity

The very small DoF dictated by the short wavelength and the high numerical aperture of the 193 nm immersion systems and the constraints that derive from the maximum aspect ratio of the resist pattern on the critical features pose severe limitations on the resist thickness in these processes. For example, for the 45 nm IC fabrication node, the maximum possible resist thickness is around 150 nm and is expected to decrease in next-generation technologies.

The main problem with the use of very thin resist layers, which is quite common in advanced lithographic methods, is the poor resistance of the resist layers to the plasma etching processes that are normally carried out after resist development in order to transfer the pattern to the material of interest located under the resist mask (see Fig. 8.1), which in CMOS technology is often silicon or silicon oxide. Besides thickness, the resist chemical composition can also have an impact on its plasma etching resistance.

The resistance of the resist layer to plasma etching processes is normally estimated by determining the etching selectivity of the target material with respect to the photoresist, which is calculated as the ratio between the target material etch rate and one of the photoresists in the same process. If the selectivity is high, the process etches the resist slowly compared to the target material.

To give an example, in a CF_4 plasma process used to etch SiO_2 that presents a rate of 100 nm/min on SiO_2 and 50 nm/min on the resist layer, the selectivity of the etch process toward photoresist is estimated to be 2. The calculation of the selectivity provides a quick measure to estimate the maximum possible depth that can be obtained with the etching process when a resist layer is used as a mask for it, since, for instance, with a selectivity of 2, a resist layer that is at least as thick as one half of the target etching depth will be necessary. If the plasma etching selectivity on resist is high, a thin mask layer can be used for etching a relatively large thickness of the material of interest.

Quite reasonably, the selectivity depends on the characteristics of the plasma etching process adopted and on the material properties of the photoresist layer utilized but, excluding second-order effects, not on its thickness. Since the characteristics of photoresists are specifically designed to give a satisfactory yield in lithographic processes performed at a specific wavelength, it is natural that the composition and consequently the material properties of resist layers developed for different exposition wavelengths may differ. Comparing, for instance, the etching rate in typical plasma etching chemistries used in IC technology (CF_4, Cl_2, HBr, Ar), the photoresist materials used for the 248 and 193 nm technologies show a different behavior, with the 193 nm photoresists providing significantly lower selectivity in these etching processes.

An empirical model has been developed to evaluate the plasma etch rate of photoresist depending on its chemical composition through the Ohnishi parameter P_O, defined as [5]:

$$P_O = \frac{N}{N_C - N_O} \tag{8.5}$$

In the formula, N is the total volume density of atoms in the polymer, whereas N_C and N_O are the volume densities of carbon and oxygen atoms, respectively.

In photoresists, the etching rate in plasmas is roughly proportional to the Ohnishi parameter, so a high P_O is generally associated with a poor selectivity of the etching process toward the resist. This happens because the etch rate in polymers consequent to ion bombardment (which is the main

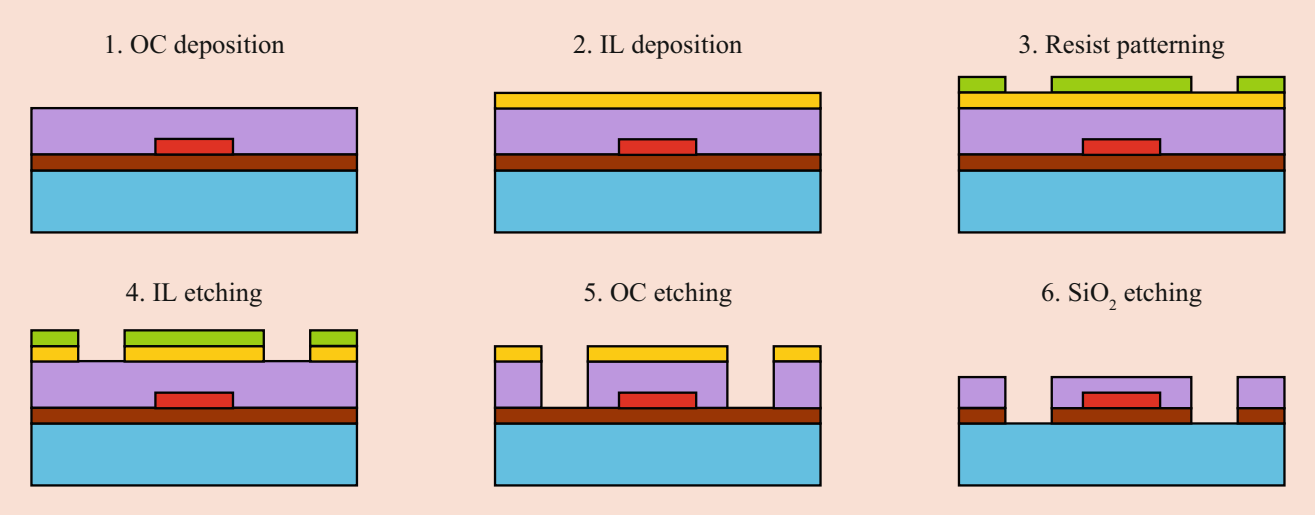

Fig. 8.8 Lithographic patterning procedure based on hard masking

reason for resist etching in plasmas in which ion sputtering is always present) depends on the concentration of C-O groups in the polymer. Polymers containing a high concentration of such groups present a sputter etch rate that is much higher than carbon, because of the presence of oxygen atoms bound to carbon in the material. That is the reason why the Ohnishi parameter reports at the denominator the difference between the carbon and oxygen atom concentrations in the material, since this represents the effective carbon content related to its sputter etching resistance.

In order to increase the effective carbon content of resist layers after development and increase their resistance to plasma etching, peculiar curing processes have been developed, such as the exposition of the patterned photoresist to an HBr plasma before etching. Such kinds of plasma produce an UV light in vacuum that is able to suppress the lactone and ester groups in the resist, increasing its carbon content and consequently reducing the Ohnishi parameter. Another benefit of these treatments comes from the fact that the chemical groups that are removed from the resist by the UV light irradiation in vacuum tend to become volatile in the plasma and redeposit on the resist pattern as graphitic residues. Such residues are deposited on both the horizontal and the lateral surfaces of the patterned resist and consequently increase the resistance of the lateral walls of the pattern to the plasma, helping maintain the critical feature size during etching.

As the shrinking of the critical dimensions of ICs proceeded in history, the methods used to increase the etching selectivity proved to be insufficient to keep using the plain photoresist layer as a mask, and, from a certain point onward, the technique of hard masking was adopted with increasing frequency. Hard masking consists in using a multiple mask composed by overlapped layers, in which the top mask layer is composed by photoresist, as in the traditional soft masking procedure, whereas the layers underneath are used because they provide a higher selectivity than resist in the plasma process that has to be subsequently adopted for the pattern transfer on the material of interest.

The most common hard masking strategy employs alternated organic and inorganic layers within the mask stack, as shown in Fig. 8.8, in which a sample hard masking process for patterning of a SiO_2 layer on a non-planar wafer is schematically illustrated. First the wafer is covered with an organic coating (OC) that is generally thicker than the photoresist layer used for the lithography and can be also used for planarization, improving the focus budget. Afterward, a thin inorganic layer (IL) is deposited on top of the OC, and finally the photoresist is spun and patterned as the third layer of the stack. The function of the inorganic layer, which is typically a silicon-rich material, is to increase the etching selectivity of the mask, providing a better resistance to the plasma etching.

Since it is also used to reduce the reflection of the light during resist exposure, such IL is often named Si-ARC (silicon containing anti-reflective coating). The OC, which is sometimes named OPL (organic planarizing layer), is typically a carbon-rich layer with high plasma etching resistance that can be deposited by spin-On or PECVD technique.

After resist patterning on the top of the stack (step 3 in the figure), the pattern is transferred to the inorganic layer underneath by a highly selective plasma process, such as a fluorine-based plasma, and subsequently to the OC by oxygen- or hydrogen-based plasmas. This technique permits to reach a higher overall selectivity with respect to the application of a plain resist mask because oxygen or hydrogen plasmas have a very slow etch rate on inorganic materials and consequently permit to etch a relatively thick OC without completely consuming the upper IL, on which the pattern is transferred with the first etching step.

On the other hand, the high selectivity of the OC etching process on the IL allows to reduce its thickness, avoiding selectivity problems on the resist with the fluorine-based plasma that is utilized to pattern the IL. Thanks to the much higher overall thickness obtained with the hard mask, and to the slow etch rate the plasmas used for SiO_2 or Si etching on the OC, the pattern can be successfully transferred to the target materials even using very thin resist layers, without major etching selectivity issues.

Immersion lithography with hard mask technology has been utilized for the 80 and 40 nm IC nodes, in which the critical feature size is much below the 193 nm wavelength of the radiation used, but any further shrinking of the pattern dimensions by direct improvement of the resolution of the lithographic equipment seems to be economically impractical, nowadays. For this reason, in order to satisfy the always growing demand for more scaled ICs, alternative solutions have been investigated to decrease the critical size of the pattern without further improving the resolution of the lithographic systems.

8.2.2 Multiple Patterning Techniques in ArF DUV Lithography

One of these techniques is double patterning (DP), which has also been applied to improve the resolution of ArF DUV lithography and is based on the multiple exposure of the resist using two or more patterning procedures that are performed subsequently and with a controlled offset [6–10]. These multiple exposures of the resist are followed by one or more anisotropic etching steps that are used to aid the definition of the differential pattern and transfer it to the wafer. This technique has been fundamental for the development of the 32 and 22 nm IC technology nodes in recent years.

Several techniques can be used to implement the double patterning technology. In the lithography-etch-lithography-etch (LELE) approach, for instance, the resist is exposed twice using a controlled overlay between the two exposure/etch procedures in order to obtain the minimum feature by the partial overlap of two patterns that, individually, present a larger critical size. The LELE approach has been used to extend the application of ArF DUV immersion lithography to the 32 nm technological node.

DP is nowadays the only commercial technology that allows to pattern a critical length of 40 nm. The LELE DP starts by creating a first pattern with a pitch that is approximately twice the final one. After transferring this pattern to an intermediate hard mask layer by plasma etching, a second lithographic step is carried out over the already etched mask layer, using a proper shift of the new pattern with respect to the former one, in order to obtain the critical length desired by the overlap of the two patterned geometries, each characterized by a larger pitch (Fig. 8.9). A cheaper process with only one lithography step, similar to the one represented in Fig. 8.10, may be adopted to reduce the feature size with an isotropic etching, obtaining an improvement on the line width without scaling the line distance. This technique presents the big advantage of being implementable with already established lithographic processes, without any modification of the available equipment, and was utilized to demonstrate the possibility to obtain a 32 nm half-pitch resolution in laboratory tests.

Another option for DP is the self-aligned double patterning (SADP), which is essentially a spacer technology. With this method, a so-called mandrel pattern is first transferred onto the photoresist or onto a hard mask under it; subsequently, a spacer layer (SL) is deposited over it with a conformal deposition method (a method that maintains a homogeneous thickness of the layer independent of the inclination of the deposition surface). After deposition, the SL is etched back maskless to remove it from the horizontal surfaces of the mandrel pattern, leaving spacers on its vertical sidewalls, and the patterned resist or OC is etched selectively, in such a way that the spacers remain on the wafer and can be used as a hard mask to etch small lines on the substrate (Fig. 8.10). With this method, the width of the critical feature does not depend directly on the photoresist patterning resolution, since it is determined by the thickness of the SL.

Different than the LELE method, the spacer technique requires additional processing steps besides the exposure and the development of the resist, since it relies on the deposition of a conformal mask layer on a previous pattern, with specific processing steps such as the SL etchback that are not foreseen in conventional patterning procedures (SiO_2 and SiN_x are often used as spacer layers). The spacer technology or SADP has been widely applied in the fabrication of FinFET devices. Other possible multiple patterning technologies that are even more sophisticated involve the use of SADP twice to increase the density of critical size structures. Such techniques are named self-aligned quadruple patterning (SAQP).

Despite the impressive results reported in recent research works, the industrial implementation of robust SADP or SAQP processes based on ArF DUV lithography presents a number of technical challenges. Most of the problems that are encountered in these techniques are related to the integrity of the spacers during the process. Spacers are generally thin structures with rather high aspect ratio and consequently present a limited mechanical strength. On the other hand, the outcome of the process can be good only in case the spacers are maintained intact and as vertical as possible until the completion of the etching steps in which they are used as hard mask lines.

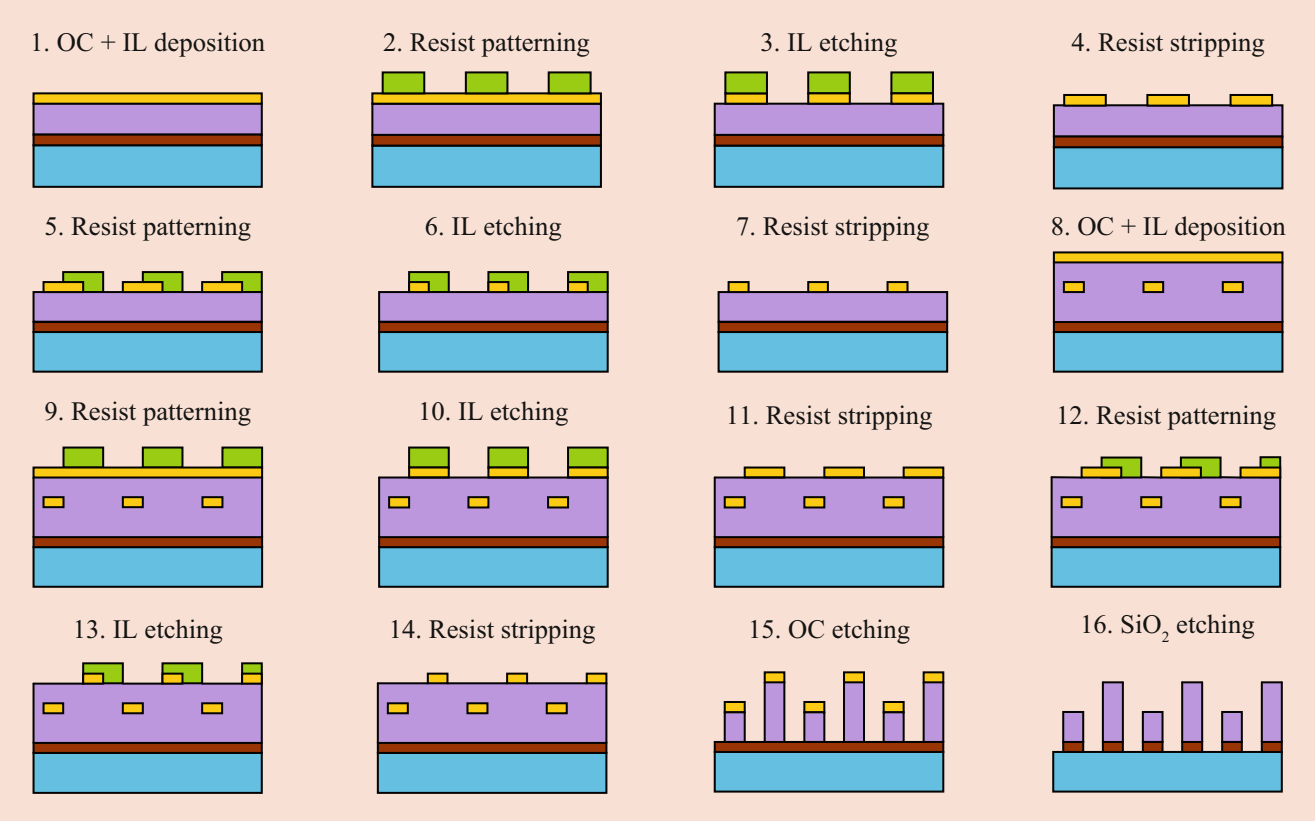

Fig. 8.9 Example of LELE lithographic procedure for full half-pitch resolution doubling

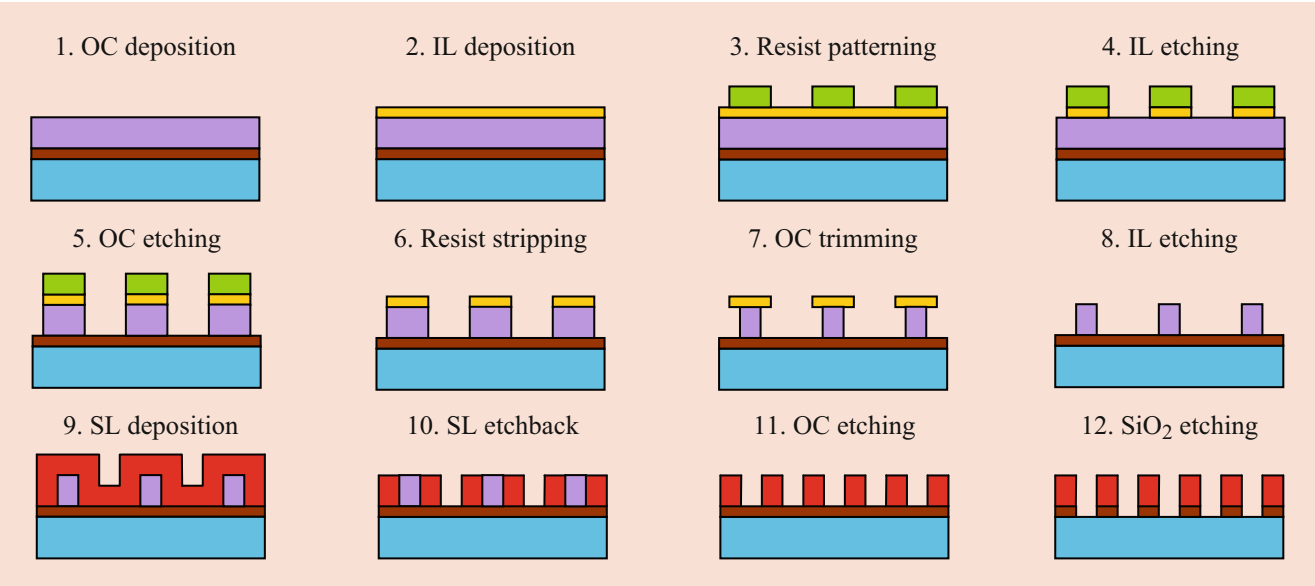

Fig. 8.10 Example of SADP lithographic procedure for full half-pitch resolution doubling

A possible source of damage for spacers are the capillary forces that develop during the various wet cleaning steps needed during the pattern transfer procedures in IC fabrication. In particular, the capillary forces on the two sides of the spacers may not be well compensated in case the pattern is not symmetrical, giving rise to lateral forces that may

bend or break the spacers. Since the intensity of the resulting bending moment that the capillary forces may produce on the pattern depends on the cube of the aspect ratio of the spacers, such forces may easily exceed the yield strength of the spacer material and induce a plastic pattern deformation (pattern collapse) that is not beneficial for the process yield.

The materials that are more often used in SADP processes to realize the spacers are SiN_x or SiO_2 layers deposited at low temperatures on a photoresist or an OC mandrel pattern. When plain photoresist or other organic layers are used for the mandrel, their removal can be simply performed with an O_2 plasma, which is a dry procedure and consequently does not lead to problems related to capillary forces. However, in some cases, an inorganic Si-ARC layer is also used, whose removal may require additional steps. Evidently, when the line width resolution of the patterning process goes below 20 nm, high aspect ratio spacer structures are inevitably necessary to sustain the subsequent pattern transfer by plasma etching as hard masks. Such high aspect ratio structures are unfortunately prone to pattern collapse problems. The presence of the IL is often critical in this respect, since in OC patterns with 20 nm resolution, it has to be removed by wet HF dips, in which capillary forces are developed. As a rule of thumb, wet cleaning procedures should not be applied to patterns with aspect ratio larger than 5.

Other pattern deformation phenomena in SADP processes may appear as a consequence of the residual stress of the material deposited on the mandrel in order to create the spacers. Residual mechanical stress is present in principle in any deposited layer and results in a tendency of the layer to expand or contract more than the underlying substrate after the deposition process, developing a fixed tensile or compressive strain that remains in the film after the growth is completed. Since, while the film grows during deposition, such strain may change in value, a strain gradient may also develop along the film thickness direction, which naturally produces a bending when the layer is released from the substrate.

For the case of the spacers, the residual strain gradient of the film that may be present on the vertical parts of the pattern is particularly dangerous, because it may bend the spacers like capillary forces do during the wet cleaning procedures. The phenomenon of spacer deformation that is purely due to residual strain effects on the deposited spacer material is named wiggling [7]. Young's modulus of the material, besides the residual strain, also plays a role in wiggling, since more rigid materials (such as SiN) tend to bend less when subjected to strain gradients than more slender materials characterized by a lower stiffness (such as SiO_2). In this case also, the presence of a large aspect ratio makes the problem of wiggling more critical, and possible strain changes induced by the chemical processes performed on the spacers during the patterning procedure may more easily affect the final result. Typically, relevant wiggling problems are observed for spacer aspect ratios larger than 7.

Although, in theory, the capabilities of ArF technology with multiple patterning in terms of resolution may be further improved, the fact that additional processes are needed in these methods increases the cost of ownership of the corresponding production lines and makes the economical viability of the technology questionable. Since the cost of these complicated patterning flows mainly depends on the number of process steps involved, new materials have been studied in order to decrease the additional etching or deposition steps needed.

In [8], the cost of several SADP and SAQP processes with critical size scaled down to 5 nm was compared, considering that the number of steps and consequently the process cost generally increase with the downscaling. Since, however, the density of transistors that can be fabricated in the process also increases with the reduction of the critical size, a significant figure to make a sound cost comparison of processes with different scaling level is the cost per transistor, simply calculated dividing the process cost per wafer by the number of transistors that can be fabricated on a single substrate. By calculating such figure, it is found, for instance, that a reduction of the cost per transistor of a factor of 0.71 can be obtained by shifting from the 14 nm to the 10 nm node, whereas from 14 nm to 7 nm, the cost reduction factor is only 0.86. A cost reduction factor higher than 0.8 may be insufficient to motivate the setup of the 5 nm node in massive IC production. For this reason, alternative solutions for the technological generations with critical feature scaling beyond 14 nm are presently under investigation.

8.2.3 Photoresists for 193 nm DUV Lithography

Since photoresist is essentially a material whose solubility in a developer may be enhanced (positive resist) or suppressed (negative resist) by the exposure to an optical or ionizing radiation, the core subject of the development of new photoresist materials is the sequence of chemical reactions initiated by their exposition to a specific type of radiation. As discussed before for the case of optical lithography, different radiation wavelengths have been utilized through the years, with a constant trend toward the use of shorter wavelengths to improve the resolution of the patterning and meet the market demands in terms of scaling of the IC critical size. Independent of the utilized wavelength, the exposure dose required to complete the chemical reactions that are needed to change the resist solubility is always a critical parameter for the throughput of the process measured in number of processed wafer per hour (WPH). Consequently, the irradiation dose of the resist

must be sufficiently low, or, equivalently, the sensitivity of the resist to the light exposure needs to be high enough to allow a short exposure time.

In order to cope with these demanding sensitivity requirements, the development of the resist for the 193 nm wavelength was carried out from the beginning as an extension of the chemically amplified photoresists already developed for the former 248 nm technology. Given that the first ArF exposure systems were similar to the KrF one used until then, the initial challenge for the development of the new photoresists was the need to find a material that could extend to shorter wavelengths the same properties that had been exploited in the phenolic and styrene-acrylate polymers used in the chemically amplified resists (CARs) for the 248 nm lithography.

In these resists, the chemical amplification mechanism was introduced in order to decrease the exposure dose needed and improve the throughput of the lithographic process. Chemical amplification relies on the action of a photoactive molecule that is able to generate a catalyzer for a dissociation reaction in the polymer. Onium salts are a typical example of such molecules. They are added to polymers like polyhydroxystyrene (PHS) that are normally insoluble in water-based developers. Under UV irradiation, the onium salt molecules can interact with a single photon and undergo a dissociation reaction that generates an acid. Such acid molecule acts as a catalyzer of another reaction that is able to modify the structures of the polymer chain, usually removing a molecule group that makes it insoluble in the developer. Since the photon-generated acid molecule is a catalyzer, it is not consumed by the reaction involving the modification of an individual polymer chain and can catalyze a large number of similar reactions in sequence.

These reactions that modify the chain of the polymer making it soluble in the resist developer are often promoted by a high-temperature treatment of the resist that takes place after exposure, which is named post-exposure bake (PEB). Since a single acid molecule generated by the interaction of a photon with the onium salt can catalyze the chemical modification of a large number of polymer chains, it is easy to understand why this type of photon-induced modification of the resist was denominated chemical amplification, since the action of the irradiating photons is amplified by the chemical reaction catalyzed by the acid molecule. The amplification factor of such resists is sometimes calculated by estimating how many groups can be detached from the polymer chain by an individual molecule of catalyzing acid. This factor can exceed 100 in typical CARs. Thanks to the chemical amplification, the new resists developed for the DUV systems were able to work with very low irradiation doses, in the range 10–50 mJ/cm^2, with large benefits on the throughput of the lithographic processes. The chemically amplified resists were also more transparent to the UV radiation compared with the resists that were used with NUV light, generally based on novolak resins. In this way, a better profile of the resist pattern owing to a more uniform irradiation of the layer along its thickness was possible.

During the development of the resists for the new DUV wavelength, the advancement of the equipment was also considered. The first ArF equipment, in fact, operated in air just like the KrF ones used before ("dry" lithography), whereas, later on, in order to improve the numerical aperture and consequently the resolution, water immersion systems were built, in which the space between the last lens of the projection system and the wafer surface was filled with water to increase the refraction index of the environment ("immersion" lithography). Immersion lithography combined with multiple patterning techniques was able to push the application of ArF systems up to scaling levels that were not expected at the beginning of the development of the technology. Considering the differences in the chemical environment and the pattern transfer procedures involved in all these different patterning methods, it is easy to understand how deep the impact of the compatibility with these requirements was on the resist material development.

In order to cope with all the requirements of dry and immersion ArF lithography, including SADP methods, the resist material should ideally:

- Enable the completion of the lithographic procedure with a single layer of material, to limit fabrication costs and keep the process simple.
- Provide high exposure sensitivity and, at the same time, the possibility to obtain vertical pattern profiles after development.
- Assure sufficient adhesion on all the materials of interest for patterning.
- Be thermally curable beyond its glass temperature transition (T_g) in order to provide good etching selectivity after annealing.
- Comply with an exposure dose between 10 and 50 mJ/cm^2.
- Provide a high selectivity to typical SiO_2 and metal plasma etching processes (such as CF_4/O_2 or Cl_2/BCl_3 plasmas).
- Be compatible with the use of standard industrial tetramethylammonium hydroxide (TMAH)-based developers.

The initial investigations about the possible compatibility of 248 nm CARs with shorter wavelengths immediately put into evidence that phenolic polymers were too much absorbing at 193 nm to be used as resist layers, whereas polyacrylate polymers were almost transparent in that range, showing good promises for the application. The first resist technology for ArF light, indeed, was developed at the IBM laboratories and was based on a polymer containing the methyl methacrylate (MMA), t-butyl methacrylate (TBMA),

and methacrylic acid (MAA) monomers in the chain [11]. The resist allowed the creation of positive patterns by means of an acid-catalyzed reaction removing t-butyl groups in the material to create carboxylic acid and showed good compatibility with mixing with acid-generating compounds, fair adhesion to the substrate, and high glass transition temperature. However, some drawbacks were also present, since the resist layer after development presented a rather high oxygen content that decreased its selectivity toward plasma etching and was not compatible with TMAH developing solutions with the standard concentration of 0.26 N, because it required a much higher dilution to work well (0.02 N).

Some improvements were introduced in the next-generation resists, by including alicyclic groups in the polymer to enhance its dry etching resistance, thanks to the presence of carbon atoms in the ring structure of these molecules, according to the Ohnishi principle discussed earlier. Being non-aromatic, alicyclic groups also provided high optical transparency at 193 nm, which was another attractive property for lithography. Another approach followed to improve the plasma etch resistance of the resist was the introduction in the polymer backbone of alicyclic moieties as inert side chain groups.

The only drawback related to the inclusion of alicyclic groups in the resist was the fact that, in high concentration, they increased the hydrophobicity of the material making the development procedure in aqueous solutions (such as the standard alkaline developers) difficult. This problem was addressed including polar groups in the chain and additional methacrylate monomers that were able to solve the development problems in aqueous solutions and achieve the desired compatibility with the 0.26 N developer solutions based on TMAH. The resulting photoresist materials showed good substrate adhesion, T_g larger than 200 °C, and minimum swelling during development, also thanks to the reduced amount of carboxylic acid included in the mixture.

After scaling of the critical size below 100 nm, immersion projection had to be adopted to improve resolution. Ultrapure water was the liquid of choice, providing a refraction index of 1.44 and a very low absorption coefficient at 193 nm. The use of the commercially available CA resist previously developed for 193 dry lithography was the first challenge that had to be faced since the exposition to the water environment could produce undesired effects, such as the dissolution of resist components in aqueous solution, water incorporation in the film, and generation of bubbles that may reflect the UV light because of outgassing from the resist during exposure. These problems were addressed through two main complementary strategies: the development of protective coatings that could be used during resist exposure and the addition of chemical compounds to the resist mixture in order to improve its usability in water.

The coating materials had the main function of preventing in- or out-diffusion of components from the water environment to the resist film and vice versa. The first compositions of such films, which had to be insoluble in water, could only be removed with organic solvents after use, and this was a disadvantage because it required the introduction of additional steps in the patterning process compared to dry lithography. For this reason, a second generation of protective coatings that were soluble in the standard TMAH aqueous solutions was developed. Different chemical compositions of the coating material were utilized, often containing hydrocarbon, fluorocarbon, and organosilicon functional groups in the chain. Among them, acrylic polymers containing fluoroalcoholic groups that had been previously developed as CA resists for F_2 157 nm lithography were particularly successful because they were very transparent at 193 nm and able to provide a very good wettability of most of the mainly used 193 nm photoresists. In general, the main challenge in using protective coatings during immersion lithography was the need to minimize the defect density induced by the additional processing steps needed for the application of the coating and to limit the possible undesired effects during exposition that may affect the subsequent processing steps, such as the formation of post-development skin layers or residual water droplets after exposure.

A possible way to completely avoid such problems consisted of developing new materials that could be directly utilized in water as photoresist layers, without the adoption of any protective coating. The possibility to avoid the additional processing steps required by the application of the protective layers also represented an important driving force for the achievement of this target. However, the initial strategy of introducing hydrophobic monomers in the resist (such as fluorinated alicyclic-based monomers) to reduce its interaction with water and change the acid precursors in such a way that the generated acid products after irradiation were not soluble in water proved to be very challenging. Consequently, a different strategy was preferred in the end, which consisted of adding to the resist mixture some components that may work as in situ self-assembling coatings. The additives used for this purpose were chosen in order to present a lower surface energy than the other components of the mixture and consequently be able to reach a higher concentration on the top surface of the resist layer after spin coating. Such high concentration at the surface of the layer played the role of a protective coating, without the need of any additional deposition steps and with no interface problems, different than the specific coating layers described before.

Among the possible additive formulations, organosilicon- and fluorine-containing polymers were explored, in which low surface energy groups were introduced either in the backbone or in the side chain of the polymer. These mate-

rials were often composed by a polymethacrylate backbone in which silicon- and fluorine-containing additional groups were introduced. Another important aspect was the fact that the self-assembled protective layer had to be easily soluble in the development solution, since possible solubility problems may lead to the creation of surface roughness and defects in the resist after development. The needed solubility in the top part of these photoresists was achieved by adding some non-polar labile acid groups in the chemical formulation of the additive material, in such a way that during exposure and subsequent PEB, the acid-catalyzed deprotection reactions could take place simultaneously in the upper and lower parts of the layer assuring a complete dissolution of the material in the developer solution without creating significant defects. The successful creation of water-compatible photoresist layers incorporating such in situ assembled protective coatings was the key solution to return to the cost-effective single layer resist strategy that was initially developed for the dry processes also in immersion lithography.

Since after scaling to the 22 nm node, multiple patterning techniques such as LELE or SADP had to be adopted to cope with the new resolution requirements, new specifications for the photoresist performance became necessary. The first double patterning technique employed was conceived in order to keep the established processes as much as possible unmodified in the patterning technology. This was possible with a simple double exposure procedure, in which two photoresist layers were exposed subsequently after an intermediate etching step in order to achieve the desired resolution with a controlled shift between the two patterns. In this way, the requirements about the resolution of the two individual patterning procedures could be less demanding, and consequently an established patterning process was expected to be applicable to each of them, with no major modifications introduced in the photoresist composition or in the photolithographic process. From the development of the first plants for the 22 nm node onward, different double exposure processes have been proposed [12, 13].

One of the possible implementations of DP was the LELE approach in which two subsequent lithographic patterning and etching processes with subcritical resolution are performed to etch the critical feature. This approach was adopted rapidly because it could basically use standard approaches for all the processing steps and did not require any modifications of the materials and procedures used for its implementation. Possible variants of the LELE process are the litho-litho-etch (LLE) process, in which the patterning of the second resist layer is made over the first one without any etching process in between [14], and the litho-freeze-litho-etch (LFLE) process, in which after patterning the first resist layer, a chemical procedure name "chemical freezing" is carried out, which induces additional cross-linking of the first resist layer in order to make it insoluble in the solvent utilized in the second resist spinning and improve the yield of the process [15, 16].

Compared to LELE and its variants, the self-aligned double patterning (SADP) technique discussed before provided more advanced performances in terms of scaling and density of the pattern [17]. In this case, after realizing a first patterning on the resist layer, an inorganic coating has to be deposited in order to create spacers on the side of the pattern features that are used for the final patterning. However, the implementation of the SADP is more problematic for the compatibility issues related to the deposition of the inorganic layer on the resist, the polishing process, and the resist removal.

8.3 Non-optical Lithographic Methods

There are also lithographic techniques that are not based on optical exposure, such as electron beam lithography (EBL) and nanoimprint lithography (NIL).

8.3.1 Electron Beam Lithography

Besides UV light, electron beams have also been utilized for resist patterning in electron beam lithography (EBL). The main advantage of EBL is the fact that the wavelength associated with the electrons of the beam (whose energy is typically in the range 10–100 keV) is very short and consequently a high resolution can potentially be obtained, as predicted by Eq. (8.1).

However, EBL is essentially a direct writing method, in which the beam must be scanned from point to point on all the patterns that have to be transferred to the resist, and consequently is basically a slow process that cannot cope with the throughput requirements of modern plants for IC mass production. For this reason, EBL has been so far mainly utilized for the fabrication of the masks used in optical projection systems rather than for the direct pattern transfer on the wafers.

Resists for EBL are different than UV photoresists because they must be sensitive to electron irradiation rather than to light exposure. Electron-sensitive resists with positive and negative tone have been developed, which is important to decrease the e-beam writing time when realizing DUV masks, depending on the density of the clear and dark areas required on them. In these materials, for example, poly(methyl methacrylate) (PMMA), EBR-9 (an acrylate-based resist), PBS (poly(butene-1 sulfone)), and ZEP (a copolymer of chloromethacrylate and methylstyrene), the resist sensitivity to the electron irradiation, related to the exposure time, and the contrast obtained on the pattern, related to the resolution,

are key and sometimes competing properties that have to be tuned for the specific application.

However, although EBL was newly included in the ITRS roadmap as a possible alternative for the implementation of the 32 nm technological generation [18, 19], as the cost of 193 nm UV equipment increased sharply with the progressive decrease of the critical size, the recent advent of extreme ultraviolet lithography (EUVL) has terminated all the efforts toward EBL for IC production.

8.3.2 Nanoimprint Lithography

Nanoimprint lithography (NIL) is actually a molding technique that is employed to pattern the resist by the mechanical action of a master stamp, in which the negative of the desired geometry must be preliminarily impressed [20]. Different than in all the other lithographic methods, the geometry of the resist pattern is not determined by the exposure contrast and by the action of the development process, but, instead, by the resist reflow during the application of a mechanical action to the mask. Consequently, the involved physical processes are quite different compared to all the other lithographic methods. Since some reflow of the resist material is necessary for the NIL procedure, the viscosity of the resist during the imprint must be low enough. After the process, on the contrary, the imprinted resist must provide a sufficient mechanical strength to maintain the acquired shape during the subsequent pattern transfer processing such as plasma etching, just like the patterns obtained by optical and electron beam lithography.

Such control of the viscoelastic properties of the resist layer during NIL can be obtained using either thermal treatments (thermally assisted NIL) or UV curing (UV-assisted NIL). In thermally assisted NIL, the polymer that is used to transfer the pattern from the master stamp to the wafer is heated above its glass transition or fusion temperature, in order to achieve a sufficient fluidity and permit a correct molding of the pattern. After imprint, the wafer is cooled down to solidify the imprint material before detaching the stamp and proceed with the process.

In UV-assisted NIL, the imprint material utilized is actually similar to a negative resist, in which cross-linking can be promoted by UV exposure. Before being irradiated, the resist is sufficiently fluid to allow a correct imprint process, and consequently the stamp can be applied straightforwardly. However, after molding, UV exposure must be performed in order to fix the shape of the resist before removing the stamp. This is usually done by utilizing stamps that are transparent to the UV radiation used. After light exposure, the resist becomes solid, and the stamp can be removed before going on with the subsequent pattern transfer processes.

In NIL, the fabrication of the master stamps is a critical issue since they play the same role of the masks in photolithographic processes. However, different than in projection systems, no size reduction of the mask geometry is allowed, and consequently the stamp must be patterned with the same resolution required on the wafer, involving the use of nanopatterning and nanofabrication techniques. A possible way to produce NI rigid master stamps is resist patterning with EBL followed by high aspect ratio plasma etching on Si or glass substrates. Recently, new UV-assisted NIL techniques based on soft master stamps that are more tolerant to the possible presence of particles on the wafer during the imprint process have been developed, in which the soft stamps are molded from a nanofabricated rigid master using a thermally cured PDMS layer deposited on a thin glass layer.

Compared to projection UV systems, NIL is a potentially cheaper technology and is considered a viable alternative for the future implementation of the fabrication of memories. In order to become competitive, further improvements would be needed on NIL in terms of presence of defects in the pattern. However, the recent improvements achieved have been very fast, and the future of NIL in next-generation advanced patterning processes for memories is considered potentially bright. Due to its low cost, NIL is also a valuable alternative to DUV or EBL for non-IC technologies that may need at least one level of nanopatterning, such as LEDs, MEMS, and displays.

8.4 Extreme Ultraviolet Lithography

The latest frontier in lithography resolution improvement is extreme ultraviolet lithography (EUVL), which is based on light sources operating at a wavelength of 13.5 nm [21, 22]. Such new technology, for the very short wavelength used in the source, promises to solve the resolution issues related to the development of the next IC technology nodes but, at the same time, poses new challenges in several aspects of the lithographic process.

One of these challenges concerns the photoresist, since the EUV radiation is much more energetic than the DUV one, and is likely to produce ionization effects in the material after irradiation, generating free or excited electrons that may affect the irradiation energy deposition in the material and consequently the quality of the pattern. This effect, which might have appeared undesired at first, was actually exploited for the development of EUV photoresist chemistry, which is actually an ionization chemistry rather than a pure photochemistry as in NUV and DUV resists. In the development process, the generation of the acid molecule that changes the solubility of the resist in the developer is initiated by the optical irradiation and mediated by additional molecules such as photoacid generators (PAGs) and quenchers. These

mechanisms will be treated more thoroughly in the next section devoted to EUVL photoresists.

Other very demanding requirements for EUVL come from the need of a stable and powerful light source at 13.5 nm that can be suitable for high-throughput IC production. It was calculated that in order to match the requirement of 125 WPH, a light source of at least 200 W is needed for these systems. The development of EUV sources will be discussed in greater detail in the following in a dedicated section.

Even the mask used in EUV cannot employ the traditional materials used for DUV radiation. Since no material with sufficient transparency at 13.5 nm is available, EUV reticles must work in reflection rather than in the typical transmission mode adopted in the traditional lithographic masks. In order to keep them free from particle contamination, special protection materials have been developed, on which an intense research work is still being carried out.

As discussed before, most modern industrial plants producing ICs are based on scanners containing ArF deep-UV sources that produce monochromatic light at a wavelength of 193 nm, reaching a minimum lithographic pitch resolution around 80 nm, which can be improved by adopting multiple patterning techniques like LELE or SADP. Given the dependency of lithography resolution on wavelength and the importance of scaling of the critical dimension of ICs in Moore's law, it is not surprising that the research on advanced lithography has progressively led to the use of light sources with decreasing wavelength of operation. The ultimate target of wavelength scaling in optical lithography is EUVL.

Dating back to the first experiments carried out in the 1980s [23, 24], the research on EUVL systems has recently produced the first prototypes, which have been in the field for a few years in IC foundries, such as the ASML's 0.33 NA EUV scanner operating at 13.5 nm, which has demonstrated a 13 nm line/space resolution with both CA and non-CA resists [25]. With EUVL, the mask set used for lithography can also be reduced compared to present state-of-the-art processes, in which multiple masks are often needed for a single lithographic step in order to overcome the limitation in resolution, up to using a single mask for the litho step, with evident economic advantages. The development of suitable photoresist materials for the wavelength of 13.5 nm has been a fundamental theme in the research related to the development of EUVL systems.

8.4.1 Requirements for EUVL Photoresists

EUVL photoresists, as almost all photoresists used in IC technology in the last 30–40 years, have been based on the concept of chemical amplification, which was developed between the late 1970s and the early 1980s to handle the limited power of the optical sources used at that time. For EUV, new resists have been developed, also without chemical amplification, to address the specific problems of CARs in extreme ultraviolet lithography, such as low optical absorption, insufficient resolution, stochastics, and risk of resist line collapse.

For the possible industrial use of a new photoresist, several issues must be taken into account. The first characteristic is patterning performance, which is fundamental. Other important issues are edge placement, stochastic control, stability, sensitivity, current specifications of the tool, resolution, and defectivity. Resolution was demonstrated with both chemically amplified and non-chemically amplified resist, as mentioned above. Compared to traditional CARs, the new resist chemistries developed for EUV may have more problems in quality control and manufacturing, since CARs are very well established in current industrial processes and can rely on a large number of manufacturers. Other possible problems may come from the risk of metallic contamination in case the new developed resist chemistry contains metals, which is sometimes the case.

Edge placement error (EPE) is one of the key issues related to patterning quality. It is the superposition error of the pattern that is transferred to the photoresist with respect to a previous pattern already transferred to the substrate. Generally speaking, the edge placement error is composed of two contributions: the overlay error and the critical dimension (CD) error. The overlay contribution is directly related to the placement accuracy of the pattern during the scanning procedure. Using EUV, the overlay error is expected to be improved, thanks to the use of a single mask in place of the multiple masks utilized in ArF scanners. The CD EPE, instead, depends on a number of factors that may affect the critical dimension of the pattern and, consequently, the alignment with the underlying reference, such as mask/projection effects, resist stochastic variation in thickness, roughness, and profile. The acceptable CD stochastic variations in a lithographic process depend on the feature size that has to be transferred on the resist. In [26], for instance, it was reported that the maximum CD variation that can be accepted when fabricating 20-nm-wide vias is 3 nm. Considering the resolution that is possible in EUVL, it is easy to understand the importance of EPE control in this technology.

Considering a die containing N vias, the yield probability of the die (Y) is the complement of the failure probability of any via in the die, since the correct operation of a logic circuit requires all the vias in the die to yield. Consequently, if f_V is the failure probability of an individual via, considered statistically independent from one of any other vias of the die, we may write:

$$Y = (1 - f_v)^N \tag{8.6}$$

because the die yield probability coincides with the probability that no via among the N in the die fails. If the via

failure probability f_V is very small, as it should be in a good lithographic process, we may approximate Eq. (8.6) in the following way:

$$Y = 1 - Nf_v \tag{8.7}$$

By rearranging Eq. (8.7), we may write:

$$f_v = \frac{1 - Y}{N} \tag{8.8}$$

This form of the approximate equation allows to understand how demanding the requirement on the failure probability of the via f_V may be, considering a target die yield Y.

For instance, if a target yield of 99% is sought for the lithographic process and the number of vias in the die is in the order of ten billion (10^{10}), which is not uncommon in modern logic ICs, a failure probably f_V in the order of 10^{-12} is required. Consequently, the lithographic process needs to be very robust.

This challenge brings with it the need to control the stochastic effects in resist patterning, which depend on a number of factors. This challenge has been cyclically faced by the semiconductor industry during the shrinking of the critical dimension of ICs, particularly when shorter wavelengths were explored for the optical source. Chemically amplified resists, for instance, were invented between the late 1970s and the early 1980s to handle the problems related to the low intensity of the new lamps employed in 248 nm lithographic systems. An analogous development path is underway to bring EUV systems to the market.

Since, essentially, all the phases of resist exposure and development may in principle contribute to stochastic effects (photon absorption, generation of secondary electrons, quenchers, development process etc.), the sequence of chemical reactions involved in the development must be carefully investigated for the new photoresists used in EUVL. This is essential to achieve a good control of resist stochastics and consequently a sufficient yield of the patterning process.

In this respect, the chemistry of EUV CARs is peculiar [27], because, different from 193 nm resists, it is not pure photochemistry. EUV photons generate secondary electrons within the photoresist that interact with the photoacid generators (PAGs) to mediate the resist development reactions, so EUV CARs are essentially electron-sensitive resists.

One of the sources of resist stochastics are statistical variations in photon irradiation during exposure. The problem is particularly relevant in EUVL, in which the photon density during exposure is significantly lower than the case of ArF technology. To give an example, considering an exposure intensity of 20 mJ/cm^2, an ArF source develops 194 photons/nm^2, whereas an EUV source at 13.5 nm delivers only 14 photons/nm^2. This is an obvious consequence of the higher energy quantum associated with the single photon in EUVL, due to the shorter wavelength. The lower number of photons increases the impact of photon shot noise on EUV resist stochastics.

Table 8.1 Photon and quencher statistics in chemically amplified EUV resists [29]

Dose	20 mJ/cm^2	50 mJ/cm^2
Area	314 nm^2	314 nm^2
Volume (h = 2*CD)	12,560 nm^2	12,560 nm^2
Absorption	5 μm^{-1}	5 μm^{-1}
Generated electrons (2–4/photon)	1100–2200	2750–5500
PAGs (0.15/nm^3)	1885	1885
Quenchers (0.2/PAG)	377	377
7σ photon variation (%)	30	19
7σ Q variation (%)	36	36

Considering the case of patterning of 20 nm holes, the theoretical stochastic variability can be calculated considering the typical density of photoacid generators (PAGs) and quenchers, which are both essential molecules for the irradiation-induced reaction in EUV resists, within the holes [27, 28]. In Table 8.1, the cases of 20 mJ/cm^2 and 50 mJ/cm^2 are considered.

Due to the small area of the 20 nm hole, the number of quencher molecules within the dot is comparable with the number of absorbed photons during exposition, even though with the higher irradiation dose considered in the Table (50 mJ/cm^2), the number of absorbed photons is high enough to make quencher statistics dominant. In particular, the stochastic variability of the quencher molecules should be considered to characterize the two stochastic processes since they are random processes. With such a high variability in the distribution of the quenchers, it is likely that in some areas of the sample, no reaction at all occurs during resist exposure.

Similar considerations can be done for other resist chemistries. Generally speaking, the dominance of quenchers stochastics makes the effect of a high exposure dose on the critical dimension less effective compared to the situation in which photon stochastics is more important, because even in the presence of a higher number of photons, the variability of the critical dimension may not improve simply because many photons do not produce any secondary electron and consequently do not give rise to any reaction in the resist because of the low density of quenchers within the feature.

Due to these statistical effects, the typical result after development of small features such as a 20 nm hole in a EUV resist is the appearance of some statistical distribution of the feature size, which normally present some tails below and above the nominal value. The control of the tails of such a distribution is very important because it is enough to have one via that is too small (or too large) to produce a failure of the entire circuit, as mentioned before.

Concerning photon shot noise, a possible way to reduce its effect on resist stochastic variations is adopting new resist composition with increased photon absorbance, such as metal oxide resists [30].

In general, in order to bring EUV to the needed standard for industrial IC production, the following improvements will be needed:

- Increase of the photon absorption of the photoresist.
- Enhancement of the efficiency of secondary electron production by the photons in the resist: every photon should be able to produce a secondary electron and initiate the reaction.
- Achievement of an ordered structure of the photoresist in order to decrease stochastic variability of the properties from point to point in the material.
- Enhancement of the resist dissolution process in the developer.

At the present state of the art, no EUV resist developed so far meets all these requirements. In particular, in the literature, researchers concentrate on three requirements, abbreviated as the RLS triangle, in which the scope is minimizing resolution (R), line width roughness (L), and sensitivity (S). There is a trade-off between these parameters, where not all the three metrics can be minimized simultaneously.

In order to reach these goals, a deep understanding of the chemical and physical processes involved in the photoresist exposure and development process will be needed, such as photon absorption, secondary electron generation, energy distribution, and mean free path.

EUV lithography was formerly known as soft X-ray lithography and was developed within research laboratories starting from 1986, initially utilizing synchrotron radiation as a light source. More recently, commercial systems have been produced using laser-assisted plasma sources able to produce a power light of 250 W at intermediate focus, which proved to be necessary in order to overcome the power limitations of synchrotron radiation. In 2019, EUVL systems with NA of 0.33 have entered high-volume IC production, whereas an intense research work is still being done to extend the results obtained so far to 0.55 NA systems and possibly to shorter wavelengths than 13.5 nm. In this research, synchrotron radiation facilities are likely to maintain an important role.

8.4.2 Laser-Assisted Plasma Sources for EUVL

Light sources for massive EUV fabrication need to provide high power (to guarantee the required throughput in terms of number of wafers per hour) and stable irradiation dose for high yield. Moreover, they are required to comply with the specifications about the spectral content of the produced light that are necessary for the process. Nowadays, EUVL scanners are equipped with laser-assisted plasma sources that are the result of a 15-year research development.

EUVL was initially proposed considering the wavelength range 4–40 nm, which spans across the extreme ultraviolet and soft X-ray regions of the spectrum. In the initial development phase of EUV sources, synchrotron radiation and laser-assisted plasmas were competing technologies. In the 1990s, the power requirements for the sources were still low, in the order of 250 mW for the 12.5–15 nm range. With such power requirements, synchrotron radiation was more competitive at that time compared to laser-produced plasmas (LPP) because it was able to generate a much larger power. Another apparent advantage of synchrotron radiation compared to LPP was the fact that one synchrotron could produce more than one light source and potentially feed different lithographic systems.

Later on, it became clear that in order to be able to compete with the 193 nm lithographic systems, EUV source power requirements had to be around 250 W, and this put out of question synchrotron radiation. Moreover, the possibility to have a different source of light for each lithographic system is now considered an advantage because it makes a complete stop of the plant less probable in case of a source stop. From this point of view, the generation of multiple beam lines from a synchrotron equipment for different EUVL systems is no more considered desirable.

During the development of LPP EUV light sources, several types of laser were investigated, such as KrF at 248 nm, XeCl at 308 nm, XeF at 351 nm, CO_2 at 10.6 μm, and Nd:YAG lasers at 1064 nm and 532 nm (which is a solid-state laser). One of the most important criteria for the choice of the laser was the efficiency of the conversion of the excitation laser light into the useful EUV light. From this point of view, Li, Sn, and Xe appeared to be the most promising elements, since Sn and Xe show relatively broad emission bands in the wavelength range 13–14 nm, whereas Li has a sharp emission line at 13.5 nm. The existence of these emission bands (and the reflectivity of the available mirrors for the corresponding wavelength) leads to the choice of 13.5 nm as the preferred wavelength for EUV systems [31].

In Fig. 8.11, a typical LPP EUV system is schematically represented. It is composed by a CO_2 laser in a master oscillator power amplifier (MOPA) configuration, a beam transportation system, a set of focusing optics, and a vacuum chamber containing a Sn droplet generator onto which the CO_2 laser light is focused in order to produce the EUV light by secondary emission from the droplets. The interaction between the CO_2 laser and the Sn plasma occurs in the primary focus of an ellipsoidal mirror, in such a way that the generated EUV light from the plasma is reflected by the mirror and collimated on its secondary focus.

The principle of operation of the plasma is the following. Two pulsed laser beams, a pre-pulse and the main pulse,

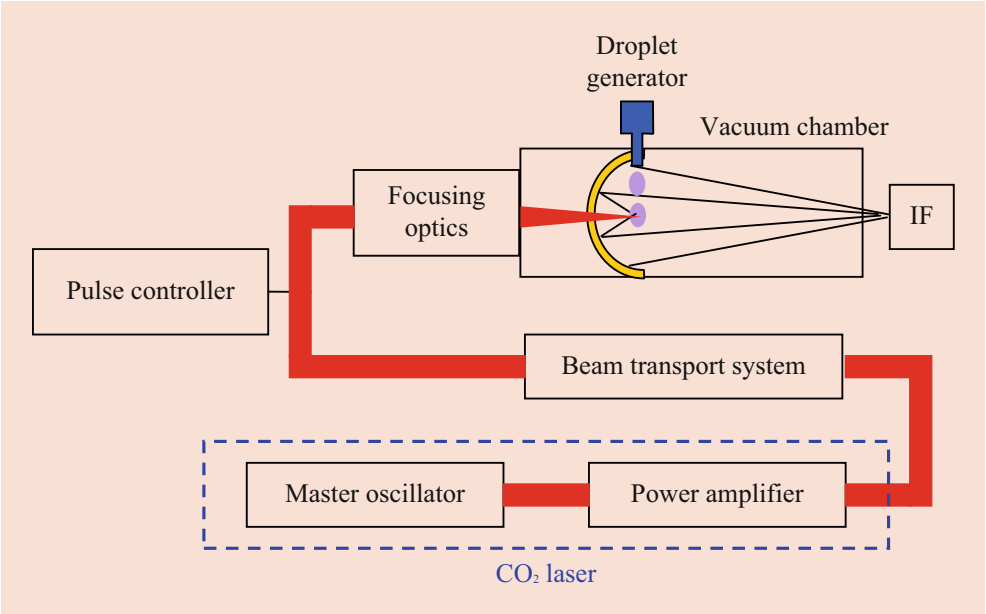

Fig. 8.11 Schematic representation of LPP EUV source

are directed toward the tin droplet plasma and activated at different times. Both lasers are generated by a seed and then amplified before being directed to the plasma chamber through the beam transportation system. The beams are also spatially separated in the chamber, since the function of the first laser pulse is increasing the surface of the Sn droplets by changing their shape, in order to reach an interaction surface of about 500 μm with the subsequent beam. In this way, the efficiency of the secondary emission from the plasma is remarkably enhanced. In order to fully exploit the potential of the method, the second laser beam is focused below the first one, in order to be able to interact with the particles after their shape change.

The setup of the system is designed in such a way that the interaction with the lasers with the particles takes place on one specific droplet at a time. As a consequence of this requirement, the repetition rate of the droplet emission needs to be sufficiently high, and the laser emission must be synchronized with it in order to guarantee that the laser-droplet interaction is repeated frequently enough to produce an intense secondary light emission.

Typical parameters of these systems are a repetition rate of 50 kHz for the droplet production, with a sufficient speed (80 m/s) to assure a relatively large separation between the adjacent droplets (around 1.5 mm). Thanks to the distance maintained, the plasmas generated by different droplets do not disturb each other. The atmosphere of the chamber is low-pressure hydrogen that also acts as a stopping gas for the Sn ions produced by the plasma.

Since the interaction of the primary laser with tin produces undesired effects such as ablation, clusters of particles, and fast Sn ions within the plasma, the system is designed in order to limit the amount of tin used, by reducing the droplet size and carefully controlling the timing of the droplet-laser interactions.

The EUV scanner contains several reflecting surfaces (one of which is the one represented in Fig. 8.11), which are used to collect the produced UV radiation and focus it on the processed wafer. Such reflecting surfaces have a key role in determining the attenuation of the light during the exposure procedure, since at every reflection the originally produced power is reduced. The technology of choice for the reflecting surfaces in EUVL systems is a multilayer Mo/Si technology that reflects around 67% at the Sn emission wavelength of 13.5 nm. This reflectivity is not very high but at the present state of the art is the best one available. As a consequence of the limited reflectivity of the Mo/Si mirrors and the different reflections that are used in the scanners, a very high attenuation of the emitted radiation takes place during the focusing process, leading to a projected power that is only 2% of the one produced by the Sn plasma, considering a number of reflections of 10 in the projection and illumination systems. This limitation in the efficiency of the illumination and projection systems based on Mo/Si mirrors has been the driving force for the development of EUV sources with increasing power, because, as widely discussed formerly, the intensity of the light projected on the wafer is a key issue for the wafer throughput of the lithographic process.

Another important aspect in EUV sources for 13.5 nm is spectral content control. Even though the secondary emission of the Sn plasma is related to the energy of the laser pulse that interacts with the droplets, with increasing secondary

emission power with increasing laser pulse, it is not granted, in general, that the central wavelength of the emission peak is always located at 13.5 nm independent of the energy of the primary laser. Since a well-centered distribution of the spectral power on the wavelength of interest is important for the yield of the lithographic process, the plasma should operate in such a way that the spectral content of the secondary emitted light is essentially independent of the power of the excitation laser pulse.

In the latest generation of EUVL sources, measured spectra of the emitted light for different energies of the laser pulse have been reported [32], showing a very good control of the wavelength of the emission peak, which is always centered at 13.5 nm. In this way, the center of the emission spectrum is also matched with the peak reflectivity of the Mo/Si mirror, which, being a multilayer structure, presents a rapidly decaying reflectivity as wavelength deviates from the peak value.

Concerning conversion efficiency, modern EUVL systems are able to reach a relatively low conversion efficiency around 6% of the pulse laser energy, which is almost constant within a threefold variation of it, considering that all the other parameters of the plasma are kept at a constant level and that only the laser pulse energy is varied.

The required power for the light source in EUV can be quite straightforwardly calculated by taking into account that in order to assure a wafer throughput of 100 wafers per hour (WPH) with the typical duty cycle of 60% used during the scan, a projected power of 550 mW on the wafer is needed. Since the emitted EUV radiation must undergo more than ten reflections in the mask, illumination, and projection system, and considering the reflectance of the Mo/Si multilayer mirrors at 13.5 nm around 67%, a required power of 200 W for the light source can be calculated. This power requirement is somehow more demanding than one of the 193 nm ArF scanners for which a source power around 90 W is enough to fulfill the requirements for 100 WPH throughput.

Since the irradiation dose on the wafer may vary according the requirements of the lithographic process (for instance, for yield issues, as explained before), it can be interesting to calculate the WPH expected by considering different combinations between the source power (measured in W) and the irradiation dose (measured in mJ/cm^2) because, quite reasonably, a larger irradiation dose generally leads to a lower throughput if the source power is constant. A possible way to represent the WPH variation with the source power and irradiation dose is plotting the dependency of the WPH on the ratio source power/irradiation dose, measured in Wcm^2/mJ.

The typical shape of the wafer throughput versus the ratio light power/irradiation dose is reported in Fig. 8.12 [32].

Depending of the numerical aperture (NA) of the projection system, different curves are obtained in which an initial monotonic increasing behavior of the throughput is observed

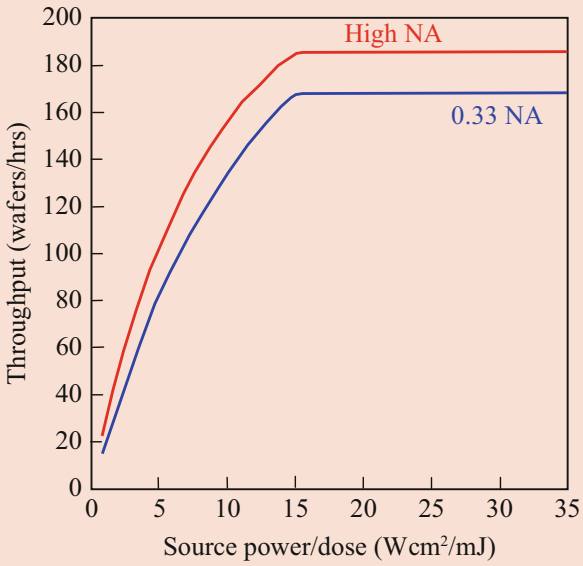

Fig. 8.12 WPH versus ratio source power/irradiation dose [32]

up to a saturation point beyond which a further increase of the source power/dose ratio is no more useful to improve the WPH.

Since the overall power of the plasma depends on the energy of the primary laser pulse and on its repetition rate, the light power produced by the system in the secondary focus of the main reflecting mirror (see Fig. 8.11) is also a function of the laser pulse and in particular of its peak power during plasma generation. Considering the efficiency of the secondary emission from Sn droplets, which is around 6%, and the lost power during exposure, also taking into account the optical transmittance of the plasma gas within the chamber, a peak laser power of 20 kW is needed in order to obtain a plasma laser source power of 200 W in the intermediate focus of the first reflecting mirror of the system.

The adoption of EUVL for high-volume manufacturing (HVM) has been hindered for years by the insufficient power of the sources. The recent achievement of stable emission with power of 250 W in EUV sources has paved the way to the adoption of this technology in HVM. Different laser architectures have been explored during the path toward power upscaling of EUV sources. The first laser architecture adopted was an unseeded laser scheme without master oscillator, named NOMO (no master oscillator) laser. In that scheme, the laser light directed toward the Sn droplets by the power amplifiers was fed back in the laser cavity after reflection from the plasma, exploiting the good reflectivity of the metal droplets. In this way, an unseeded self-sustaining active emission could be achieved. However, the power obtained with this solution was not satisfactory for the throughput requirements discussed before.

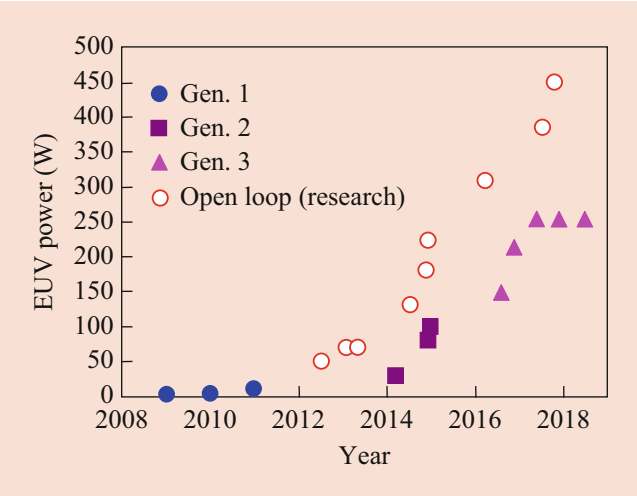

Fig. 8.13 Power scaling of EUV sources through the years [32]

The adoption of a laser seed in the master oscillator power amplifier (MOPA) configuration was a key innovation to increase the conversion efficiency and substantially increase the emission power. Another important innovation was the adoption of the pre-pulse used to increase the interaction area between the seed laser and the droplets. In the end of this development pathway, a tenfold increase of the emission efficiency in the Sn-based EUV source was obtained.

The much larger optical energy accumulated in the Sn plasma with these new system configurations also dictated more stringent requirements on the optical isolation of the laser system toward the external environment. All the technical innovations introduced to improve the optical isolation of the laser were key factors to further increase the power scaling after 2016.

In Fig. 8.13, the power scaling of the EUV source starting from 2009 to nowadays is represented in a plot, in which the potential capability of reaching 500 W for next-generation EUV sources in the near future appears likely.

In particular, the open-loop power obtained without any dose control in research system prototypes is very promising for potential improvement of the emitted power in future commercial equipment.

Another fundamental requirement for the source is power stability, which ultimately determines the irradiation dose reproducibility on the wafer, which is a key issue for the yield of the lithographic process, as discussed before. Recently, in 2017, the stable operation of 250 W power EUVL sources that can be employed to achieve 125 wafers per hour was demonstrated, with both power measurements performed in the source and irradiation dose measurements carried out in the far field of the projection system. In order to reach such stability, the control of the droplet generation and the stability of the pointing laser on the droplets were key issues. In these systems, the fleet average dose of the scanner is more than 99.99%, which means that in 99.99% of the cases, the irradiated dose projected on the wafer by the system is within the specifications required for a correct patterning of the resist.

Another aspect related to the stability of the source is the long-term degradation of the reflectivity of the collector mirror during the operation of the plasma. Such effect is mainly due to the possible deposition of Sn droplets that are produced within the plasma on the mirror surface. In order to maintain the reflectivity of the collector mirror over time, it is important to protect it from tin droplet deposition.

The degradation of the mirror reflectivity due to this phenomenon is normally measured in percentage per gigapulse, which is the percent degradation of the mirror reflectivity that occurs in the system after one billon pulses of light produced by the plasma. Modern mirror protection methods assure a mirror degradation ratio in the range 0.1–0.3%/Gp. Very recent developments reported in the literature have shown that the degradation ratio of the Mo/Si collectors can be reduced by designing the camera in order to bring the particle flow away from the critical region effectively, demonstrating a degradation ratio of only 0.03%/Gp over 32 gigapulses.

8.4.3 EUVL Chemically Amplified Photoresist Chemistry

The chemistry of EUV photoresist is a radiation chemistry that is similar to the one governing the behavior of electron beam (EB) resists. PMMA, for instance, is a material that can be conveniently used as both EB and EUV non-chemically amplified resist. In PMMA, the acid-catalyzed deprotection reaction that makes the polymer soluble in the developer can be initiated by both electron beam irradiation and EUV exposition, since in both cases the interaction with the radiation can induce a decrease of the molecular weight of the polymer within the exposed regions as a consequence of a chain scission straightforwardly induced by the interaction of the polymer with the radiation.

In chemically amplified EUV photoresists (which can be often used also as EB chemically amplified photoresists), the physical and chemical processes involved in the patterning process show some similarities to the mechanisms already described earlier for DUV chemically amplified resists, but are more complicated.

The main reason for these differences comes from the fact that the EUV radiation, whose wavelength is 13.5 nm, is so energetic that its photon energy (92.5 eV) exceeds the ionization threshold of the polymer molecules that constitute the backbone of the material. This was not the case for ArF DUV lithography in which the energy associated with the 193 nm wavelength used was much lower, largely

below the ionization threshold of the polymer molecules. These ionization phenomena, which take place during resist exposure, play a fundamental role in the resist chemical amplification mechanism that governs the patterning process. Indeed, the generation of the acid molecules that catalyze the deprotection reaction of the polymer chain during the PEB and make the material soluble in the developer are closely related to the free electrons created in the material by the ionization of the polymer molecules. This is the reason why, different than in DUV resists, the patterning process of EUV resist is regulated by radiation-induced rather than photon-induced chemical phenomena.

It is worth noticing that, since the photon energy in the ionizing EUV radiation is lower than the energy of electrons utilized in EBL (1–100 keV), the mentioned ionization phenomena can also explain why, generally, EUV photoresists can also be used as EB chemically amplified photoresists, exploiting similar chemical reactions initiated by the electron-induced ionization of the polymer molecules. Consequently, understanding the radiation chemistry of EUV CARs may also lead to the understanding of their sensitivity to electrons and their possible use in EBL. This is important since although EBL is not considered, at the moment, as the main candidate for mass production of next-generation ICs, it remains fundamental for the fabrication of the photomasks used in projection photolithography, such as EUVL. Improving the performance of EBL in photomask fabrication is gaining increasing importance as the requirements on mask quality in advanced projection lithography are becoming more stringent, not only because of the shrinking of the critical dimensions of the pattern but also owing to the adoption of new sophisticated technologies that can improve the projection process, such as optical phase shift [33].

The patterning process in EUV CARs can be summarized as follows. The first step, as in any lithographic exposure, is the selective exposure of the resist to the EUV radiation, which generally takes place through a projection system in which the photomask, different than in DUV and NUV lithography, is used in reflection rather than in transmission mode. The irradiation of the EUV resist, as mentioned before, produces ionization phenomena involving both the polymer molecules and other acid generator molecules, which are added to the mixture in order to produce the acid catalyzers that are necessary in the chemical amplification reaction. Even if the dissociation of the acid generator can be also directly produced by the EUV or the electron irradiation of the resist, it was demonstrated by specific investigations that this phenomenon is statistically unimportant in the acid generation process that takes place after irradiation. Most of the acid generator dissociation in the resist, indeed, occurs by dissociation reactions involving the acid generator molecules and the ionized electrons produced by the ionization of the polymer molecules.

Therefore, the effect of radiation on the acid generator is indirect, since the EUV radiation does not act directly on the acid generator molecule to form the catalyzing acid. Instead, the radiation acts on the polymer molecules, producing free electrons that subsequently give rise to the acid molecule by reacting with the acid generator. These free electrons, after thermalization, interact with the acid-generating species giving rise to the acid catalyzers.

During the dissociation reaction mediated by the thermalized electrons coming from the polymer ionization, the acid generator molecule captures a free electron and releases an acid counteranion, which represents a fixed charge in the polymer matrix. After the latent image constituted by such molecules is formed, the acid counteranions initiate a deprotection reaction on the polymer molecules, usually during a PEB step, which is mediated by the presence of protons (hydrogen ions) provided by other chemical reactions involving the acid anions and the polymer molecules, both in ionized form and in the fundamental state. Such reactions finally allow the material to become soluble in the developer solution.

The same fundamental mechanism is followed in case the resist is exposed using an electron beam instead of EUV radiation, except for the fact that the energy deposition from the radiation that takes place during the ionization of the polymer molecules is governed by different physical phenomena, whereas, after ionization, the sequence of chemical reactions is similar.

Compared to a purely photon-induced chemical amplification, the chemical mechanisms of EUV CARs involve more elements, such as the secondary electrons and the protons, whose impact on the performance of lithography is important and must be evaluated when developing new EUVL materials with chemical amplification.

Thanks to the reduced wavelength utilized for the exposure, EUVL CARs have demonstrated a sub-20 nm patterning capability with high sensitivity to the irradiation (doses in the range 10–20 mJ/cm^2 are sufficient for a successful development process). However, the line width roughness (LWR) is still larger than the value (<1 nm) that would be needed for the node that requires a 20 nm feature size, and a trade-off among resist sensitivity, resolution, and LWR seems to exist in the technology.

The origin of LWR in EUV lithography has been investigated in several studies and appeared to be mainly dependent on the chemical gradient on the borders of the exposed areas, which is the gradient of the chemical species involved in the development, for instance, the concentration of unprotected monomer units in the material that are responsible for its solubility in the developer. In developing EUV photoresists, strategies to enhance the chemical gradient should be elaborated in order to improve LWR without affecting resolution and sensitivity.

In order to analyze in detail the chemistry of EUVL CARs, the following subsequent steps involved in the exposure-development procedure of these resists have to be considered:

- Accumulation of the radiation energy (EUV or EB) in the resist material.
- Formation of a pair composed by a radical cation and a secondary electron as a consequence of ionization phenomena induced by the irradiation.
- Generation of an acid counteranion by dissociative electron attachment of acid generator molecules.
- Proton generation through ion-molecular reactions between the polymer and the radical cations produced by the irradiation.

In the following, each of these steps is analyzed in greater detail.

Accumulation of Radiation Energy Within the Resist

In EUVL, the irradiation on the photoresist transfers energy to the material through atom ionization and electron excitation. This happens because the ionizing radiation loses energy in favor of the valence electrons of the atoms of the resist material, generally a polymer, as a consequence of inelastic interactions of the photons with the atoms. Due to the energy gained during the inelastic scattering events, some electrons may reach a higher energy state than the fundamental one (excitation). If the energy gain is high enough, the electron may be detached from the atom and become a free electron, leaving a positively charged ion in the reticule (ionization). In EB and EUV photoresists, the dominant energy deposition mechanism due to irradiation is ionization.

Like in conventional DUV lithography performed with ArF of KrF lasers, the energy deposition profile of EUV light can be calculated using Lambert's law :

$$\frac{\mathrm{d}I}{\mathrm{d}z} = \alpha I(z) \tag{8.9}$$

where I is the photon irradiation intensity, α the optical absorption coefficient, and z the depth of the path travelled by the photons from the surface of the photoresist layer during irradiation.

Following Eq. (8.9), the acid yield, which is the number or acid molecules generated per incoming photon in the resist, has been studied as a function of thickness in a resist layer constituted by poly(4-hydroxystyrene) (PHS) with 10 wt% triphenylsulfonium triflate (TPS-tf) [34]. This material is a chemically amplified resist that may be used with both EB and EUV exposure.

In order to estimate the acid yield, in this kind of experiments, an acid-sensitive dye (Coumarin 6) was added to the photoresist to observe the concentration of acids after irradiation. Such additive permits to measure the acid yield through the concentration of proton adducts produced by the acid-sensitive dye, which is known to be proportional to the acid yield. By exposing the resist to a 75 keV EB on layers with different thicknesses, it was found that the acid yield was approximately proportional to the thickness of the resist. This is due to the fact that the transmittance of the high-energy electrons on the resist is high and by consequently increasing the resist thickness, the number of scattering events produced by each irradiating electron increases, yielding a higher probability to generate an acid molecule after the whole resist exposition process.

Using EUV radiation instead of electrons, the behavior of the acid yield with resist thickness is completely different, since it rapidly saturates to a constant value as soon as the thickness reaches a critical value around 800 nm. This happens because the absorption of EUV photons in the resist is very high and consequently the penetration depth of the ionizing radiation is limited, different than the case of EB irradiation. Consequently, after the thickness threshold of 800 nm, the number of interactions of the radiation with the resist atoms no longer increases, and the probability to ultimately yield an acid molecule also saturates.

Another finding of these experiments was the fact that the absorption coefficient of the photons in the resist, and consequently the critical thickness for acid yield, was essentially independent of the acid generator concentration in the resist. This was found to be also true for EB adsorption, confirming that the direct interaction of the incoming electrons or photons with the acid generator molecules during the lithographic process is negligible in these types of chemically amplified resists.

It is also important to note that the interaction of photons with the polymer molecules is fundamentally different than one of the primary electrons when using EB.

Actually, whereas a high-energy electron can undergo different scattering events and ionize more than one molecule directly before completely losing its energy and stopping within the material, a photon can be absorbed only once by a molecule, generating a high-energy secondary photoelectron. Such electron, however, may be energetic enough to ionize other atoms, similar to what happens with primary electrons in EB irradiation (this phenomenon can actually take place also with EB irradiation but is less probable). Consequently, the secondary electron tends to interact with other polymer molecules until it loses enough energy to fall below the energy ionization threshold of the molecules and, afterward, initiates a thermalization process slowly losing its remaining energy up to reaching thermal equilibrium.

Since the mean free path of the photoelectrons generated by the EUV radiation is around 1 nm, the ionization and electron excitation events occurring as a consequence

of the photon absorption are quite concentrated around the absorption point. This is not true for EB and X-ray resists, in which secondary electrons can be very energetic, and this is the reason why a higher patterning resolution is expected with EUV, since in this case the generation of high-energy secondary electron is a less important concern. However, the problem of the thermalization distance has to be similarly considered in the two cases.

The problem of radiation absorption from the material molecules is of paramount importance in photoresists. Particularly, it is important to determine which molecule is absorbing the incoming radiation during the exposition process. DUV photoresists, for instance, are designed in order to concentrate the absorption on the acid generator molecules and reduce as much as possible the absorption by the polymer. For ionizing resists, this is not possible, since, as mentioned before, it was verified that the absorption from the acid generator molecules is negligible up to a weight percentage of 20% of them in the mixture, and absorption is mainly owing to the polymer molecules. Consequently, in order to obtain a desired absorption coefficient, it is necessary to rely on the overall polymer composition and not simply on the acid generator. Since the number of secondary electrons generated per unit volume in both EB and EUV resists increases with the absorption coefficient, because more photons absorbed or more interactions with primary electrons give rise to a larger number of secondary electrons, the acid yield in such materials is typically dependent on their absorption coefficient.

The absorption in EUV resist depends on the density of the material and on the absorption cross section of the polymer atoms at the wavelength used. In principle, the absorption coefficient of a material can be calculated by knowing its density and the absorption cross sections of the constituent atoms. Among the atoms that can be used in resists, fluorine is one with the highest cross section for EUV absorption, and this is the reason why the fluorination of polymers is considered a promising strategy to increase the absorption in these materials.

Quite reasonably, the increase of the resist absorption coefficient also increases the gradient of the acid generation through the thickness of the material, since photons are rapidly absorbed while penetrating deep into the material. For this reason, the thickness of heavily absorbing resist layers must be reduced for a good outcome of the lithographic process. Although absorption cannot be increased indefinitely because of the problem of sidewall degradation of the resist pattern (due to insufficient acid generation at the bottom of the layer and consequently to incomplete development of the pattern), it was calculated that with a 20-nm-thick EUV resist, a polymer with an absorption coefficient of 16 μm^{-1} could be used, leading to a sensitivity enhancement of four times in the resist without affecting resolution and line edge roughness (LER) [35].

In order to calculate the number of ionized atoms after resist irradiation, the energy required to ionize an ion-electron pair in the material must be considered. Such parameter, usually indicated with W, is almost independent of the electron energy for ionization energy levels above 1 kV. For electrons, W slightly increases with decreasing electron energies because the ratio between the ionization and excitation probability decreases with the energy. For photons, the effect is also present but is much smaller, excluding the wavelength range slightly above the absorption edge of the atoms. Considering the above mentioned PHS as a resist material, a value of W around 22.2 eV was measured and found approximately the same for irradiation with electrons and photons [36]. Consequently, considering the typical energy of an EUV photon of 92.5 eV, the number of electrons generated on the average by each photon is around 4.

This estimation is motivated by the fact that, after ionization, the secondary electron loses energy through the interaction with the material. Since its initial energy is on the average much higher than the ionization energy of the polymer W, such electron is likely to produce other secondary ionization events up to reaching a residual energy that is below the W of the material. Besides ionization, also electron excitation events without ionization may take place during the energy loss process that involves the ionized electron.

When the energy of the secondary electron decreases below the ionization energy, its residual energy is lost through intramolecular vibration interaction and, in the subvibrational regime, with interaction with intermolecular vibrations and phonons. This phenomenon is very fast in condensed materials, and equilibrium is reached after electron ionization within about 1 ps, preventing any possible direct observation. However, the thermalization distance, that is, the distance that the electron travels during the thermalization process from its initial position, can be estimated starting from the initial energy distribution and applying Onsager's theory. Such distance varies according to the compound considered: it was found to be between 3 and 5 nm in aromatic compounds and between 5 and 7 nm in alkane compounds.

This is a significantly higher distance than the mean free path of electrons in the material with initial energy in the range 20–100 eV, and consequently its effect has to be taken into account. Such relatively high travel distance of electrons during the thermalization process is owing to the fact that the electron energy loss below the excitation energy of the molecules in the material is ineffective and consequently slow.

Once the ionized electron thermalizes, its motion stops at a distance of a few nanometers from the ionized atom, forming a cation-electron pair that is named spur. Considering the typical distribution of thermalized electrons and ions after resist irradiation, the ionized electrons are generally much closer to the generating ion compared to all the other ions.

This means that their diffusion distance from the generating atom is much lower than the Onsager length, which is the length at which the thermal energy of the electron equals the potential energy of the electrostatic force that attracts it back toward its father cation (equal to about 28 nm in benzene derivatives). The reasonable consequence of this situation is the fact that the ionized electron tends to move back toward the cation because of the electrostatic attraction force until the spur finally recombines. Such reaction is named geminate ion recombination and is important because the electrons that recombine with the generating ions are not useful for the acid production process.

The Coulomb interaction between the ions and the electrons can be actually complicated from the description given above by the presence of overlapping spurs in the material, in which the calculation of electrostatic forces is less straightforward. In general, there may be two situations related to overlapping spurs. The first one consists in the overlap of spurs generated by the same electron or photon at a close distance from each other. The second is the possibility that two overlapping spurs are generated by different ionizing electrons or photons, a case that is more probable for high irradiation doses and is expected to depend on the dose of the ionizing radiation.

The possible formation of overlapping spurs within photoresist coming from individual irradiating photons or electrons can be studied by Monte Carlo simulations. The situation is different for EUV and EB resist mainly because the generation of the first electron depends on photon absorption in one case and on inelastic electron-electron interaction in the other case.

Consequently, the probability to create more than one spur is different in the two cases, being much higher for EUV in which the photon absorption always generates a secondary electron with energy gain equal to one of the irradiation photons, and consequently the probability that this secondary electron generates more spurs at a close distance is not negligible. For electrons, the inelastic interaction with the molecule can have a broader range of energy exchange with the ionized molecule, and this naturally determines a lower probability to generate overlapping spurs coming from the same ionizing electron.

From calculated probabilities of overlapping spur generation performed by Monte Carlo simulations, the average number of overlapping spurs generated per ionizing radiation was found to be 1.5 for electrons and 4.2 for EUV photons [37].

Anion Generation

In EUV and EB photoresists, the generation of the acids that are necessary for the resist development takes place through the dissociation of the acid generator molecules. These molecules, in general, may dissociate both through inelastic interaction with a high-energy electron or photon and by reaction with already dissociated electrons coming from the polymer molecules after completion of the thermalization process.

In DUV photoresists, the decomposition of the acid generators mainly occurs by direct absorption of the photons from the acid generator molecule. In ionizing radiation resists, such as EB and EUV resists, the percent of the direct dissociation of the acid molecules upon the overall acid generation process depends on their concentration in the material but is generally low compared to the case of DUV resists.

For a typical acid generator concentration of 10% wt, the direct dissociation of the molecule due to the interaction with the ionizing radiation is responsible for only 10% of the overall acid generator dissociation for EB and between 2% and 8% for EUV resists, and, consequently, the overall phenomenon of acid generation is mainly dependent on an indirect chemical reaction that involves the thermalized electron attachment to the acid generators [38].

The acid yield and distribution after irradiation in the resist can be calculated by solving a diffusion equation describing the diffusion of the thermalized electrons in which the Coulomb attraction from the ions and the electron dissociation reaction by interaction with the acid generator molecules are accounted for [39]. In the equation, the presence of single or multiple spurs can be considered. For EB resists, the simplified calculation that considers only single spurs does not differ much from the one that considers multiple spurs. This is not the case for EUV resist, in which on the contrary the effect of overlapping spurs is more important. This is due to the higher generation probability of multiple spurs close to each other discussed before, which represents an important difference between ionizing EB and EUV radiation.

Considering the multispur effect, generally speaking, the acid generation efficiency decreases because, in this situation, electrostatic forces on electrons are higher and this enhances the recombination probability of the spur, which competes with the acid electron dissociation reaction. The acid generation efficiency, in fact, presents a trade-off with patterning resolution, according to which a low blur of the acid generation is generally needed. In order to decrease blur, the thermalization distance of electrons after ionization should be reduced, because this would positively affect resolution and, at the same time, have no significant influence on the acid generation efficiency.

Considering the acid generator concentration, an increase of it would beneficially affect both resolution and efficiency, so there is no trade-off in this respect. By increasing the acid generator concentration, the resolution blur is found to decrease because the direct decomposition of the acid generator during exposure becomes less relevant [40]. This is the reason why the concentration of the acid generator is

generally much higher in ionizing radiation resists such as EUV and EB compared to DUV resists.

The reaction of thermalized electrons with acid generators discussed so far is not always straightforward since, depending of the type of resist, other elements may be involved, like the polymer molecules. In this respect, it is possible to distinguish three different reaction schemes of thermalized electrons in the formation of the acid anions.

Case (I): The thermalized electrons mainly react with the acid generator molecules to produce the anions. This is the case of resists like PHS and novolak, in which the reactivity of the polymer molecules with thermalized electrons is low.

Case (II): The thermalized electrons react with both acid generator and polymer molecules. This is the case, for instance, of PMMA, in which the interaction of the electrons with the polymer molecules is significant and gives rise to polymer radical cations. After the formation of such cations, some electrons in excess are transferred to the acid generator to form the acid anions. In this situation, the acid generator dissociation is somehow mediated by the reaction of the thermalized electrons with the polymer molecules.

Case (III): The thermalized electrons mainly react directly with the polymer to form the acid anions, without the contribution of any acid generator molecule. This behavior has been observed in single-component photoresists based on a dehalogenation of brominated polymer molecules that consists in the generation of bromine anions by dissociative electron attachment, in which acid protons are produced from the deprotonation of the polymer radical cations.

Proton Generation

As mentioned before, in some photoresists, proton generation after irradiation takes place through deprotonation reactions involving polymer radical cations and not directly by the decomposition of the acid generator molecules, from which only an anion and a neutral radical are produced. The deprotonation mechanism depends on the type of polymer that is used in the resist and is important for the yield of the lithographic process since protons are involved in the acid pattern formation process.

In aromatic polymers, the protons are generated by the hydroxyl groups that are present in the polymer radical cations after irradiation. In these materials (for instance, phenolic compounds), radical cations form as a consequence of irradiation, which subsequently generate protons through a deprotonation reaction. The type of deprotonation reaction that takes place and its efficiency in the proton generation depend on the aromatic polymer considered. In all cases, the acid yield is strongly correlated with the efficiency of the deprotonation reaction involved.

The deprotonation reactions in PHS are supposed to be the following ones [41]:

$$\mathrm{MOH} \rightarrow \mathrm{MOH}^{+} + e^{-} \tag{8.10}$$

$$\mathrm{MOH}^{+} + \mathrm{MOH} \rightarrow \mathrm{MO} + \mathrm{MOH_2}^{+} \tag{8.11}$$

in which MOH is the PHS molecule, MOH^{+} the radical cation of the molecule, MO the phenoxy radical, and $\mathrm{MOH_2}^{+}$ its proton adduct. The reaction has been studied in liquid phase, but it is believed to be valid also for the solid phase of the resist because in solid PHS films, the hydroxyl groups for both intra- and intermolecular connections with other similar groups, like in liquid phase. If a protection molecule for the hydroxyl groups is used in the polymer, the efficiency of the proton generation reaction depends on the chemical structure of the protecting group.

In methacrylate polymers, such as PMMA, the polymer molecules are ionized or excited by the incoming radiation, giving rise to radical cations (ionized molecules), excited neutral molecules, and also radical anions by reaction with the free electrons. All these molecules can react to generate protons by decomposition. The deprotonation reaction in this material takes place after a side chain detaches from the polymer forming a macroradical that subsequently undergoes a β-scission reaction that generates protons. The chain scission is also induced by UV light. Since PMMA after irradiation becomes acidic, the proton generation can take place even without the presence of any acid generator molecules.

Consequently, the proton generation mechanism in PMMA consists of two paths: the reaction that takes place directly from the polymer molecules and the one that involves the acid generator molecules. Since the direct reaction of the polymer molecules depends of the concentration of excited atoms, which are mainly created during the recombination of thermalized electrons with the generating ions, the presence of acid generator molecules in high density tends to suppress it because it decreases the recombination events by capturing most of the thermalized electrons before recombination. This is also true for polymer cations, since the presence of electron scavengers (compounds that tend to bind to a free electron) tends to limit the recombination of the cations with the emitted electrons.

As a consequence of this phenomenon, depending on the concentration of the acid generator in the resist, two different regimes may be distinguished: the polymer-limited regime and the acid generator-limited regime. For instance, at acid generator concentrations below 0.1 mol/l, the yield of trifluoromethanesulfonic acids is completely determined by the reaction of the acid generators with thermalized electrons, because the proton generation reactions are very efficient and the protons are abundant in the irradiated resist. Above this threshold, instead, the proton yield is smaller

than one of the acid anions produced by the acid generator decomposition, and the acid generation efficiency turns out to be limited by the deprotonation efficiency of the radical cations of the polymer. Such deprotonation efficiency is lower in PMMA compared to PHS because the deprotonation reactions are not the same in the two cases. In PMMA, however, the ionized electrons tend to be trapped by the same molecules of the polymer, and consequently the addition of acid generator molecules does not generally affect the acid yield significantly.

Proton Migration

In EUV resists, quencher compounds are normally added to the mixture. Their function in the photolithographic process is limiting the diffusion of the acids produced during the chemical reactions that follow the irradiation of the resist in order to make the resist development profile sharper, reduce LER, and improve the stability of the material in air. In order to produce this effect, quenchers generally act as proton traps or buffers.

The reaction of acids with quenchers is essential for pattern formation in resists. Such reactions are named neutralization reactions, since they produce a deactivation of the acid. Different possible neutralization reaction mechanisms have been proposed to explain the interaction of quenchers with acid molecules [42–45].

However, in spite of the action of quenchers, the protons produced by the chemical reactions initiated by the irradiation in the resist must migrate to their protonation site to complete the pattern formation process. In chemically amplified photoresists, several types of protonation sites exist in the material, such as oxygen atoms, ester or ether groups, hydroxyl groups, amines, and counteranions. Since protons are mainly generated by acid counteranions, which are in turn generated by the reaction of the polymer molecules with electrons that are far from the radical cations (otherwise they would recombine with them before taking part in the reaction), it may be assumed that the generated protons are initially located away from the counteranions. Since counteranions are negatively charged, they attract the protons that are positively charged with a Coulomb force.

The mechanism of proton migration toward the counteranion is believed to take place through the protonation sites mentioned above, until the proton reaches the site with maximum proton affinity in close proximity to the counteranion, in which its position becomes stable. This migration takes place before the post-exposure bake (PEB) of the resist. Since quenchers present a high proton affinity, a certain number of protons tend to stabilize on quencher molecules, while the remaining ones are trapped in the other protonation sites that are present in the exposed resist. Such proton migration mechanisms imply that the quencher-acid neutralization reaction can take place in high activation energy resists even at room temperature, before PEB, which is a process that deactivates the chemical protectors of the material.

This room-temperature neutralization phenomenon allows to improve the image contrast and the quality of the pattern borders by suppressing the deprotection in the areas of the pattern in which the irradiation dose is low (such as the borders of the pattern). In low activation energy resists, on the contrary, both deprotection and quencher neutralization may take place at room temperature, and consequently they are competing phenomena that are initiated by the resist exposure, different from the case in which deprotection is only owing to the PEB procedure. However, even in low activation energy resists, it is possible to enhance the deprotection of high-dose compared to low-dose irradiation regions in the resist and consequently increase the image contrast, by enhancing the deprotection reaction efficiency over the neutralization one. That is the reason why image contrast in low- and high-energy activation resists is not significantly different at the present state of the art.

8.5 Conclusion

The continuous shrinking of the critical size of ICs over the years has pushed the evolution of advanced lithography toward increasingly sophisticated techniques and to a progressive wavelength scaling of the light used for resist exposition. Another driving factor in the evolution of advanced lithography has been the need to improve the productivity of the lithographic systems, measured in terms of processed WPH. These factors have led to the development of the more advanced equipment that are widely spread nowadays in IC mass production plants, which are based on ArF laser projection systems operating at 193 nm. From the point of view of the development of the resist materials, a key innovation to meet the requirements of the market in terms of WPH was the introduction of chemically amplified resists, which allowed for a dramatic decrease of the lithography processing time. Since the critical size needed in modern ICs has decreased largely below the wavelength of 193 nm in recent years, the lithographic processes based on ArF systems had to be complicated in order to be able to obtain deep subwavelength patterning capabilities, with the introduction of techniques like immersion lithography and multiple patterning. After implementing the 40 nm node, advanced lithographic processes based on ArF systems are reaching the limit both in terms of scaling and in terms of cost-effectiveness, and the introduction of a completely new technology seems now necessary to proceed with the scaling of the IC critical size meeting and, at the same time, the cost and throughput requirements of massive industrial production.

The technology of choice for this revolution in advanced lithography is EUVL. This new method shows some continuity with the past since it is always an optical lithography that can be employed in projection systems, just like the ArF scanners. However, the wavelength scaling compared to the nowadays dominant technology is dramatic, shifting from 193 to 13.5 nm, and this leads to a number of technical issues that are entirely new for optical lithography, such as the need to develop resists based on atom ionization similar to those employed in EBL and the use of masks that operate in reflection instead than in transmission mode. Despite these problems, and the several open issues that remain in the technique, the first commercial EUVL systems have already been developed, and the future of the technology in massive IC production appears bright.

Other types of lithography, such as EBL and NIL, may compete with EUVL on the patterning resolution but do not seem to cope with the cost and throughput requirements of industrial IC production. However, EBL remains fundamental for the fabrication of the masks utilized in optical projection systems (including EUVL), and NIL is important in More than Moore applications and in peculiar semiconductor devices like memories.

Abstract

The technology of future nanoelectronic devices faces substantial challenges, in terms of increased power consumption, saturation of performance, large variability, and reliability. In this respect, novel materials and innovative device architectures are necessary for nanoscale FETs.

This chapter presents a number of promising solutions for the "end of the roadmap," with multi-gate devices, nanowires, tunnel transistors, ferroelectric FET, and hybrid nanocomponents using, for instance, phase change materials or nanofilaments. Other alternative materials, like ultra-thin films, 2D and 1D nanostructures, and heterostructures using strained and III–V materials, will allow to boost the performance of advanced nanotransistors.

9.1 Introduction

Silicon has been until now the leading semiconductor in the electronics industry. A large majority of the integrated circuits is fabricated with Si-based devices. In ultra-large-scale integration (ULSI) circuits, such as processors or memories, the basic component is the metal-oxide-semiconductor field-effect transistor (MOSFET). The first device of this type was proposed and fabricated in the 1960s [1, 2] and extensively developed during the following 50 years. Important advantages of the MOSFET are the quality of the Si/dielectric system and the possibility of realizing high-performance and low-power components. The Si/Si dioxide interface and, more recently, the Si/high-k interface have been improved over these years, leading to high-performance and reliable transistors with a very low defect density. Compared with their bipolar counterparts, the advantages of MOSFETs are low cost, high density, and low-energy consumption. However, bipolar devices are still widely used for some applications needing very high speed and/or low noise.

CMOS, now the dominant MOS technology, uses both n- and p-channel MOSFETs (Fig. 9.1). Historically, the architecture has been adopted due to its potential low-power consumption compared with other ones. The general trends in micro-/nanoelectronics of the last decades have been the

reduction of device geometry, which allows one to obtain an improvement of device performance and integration density. Other very important issues in this field are the decrease in power consumption, the enhancement in reliability, and the reduction in the variability and cost of electronic systems.

However, device scaling in the range of tens of nanometers (decananometer range), which pushes MOSFETs toward their physical and technological limits, faces formidable challenges. Indeed, the scaling scenario put forth in widely accepted industry roadmaps (ITRS/IRDS, NEREID) calls for about 10nm gate length MOSFETs in the next decade. In this range, transistor optimization needs a particularly good control of the electrostatic potential and charge in the active Si region, or in the alternative layer, in order to reduce the parasitic effects (for instance, short-channel effects and leakage currents) and improve the device performance (e.g., in terms of drain current and transconductance).

All these aspects, along with other advantages presented in the next section, are afforded by other Si-based or alternative device types, like the silicon-on-insulator structures, multi-gate devices, ultra-thin channels used as 2D materials, or 1D nanowires or nanotubes.

The significant increase in power consumption and heating, which is one of the main limitations of IC integration and performance, may also require the adoption of beyond-CMOS nanodevices [3] at the end of the IRDS Roadmap, in particular, steep-slope nanoelectronic devices, which in turn require disruptive concepts, nanomaterials, and architectures, like tunnel FETs, negative capacitance FET, or hybrid devices. The next sections show some of the most promising of these alternative devices and materials.

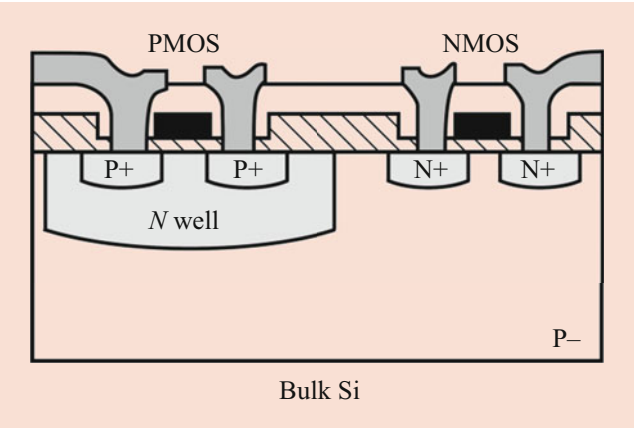

Fig. 9.1 Bulk Si CMOS structure

9.2 Nanoscale CMOS

The trend in micro-/nanoelectronic technology in the last decades has been that of increasing both speed and density by scaling down the electronic devices and of reducing energy dissipation. Future ICs are facing dramatic challenges in performance and power consumption, which must be overcome with the adoption of disruptive concepts, device architectures, technologies, and materials. Promising solutions for the nano-CMOS architecture include ultra-thin films, III–V/Ge channels, 2D layers, multi-gate structures, and nanowires or nanotubes.

The worldwide energy consumption has increased by 40% in the last 20 years. The ICT part represents 15% of the electricity consumption and will likely increase by a factor of 3 in the next 20 years. Therefore, research on the ultimate reduction of power dissipation in computing devices is strongly needed for the development of future low-power and high-performance tera-scale integration and autonomous nanosystems.

9.2.1 FDSOI

Figure 9.2 shows the SOI CMOS structure. A buried insulator is fabricated in the silicon substrate using various methods, the leading one being the Smart Cut technology, using hydrogen implantation and wafer bonding. SOI structure provides a number of advantages, suitable for many applications, and allows us to push back the limits intrinsic to the bulk Si structure [4, 5]; among them are:

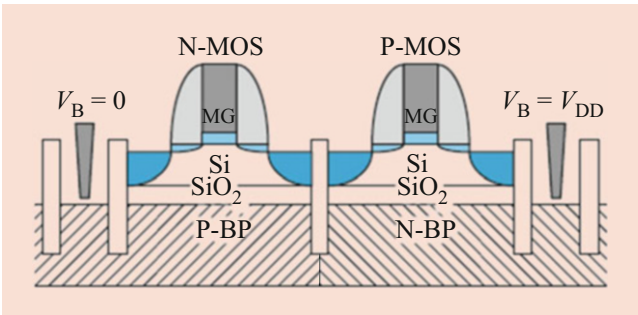

Fig. 9.2 Silicon-on-insulator (SOI) CMOS structure, with possible back gate control for optimizing device performance

1. The parasitic *n-p-n-p* structure (thyristor) which can be triggered in bulk CMOS structures is suppressed by the dielectric isolation available in the SOI technology.
2. Ultra-thin SOI films, inducing a full depletion or inversion ("fully depleted" or "fully inverted" devices, respectively) of the active silicon layer, can easily be fabricated. They have been found to exhibit very interesting behaviors, e.g., low-threshold voltage together with small leakage currents. Another advantage of thin SOI films is related to higher drain current and device speed.
3. The parasitic junction capacitances of source and drain are reduced using thin-film SOI, this opening the possibility of high-frequency operation.
4. The exponential increase in the leakage current with temperature is the main limitation of the circuit functionality in conventional CMOS operation at high temperature. SOI devices are fully functional up to 300 °C and beyond and can be used in analog and digital circuits, for example, in automotive and avionic applications.
5. In the field of memories, the SOI structure improves the performance for the integration of DRAM, SRAM, and non-volatile memories.
6. SOI MOSFETs are of great interest for niche applications, e.g., those requiring radiation hardness [advantage in transient ionizing and single-event upset (SEU)] for both space and nuclear radiation environments, owing to the small active volume. This was in fact the first application of the SOI technology. Other examples are low-temperature electronics and quantum engineering, where the SOI structure prevents some harmful parasitic effects (e.g., the absence of the kink effect for thin-film SOI) observed in the liquid helium temperature range.
7. The dielectric isolation afforded by the buried insulator opens the way to integrate complementary devices into a state-of-the-art CMOS process. Thus, the SOI technology leads to new "system on chip" concepts.
8. The special SOI structure can be advantageously used for developing new devices, like the volume inversion MOSFET with fully inverted channel (with two gates, three gates, or a gate all around the active Si layer), and quantum devices (extremely thin Si film, quantum wires, single electron transistors, etc.).
9. Some process simplifications are made possible by the SOI technology, mainly in the isolation and high-energy implantation.

However, some parasitic effects may be observed also in SOI devices. In this respect, electrical and thermal floating body effects are the main drawbacks of the SOI technology. These phenomena can be reduced or suppressed in advanced technologies by adopting ultra-thin Si film and/or very thin buried oxides.

In the last two decades, the static and dynamic power consumption of advanced nanodevices have strongly increased due to the slowing down in V_{dd} scaling and the parallel increase in the subthreshold leakage. This power challenge is due to the subthreshold swing limit S, which is 60 mV/dec at room temperature using thin-film SOI or multi-gate structures. As shown in [6], there exists a lower limit in energy per operation exists, which is reached for

$$V_{ddmin} \sim S$$

corresponding to the minimum energy:

$$E_{min} \sim C \,.S^2.$$

This shows that the limit depends on the subthreshold swing S and device capacitance C.

The definition of swing S is:

$$S = \frac{\partial V_g}{\partial (\log I_d)} = \underbrace{\frac{\partial V_g}{\partial \Psi_s}}_{m} \underbrace{\frac{\partial \Psi_s}{\partial (\log I_D)}}_{n} = \left(1 + \frac{C_s}{C_{ins}}\right) \frac{kT}{q} \ln\ 10 \tag{9.1}$$

Hence, its reduction may be achieved in two ways:

(i) Reducing m, the transistor body factor, which can be achieved by using ultra-thin body SOI, multi-gate or nanowire MOSFETs, carbon nanotube or 2D channels (this leads to $m \sim 1$), and negative capacitance FETs or MEMS/NEMS structures (this leads to $m < 1$)
(ii) Reducing n, which can be achieved by adopting a low-temperature operation (this solution, however, is not applicable in traditional applications), or using a modification of the carrier injection mechanisms with impact ionization or band-to-band tunneling, or considering hybrid devices combining several physical mechanisms

The MOSFET devices most suitable for obtaining a value of S close to its minimum use fully depleted [7–10] channels (e.g., FD SOI MOSFETs with very thin buried oxide [10]) or fully inverted devices [11]; the latter solution is preferable also because it optimizes the control of the electrostatics in the structure (e.g., double-gate, bulk, or SOI tri-gate/FinFET, gate-all-around MOSFET, or nanowire FET [12]).

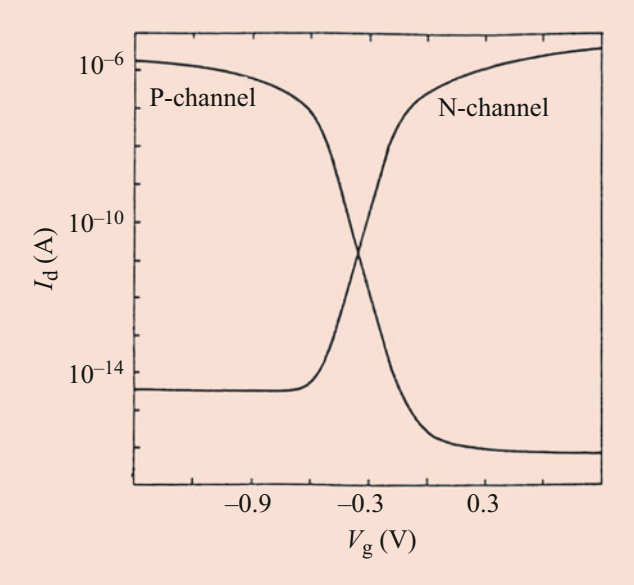

Fig. 9.3 Transfer $I_d(V_g)$ characteristics obtained by numerical simulation for fully depleted N- and P-channel SOI MOSFETs, showing a 60 mV/dec subthreshold swing (10^{14} Si doping, 600 nm Si film)

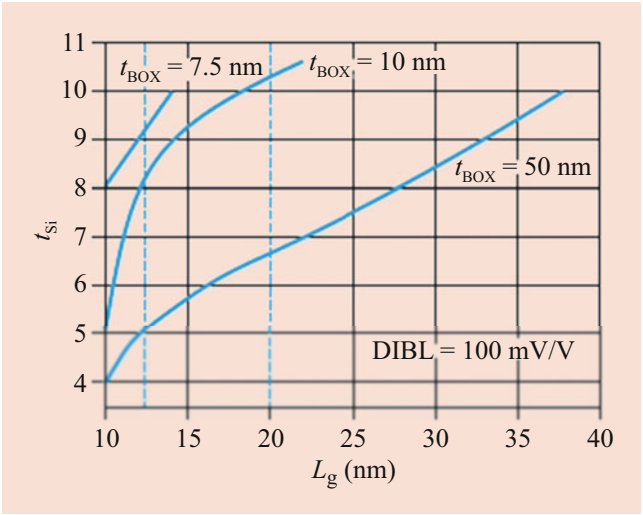

Fig. 9.4 Si film thickness and gate length needed to obtain a drain-induced barrier lowering (DIBL) effect of 100 mV/V for various thicknesses of the buried oxide

The first SOI MOSFETs of the fully depleted type were fabricated on SOS materials [7]; however, the quality of the Si film obtained with this technology was poor. Using simulation, the first fully depleted SOI MOSFET exhibiting an ideal swing of 60 mV/dec (Fig. 9.3) was demonstrated in 1985 [8]. In 1986, the first experimental demonstration of a FD SOI MOSFET showing a swing of about 60 mV/dec was published [9]. The first theoretical and experimental multi-gate MOSFET with volume inversion was shown in 1987 [11].

Considering logic and/or RF applications, in future ULSI circuits, the standard silicon channel could be replaced by other high-mobility materials. From this viewpoint, heterogeneous two-dimensional atomic crystals, in particular transition metal dichalcogenides (TMD), exhibit atomically smooth surface without thickness fluctuations, no dangling bonds, and good mobility in CVD-deposited films; for these reasons, they are very promising for ultimate nanoscale transistors and 3D ICs.

A TMD 3D transistor technology, based on novel hybrid Si/MoS_2 channel FinFET and NWFET, with improved electron mobility and I_{on}, has been demonstrated in [13].

The buried oxide thickness is another important parameter for alleviating short-channel effects. A significant attenuation of the threshold voltage shift by drain-induced barrier lowering (DIBL) in the 10–20 nm gate length range is observed when we reduce the buried oxide thickness down to sub-10 nm (Fig. 9.4) [14].

9.2.2 Quantum Effects

Ultra-thin Si films are a promising architecture for reducing short-channel effects, improving high-speed performance, and eliminating parasitic phenomena; so far, 2-nm-thick silicon films have been realized [15]. In contrast with the standard architectures, in which the electrons form a 3D system, in ultra-thin films, the electron system transits from 3D to 2D, and quantum mechanical effects (energy quantization) appear. Figure 9.5 shows an example of the variation of the threshold voltage V_t due to such a transition [16]. The analysis based on classical mechanics indicates that in fully depleted MOSFETs, the threshold voltage V_t is reduced when the film thickness decreases; this is due to the reduction in the depletion charge. In contrast, the quantum mechanical calculation shows an increase of V_t for thicknesses of the Si film below 10 nm; the phenomenon is explained by the formation of a 2D subband system, in which the ground state of the electrons is above the bottom of the conduction band Ec. Quantum mechanical influences, especially at low temperature, are also present in extremely thin SOI layers (<10 nm), where they have been found to enhance short-channel effects [17]. The quantum effects must be considered for the design of advanced SOI devices. On the other hand, SOI devices can also be fabricated with very small surfaces and volumes, this giving rise to ultra-small capacitances;

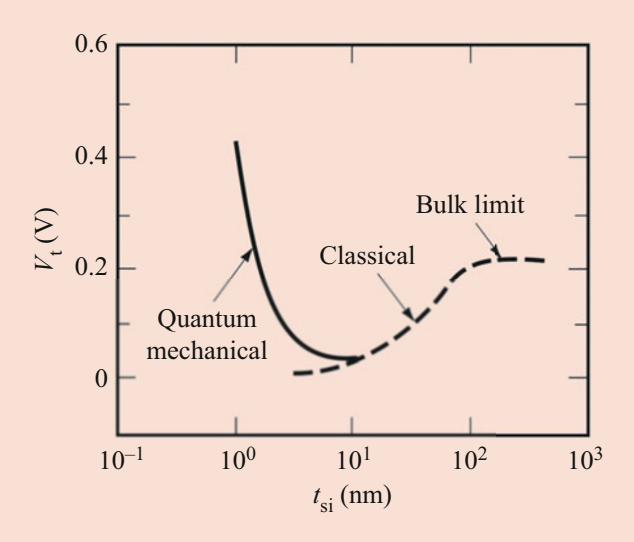

Fig. 9.5 Theoretical threshold voltage variation versus Si layer thickness showing the occurrence of quantum effects for an ultra-thin Si film ($t_{ox1} = 7$ nm, $t_{ox2} = 80$ nm, $N_a = 10^{17}$ cm^{-3}, $N_{sub} = 10^{17}$ cm^{-3}, $T = 300$ K)

for these structures, even at room temperature, the charge quantization regime leads to conductance oscillations due to the Coulomb blockade [18].

9.2.3 Variability

Figure 9.6 shows the impact of doping fluctuations on the threshold voltage variability for various devices. Ultra-thin body SOI and multi-gate devices show the best (i.e., smallest) variability compared with bulk transistors, even for more advanced MOSFETs, due in particular to the possible use of very low channel doping [19].

9.2.4 Strained Channels

The method for modifying the band structure of semiconductors (Ge, III–V, etc.) by means of the application of a suitable strain (uniaxial or biaxial, tensile or compressive), globally indicated with "strain engineering," has extensively been used since the early 2000s. The method has also the effect of boosting electron or hole carrier mobility and velocity.

An example of the effect of strain in a 18 nm gate length, N-channel SOI MOSFET fabricated on ultra-thin SOI films ($t_{si} = 2.5 - 11.8$ nm) is shown in Fig. 9.7. For a given OFF state current, the driving current in strained devices (sSOI) is about 40% higher than in non-strained SOI films, even for ultra-thin Si layers down to 2.5 nm. This behavior is ascribed to a higher carrier injection velocity at the source [20].

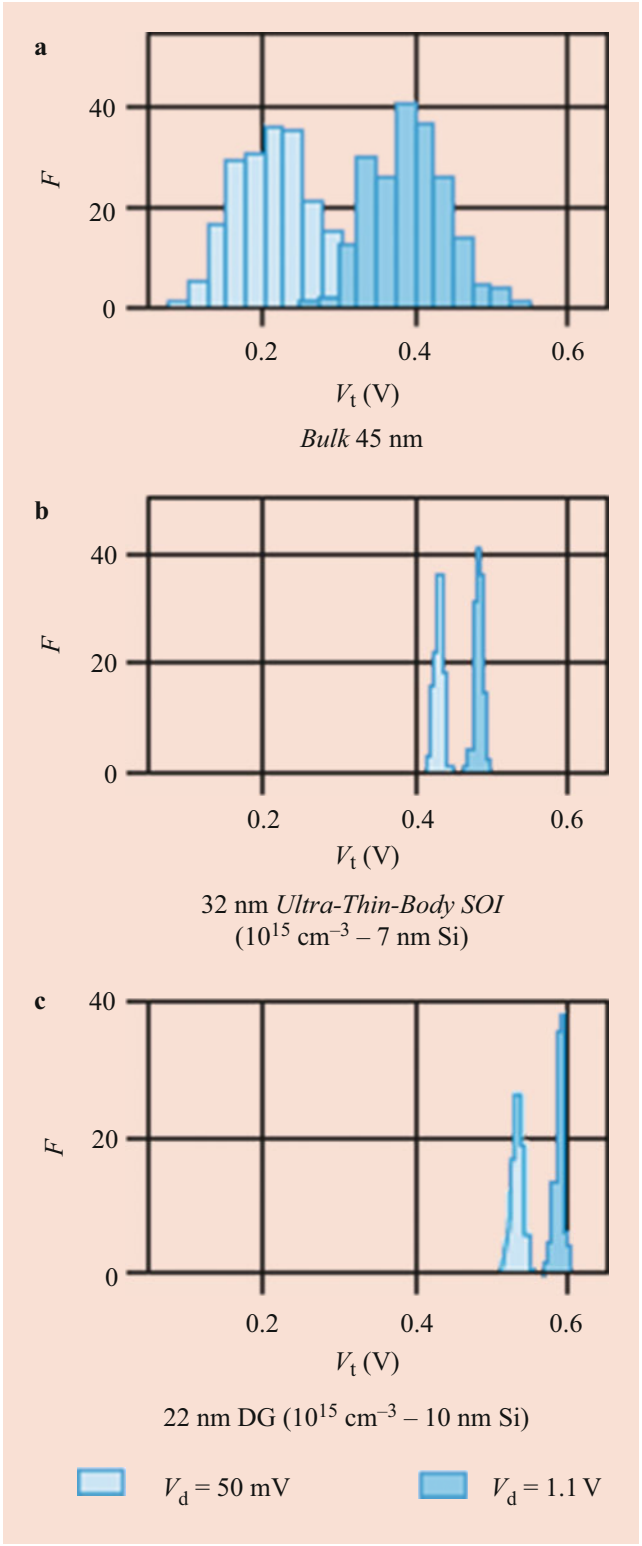

Fig. 9.6 Impact of channel doping fluctuations on threshold voltage variability for various architectures ((**a**) 45 nm bulk, (**b**) 32 nm UTB SOI and 7 nm Si film, (**c**) 22 nm double-gate and 10 nm Si film) and drain biases

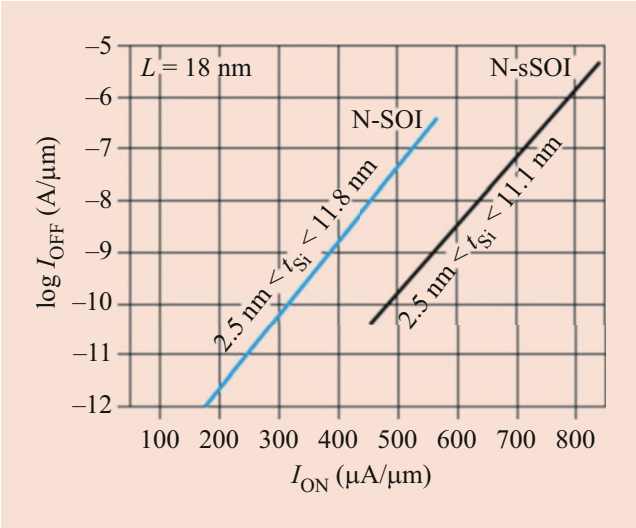

Fig. 9.7 Impact of strained Si on advanced N-channel SOI MOSFETs realized with various Si film thicknesses

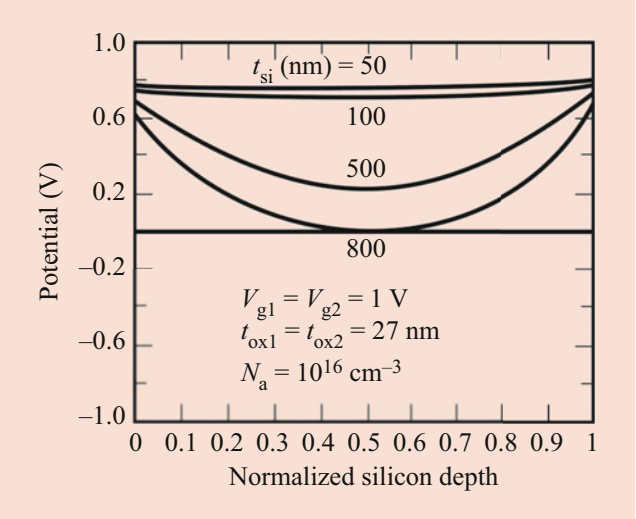

Fig. 9.8 Potential profile inside the Si layer showing the volume inversion regime for thin film (≤100 nm) DG SOI MOSFETs; the occurrence of a volume inversion (with a quasi-constant potential > $2\Phi_F$ in the whole Si layer) depends on the Si film thickness and doping (here a very low doping is used in the numerical simulation)

Another booster for transport parameters is to use alternative channel or substrate orientations [21].

9.2.5 Ultimate Device Architectures

The gate of a MOSFET induces an inversion channel located at the Si/SiO_2-high-k interface, with a typical length of a few nanometers. The multi-gate control of an SOI or bulk MOSFET makes it possible to force the whole silicon film in the strong inversion condition and gives rise to the "volume inversion (VI)" concept for "fully inverted" (or "fully accumulated") devices (Fig. 9.8) [11]. The fact that the current drive of the VI-MOSFET is governed by two, three, or four gates and that carriers are no longer confined at one interface presents remarkable advantages: they are the enhancement of the number of electrons or holes, the increase in carrier mobility and velocity due to reduced influence of scattering associated with oxide charges and surface roughness, the increase in drain current and transconductance, and the reduction of short-channel effects and subthreshold swing [22, 23]. The subthreshold swing S_{vi} and threshold voltage V_t of the VI-MOSFET are calculated using a constant potential in the whole silicon layer [24], which is a very good approximation for $V_g \leq V_t$:

$$S_{vi} = \frac{kT}{q} \ln(10) \left(\frac{C_{ox} + C_{ss}}{C_{ox}} \right) \tag{9.2}$$

$$V_t = V_{FB} + 2\Phi_F + \frac{qt_{si}N_a}{C_{ox}} - \frac{Q_{ss}(2\Phi_F)}{C_{ox}} \tag{9.3}$$

In (9.2, 9.3), C_{ss} (= qN_{ss}) is the interface-state capacitance, C_{ox} the gate oxide capacitance (it is assumed that the interface-state densities $N_{ss} = Q_{ss}/q$ and oxide thickness are similar at the upper and lower Si film interface), V_{FB} the flat-band voltage for both front and back gate, Na the silicon layer doping, Φ_F the Fermi potential, and $Q_{ss}(2\Phi_F)$ the interface-state charge for a surface potential equal to $2\Phi_F$.

It is worth pointing out that, although in general the inversion charge Q_i within the expression of the threshold voltage is neglected with respect to the depletion charge Q_d, this is not possible in the case of volume inversion because, at threshold, it is $Q_i = Q_d$.

A reduction of hot-carrier effects (substrate current, photon emission, and hot-carrier-induced degradation) has also been reported in multi-gate SOI MOSFETs [25, 26]. Various SOI structures (double-gate [27], DELTA or bulk/SOI FinFET [28], GAA (gate-all-around) [29]) have been proposed in order to take advantage of this original feature (Fig. 9.9a, b). Figure 9.10 shows how, in the volume inversion functioning, the performance of the device improves with respect to that of a conventional single-gate SOI operation [29], highlighting a transconductance up to three times larger. The VI-MOSFET proved to be particularly suited for alleviating short-channel effects in ultimate ultra-short-channel MOS transistors [30], affording a substantial decrease of DIBL (Fig. 9.10b) and charge-sharing phenomena [31]. These advantages are obtained together with very large driving current and very small leakage currents for drain bias up to 1.5 V in a wide Si film thickness range. Whatever the architecture, decreasing the thickness of the Si film (down to 5 nm) and

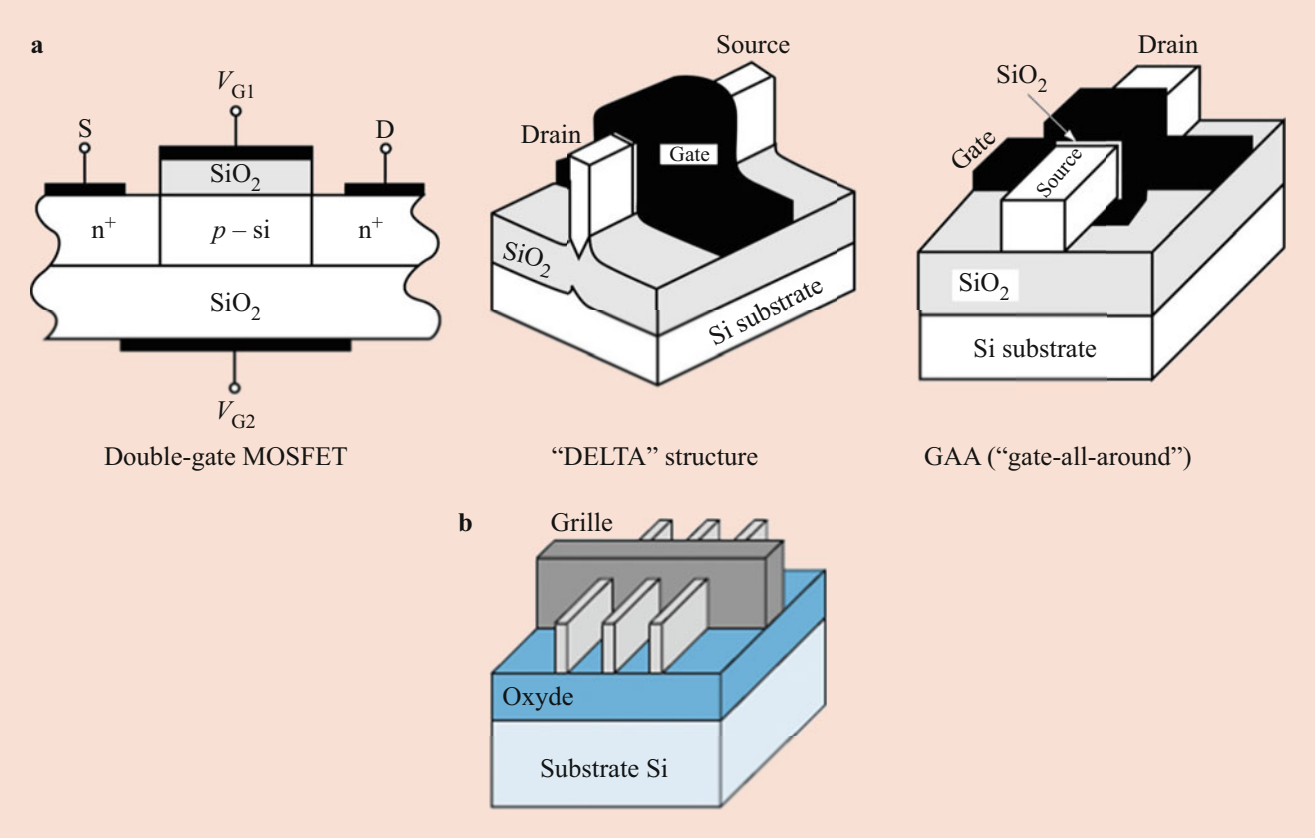

Fig. 9.9 (**a**) Various SOI structures using the concept of volume inversion in order to obtain fully inverted devices: double gate, DELTA or FinFET or tri-gate, and gate-all-around. (**b**) FinFET structure on insulator with parallel fins

the concentration of dopant also reduce the short-channel effects (Fig. 9.10b). A reduced sensitivity on the silicon film thickness and doping is also observed in double-gate devices.

This transistor appears to be the best candidate for the ultimate integration of silicon and could be proposed for fabricating devices down to the sub-10 nm range, even if the IRDS Roadmap currently does not plan an integration in such a range.

Indeed, Fig. 9.11 shows the subthreshold slope for different architectures of ultimate FET nanodevices (Ω-gate nanowires, GAA carbon nanotubes, 2G Si MOSFET for gate lengths beyond the end of IRDS Roadmap down to 5 nm). We can see that multi-gate nanowires with volume inversion overcome short-channel effects down to ultimate lengths while maintaining very good switching behavior between the OFF and ON states ($S \approx 70$ mV / decade) [32].

Multi-channel MOSFETs fabricated with multi-gate devices, realized with the silicon-on-nothing technology, have also been proposed to boost the driving current using several channels. The N- and P-MOS MCFET using high-k TiN/HfO_2 gate oxides provides very good characteristics (Fig. 9.12) [33].

Double-gate devices with gate underlap led also to a very good Idsat, a reduction in the DIBL and drain to gate tunneling current, and a decrease of the gate capacitance, propagation delay, and power consumption [34].

Evaluation of swing and DIBL in DG and SOI structures using 2D materials from one layer to three layers of MoS_2, as well as in Si UTB DG FETs, has shown that MoS_2 FETs have better electrostatics than Si devices due to the minimum thickness of the films (atomic dimension). SOI topology can only present good electrostatics for one-layer TMDs, while DG topology can present interesting performance for up to three layers. The best performance is obtained for a double-gate MOSFET with a single layer of MoS_2, with a similar swing as the previous Ω-gate nanowires (Fig. 9.11) in the 5 nm gate length range (Fig. 9.13) [35].

A theoretical comparison of scaling limit for TMDs, phosphorene/black phosphorus (BP), and Si MOSFETs is carried out in [36]. The best results for scaling properties are obtained for TMDs (MOS_2 and SnS_2) and BP channels due to ultrathin channels (monolayers) and reduced dielectric constant compared with Si (Fig. 9.14).

It has also been shown experimentally that the bandgap of 2D layers can be modulated by transverse electric fields in bilayer graphene ribbon (100 nm) and in bilayer MoS_2 [37].

Another interesting possibility at the end of the roadmap is the use of semimetals for the channel and source/drain

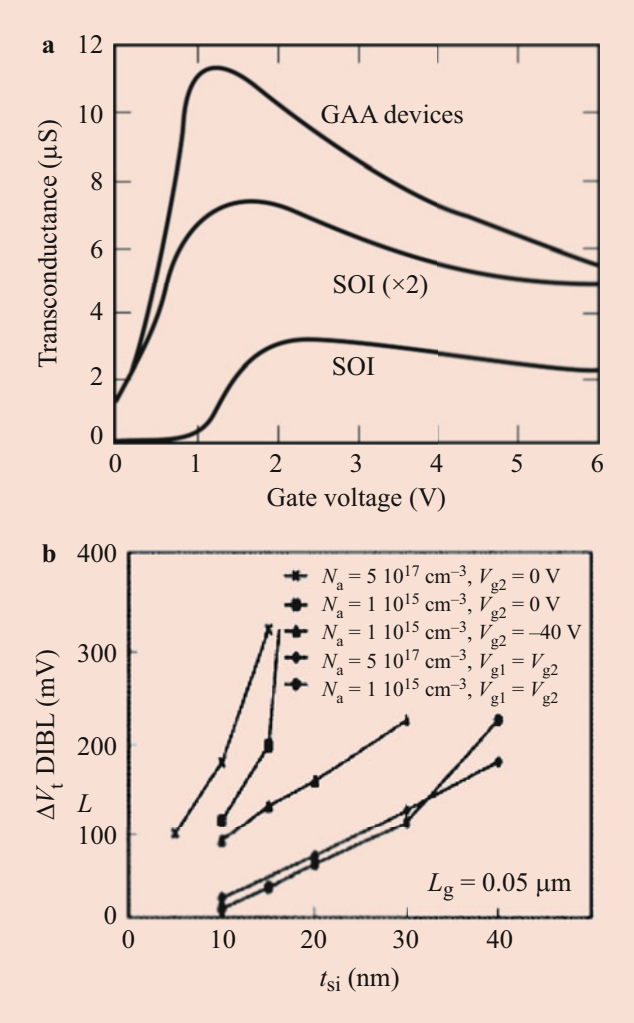

Fig. 9.10 (**a**) Transconductance in a conventional SOI MOSFET, a DG transistor without volume inversion, and a GAA device with volume inversion ($W/L = 3\ \mu m / 3\ \mu m$, $V_d = 100$ mV. (**b**) DIBL effect versus silicon film thickness for 50 nm μm single-gate SOI MOSFETs ($t_{ox2} = 380$ nm, $t_{ox1} = 3$ nm) with high doping ($N_a = 5 \times 10^{17}$ cm^{-3}, $V_{g2} = 0$ V), low doping ($N_a = 10^{15}$ cm^{-3}, $V_{g2} = 0$ V), and back channel accumulation ($N_a = 10^{15}$ cm^{-3}, $V_{g2} = -40$ V) and for DG SOI MOSFETs ($t_{ox1} = t_{ox2} = 3$ nm, $N_a = 10^{15}$ cm^{-3} and $N_a = 5 \times 10^{17}$ cm^{-3} with $V_{g1} = V_{g2}$)

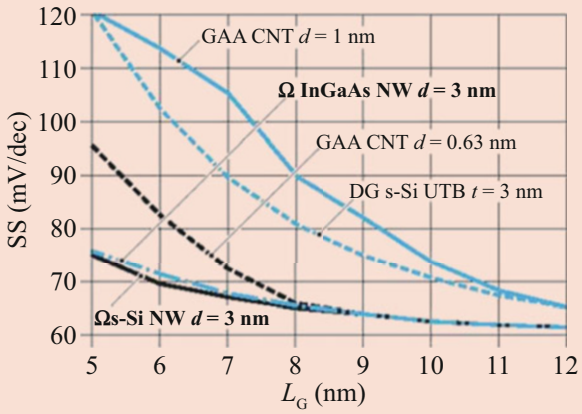

Fig. 9.11 Subthreshold swing obtained by quantum simulations as a function of gate length for various MOSFET architectures: Ω-gate sSi and InGaAs nanowires (3 nm diameter), gate-all-around carbon nanotubes (0.63 and 1 nm diameter), double-gate ultra-thin body MOSFET (3 nm Si film thickness)

regions. Indeed, for 1D devices, the bandgap of semiconductors and semimetals increases when the nanowire diameter decreases. Therefore, a semimetal becomes a semiconductor in the sub-10 nm range (Fig. 9.15). A 1D structure could thus be used for the channel and a thicker source/drain region with the same materials (e.g., Sn, Bi) for source and drain with a metallic behavior, without any doping. Very good electrical properties have been shown by simulations for 1 nm GAA Sn NW with a 2.3 nm gate length, leading to a 72 mV/dec swing and I_{on} of 3 mA/μm at $V_d = 250$ mV [38].

High-performance Si transistors can have gate lengths as short as 5 nm before source-drain tunneling, but below this value, the loss of electrostatic control leads to unacceptable leakage currents when the device is off. The use of MoS_2 as a channel material has recently been studied using a 1 nm physical gate length with a MoS_2 bilayer and a single-walled carbon nanotube as the gate electrode. Very good switching characteristics, swing (~65 mV), and on-off state current ratio of ~10^6 were observed [39].

The electrical characteristics for this 1D2D-FET (Fig. 9.16) show that the MoS_2 extension regions (the underlapped regions between the SWCNT gate and S/D contacts) could be heavily inverted (i.e., n+ state) by applying a positive back-gate voltage of $V_{BS} = 5$ V to the Si substrate. The I_D-V_{BS} characteristics (Fig. 9.17) show that the MoS_2 flake was strongly inverted by the back gate at $V_{BS} = 5$ V. The I_D–V_{GS} characteristics for the device at $V_{BS} = 5$ V and $V_{DS} = 50$ mV and 1 V (Fig. 9.17a) demonstrate the ability of the SWCNT gate to deplete the MoS_2 channel and turn off the device.

9.3 Nanoscale TFET, FE-FET, and Hybrid Devices

In order to reduce static and dynamic power consumption in nanoscale FETs at the end of the roadmap, sub-60 mV/dec subthreshold swing (e.g., TFET, NC/FE-FET) are needed (Fig. 9.18) [40].

Figure 9.18 presents the comparison of the theoretical subthreshold swing vs gate length for the most advanced nanoscale FET architectures and materials available in the literature. The IRDS (International Roadmap for Devices and Systems) needs for logic devices are also shown vs time

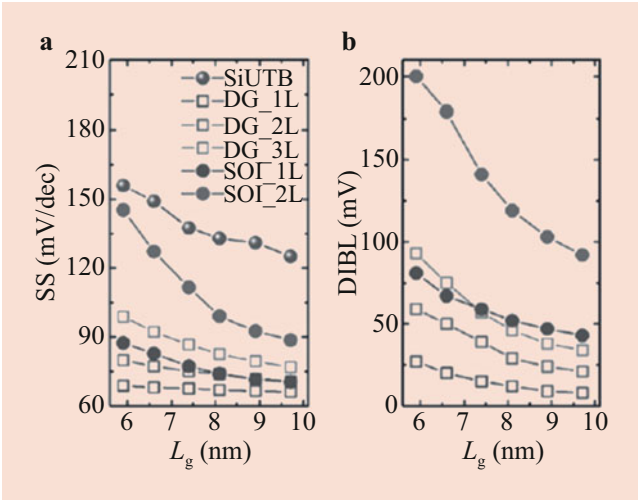

Fig. 9.13 (**a**) Subthreshold swing (SS) and (**b**) drain-induced barrier lowering (DIBL) with gate length scaling for MoS_2 MOSFETs realized with various numbers of layers and Si-based ultra-thin body double-gate MOSFETs with a symmetrical top and bottom gate dielectric; in SOI, the bottom dielectric is a 50-nm-thick SiO_2, and the bottom gate is grounded

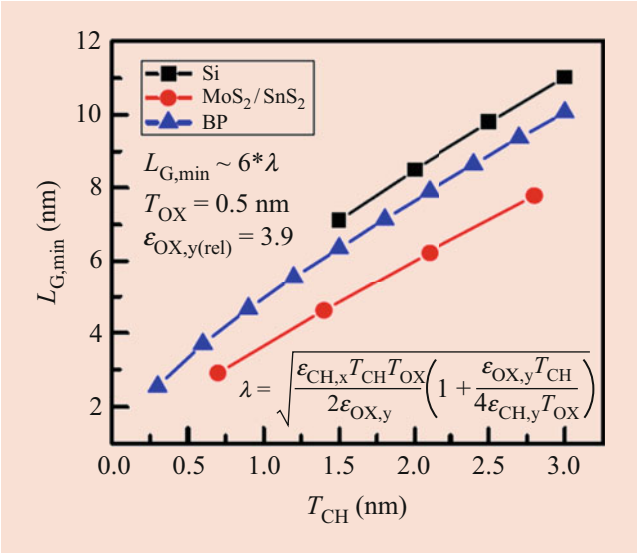

Fig. 9.14 $L_{G,min}$ vs $T_{channel}$ for 2G Si ($\epsilon = 12$), BP ($\epsilon = 9$, $T_{ch} = 0.3$ N), and TMDs ($\epsilon = 4$, $T_{ch} = 0.7$ N) (N = nb of layers)

horizons. The best performances for the swing of CMOS devices at the end of the roadmap (close to 60 mV/dec) are obtained for multi-gate (Ω-Gate in the figure) nanowire FET with very small wire diameter (3 nm) and double-gate MOSFET with TMD (MoS_2 in the figure) channel. However, at the end of the next decade, sub-60 mV/decade swing may be necessary, which are obtainable only with small-slope switches (an example with tunnel FET with III–V or 2D channels in the figure).

To outperform CMOS, these new devices, called the small swing/slope switches (Fig. 9.19), need an I_{on} in the range of

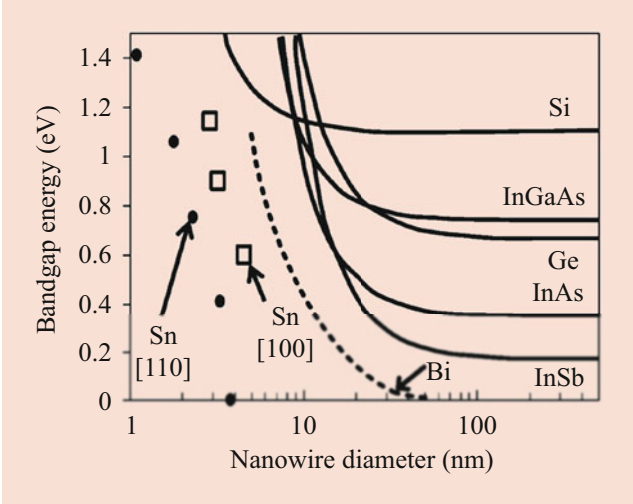

Fig. 9.15 Bandgap as a function of nanowire diameter for various semiconductors and semimetals

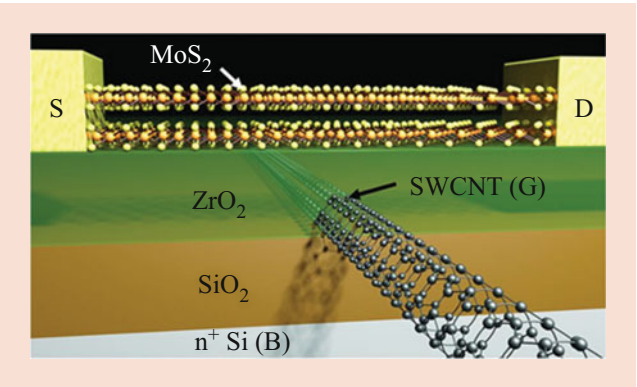

Fig. 9.16 Bilayer MOS_2 1nm gate length controlled by a single-walled carbon nanotube as the gate with ZrO_2 gate oxide

hundreds of μA, an average subthreshold swing far below 60 mV/dec for at least four to five decades of I_d, a ratio I_{on}/I_{off} larger than 10^5, and V_{dd} lower than 0.5 V.

9.3.1 Tunnel FETs

A very interesting option is provided by tunnel FETs exhibiting with source-to-drain tunneling (Fig. 9.20). The same boosters developed for MOSFET can be proposed to boost the performance of TFETs, for which opposite source and drain doping are used (Fig. 9.21). These types of devices are in fact able to overcome the subthreshold swing limit of 60 mV/dec, which is the minimum of MOSFETs at 300 K. Multi-gate, high-k dielectrics, ultra-thin films, alternative materials (Ge, III–V), and strains are leading to improved TFET properties (Fig. 9.21). Numerical simulations demonstrate very good values of the subthreshold swing, showing that low-voltage operation (i.e., in the sub-0.5 V range) is possible, still with small leakage currents. The main challenge is to obtain at the same time high drain currents, which is very difficult experimentally. Therefore, these tunneling devices are very interesting for ultra-low-power operation and low/medium performance.

Figure 9.20 shows the basic operation of a tunnel FET. The tunneling between source, channel, and drain of the TFET, controlled by the gate, allows for low slopes, below 60 mV/dec at room temperature.

The functioning of the TFET devices exploits the interband tunneling that occurs in heavily doped p+n+ junctions; the band bending is controlled by V_g and by a reverse-biased p-i-n junction. The suppression of the ambipolar effect is suppressed by making the transistor structure asymmetric. In order to maximize the band-to-band tunneling, the transmission probability is optimized by reducing the effective tunnel mass m^*, the source bandgap E_g, and/or the tunneling length λ and by increasing the band offset $\Delta\Phi$ between the conduction/valence band of the source/channel, to enhance I_{on} and reduce S for several decades of current.

Optimizing E_g, m^*, and $\Delta\Phi$ requires a change in the materials. In turn, λ can be decreased by a change of device dimension, doping, gate capacitance, gate overlap on tunnel region, and bandgap using a reduced t_{ox} and t_{si}, a high-k gate, an abrupt doping profile, a high source doping, a multi-gate structure, or other materials than Si.

It is also worth noticing that a TFET with a heterostructure is preferable (small bandgap at S and large bandgap at D) and that complementary TFETs are needed for logic circuits.

Figure 9.22a shows the experimental characteristics of SOI TFETs. A very good subthreshold swing down to 42 mV/dec is obtained for p-channel operation [41]. Using SGOI and GOI TFETs yields a strong increase of I_d, up to several thousand times, with respect to SOI transistors (Fig. 9.22b). I_{off} is very low, but I_{on} is only of the order of several μA/μm for the best GOI TFETs, which is very small compared with MOSFETs.

As in the case of MOSFETs, technology boosters can also be used for TFETs. The results obtained by numerical simulation are illustrated in Fig. 9.23, where we can see that short-channel, thin Si film double-gate TFETs with high-k gate dielectrics and stress at the source junction lead to the best performance with a substantial increase of I_{on} and reduction of S [42].

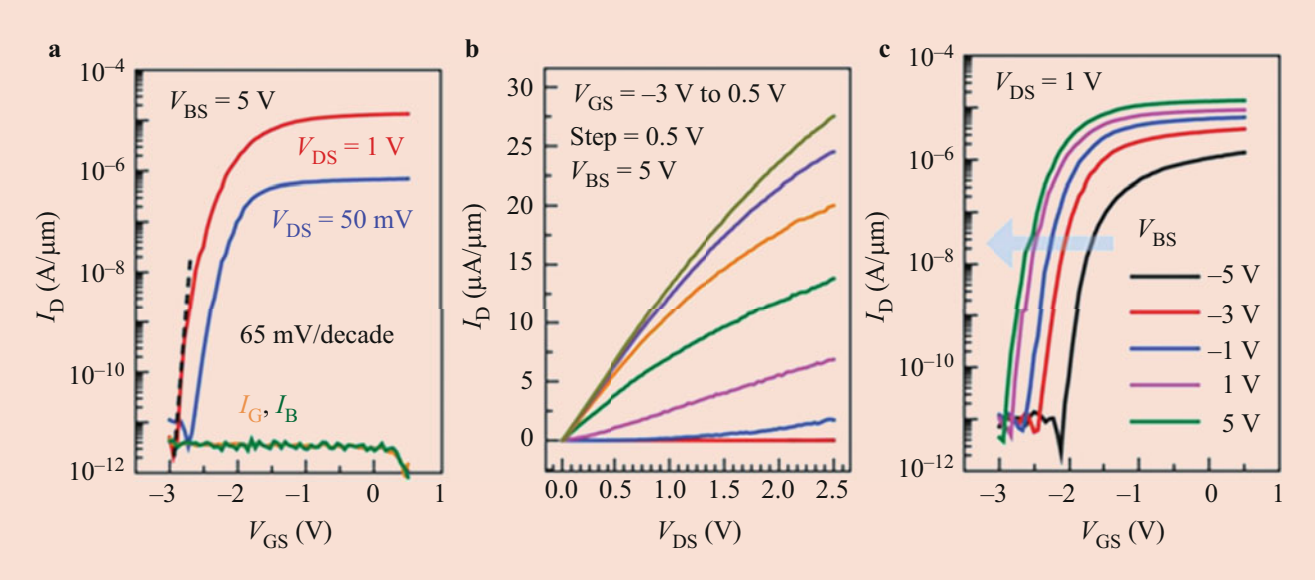

Fig. 9.17 Electrical characterization and TCAD simulations of 1D2D-FET (**a**) I_D–V_{GS} characteristics of a bilayer MoS_2 channel SWCNT gated FET at V_{BS} = 5 V and V_{DS} = 50 mV and 1 V. (**c**) I_D–V_{GS} characteristics at V_{DS} = 1 V and varying V_{BS} illustrating the effect of back-gate bias on the extension region resistance

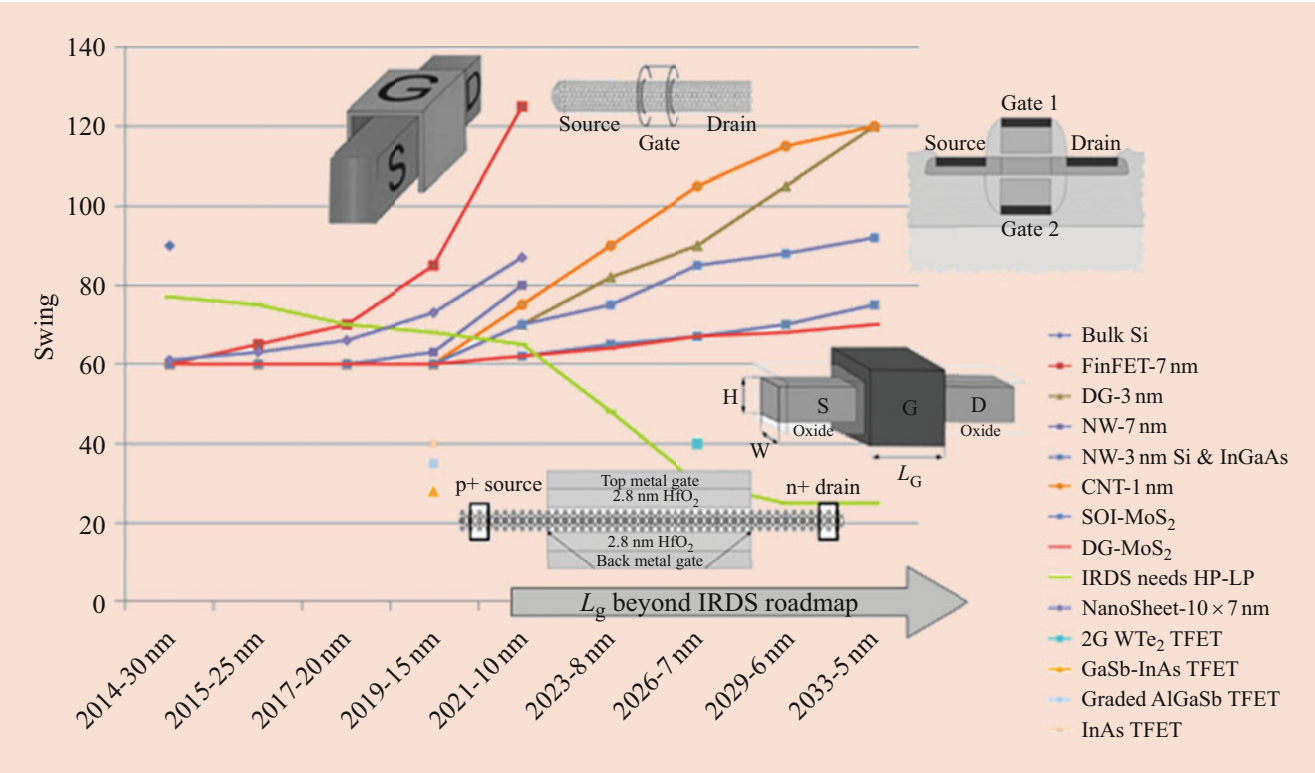

Fig. 9.18 Advanced simulations of subthreshold swing (mV/decade) vs gate length (beyond the IRDS Roadmap for the gate length). Time horizon for various device architectures (bulk Si, FinFET, double gate, nanowire with various diameters, carbon nanotube, MOSFET on insulator, nanosheet) and channel materials (Si, InGaAs, InAs, heterojunction GaSb-InAs, graded AlGaSb, MoS_2, WTe_2), compared with IRDS needs (2017) for the next 15 years

Better performances than those of Ge TFETs have been obtained using GeSn TFETs (Fig. 9.24) that exhibited a strong increase of the I_d along with a substantial reduction of S [43].

Experiments carried out on feedback TFETs [44] and Z2-FET [45], with a forward-biased PiN diode, showed a very small swing (a few mV/dec) along with good driving currents; this happens, however, for biases larger than 0.5 V.

Good performances have also been demonstrated by strained Ge double-gate TFETs with asymmetric S/D structure, exhibiting values of swing down to 50 mV/dec and I_{on} up to 300 μA/μm for high V_d [46]. However, due to the presence of different front- and back-gate oxides, the experiments have been carried out using different biases for the front and back gates; we have shown that an application of V_{g2}/V_{g1} proportional to t_{ox2}/t_{ox1} gives an overestimation of the device performance [47].

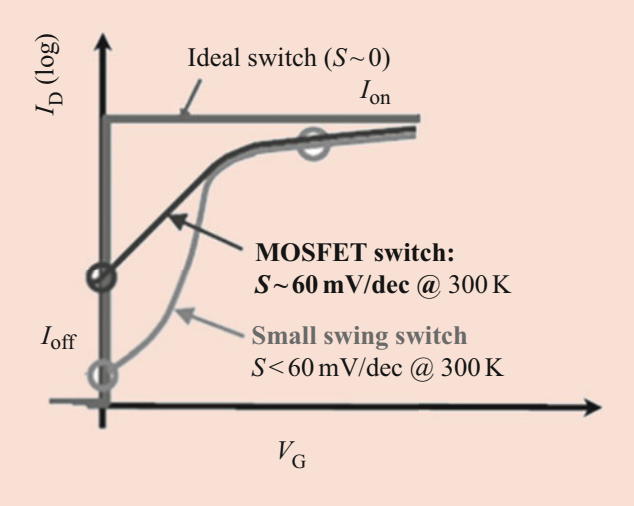

Fig. 9.19 Comparison between the MOSFET switch, the small swing/slope switch, and the ideal switch

Single-gate, double-gate, and GAA InAs TFETs exhibit very good theoretical results (for $V_g = V_d = 0.2$ V), with S lower than 20 mV/dec for small wire diameter (down to 2 nm), thanks to the small effective masses and bandgap of these III–V materials.

For very short gate lengths, small wire diameters are also needed, down to 5 nm or below, as in the case of MOSFETs, in order to obtain a good subthreshold swing (Fig. 9.25) [48].

High performances, with I_d up to 1 mA/μm at low V_d, have been demonstrated by quantum transport simulation on strained InAs NW TFET (Fig. 9.26), the best result being obtained for a biaxial strain [48].

However, if traps are present, the improvements in I_{on} are limited by the degradation of the swing due to trap-assisted tunneling. Both traps and surface roughness can also be a relevant source of device variability for tunnel FETs [49].

The first experimental demonstration of a swing lower than 60 mV/dec (on less than one decade of I_d) using III–V materials has been shown with InGaAs heterojunction 150 nm gate length TFETs using thin EOT and high source doping, with I_{on} of only a few μA/μm [50].

Carbon-based tunnel FETs were the first devices in which S <60 mV/dec was experimentally demonstrated, down to 40 mV/dec, albeit with a very low I_{on} (<1 nA) [51]. The advantages of carbon materials are many, in particular, small effective mass, small and direct bandgap, and excellent elec-

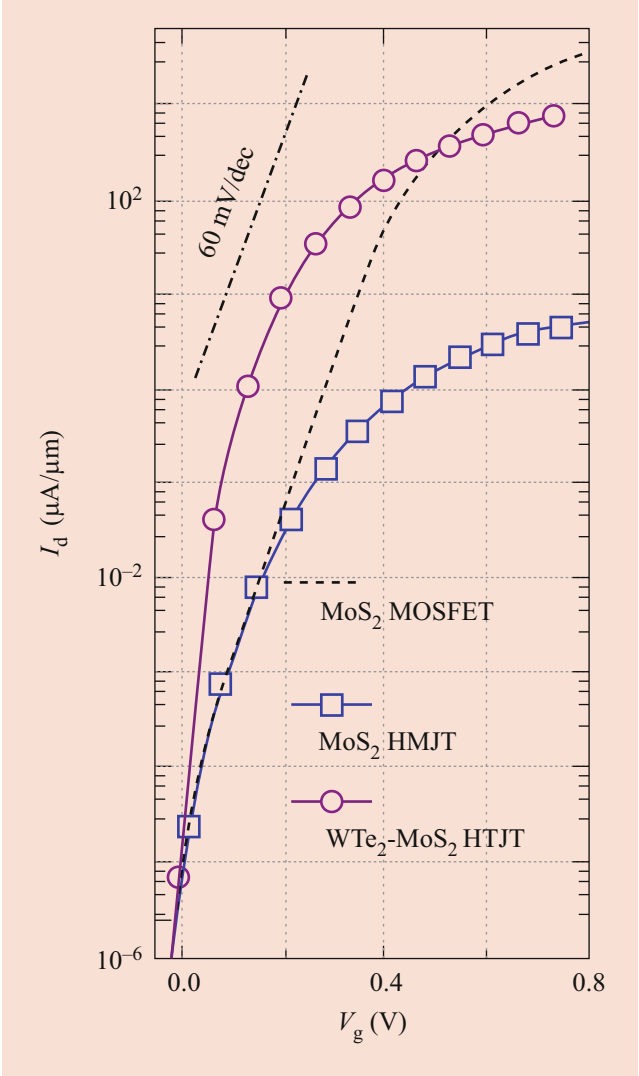

Fig. 9.31 $I_d - V_g$ transfer characteristics for homojunctions MoS_2 and heterojunction WT2-MoS_2 TFETs compared with MoS_2 MOSFET, V_d = 0.5 V, L_g = 12 nm

has been shown by simulation [52] (I_{on}= 100 s of µA/µm, I_{off} = few pA/µm, S = 20 mV/dec, E_{gap} = 200–300 meV, $I_{on}/I_{off} > 10^3$ at V_d = 0.1 V) but has not been replicated experimentally.

The best trade-off obtained by simulation for complementary TFET performance has been shown with Ge/InAs TFETs, leading to an increase of I_d by several hundreds compared to Si TFETs (Fig. 9.27) [53].

However, the experimental results are today very poor compared with numerical simulation. No experimental demonstration of TFET with $I_{on} > 100$ µA/µm and $S < 60$ mV/dec has been shown so far.

Comparisons have been carried out between CMOS and TFET inverters. The Ge/InAs TFET heterostructure showed an abrupt transition from the 1 to the 0 state with the highest differential gain and best noise margins. However, large Miller effects are obtained due to the special capacitance behavior in TFET, leading to larger effective load capacitance and increased delay time. The best power-delay product has been shown so far for CMOS compared with TFETs [54].

Tunnel FETs seem presently better in energy efficiency for applications with frequency lower than 1 GHz (Fig. 9.28) [55].

Recently, a substantial improvement of TFET performance has been experimentally reported in III–V devices using a vertical InAs/GaAsSb/GaSb NW TFET (Fig. 9.29) [56].

The maximum current for which a 60 mV/dec swing is obtained (I_{60}) is 0.056 µA/µm and 0.31 µA/µm at V_{ds} = 0.1 and 0.3 V, respectively, representing an experimental record. The minimum swing is $S_{min} \sim 50$ mV/dec at 300 K (Fig. 9.29a), and the best driving current is obtained for these nanowires for $V_g < 0.25$ V, compared with other TFETs and MOSFETs (Fig. 9.29b).

Very good simulated performances have also been obtained for double-gate 2D TMD TFETs based on WTe_2 [57], WTe_2/MoS_2 heterojunctions [58], and van der Waals-bonded materials [59].

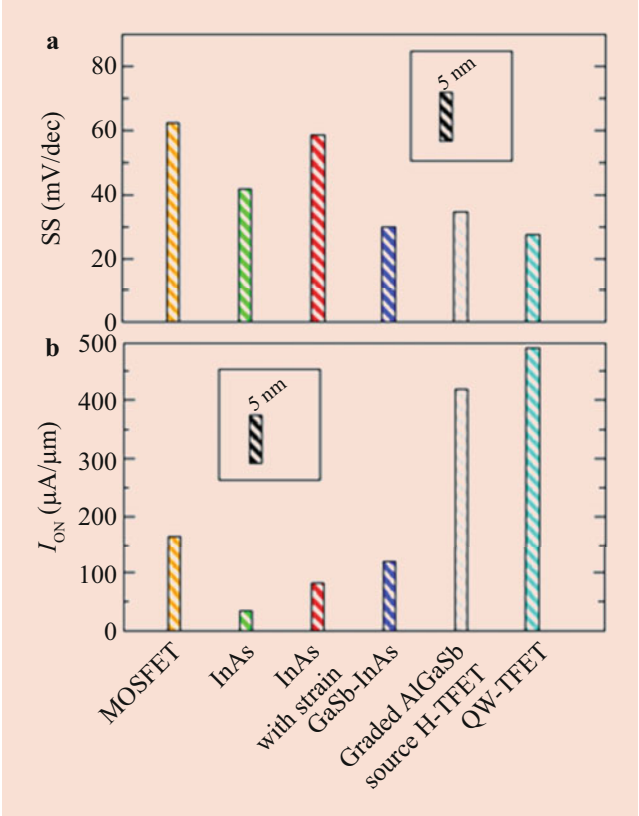

Fig. 9.32 (**a**) Subthreshold slope and (**b**) I_{on} for different nanowire architectures (d = 5 nm, L_g = 17 nm, I_{on} at I_{off} = 5 nA/μm): MOSFET, TFET InAs, TFET InAs with strain, TFET with GaSb-InAs heterostructure, graded source heterostructure TFET with T_{grad} = 5 nm, quantum-well InAs-GaSb-InAs TFET with T_{well} = 3 nm

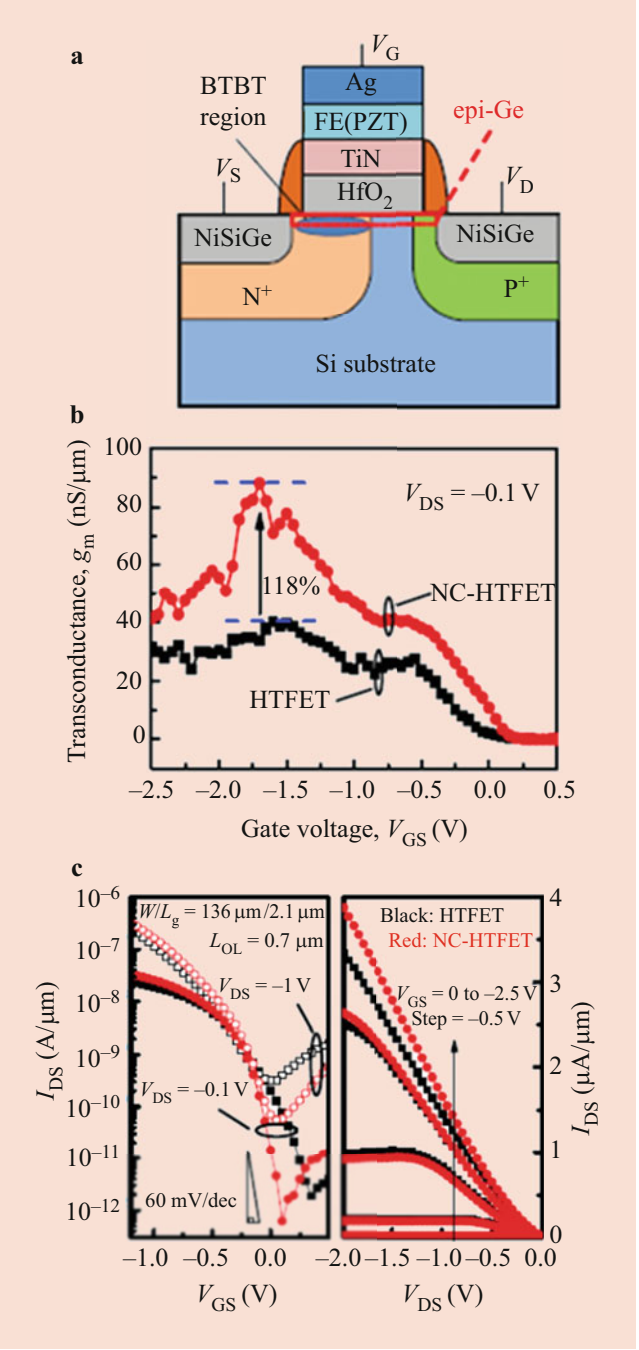

Fig. 9.33 (**a**) Hybrid device FeTFET combining a tunneling transport between source and drain tunneling (TFET) and a ferroelectric gate for improving the subthreshold slope (**c**), the drain current (**c**) at the ON state, and the transconductance (**b**)

The integration limits of TFETs made on a 2D WTe_2 layer have been studied by quantum simulation (Fig. 9.30). A WTe_2 dual-gate TFET shows a possible integration down to 7 nm gate length with very good I_{on}. Below this value, a substantial degradation of the swing results, with a value that goes above 60 mV/dec [57].

The comparison between homojunction and heterojunction 2D TFETs by quantum simulation is shown in Fig. 9.31. The WTe_2-MoS_2 heterojunction leads to a better I_{on} than the homojunction MoS_2 TFET, and a better ON current compared with MoS_2 MOSFET for a gate bias lower than 0.4 V [60], showing the interest of these devices for ultra-low-power operation.

Figure 9.32 shows a comparison, obtained by quantum numerical simulation, of different TFET nanowires made on III–V materials with silicon MOSFET. The best electrical properties are obtained for a quantum-well TFET at the InAs-GaSb-InAs source, leading to a slope of the order of 30 mV/dec and a drain current at the ON state of the order of 500 mA/μm [61]. However, these technologies have to face many challenges, e.g., integration of new III–V materials, innovative architectures of components, and reduction of the densities of defects, in order to eliminate the trap-assisted tunneling that degrades the slope in weak inversion and the current in the ON state.

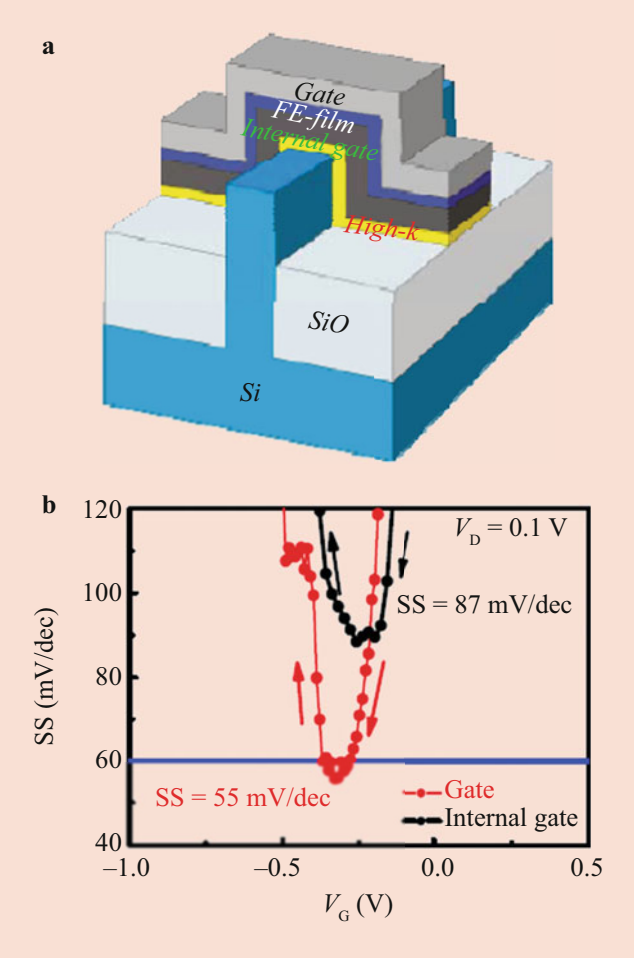

Fig. 9.34 Ferroelectric gate FinFET (**a**) showing a significant improvement of the swing (**b**) compared with traditional FinFET

9.3.2 Ferroelectric Gate Devices

Since it is currently difficult to obtain good experimental performance in drain current at the ON state of tunnel FETs, an interesting option is to combine the tunnel transport between source and drain with a gate using a ferroelectric material, this leading to a possible negative capacitance of the MOS structure. Such a combination significantly improves the subthreshold slope, the drain current, and the transconductance compared to the TFET with a traditional gate (Fig. 9.33) [62].

An improvement in the subthreshold slope, namely, a decrease with respect to the 60 mV/dec limit of traditional MOSFETs, is possible also by combining a ferroelectric gate material and an advanced MOSFET architecture (FinFET), as shown in Fig. 9.34 [63].

Recent experiments have shown that FinFETs using a ferroelectric gate ($HfZrO_2$) and a Ge channel, and therefore a negative capacitance, exhibit a sub-60 mV slope, down to 43 mV/dec, which could lead to larger driving current than TFETs (Fig. 9.35) [64].

SOI MOSFETs realized with PZT and HfO_2/SiO_2 gate in order to obtain a non-hysteretic ferroelectric SOI FET with positive Ctotal have recently been fabricated. A swing down to 20 mV/dec has been found (Fig. 9.36) [65].

9.3.3 Hybrid Devices

Other hybrid devices have also recently shown interesting properties, such as a swing of 4 mV/dec in phase-change

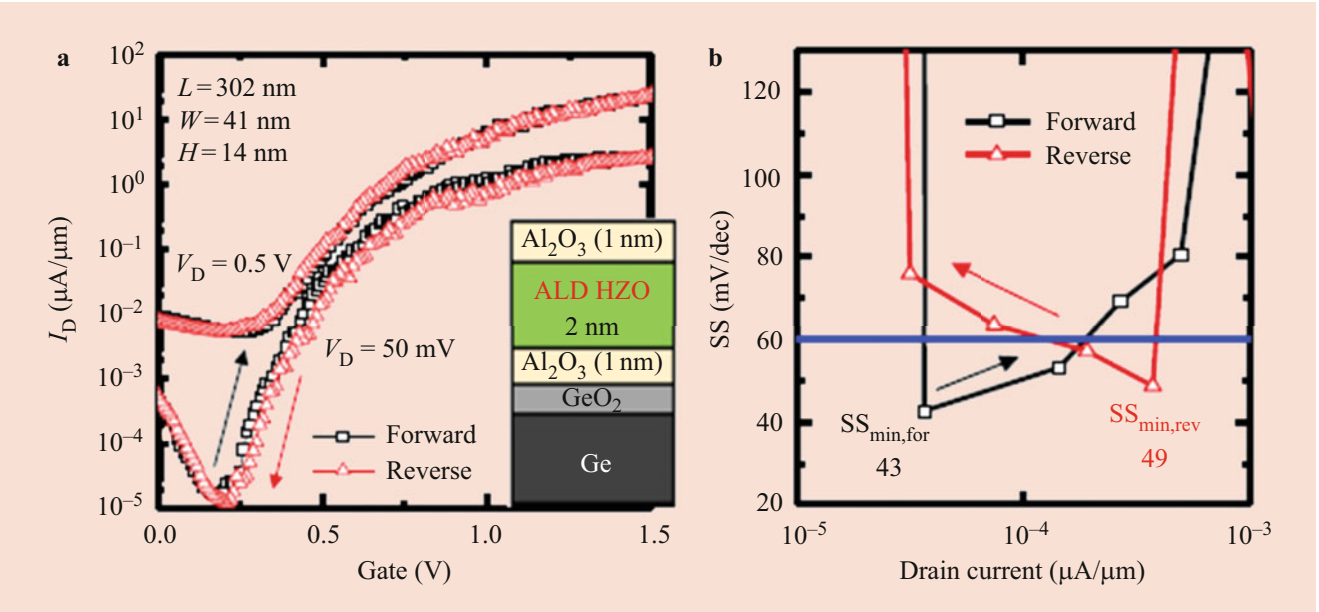

Fig. 9.35 (**a**) Ge channel FE-FET with HfZrO ferroelectric gate showing the transfer characteristics (**b**) and the sub-60 mV/dec subthreshold swing in forward and reverse modes

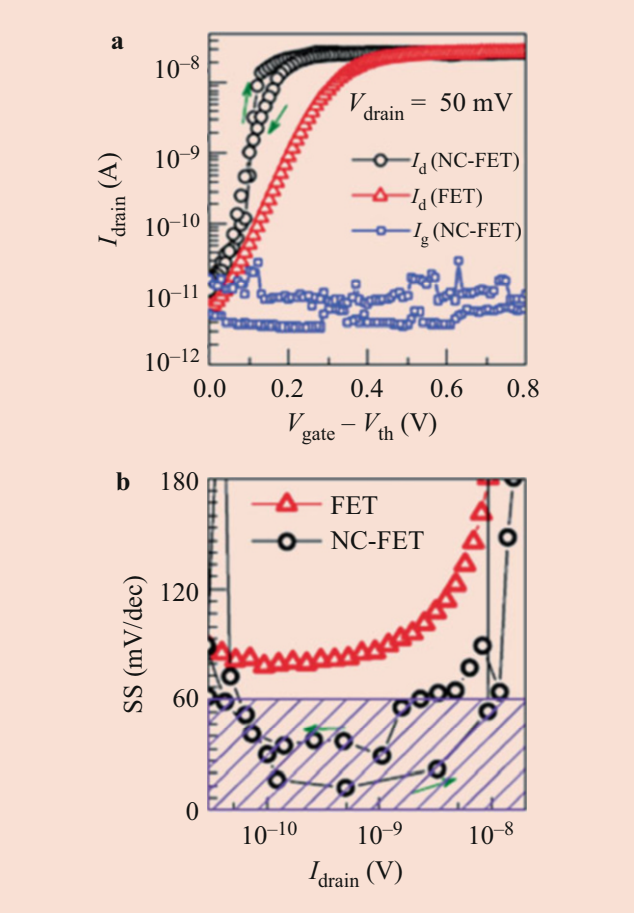

Fig. 9.36 Large surface SOI MOSFET, $t_{si} = 30$ nm, $t_{ox2} = 145$ nm, with PZT + HfO_2/SiO_2 gate for non-hysteretic FE SOI FET with positive C_{total}, (**a**) transfer characteristics, (**b**) subthreshold swing

TFET with a vanadium dioxide layer in the gate (Fig. 9.37) [66].

Another hybrid device using a metal filament (Ag or Cu) formed at the drain of a Si MOSFET under a sufficiently high applied bias led to a sharp subthreshold swing for several decades of I_d (Fig. 9.38) [67].

9.4 Conclusion

Nanoelectronic devices of future generations face substantial challenges: the most important are increased power consumption, performance saturation, large variability, and reliability limitation. To cope with these challenges, novel materials and innovative architectures are necessary for realizing nanoscale FETs.

This chapter has presented the more promising technologies for advanced materials and devices for the end of the roadmap with multi-gate nanodevices, nanowires, tunnel transistors, ferroelectric FET, and hybrid nanocomponents using, for instance, phase change materials and nanofilament. Other alternative materials, as ultra-thin films, 2D and 1D nanostructures, and heterostructures using strained or III–V materials, also allowing to boost the performance of these advanced nanotransistors, have been described.

Acknowledgments The author would like to thank the EU for the H2020 NEREID European Project on Nanoelectronics Roadmapping and the Sinano Institute Members.

Abstract

The chapter has two main parts: the first one addresses the functioning of the MOS capacitor and MOS transistor, considering the case of a p-type substrate. The description of the MOS capacitor is extended to that of the photocapacitor, to be later applied to the case of solid-state imagers. The transistor structure considered in this chapter is simple (i.e., planar); the analysis, however, is carried out in detail, leading to models for the drain current applicable to different functioning regimes of the channel (depletion, weak and strong inversion, saturation). From this, the simpler linear-parabolic model is derived, for both the p- and n-type substrates, necessary to set up the elementary theory of the CMOS inverter. A brief analysis of the scaling rules for MOSFETs is carried out as well.

The second part illustrates the functioning of two important types of charge-transfer devices, CCD and CID, along with some applications, of which the most important are in the field of optical sensing. The architecture of imagers using CCD or CID is illustrated, and different aspects of their performance are analyzed.

10.1 Metal-Insulator-Semiconductor Capacitor

The metal-insulator-semiconductor (MIS) capacitor, sketched in one dimension in Fig. 10.1, is the basic ingredient of the field-effect transistor used in the integrated-circuit production. It is also an important tool for investigating the semiconductor-surface properties [1]. The device is realized by placing (using deposition or thermal growth) an insulator layer over a semiconductor substrate; then, the gate and bulk contacts (indicated in the following with the generic term "metal") are deposited onto the insulator and the substrate, respectively.

In the standard silicon technology, the insulator layer is made of thermally grown silicon dioxide: this explains why t_{ox} is the typical symbol for the insulator thickness; accordingly, the insulator permittivity is indicated with ε_{ox}, and the device is called *MOS* capacitor. In fact, silicon dioxide has been used as gate material for decades; in last-generation devices, due to progressive scaling down and to the need of preventing dielectric breakdown and leakage by tunneling, silicon dioxide is being replaced by materials affording larger permittivities (*high-k dielectrics*).

The theory is expounded with reference to a one-dimensional structure, aligned with the x-axis (Fig. 10.1); the semiconductor-insulator interface coincides with the origin. A spatially constant dopant distribution in the semiconductor is considered, and the non-degeneracy and complete-ionization conditions are assumed to hold [2]. The dopant is of the p-type; with suitable changes in the symbols, the analysis carried out here applies also to a semiconductor of the n-type.

With reference to Fig. 10.2, the gate metal, oxide, and semiconductor are initially considered separate from each other and in the equilibrium condition. Symbols E_C^m and E_F^m indicate the lower edge of the conduction band and the Fermi level of the metal; the minimum energy necessary for an electron to transit from the metal into vacuum is the metal work function $W = E_0 - E_F^m$, with E_0 the vacuum level (left part of Fig. 10.2). For an insulator or a semiconductor, the minimum energy necessary for transiting into vacuum (*electron affinity*) is $A^{ox} = E_0 - E_C^{ox}$ or $A = E_0 - E_C$, respectively. When the materials are brought into contact, they form a single, non-uniform system where the Fermi levels align with each other. As the vacuum levels align as well, the bands adapt

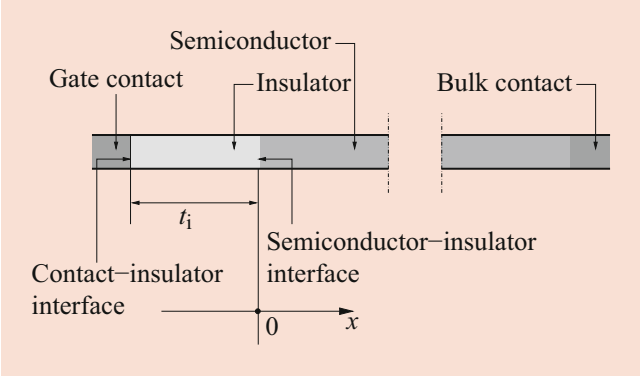

Fig. 10.1 Cross-section of the MIS capacitor (the layer thicknesses are not in scale; after [2])

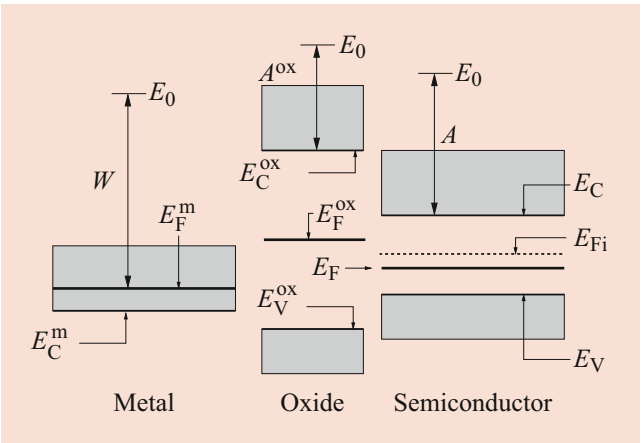

Fig. 10.2 The three materials forming the MOS capacitor shown separately (see text). Symbol E_{Fi} indicates the Fermi level of the intrinsic case. (After [2])

to compensate for a possible charge redistribution occurring when the materials contact each other. The values of W, A in Fig. 10.2 have been selected as to fulfill

$$W - A = E_C - E_F, \tag{10.1}$$

whence, in this case, the bands do not deform; this is visible in Fig. 10.3, representing the situation after the materials have been brought into contact: the bands are everywhere parallel to the Fermi level (*flat-band condition*); as shown later, the more realistic case $W - A \neq E_C - E_F$ is easily incorporated into the analysis.

When the bulk contact is considered, Figs. 10.2 and 10.3 are completed by adding the band structure of the metal on the right of the semiconductor; for simplicity, it is assumed that the gate and bulk contacts are made of the same metal. In the interior of each material, the electric potential is constant due to spatial uniformity, and the electric field is zero.

Let now a voltage V_G be applied between the gate and bulk contacts, such that $V_G > 0$ when the electric potential of the gate contact is larger than that of the bulk contact. In steady-state conditions, the insulator prevents a current from flowing

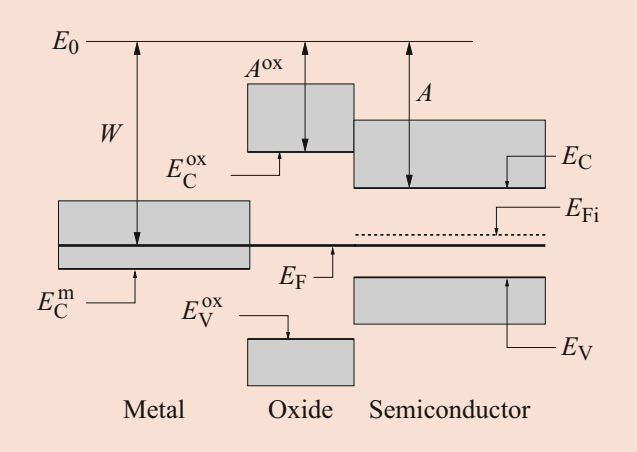

Fig. 10.3 The structure of the MOS capacitor obtained by bringing into contact the three materials of Fig. 10.2. (After [2])

through the device; therefore, during the transient consequent to the application of V_G, the electric charge adjusts itself to the new boundary conditions. At the end of the transient, the device is again in an equilibrium condition, while the form of the bands is different from that of Fig. 10.3. Similarly, the electric potential in the oxide and semiconductor is not constant any longer; its form is found by solving the Poisson equation in each region.

10.1.1 Surface Potential: p-Type Substrate

The solution of the Poisson equation in the uniformly p-doped region is carried out here; the region extension along the x-axis is large, so that, far away from the semiconductor-insulator interface, the semiconductor behaves as if it were isolated. This fixes the carrier-equilibrium concentrations in the bulk; the asymptotic value of the electric potential is set to zero, $\varphi(+\infty) = 0$ whence, remembering that the non-degeneracy and complete-ionization conditions hold, and letting N_A be the constant dopant concentration, it is

$$p^{(0)} = p(+\infty) = p_{p0} \simeq N_A, \quad n^{(0)} = n(+\infty) = n_{p0} \simeq \frac{n_i^2}{N_A}, \tag{10.2}$$

where p and n are the concentrations of holes and electrons, respectively, and n_i is the intrinsic concentration. Indicating the derivatives with primes, the Poisson equation in the semiconductor then reads

$$u'' = \frac{1}{L_A^2} A(u), \qquad A(u) = \frac{n_i^2}{N_A^2} \left[\exp(u) - 1\right] + 1 - \exp(-u), \tag{10.3}$$

with $u = q\varphi/(k_B T)$ the normalized electric potential and $L_A^2 = \varepsilon_{sc} k_B T/(q^2 p_{p0})$, where k_B is the Boltzmann constant, T the lattice temperature, and q the absolute value of the electron charge. The normalized charge density $A(u)$ has the same sign as u; apart from the trivial case where $u = 0$ identically, it is $u' \neq 0$ whence multiplying by u' both sides of the first equation in (10.3) and integrating from $x \geq 0$ to $+\infty$ yield

$$\left(u'\right)^2 = \frac{2}{L_A^2} B(u),$$

$$B(u) = \frac{n_i^2}{N_A^2} \left[\exp(u) - 1 - u\right] + u + \exp(-u) - 1. \tag{10.4}$$

One finds that B is non-negative and u monotonic; the sign of u' is fixed by the boundary condition V_G, which in turn may be either positive or negative. In conclusion,

$$u' = \pm \frac{\sqrt{2}}{L_A} F(u),$$

$$F(u) = \sqrt{\frac{n_i^2}{N_A^2} \left[\exp(u) - 1 - u\right] + u + \exp(-u) - 1}, \tag{10.5}$$

where the sign must be found on a case-by-case basis. Much information is gained directly from (10.5), without the need of another integration. To this purpose, one notes that the electric potential is continuous at the semiconductor-oxide interface; in fact, the normalized charge density in the semiconductor (10.3) has no charge layers in it; hence, it cannot contribute to a double charge layer at the interface. As a consequence, one can adopt the same symbol φ_s for the electric potential at $x = 0$, without distinguishing between the two sides of the interface; φ_s is called *surface potential*, while $u_s = q\varphi_s/(k_B T)$ is the *normalized surface potential*. In contrast, the electric field is discontinuous at the same interface; for this reason, one defines

$$u_s' = \lim_{x \to 0^+} \frac{du}{dx}, \qquad E_s = -\frac{k_B T}{q} u_s', \qquad E_{ox} = -\lim_{x \to 0^-} \frac{d\varphi}{dx}. \tag{10.6}$$

The relation between E_s and E_{ox} is found from the continuity of the electric displacement across the interface and reads

$$\varepsilon_{sc} E_s = \varepsilon_{ox} E_{ox}. \tag{10.7}$$

To find E_{ox}, one observes that in a one-dimensional medium free of charge, the electric potential is linear, whence E_{ox} is given by the negative potential drop across the oxide divided by the oxide thickness t_{ox}. To complete the analysis, it is then necessary to consider the interface between oxide and gate metal. In the interior of the metal, the electric potential is uniform; its value with respect to the metal of the bulk contact is V_G. However, in the solution of the Poisson equation within the semiconductor, the asymptotic condition $\varphi(+\infty) = 0$ has been chosen, which holds inside

the semiconductor region; the surface potential φ_s is referred to such a zero as well. If (10.1) holds, the distinction between bulk contact and bulk semiconductor does not matter because the electric potential is the same; however, in the realistic cases, it is not so, whence V_G and φ_s are referred to two different zeros. Assuming that the interior of the oxide and the semiconductor-oxide interface are free of charge and that the gate and bulk contacts are made of the same material, the difference between the external zero (namely, that within the bulk contact) and the internal zero (given by the asymptotic condition) is the built-in potential Φ_{mp} between the bulk contact and the p-type semiconductor; thus, the gate voltage referred to the internal zero is $V'_G = V_G - \Phi_{mp}$. Also, the electric potential is continuous across the interface between the oxide and the gate metal, because no double layer is present there. In contrast, as $E = 0$ within the metal while $E_{ox} \neq 0$, the electric field is generally discontinuous; in fact, a charge layer of density

$$\rho_m = Q_m \, \delta(x + t_{ox}^-), \tag{10.8}$$

with Q_m the charge per unit area of the metal, builds up at the gate-metal surface. In conclusion, the electric field within the oxide reads

$$E_{ox} = \frac{V'_G - \varphi_s}{t_{ox}}. \tag{10.9}$$

10.1.2 Relation Between Surface Potential and Gate Voltage

Combining (10.5), (10.6), (10.7), and (10.9), one finds

$$C_{ox}\left(V'_G - \varphi_s\right) = \mp \varepsilon_{sc} \frac{k_B T}{q} \frac{\sqrt{2}}{L_A} F(\varphi_s), \qquad C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}}, \tag{10.10}$$

where C_{ox} is the *oxide capacitance per unit area* and $F(\varphi_s)$ is obtained by replacing u with $q\,\varphi_s/(k_B T)$ in the second relation of (10.5). The left-hand side of (10.10) is the charge per unit area Q_m in the gate metal. This is easily found by integrating $\mathrm{d}D/\mathrm{d}x = \rho$ across the metal-oxide interface, using (10.8), and observing that the metal interior is equipotential; one finds

$$Q_m = C_{ox}\left(V'_G - \varphi_s\right). \tag{10.11}$$

Due to the global charge neutrality, the following relation holds between the charge per unit area in the gate metal, Q_m, and that within the semiconductor, Q_{sc}:

$$Q_m + Q_{sc} = 0, \qquad Q_{sc} = \int_0^\infty q\,(p - n - N_A)\;\mathrm{d}x = -C_{ox}\left(V'_G - \varphi_s\right). \tag{10.12}$$

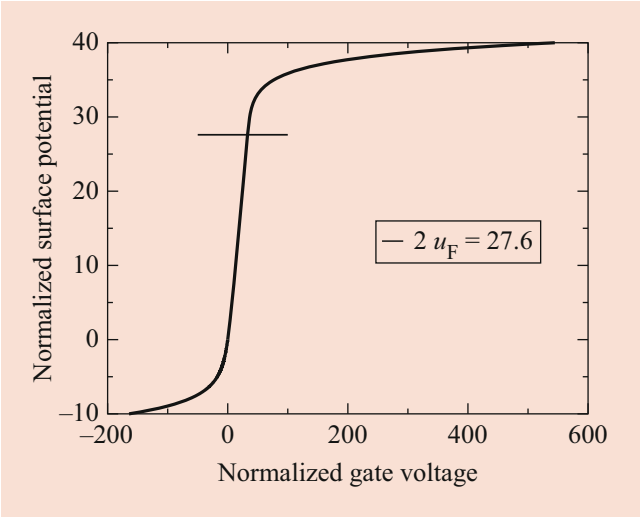

Fig. 10.4 Normalized surface potential u_s in an MOS capacitor with a p-type substrate ($N_A = 10^{16}$ cm^{-3}), as a function of the normalized gate voltage u'_G. (After [2])

In conclusion, (10.10) provides the relation between surface potential and gate voltage. When $\varphi_s = 0$, the electric potential vanishes everywhere in the semiconductor, namely, $V'_G = 0$ corresponds to the flat-band condition. When $V'_G > 0$, the charge in the gate metal is positive; as a consequence, the left-hand side of (10.10) is positive as well, whence $V'_G > \varphi_s$ and the positive sign must be chosen at the right-hand side. The opposite happens when $V'_G < 0$. An example of the $\varphi_s = \varphi_s(V'_G)$ relation is given in Fig. 10.4, showing the normalized surface potential u_s in an MOS capacitor as a function of the normalized gate voltage $u'_G = q\,V'_G/(k_B T)$. The semiconductor's doping is of the p-type with $N_A = 10^{16}$ cm^{-3}, corresponding to $2\,u_F = 2\,q\,\varphi_F/(k_B T) = \log(p_{p0}/n_{p0}) \simeq 27.6$.

The $\varphi_s = \varphi_s(V'_G)$ relation lends itself to identifying different functioning regimes of the MOS capacitor. This identification can be carried out more accurately basing upon the values of the electron and hole concentrations at the semiconductor surface, $n_s = n(x = 0)$ and $p_s = p(x = 0)$. In the non-degenerate conditions considered here, the expressions of the surface concentrations read

$$n_s = n_{p0}\,\exp(u_s) = n_i\,\exp(u_s - u_F), \qquad p_s = p_{p0}\,\exp(-u_s) = n_i\,\exp(u_F - u_s). \tag{10.13}$$

Depending on the value of u_s, several functioning regimes are identified, which are listed in Table 10.1. The regimes' designations are given by comparing the carrier concentrations at the surface with the intrinsic and asymptotic ones. When $u_s < 0$, the majority-carrier surface concentration (holes, in the example used here) exceeds the asymptotic one; the regime is called *accumulation*. When $u_s = 0$, both majority-

Table 10.1 MOS capacitor, p substrate – Functioning regimes (after [2])

Norm. surface potential	Concentrations	Designation
$u_s < 0$	$n_s < n_{p0} < n_i < p_{p0} < p_s$	Accumulation
$u_s = 0$	$n_s = n_{p0} < n_i < p_{p0} = p_s$	Flat band
$0 < u_s < u_F$	$n_{p0} < n_s < n_i < p_s < p_{p0}$	Depletion
$u_s = u_F$	$n_{p0} < n_s = n_i = p_s < p_{p0}$	Mid gap
$u_F < u_s < 2\,u_F$	$n_{p0} < p_s < n_i < n_s < p_{p0}$	Weak inversion
$u_s = 2\,u_F$	$n_{p0} = p_s < n_i < n_s = p_{p0}$	Threshold
$2\,u_F < u_s$	$p_s < n_{p0} < n_i < p_{p0} < n_s$	Strong inversion

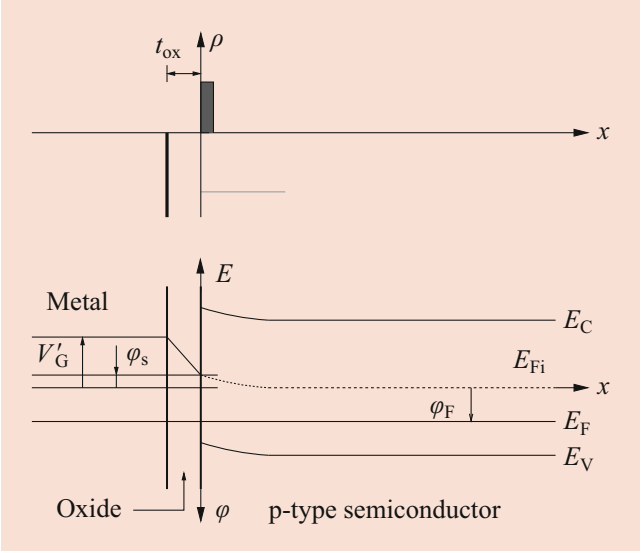

Fig. 10.5 Schematic representation of the charge density and electric potential in a p-substrate MOS capacitor in the accumulation regime. (After [2])

and minority-carrier concentrations equal the corresponding asymptotic concentrations everywhere, and the already-mentioned *flat-band condition* holds. For $0 < u_s < u_F$, the majority-carrier concentration is smaller than the asymptotic one, while the minority-carrier concentration is smaller than the intrinsic one. By continuity, the majority-carrier concentration is smaller than the asymptotic one not only at the semiconductor's surface but also in a finite region of width x_d, which is therefore depleted from carriers; for this reason, the condition $0 < u_s < u_F$ is called *depletion regime*, and x_d is called *depletion width* (the depletion width x_d is conceptually the same thing as the extension l_p of the space-charge region on the p side of a p-n junction; a different symbol is used to avoid confusion in the analysis of the MOSFET (Sect. 10.7)). When $u_s = u_F$, both majority- and minority-carrier concentrations at the surface equal the intrinsic concentration; remembering that in an intrinsic semiconductor the Fermi level practically coincides with the gap midpoint, this regime is called *mid gap*. When $u_F < u_s < 2\,u_F$, the minority-carrier concentration at the surface exceeds that of the majority carriers; however, it is still lower than the asymptotic concentration of the majority carriers: the regime is called *weak inversion*. When $u_s = 2\,u_F$, the surface concentration of the minority carriers equals the asymptotic concentration of the majority carriers, and vice versa; the regime is called *threshold of the strong inversion*, or simply *threshold*. Finally, when $u_s > 2\,u_F$, the minority-carrier concentration at the surface exceeds the asymptotic concentration of the majority carriers, and the regime is called *strong inversion*. In Fig. 10.4, the normalized surface potential at threshold, $2\,u_F$, is marked by the horizontal bar; one notes that in the strong-inversion regime, the surface potential rapidly saturates as the gate voltage increases.

The form of the electric potential and charge density is shown in Fig. 10.5 for the accumulation regime. The upper part of the figure shows the charge density, which is schematically represented by a negative charge layer at the metal-oxide interface and by the thicker, positive layer at the semiconductor-oxide interface. The lower part of the figure shows the electric potential along with the band structure of the semiconductor; note that two different vertical axes are used, in such a way that energy increases upward and the electric potential increases downward. The zero of the electric potential coincides with the horizontal part of the dashed line (in fact, here it is $V'_G < \varphi_s < 0$). The mid-gap condition, $V'_G > 0, \varphi_s = \varphi_F$, is illustrated in Fig. 10.6, whose general description is similar to that of Fig. 10.5; here, the charge layer on the gate metal is positive and balances the negative charge of the semiconductor. Due to the depletion that occurs in the region adjacent to the semiconductor-oxide interface, the charge density is dominated by the contribution from the negative acceptor ions, $\rho \simeq -q\,N_A$. In the figure, the charge density of the semiconductor is schematically indicated by the shaded area that corresponds to a charge per unit area equal to $-q\,N_A\,x_d$. Finally, Fig. 10.7 shows the form of the electric potential and charge density for the threshold condition, $V'_G > 0, \varphi_s = 2\,\varphi_F$. Again, the general description is similar to that of Figs. 10.5 and 10.6; here, there are two contributions to the negative charge of the semiconductor: the first one comes from the negative acceptor ions, whose charge density is schematically indicated by the shaded area of width x_d (note that, due to the larger value of V_G, the depletion width is larger than that of the mid-gap condition). The second contribution to the semiconductor's charge is due to the electrons, whose concentrations at the interface or near it is sufficiently large to be significant; they form a negative layer, called *inversion layer*, whose width, albeit larger than that of the positive layer located at the metal-oxide interface, is much smaller than x_d (the width of the charged layer at the metal-oxide interface is of the order of 1 nm; that of an inversion layer is of the order of 5 nm; an example is given below, with reference to Fig. 10.12).

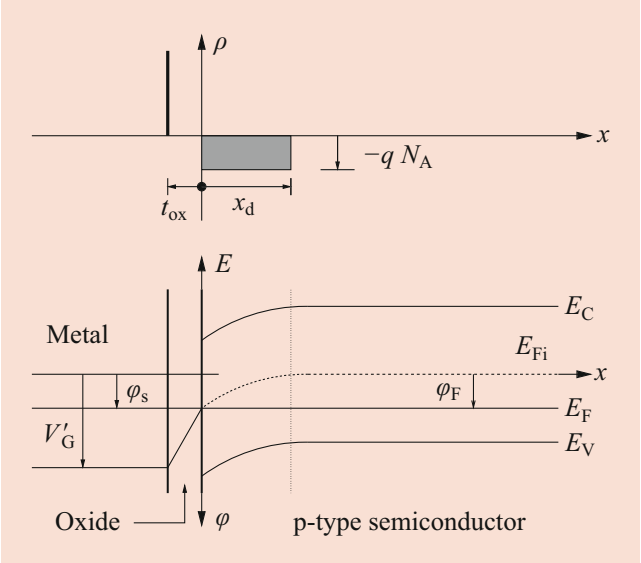

Fig. 10.6 Schematic representation of the charge density and electric potential in a p-substrate MOS capacitor in the mid-gap condition. (After [2])

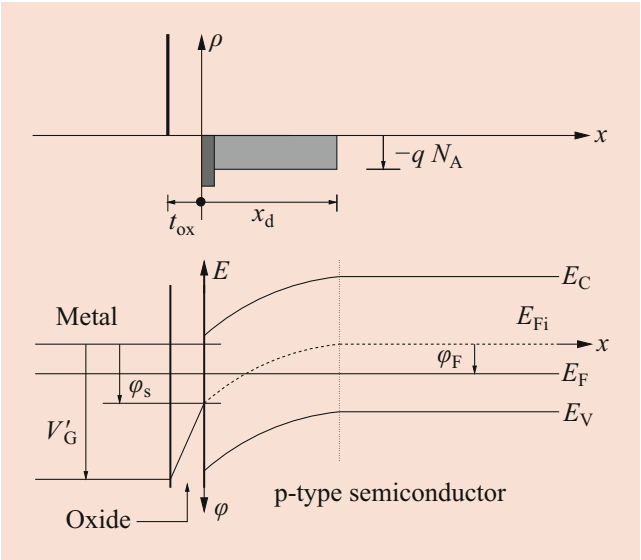

Fig. 10.7 Schematic representation of the charge density and electric potential in a p-substrate MOS capacitor at threshold. (After [2])

Numerical solutions of the semiconductor device model show that, with the exception of the accumulation regime, the semiconductor region of a uniformly doped MOS capacitor can be partitioned into a space-charge and a quasi-neutral region; the quasi-neutral region behaves as a uniform semiconductor, whereas in the volume of the space-charge region, the charge density is essentially dominated by the ionized dopants (with reference to MOS devices, the space-charge region is also called *depleted region*). In the threshold and strong-inversion regimes, also the electrons near the semiconductor-oxide interface give a significant contribution, which must be accounted for; it can be approximated as that of a charge layer at the interface. Considering the range $\varphi_s > 0$ only, namely, excluding the accumulation regime for the p-substrate MOS capacitor, the charge per unit area in the semiconductor is found to be

$$Q_{sc} = \int_0^\infty \rho \, dx \simeq \int_0^{x_d} \rho \, dx \simeq -q \int_0^{x_d} (n + N_A) \, dx = Q_i + Q_b, \tag{10.14}$$

where the first approximation is due to neglecting the charge of the quasi-neutral region and the second one to neglecting the holes in the space-charge region. Quantities Q_i, $Q_b < 0$ are, respectively, the integral of $-q\,n$ and $-q\,N_A$; they are called *inversion charge per unit area* and *bulk charge per unit area*.

10.2 Capacitance of the MOS Structure: p-Type Substrate

The MOS structure exhibits a capacitance C given by

$$C = \frac{dQ_m}{dV_G} = \frac{dQ_m}{dV'_G}, \qquad \frac{1}{C} = \frac{d\left(V'_G - \varphi_s\right) + d\varphi_s}{dQ_m},$$
$$= \frac{1}{C_{ox}} + \frac{d\varphi_s}{d(-Q_{sc})}. \tag{10.15}$$

Like in the case of the depletion capacitance of the *p-n* junction, definition $C = dQ_m/dV_G$ is coherent with the choice of the voltage reference described in Sect. 10.1; the units of C are $[C] = \mathrm{F\,m^{-2}}$. Then, one defines the *semiconductor capacitance per unit area*

$$C_{sc} = -\frac{dQ_{sc}}{d\varphi_s} = -\frac{q}{k_B T} \frac{dQ_{sc}}{du_s} = \pm \frac{\sqrt{2}\,\varepsilon_{sc}}{L_A} \frac{dF}{du_s} > 0, \tag{10.16}$$

where the positive (negative) sign holds for $u_s > 0$ ($u_s < 0$), to eventually find

$$\frac{1}{C} = \frac{1}{C_{ox}} + \frac{1}{C_{sc}}, \tag{10.17}$$

with $C_{ox} = \text{const}$ and $C_{sc} = C_{sc}(u_s)$. The limiting cases of (10.17) are found from (10.5) and $\exp(-2\,u_F) = n_i^2/N_A^2 \ll 1$, which holds in a *p*-substrate capacitor

$$F \simeq \exp(u_s/2 - u_F), \quad u_s \gg 1,$$
$$F \simeq \exp(-u_s/2), \quad u_s \ll -1, \tag{10.18}$$

$$F^2 \simeq \frac{1}{2}\left[1 + \exp(-2\,u_F)\right] u_s^2 \simeq \frac{1}{2} u_s^2, \qquad F \simeq \pm \frac{u_s}{\sqrt{2}},$$
$$|u_s| \ll 1. \tag{10.19}$$

Then, from (10.16),

$$C_{sc} \simeq \frac{1}{\sqrt{2}} \frac{\varepsilon_{sc}}{L_A} \exp(u_s/2 - u_F), \qquad u_s \gg 1, \tag{10.20}$$

$$C_{sc} \simeq \frac{1}{\sqrt{2}} \frac{\varepsilon_{sc}}{L_A} \exp(-u_s/2), \qquad u_s \ll -1, \tag{10.21}$$

so that

$$C = \frac{C_{ox}\, C_{sc}}{C_{ox} + C_{sc}} \simeq C_{ox}, \qquad |u_s| \gg 1. \tag{10.22}$$

Near the origin, one finds instead

$$C_{sc} \simeq \frac{\varepsilon_{sc}}{L_A}, \qquad |u_s| \ll 1. \tag{10.23}$$

The *flat-band capacitance per unit area* turns out to be

$$C_{FB} = \lim_{u_s \to 0} C = \frac{C_{ox}}{1 + C_{ox}\, L_A/\varepsilon_{sc}} < C_{ox}, \qquad |u_s| \ll 1. \tag{10.24}$$

Examples of capacitance-voltage curves are shown in Fig. 10.8.

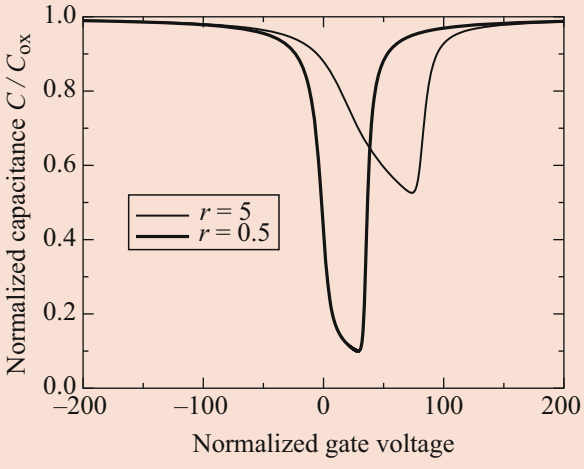

Fig. 10.8 Normalized capacitance C/C_{ox} as a function of the normalized gate voltage u'_G, in a p-substrate MOS capacitor with $N_A = 10^{16}$ cm^{-3}, for different values of $r = \varepsilon_{sc}\, t_{ox}/(\varepsilon_{ox}\sqrt{2}\, L_A)$. (After [2])

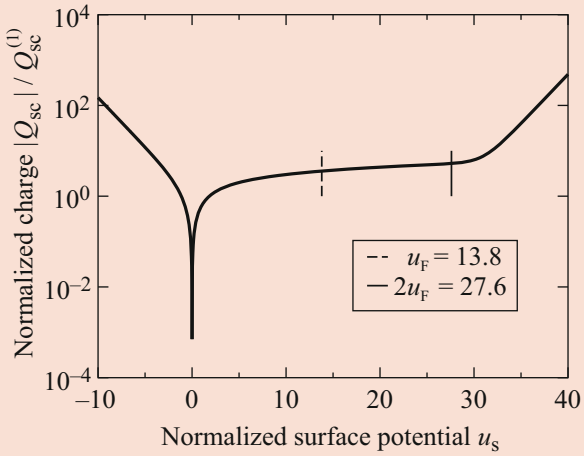

Fig. 10.9 Normalized charge per unit area as a function of the normalized surface potential, in a p-substrate MOS capacitor with $N_A = 10^{16}$ cm^{-3}. (After [2])

10.3 Simplified Expression of the Inversion Charge

A simplified form of the inversion-layer charge of the MOS capacitor is worked out here, to be later applied to the analysis of the MOS transistor. The simplified form holds in all functioning regimes except accumulation. Combining (10.10) and (10.11), one finds for the semiconductor charge per unit area

$$Q_{sc} = \pm Q_{sc}^{(1)}\, F(u_s), \qquad Q_{sc}^{(1)} = \varepsilon_{sc} \frac{k_B\, T}{q} \frac{\sqrt{2}}{L_A}, \tag{10.25}$$

where the negative (positive) sign applies when $u_s > 0$ ($u_s < 0$) and $Q_{sc}^{(1)}$ is the value of Q_{sc} corresponding to $F = 1$. The relation $Q_{sc} = Q_{sc}(u_s)$ is shown in normalized units in Fig. 10.9. The contributions of electrons, holes, and bulk charge to $F^2 = [Q_{sc}/Q_{sc}^{(1)}]^2$ are $\exp(-2\,u_F)\,[\exp(u_s) - 1]$, $\exp(-u_s) - 1$, and $[1 - \exp(-2\,u_F)]\,u_s$, respectively (Fig. 10.10). The first contribution dominates for $u_s > 2\,u_F$, the second one dominates for $u_s < 0$, and, finally, the third one dominates for $0 < u_s < 2\,u_F$.

In a p-substrate capacitor, excluding accumulation entails the inequality $u_s > 0$; thus, an approximation for F is easily derived from (10.5), whose limiting case in the depletion and weak-inversion regimes is $F \simeq \sqrt{u_s}$, $0 < u_s < 2\,u_F$. Combining the latter with (10.25) yields

$$Q_{sc} \simeq -\frac{\sqrt{2}\,\varepsilon_{sc}\, k_B\, T}{q\, L_A} \sqrt{\frac{q\,\varphi_s}{k_B\, T}} = -C_{ox}\,\gamma\,\sqrt{\varphi_s},$$
$$\gamma = \frac{\sqrt{2\,\varepsilon_{sc}\, q\, p_{p0}}}{C_{ox}}, \tag{10.26}$$

where the units of γ are $[\gamma] = \mathrm{V}^{1/2}$. A relation identical to (10.26) is obtained using the full-depletion and the abrupt space-charge edge (ASCE) approximations; in fact, letting $\rho = -q\,N_A$ for $0 < x < x_d$ and $\rho = 0$ for $x > x_d$ (compare, e.g., with Figs. 10.6 and 10.7) yields for $0 < x < x_d$ a simplified form of the Poisson equation, $\varphi'' \simeq q\,N_A/\varepsilon_{sc}$, with boundary conditions $\varphi(x_d) = 0$, $\varphi'(x_d) = 0$; the so-

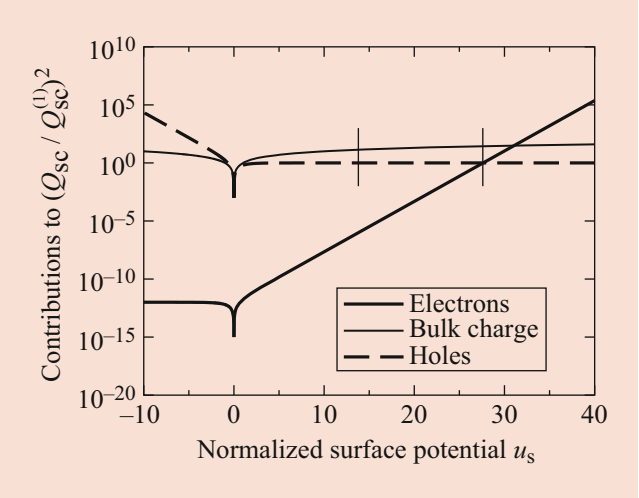

Fig. 10.10 Individual contributions of electrons, holes, and bulk charge to $F^2 = [Q_{sc}/Q_{sc}^{(1)}]^2$, as a function of the normalized surface potential u_s, in a p-substrate MOS capacitor with $N_A = 10^{16}$ cm^{-3}. (After [2])

lution of the simplified form is $\varphi(x) = q\,N_A\,(x - x_d)^2/(2\,\varepsilon_{sc})$. Setting $x = 0$ yields a relation between the surface potential and the depletion width; in turn, in the full-depletion and ASCE approximations, the bulk charge per unit area is $Q_b = -q\,N_A\,x_d$ (Figs. 10.6 and 10.7). In conclusion,

$$\varphi_s = \frac{q\,N_A}{2\,\varepsilon_{sc}}\,x_d^2\,, \qquad Q_b = -q\,N_A\,x_d = -\sqrt{2\,\varepsilon_{sc}\,q\,N_A\,\varphi_s}\,. \tag{10.27}$$

When $0 < u_s < 2\,u_F$, it is $Q_{sc} \simeq Q_b$; as a consequence, the second relation in (10.27), using $N_A \simeq p_{p0}$, coincides with the first one in (10.26). Combining $Q_{sc} \simeq Q_b$ with (10.26) and with the general expression (10.12) yields $V'_G - \varphi_s = \gamma\,\sqrt{\varphi_s}$; inverting the latter and discarding the negative sign in front of the square root yield

$$\sqrt{\varphi_s} = \sqrt{V'_G + (\gamma/2)^2} - \gamma/2\,, \tag{10.28}$$

which applies in the depletion and weak-inversion conditions. The contribution of electrons to the semiconductor charge per unit area, $Q_i = -q\int_0^{x_d} n\,dx$, becomes relevant from the threshold condition on. Like in Sect. 10.1.2, the electron charge is approximated with $-q\,n \simeq Q_i\,\delta(x^+)$, so that the space charge is still considered as entirely due to the ionized acceptor atoms also when $\varphi_s > 2\,\varphi_F$, and (10.27) still holds. From (10.14), one then finds the simplified form of the inversion-layer charge of a *p*-substrate MOS capacitor,

$$Q_i = Q_{sc} - Q_b = -C_{ox}\left[(V'_G - \varphi_s) - \gamma\,\sqrt{\varphi_s}\right] < 0. \tag{10.29}$$

applicable in the depletion, weak-inversion, and strong-inversion conditions (an analysis of the MOS capacitor that avoids partitioning the semiconductor volume into regions is feasible (Sect. 10.13.3), at the expense of the analytical representation).

10.3.1 Flat-Band Voltage

The theory of the previous paragraph must be completed by disposing of the hypothesis on which (10.1) is based and supposing instead that a fixed charge density $\rho_{ox}(x)$ is present in the oxide. This gives the Poisson equation the form $-\varepsilon_{ox}\,\varphi'' = \rho_{ox}$, whence

$$C_{ox}\,(V'_G - \varphi_s) = -\varepsilon_{ox}\,\varphi'(-t_{ox}^+) - Q_{ox}, \qquad Q_{ox} = \int_{-t_{ox}}^{0} \frac{\xi}{t_{ox}}\,\rho_{ox}(\xi)\,d\xi\,, \tag{10.30}$$

with $\varphi(0) = \varphi_s$ and $\varphi(-t_{ox}) = V'_G$. Combining with $-\varepsilon_{ox}\,\varphi'(-t_{ox}^+) = Q_m$ yields $Q_m = C_{ox}\,(V'_G + Q_{ox}/C_{ox} - \varphi_s)$, and, from $V'_G = V_G - \Phi_{mp}$, it finally follows

$$V'_G + \frac{Q_{ox}}{C_{ox}} = V_G - V_{FB}\,, \qquad V_{FB} = \Phi_{mp} - \frac{Q_{ox}}{C_{ox}}\,, \tag{10.31}$$

with V_{FB} the *flat-band voltage*. The designation is due to the fact that letting $V_G = V_{FB}$ establishes the flat-band condition in the semiconductor. If a fixed layer of charge is also present in the oxide, in addition to ρ_{ox}, its effect on V_{FB} is readily incorporated by adding to ρ_{ox} a term of the form $Q_f\,\delta(x - h)$, with Q_f the charge per unit area of the layer and h its position.

Definition (10.31) of V_{FB} does not account for the fact that, besides the fixed charge, mobile charges may be present within the oxide or at the semiconductor-oxide interface. The mobile charges within the oxide make V_{FB} unstable, whence the threshold voltage (10.82) or (10.121) of the MOS transistor becomes unstable as well. The charge at the semiconductor-oxide interface is due in turn to a distribution of interfacial electronic states, called *surface states*, whose energy belongs to the band gap. Such states are due to the disruption of periodicity caused by the finiteness of the crystal size. In a bare silicon crystal, the surface concentration of surface states turns out to be equal to that of the atoms themselves [2]; in silicon, the latter is about $(5.0 \times 10^{22})^{2/3} \simeq 1.36 \times 10^{15}$ cm^{-2}. When the semiconductor-oxide interface is considered, instead, the concentration of surface states is much smaller; the typical figures for the silicon-oxide interface range from 10^9 to 10^{11} cm^{-2}, depending on the quality of the oxide-growth process and on the subsequent annealing steps.

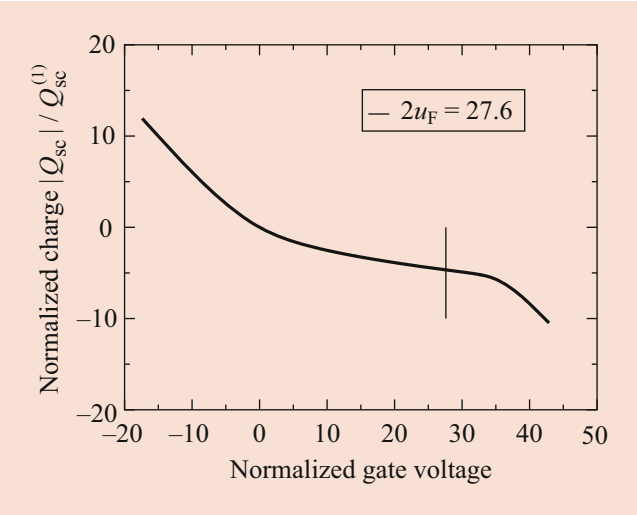

Fig. 10.11 Normalized semiconductor charge $Q_{sc}/Q_{sc}^{(1)}$ as a function of the normalized gate voltage u'_G, for a p-substrate MOS capacitor with $N_A = 10^{16}$ cm^{-3}. (After [2])

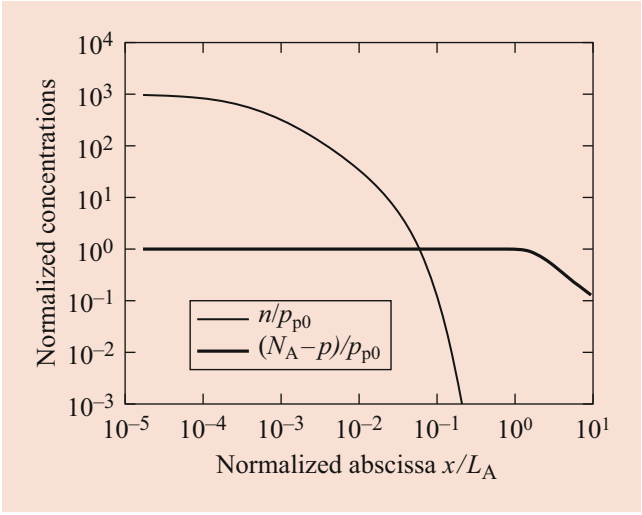

Fig. 10.12 Normalized concentrations n/p_{p0} and $(N_A - p)/p_{p0}$ as a function of position x/L_A, for a p-substrate MOS capacitor with $N_A = 10^{16}$ cm^{-3} in strong inversion ($u_s = 2.5\, u_F$). (After [2])

In the following, it is assumed that the effect of the mobile charges described here is negligible. Also, the analysis carried out in this section shows that the presence of a fixed charge density ρ_{ox} merely shifts V'_G by a constant amount. For this reason, from now on, symbol V'_G will be given the more general meaning $V'_G = V_G - V_{FB}$.

10.3.2 Quantitative Relations in the MOS Capacitor

In the p-type silicon substrate considered so far in the examples, it is $p_{p0} \simeq N_A = 10^{16}$ cm^{-3} and, at room temperature, $n_i \simeq 10^{10}$ cm^{-3}. In turn, the asymptotic minority-carrier concentration is $n_{p0} = n_i^2/N_A \simeq 10^4$ cm^{-3}; it follows $\exp(-2\,u_F) = n_{p0}/p_{p0} \simeq 10^{-12}$ and, as shown, e.g., in Fig. 10.4, $2\,u_F \simeq 27.6$. Using $k_B\,T/q \simeq 26$ mV then yields $2\,\varphi_F \simeq 0.72$ V. As $\varepsilon_{sc} \simeq 11.7 \times 8.854 \times 10^{-14} = 1.036 \times 10^{-12}$ F cm^{-1}, one finds

$$L_A = \sqrt{\frac{\varepsilon_{sc}\, k_B\, T}{q^2\, p_{p0}}} \simeq 4.1 \times 10^{-2}\,\mu\text{m}, \tag{10.32}$$

$$Q_{sc}^{(1)} = \frac{\sqrt{2}\,\varepsilon_{sc}\, k_B\, T}{q\, L_A} = \sqrt{2\,\varepsilon_{sc}\, k_B\, T\, p_{p0}} \simeq 9.3 \times 10^{-9}\ \text{C cm}^{-2}. \tag{10.33}$$

The relation $Q_{sc}(V'_G)$ is found from $Q_{sc} = -C_{ox}\,[V'_G - \varphi(V'_G)]$, where $\varphi(V'_G)$ is obtained from (10.10). The result is shown in normalized form in Fig. 10.11.

The results obtained so far have been obtained without the need of integrating (10.4). The result of a numerical integration of (10.4) is shown in Fig. 10.12, where the dependence on position of n and $N_A - p$ is drawn for a p-substrate MOS capacitor with $N_A = 10^{16}$ cm^{-3} in the strong-inversion regime ($u_s = 2.5\, u_F$). The term $(N_A - p)/p_{p0}$ is significant in a surface region of the semiconductor, whose thickness is several units of x/L_A. The term n/p_{p0} is much larger, but only in a much thinner region near the surface. If the width of the inversion layer is conventionally taken at the intersection between the two curves of Fig. 10.12, which occurs at $x/L_A \simeq 0.1$, one finds from (10.32) a width of about 5 nm.

With reference to Fig. 10.2, and using aluminum as metal and silicon as semiconductor, one has [3, Sect. 8.1] $W = 4.1$, $A = 4.05$, and $A^{ox} = 0.95$ eV. The band gap of the thermally grown silicon dioxide is about 9 eV.

10.4 MOS Photocapacitor

The operation of the *MOS photocapacitor* is readily described basing on the analysis of the MOS capacitor carried out in Sect. 10.1. The device is sketched in Fig. 10.13, where the case of a uniform, p-substrate capacitor is considered with a constant concentration N_A of acceptor dopants. For simplicity, a one-dimensional structure is analyzed, with a partially transparent contact. The incoming radiation is described by the arrows, while the black dots indicate the electrons, and the white dot indicates a hole. The resistor shown in the figure stands for the input resistance of the circuit measuring the device current.

The gate voltage $V(t)$ periodically alternates between V_{FB} and a value V_{GI} that would correspond to strong inversion in a steady-state condition. The duration T_s along which the gate voltage equals V_{FB} is termed *sampling time*, while

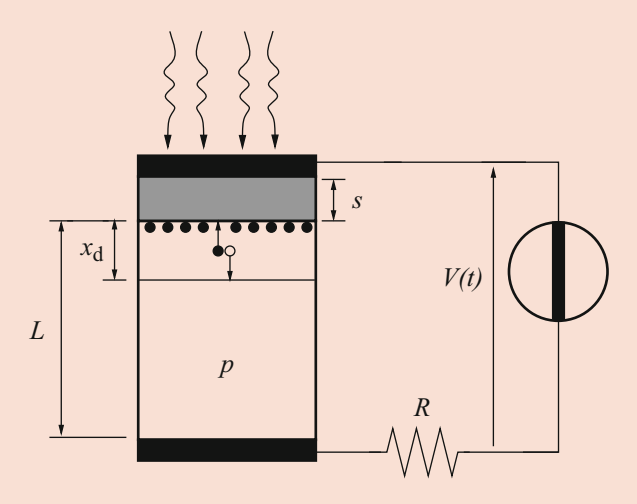

Fig. 10.13 One-dimensional sketch of the MOS photocapacitor with a uniform, p-type substrate. The relative thicknesses of the different layers shown in the figure are not realistic. (After [2])

integration time is the duration T_i along which it equals V_{GI}. It is assumed that at the beginning of the integration time, the earlier transients have vanished, so that the net local charge is negligible (this charge would be exactly zero if the illumination were missing). When the gate voltage switches from V_{FB} to V_{GI}, the majority carriers (holes) are pushed away from the semiconductor-insulator interface, and a depleted region of width x_d is formed in a negligible time; the inversion-layer charge Q_i is not present yet, so that, combining (10.27) with (10.28), one finds

$$x_d = \sqrt{\frac{2\,\varepsilon_{sc}}{q\,N_A}\,\varphi_s}\,, \qquad \sqrt{\varphi_s} = \sqrt{V_{GI} - V_{FB} + (\gamma/2)^2} - \gamma/2. \tag{10.34}$$

The value (10.34) of x_d is considerably larger than the one that would correspond to the equilibrium condition; in fact, the inversion layer is still missing. This layer builds up during the integration time, made of the combined contributions of thermal and optical generations in the depleted region; thus, x_d gradually decreases, while the modulus of Q_i increases. When the applied voltage is switched back to V_{FB}, the holes flood the depleted region and make it to disappear in a negligible time, without affecting the inversion layer. The disappearing of the depleted region makes the electric field to vanish, so that the electrons of the inversion layer start diffusing toward the substrate; in parallel, they recombine with the holes, this giving origin to a current in the external circuit. For typical operating conditions, the contribution of optical generation to the inversion layer dominates over thermal generation; thus, the measured current is essentially due to the illumination, while the effect of thermal generation is to be considered as a noise superimposed to the signal.

An estimate of the sampling time is important. For this, one solves the electron-continuity equation in one dimension,

$$\frac{\partial n}{\partial t} + \frac{n - n_{p0}}{\tau_n} - \frac{1}{q}\,\frac{\partial J_n}{\partial x} = G_s\,\exp(-k\,x)\,, \tag{10.35}$$

assuming that the weak-injection condition applies and that the absorption coefficient k is constant. The coefficient G_s of the optical-generation term reads $G_s = \eta\,\Phi_B\,k\,\exp(-k\,s)$, with Φ_B the photon-flux density on the inside edge of the contact-oxide interface and $\exp(-k\,s)$ a factor accounting for the absorption within the oxide, whose thickness is s (the origin is placed at the semiconductor-oxide interface). The excess charge Q per unit area at time t is found by integrating the minority-carrier excess concentration $n - n_{p0}$ over the semiconductor thickness L; in calculating the integral, one lets $J_n(x = 0) = 0$ due to the presence of the oxide and $J_n(L) \simeq J_n(\infty) = 0$ due to the large extent of L: in conclusion,

$$\frac{\mathrm{d}Q}{\mathrm{d}t} + \frac{Q}{\tau_n} = q\,\frac{G_s}{k}\,, \qquad Q = \int_0^L q\,\left(n - n_{p0}\right)\,\mathrm{d}x. \tag{10.36}$$

Let $t = 0$ be the instant at which the gate voltage V_G is brought from $V_G(0^-) = V_{GI}$ to $V_G(0^+) = V_{FB}$; when integrating (10.36), one observes that the minimum period of variation of Φ_B is large with respect to τ_n, so that G_s is taken constant. One finds

$$Q(t) - q\,\tau_n\,\frac{G_s}{k} = \left[Q_0 - q\,\tau_n\,\frac{G_s}{k}\right]\,\exp(-t/\tau_n)\,, \tag{10.37}$$

with Q_0 the excess minority charge per unit area at $t = 0$. This result shows that the approach to the asymptotic condition is dominated by the minority-carrier lifetime τ_n; note that in the asymptotic limit, the excess charge does not vanish; in fact, it is $Q(\infty) = q\,\tau_n\,G_s/k$. The process is considerably shortened if the photocapacitor is built within a p-type epitaxial layer of thickness a grown over an n-type substrate (Fig. 10.14): the heavily doped n^+ substrate behaves like a contact, and the excess charge vanishes in the much shorter time during which the electrons diffuse across a. As in this case the asymptotic condition $J_n(L) = 0$ does not hold any more, the time decay of Q is found by solving the continuity equation in the form

$$\frac{\partial n}{\partial t} + \frac{n - n_{p0}}{\tau_n} - D_n\,\frac{\partial^2 n}{\partial x^2} = G_s\,\exp(-k\,x)\,, \tag{10.38}$$

whose initial condition reads $n(x, 0) - n_{p0} = Q_0\,\delta(x^+)$. In (10.38), the drift term of J_n is neglected due to the vanishing of the electric field discussed above. The boundary condition at $x = 0$ is $\partial n/\partial x = 0$ at all times, equivalent to $J_n(0) = 0$, while the boundary condition at $x = a$ is $n(a, t) = n_{p0}$ because the heavily doped substrate acts as a contact. Letting $f = (n - n_{p0})\,\exp(t/\tau_n)$ transforms (10.38) into

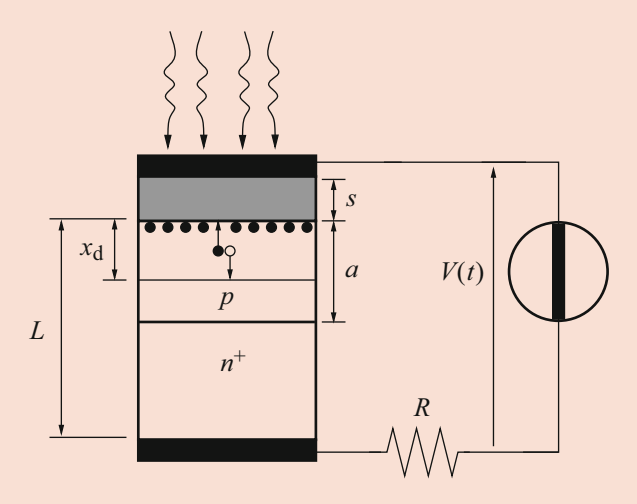

Fig. 10.14 One-dimensional sketch of the MOS photocapacitor built in a p-type epitaxial layer. The relative thicknesses of the different layers shown in the figure are not realistic. (After [2])

$$\frac{\partial f}{\partial t} = D_\mathrm{n}\,\frac{\partial^2 f}{\partial x^2} + G_\mathrm{s}\,\exp(-k\,x + t/\tau_\mathrm{n})\,, \tag{10.39}$$

whose initial condition is $f(x,0) = Q_0\,\delta(x^+)$, while the boundary conditions are $\partial f/\partial x = 0$ and $f(a,t) = 0$. The solution of (10.39) is found by Fourier expanding the unknown: let ω be a function defined in $-2\,a \le x \le 2\,a$ and even in such an interval: $\omega(-x,t) = \omega(x,t)$; also, let $\omega(x,t) = f(x,t)$ in the interval of interest, $0 \le x \le a$. Due to the evenness of ω, one writes

$$\omega = \sum_{k=0}^{\infty} \chi_k(t)\,\gamma_k(x)\,, \quad \chi_k = \frac{1}{2\,a}\int_{-2\,a}^{+2\,a} \gamma_k\,\omega\;\mathrm{d}x,$$
$$\gamma_k = \cos\left(k\,\pi\,\frac{x}{2\,a}\right). \tag{10.40}$$

By construction, the auxiliary function ω verifies the boundary condition $\partial\omega/\partial x = 0$ at $x = 0$, but not $\omega(a) = 0$. To verify the latter, one restricts the choice to those ω that are odd in the interval of length $2\,a$ centered at $x = a$, that is, $\omega(2\,a - x) = -\omega(x)$ for $0 \le x \le a$. Prescribing $\gamma_k(2\,a - x) = -\gamma_k(x)$, it follows $\cos(k\,\pi) = -1$, that is, $k = 2\,i + 1$ with $i = 0, 1, 2, \ldots$; letting $g_i = \cos[(i + 1/2)\,\pi\,x/a]$ and using the properties of ω and g_i provide

$$c_i = \frac{1}{2\,a}\int_{-2\,a}^{+2\,a} g_i\,\omega\;\mathrm{d}x = \frac{1}{a}\int_0^{2\,a} g_i\,\omega\;\mathrm{d}x = \frac{2}{a}\int_0^{a} g_i\,\omega\;\mathrm{d}x\,. \tag{10.41}$$

As $f = \omega$ in the interval $0 \le x \le a$, the Fourier expansion of f reads

$$f = \sum_{i=0}^{\infty} c_i(t)\,g_i(x)\,, \qquad c_i = \frac{2}{a}\int_0^a f\,\cos\left(\frac{x}{L_i}\right)\mathrm{d}x, \tag{10.42}$$

with $1/L_i = (i + 1/2)\,\pi/a$. From $g_i = \cos[(i + 1/2)\,\pi\,x/a]$, it follows $g_i'(0) = 0$, $g(a) = 0$, and $g_i'' = -g_i/L_i^2$; also,

$$\int_0^a g_i\frac{\partial f}{\partial t}\;\mathrm{d}x = \frac{\mathrm{d}}{\mathrm{d}t}\int_0^a g_i f\;\mathrm{d}x = \frac{a}{2}\,\frac{\mathrm{d}c_i}{\mathrm{d}t} \tag{10.43}$$

and, integrating by parts and using the boundary conditions,

$$\int_0^a g_i\,\frac{\partial^2 f}{\partial x^2}\;\mathrm{d}x = \int_0^a \frac{\mathrm{d}^2 g_i}{\mathrm{d}x^2} f\;\mathrm{d}x = -\frac{1}{L_i^2}\int_0^a g_i f\;\mathrm{d}x = -\frac{a}{2}\,\frac{c_i}{L_i^2}. \tag{10.44}$$

Multiplying by g_i both sides of (10.39), integrating from 0 to a, and using (10.43), (10.44), finally provide a first-order differential equation for c_i

$$\frac{\mathrm{d}c_i}{\mathrm{d}t} + \frac{c_i}{\tau_i} = \alpha_i\,\exp(t/\tau_\mathrm{n})\,, \quad \tau_i = \frac{L_i^2}{D_\mathrm{n}},$$
$$\alpha_i = \frac{2}{a}\int_0^a g_i\,G_\mathrm{s}\exp(-k\,x)\;\mathrm{d}x\,, \tag{10.45}$$

with the initial condition

$$c_i(0) = \frac{2}{a}\int_0^a g_i f(x,0)\;\mathrm{d}x = \frac{2}{a}\int_0^a g_i\,Q(0)\,\delta(x^+)\;\mathrm{d}x = \frac{2}{a}\,Q_0, \tag{10.46}$$

independent of i. Integrating (10.45) yields

$$c_i(t)\,\exp(t/\tau_i) - c_i(0) = \alpha_i\,\tau_i^\star\,\left[\exp(t/\tau_i^\star) - 1\right],$$
$$\frac{1}{\tau_i^\star} = \frac{1}{\tau_\mathrm{n}} + \frac{1}{\tau_i} \tag{10.47}$$

whence, turning to the original unknown $n - n_{\mathrm{p}0} = f\,\exp(-t/\tau_\mathrm{n})$,

$$n - n_{\mathrm{p}0} = \sum_{i=0}^{\infty} g_i\,\left[\alpha_i\,\tau_i^\star + \left(c_i(0) - \alpha_i\,\tau_i^\star\right)\,\exp(-t/\tau_i^\star)\right]. \tag{10.48}$$

Like in the case of the uniform substrate, the excess charge per unit area $Q(t) = q\int_0^a (n - n_{\mathrm{p}0})\;\mathrm{d}x$ does not vanish for $t \to \infty$ as long as $G_\mathrm{s} \neq 0$. Using $\tau_i = L_i^2/D_\mathrm{n}$ and the definition of the minority-carrier diffusion length $L_\mathrm{n} = \sqrt{\tau_\mathrm{n}\,D_\mathrm{n}}$, one finds

$$\tau_i = \tau_\mathrm{n}\,\frac{L_\mathrm{i}^2}{L_\mathrm{n}^2} = \tau_\mathrm{n}\,\frac{a^2}{[\pi\,L_\mathrm{n}\,(i + 1/2)]^2}\,. \tag{10.49}$$

For typical values of a and L_n, the largest decay time obtained from (10.49), τ_0, is much shorter than that found for a uniform substrate: $\tau_0/\tau_\mathrm{n} = 4\,a^2/(\pi^2\,L_\mathrm{n}^2) \ll 1$.

10.5 MOS Capacitor: n-Type Substrate

This section briefly illustrates the theory of the n-substrate MOS capacitor, which is "dual" to that of the p-substrate one. Letting N_D be the constant concentration of donor atoms, such that the non-degeneracy and complete-ionization conditions apply, and letting $\varphi(\infty) = 0$, one finds (compare with (10.2))

$$n^{(0)} = n(+\infty) = n_{n0} \simeq N_D\,, \quad p^{(0)} = p(+\infty) = p_{n0} \simeq \frac{n_i^2}{N_D}\,. \tag{10.50}$$

The Poisson equation in the semiconductor takes the form (compare with (10.3))

$$u'' = \frac{1}{L_D^2}\,A(u)\,, \qquad A(u) = \exp(u) - 1 + \frac{n_i^2}{N_D}\,[1 - \exp(-u)]\,, \tag{10.51}$$

with $L_D^2 = \varepsilon_{sc}\,k_B\,T/(q^2\,n_{n0})$, and its solution is

$$u' = \pm\frac{\sqrt{2}}{L_D}\,F(u),$$
$$F = \sqrt{\exp(u) - 1 - u + \frac{n_i^2}{N_D^2}\,[u + \exp(-u) - 1]}\,. \tag{10.52}$$

Noting that (10.7) and (10.9) hold for both the p- and n-type substrates (here, however, Q_{sc} is the integral of $q\,(p - n + N_D)$, instead of $q\,(p - n - N_A)$, over the semiconductor domain), one finds

$$C_{ox}\,(V'_G - \varphi_s) = \mp\varepsilon_{sc}\,\frac{k_B\,T}{q}\,\frac{\sqrt{2}}{L_D}\,F(\varphi_s). \tag{10.53}$$

Also in this case $\varphi_s = 0$ marks the flat-band condition. Like in the p-substrate case, from the $\varphi_s = \varphi_s(V'_G)$ relation, one identifies the functioning regimes that are listed in Table 10.2. The analysis of the functioning regimes, depletion width, form of the electric potential and charge density, and differential capacitance is similar to that of the p-substrate case. By the same token, one finds the simplified form of the inversion-layer charge that holds in all the functioning regimes with the exception of accumulation; one starts from (10.53) in the form

$$Q_{sc} = \pm Q_{sc}^{(1)}\,F(u_s)\,, \qquad Q_{sc}^{(1)} = \varepsilon_{sc}\,\frac{k_B\,T}{q}\,\frac{\sqrt{2}}{L_D}\,, \tag{10.54}$$

shown in normalized units in Fig. 10.15. The limiting case of (10.52) in the depletion and weak-inversion regimes is

$$F \simeq \sqrt{-u_s}\,, \qquad 2\,u_F < u_s < 0. \tag{10.55}$$

Table 10.2 MOS capacitor, n substrate – Functioning regimes (after [2])

Norm. surface potential	Concentrations	Designation
$u_s > 0$	$p_s < p_{n0} < n_i < n_{n0} < n_s$	Accumulation
$u_s = 0$	$p_s = p_{n0} < n_i < n_{n0} = n_s$	Flat band
$u_F < u_s < 0$	$p_{n0} < p_s < n_i < n_s < n_{n0}$	Depletion
$u_s = u_F$	$p_{n0} < p_s = n_i = n_s < n_{n0}$	Mid gap
$2\,u_F < u_s < u_F$	$p_{n0} < n_s < n_i < p_s < n_{n0}$	Weak inversion
$u_s = 2\,u_F$	$p_{n0} = n_s < n_i < p_s = n_{n0}$	Threshold
$u_s < 2\,u_F$	$n_s < p_{n0} < n_i < n_{n0} < p_s$	Strong inversion

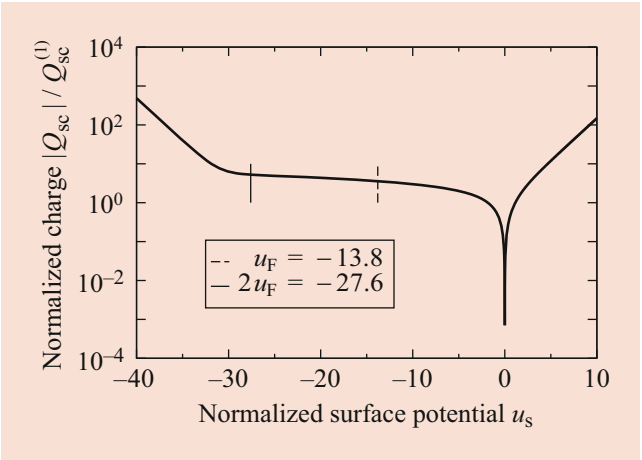

Fig. 10.15 Normalized charge per unit area as a function of the normalized surface potential, in an n-substrate MOS capacitor with $N_D = 10^{16}$ cm^{-3}. (After [2])

Introducing (10.55) into (10.54) yields, for $2\,u_F < u_s < 0$ (compare with (10.26)),

$$Q_{sc} \simeq \frac{\sqrt{2}\,\varepsilon_{sc}\,k_B\,T}{q\,L_D}\,\sqrt{-\frac{q\,\varphi_s}{k_B\,T}} = C_{ox}\,\gamma\,\sqrt{-\varphi_s},$$
$$\gamma = \frac{\sqrt{2\,\varepsilon_{sc}\,q\,n_{n0}}}{C_{ox}}. \tag{10.56}$$

The same relation as (10.56) is obtained using the full-depletion and ASCE approximations

$$-\varphi_s = \frac{q\,N_D}{2\,\varepsilon_{sc}}\,x_d^2\,, \qquad Q_b = q\,N_D\,x_d = \sqrt{-2\,\varepsilon_{sc}\,q\,N_D\,\varphi_s}. \tag{10.57}$$

When $2\,u_F < u_s < 0$, it is $Q_{sc} \simeq Q_b$; letting $N_D \simeq n_{n0}$ makes the second relation in (10.57) to coincide with the first of (10.56); then, using $Q_{sc} \simeq Q_b$ in (10.56) and combining the result with the general expression $Q_{sc} = -C_{ox}\,(V'_G - \varphi_s)$ yield $V'_G - \varphi_s = -\gamma\,\sqrt{-\varphi_s}$, namely, after discarding the negative sign in front of the square root,

$$\sqrt{-\varphi_s} = \sqrt{-V'_G + (\gamma/2)^2} - \gamma/2\,, \qquad V'_G < 0\,, \tag{10.58}$$

applicable in the depletion and weak-inversion conditions. From the threshold condition on, the contribution of holes to the semiconductor charge per unit area $Q_i = q \int_0^{x_d} p \, dx$ becomes relevant; approximating the hole charge with a layer, proceeding as for the p-substrate case (Sect. 10.1.2), and using $Q_{sc} = Q_i + Q_b$, one finds

$$Q_i = Q_{sc} - Q_b = C_{ox} \left[\left(-V'_G + \varphi_s \right) - \gamma \sqrt{-\varphi_s} \right] > 0 , \tag{10.59}$$

that holds in the depletion, weak-inversion, and strong-inversion regimes (compare with (10.29)).

10.6 Insulated-Gate Field-Effect Transistor: MOSFET

Acronym IGFET stands for *insulated-gate field-effect transistor*: the concept of insulated-gate device was proposed in the 1930s of the last century [4–7] and [1, Chap. 10]. The bipolar transistor was in fact discovered experimentally, in 1947, during the investigations about IGFETs. The first experimental FET was realized in 1948 [8]: until that time, the idea was that of exploiting the electric field to modulate the conduction of majority carriers near the device surface [9]. The use of the field to control the minority carriers was proposed in 1955 [10]; the idea of using a thermally grown oxide as gate dielectric came about in the 1960s [11], whence the more common designation MOSFET derives. This concept gave rise to the extraordinary progress of integrated circuits in the last decades; an important ingredient of this progress is the possibility to scale down the device's size. The scaling rules are briefly addressed in Sect. 10.13.4. An outline of the historical development of the device is in [12, 13]; device modeling was developed in the mid-1960s of the last century [14–16].

The device current is carried by one type of carriers only that form a charge layer at the semiconductor-insulator interface (*channel*); for this reason, the device is called *unipolar*. Such carriers are electrons in a p-doped substrate (n-*channel* MOSFET) or holes in an n-doped substrate (p-*channel* MOSFET). A view of an n-*channel* MOSFET is shown in Fig. 10.16; starting from a p-type silicon substrate with an $N_A = \text{const}$ dopant concentration, the gate insulator is formed by growing a layer of silicon dioxide, onto which the gate contact (G) is deposited. The horizontal extension L_g of the latter is the *geometrical length* of the gate. The source and drain regions are obtained by implanting a heavy dose of dopant (of the n-type in this case) and then performing an annealing step; lateral diffusion makes the gate oxide to partially overlap the n-doped regions.

The source (S) and drain (D) contacts are deposited on the two n^+ regions, while the bulk (B) metal is deposited on the p-type substrate. The three independent biases are indicated

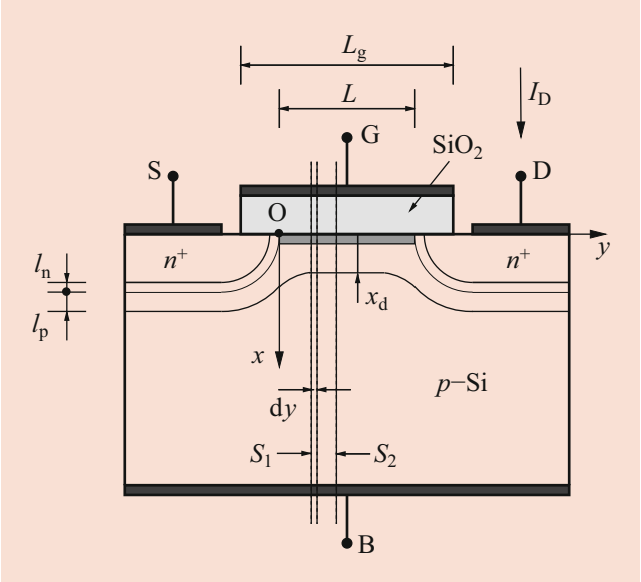

Fig. 10.16 Cross-section of an n-channel MOSFET. The black areas are the metal contacts. (After [2])

with letters, the standard choice for an n-channel MOSFET being $V_{GB} = V_G - V_B$, $V_{SB} = V_S - V_B$, and $V_{DB} = V_D - V_B$. In the typical operating regime of the device, the source-bulk and drain-bulk junctions are never forward biased, whence $V_{SB} \geq 0$ and $V_{DB} \geq 0$ (for the n-channel MOSFET), with $V_{DB} - V_{SB} = V_{DS} \geq 0$.

10.7 n-Channel MOSFET: Current-Voltage Characteristics

Purpose of this section is deriving the relations between the currents at the contacts and the applied voltages. The analysis is based on Fig. 10.16, in which the x-axis is taken normal to the semiconductor-insulator interface, with the origin (O) placed at the intersection of the source p-n junction with the interface. Symbol L indicates the intersection, along the y-axis, of the drain p-n junction with the interface and is called *electric length* of the gate, or *channel length*. The device is uniform in the z direction, with W indicating the width.

To begin, it is assumed that V_{GB} is such that at all positions y along the channel, the strong-inversion condition applies (*well-formed channel*); the layer of electrons is indicated with the shaded area in Fig. 10.16 under the oxide. In steady state, no current flows through the gate contact due to the presence of the gate insulator, and the current through the bulk contact is negligible because the source and drain junctions are never forward biased. The layer of electrons in the channel connects two heavily doped regions of the n-type: when a drain-source voltage $V_{DS} > 0$ is applied, a current I_D flows through the

channel from the drain to the source contact (the reference of I_D is visible in Fig. 10.16); given V_{DS}, the drain current I_D depends on the quantity of charge present in the channel, such a quantity being controlled by V_{GB}. In essence, the device is an electronic valve whose gate-bulk port controls the current flowing into the drain-source port; also, in steady state, the control port does not absorb energy, because the gate current is zero; this, among other things, explains the success of the MOSFET concept. The electron and hole current densities read

$$\mathbf{J}_n = J_{nx}\,\mathbf{i} + J_{ny}\,\mathbf{j}\,, \qquad \mathbf{J}_p = J_{px}\,\mathbf{i} + J_{py}\,\mathbf{j}\,, \tag{10.60}$$

with $\mathbf{i}$ and $\mathbf{j}$ the unit vectors of the coordinate axes. Due to the presence of the insulator, it is $J_{nx} = J_{px} = 0$; also, the condition of well-formed channel makes the hole concentration negligible with respect to that of the electrons (compare with Fig. 10.12; although the equilibrium condition is considered in the figure, the situation is similar). It follows $|J_{ny}| \gg |J_{py}|$, whence $\mathbf{J} = \mathbf{J}_n + \mathbf{J}_p \simeq \mathbf{J}_n = J_{ny}(x, y)\,\mathbf{j}$. Equality $\mathbf{J} = \mathbf{J}_n$ translates into symbols the property of the MOSFET being unipolar; another consequence is $\mathrm{div}\mathbf{J} = \mathrm{div}\mathbf{J}_n$ so that, observing that in a steady-state condition it is $\mathrm{div}\mathbf{J} = 0$, then it is also $\mathrm{div}\mathbf{J}_n = 0$, and the channel current

$$I = \int_{z=0}^{W} \int_{x=0}^{x_d} \mathbf{J}_n \cdot \mathbf{j}\ \mathrm{d}x\ \mathrm{d}z = W \int_0^{x_d} J_{ny}\ \mathrm{d}x \tag{10.61}$$

does not depend on y. The non-vanishing component J_{ny} in (10.61) is conveniently expressed in the monomial form

$$J_{ny} = -q\,\mu_n\,n\,\frac{\partial \varphi_n}{\partial y}\,, \tag{10.62}$$

with φ_n the electron quasi-Fermi potential. As shown above, it is $J_{nx} = 0$ so that, being $n \neq 0$ in the channel, it must be $\partial\varphi_n/\partial x = 0$; in other terms, in the channel, φ_n depends on y only (far from the channel, it does depend on x because $\varphi_n \to \varphi_F$ as x increases toward the bulk contact; however, in the bulk region where the dependence of φ_n on x is significant, the electron concentration is negligible; as a consequence, the integral in (10.61) is not affected). In conclusion,

$$I = W\,\frac{\mathrm{d}\varphi_n}{\mathrm{d}y} \int_0^{x_d} -q\,\mu_n(x, y)\,n(x, y)\ \mathrm{d}x. \tag{10.63}$$

Introducing in (10.63) the *effective electron mobility*

$$\mu_e(y) = \frac{\int_0^{x_d} -q\,\mu_n\,n\ \mathrm{d}x}{\int_0^{x_d} -q\,n\ \mathrm{d}x} > 0\,, \tag{10.64}$$

provides

$$I = W\,\frac{\mathrm{d}\varphi_n}{\mathrm{d}y}\,\mu_e(y)\,Q_i(y)\,, \qquad Q_i = \int_0^{x_d} -q\,n\ \mathrm{d}x < 0\,, \tag{10.65}$$

with $Q_i(y)$ the inversion-layer charge per unit area. As factors μ_e and Q_i in (10.65) have always the same sign, and I and W are constant, the derivative $\mathrm{d}\varphi_n/\mathrm{d}y$ has always the same sign as well. Using the inverse function $y = y(\varphi_n)$ makes the first of (10.65) separable whence, integrating over the channel,

$$\int_0^L I\ \mathrm{d}y = L\,I = W \int_{\varphi_n(0)}^{\varphi_n(L)} \mu_e(\varphi_n)\,Q_i(\varphi_n)\ \mathrm{d}\varphi_n. \tag{10.66}$$

It will be shown in Sect. 10.13.2 that the dependence of μ_e on y is weak; this simplifies (10.66) as

$$I = \frac{W}{L}\,\mu_e \int_{\varphi_n(0)}^{\varphi_n(L)} Q_i(\varphi_n)\ \mathrm{d}\varphi_n. \tag{10.67}$$

The integration limits of (10.67) are

$$\varphi_n(0) = V_{SB} + \varphi_F\,, \qquad \varphi_n(L) = V_{DB} + \varphi_F\,, \tag{10.68}$$

due to the fact that the shift in the quasi-Fermi potential on the two sides of a *p-n* junction equals the applied voltage [1, Sect. 10.2] and that $\varphi_n \to \varphi_F$ at equilibrium. To complete the calculation, it is then necessary to determine Q_i and $\mathrm{d}\varphi_n$. The former is expressed as $Q_i = Q_{sc} - Q_b$ where, in turn, the semiconductor charge per unit area Q_{sc} is found by generalizing the procedure leading to (10.29); for this, one considers Fig. 10.17, which shows an expanded view of the elementary portion of the channel, of width $\mathrm{d}y$, visible in Fig. 10.16. The Gauss theorem is applied to a volume of width W in the z direction, whose boundary in the x, y plane is the red line; the bottom part of the volume is inside the neutral region, whose boundary (the thick black line) is not aligned with the y-axis due to the lateral non-uniformity produced by the application of $V_{DS} \neq 0$. For the semiconductor charge within the volume, one finds

$$\begin{aligned} Q_{sc}\,W\,\mathrm{d}y &= \varepsilon_{sc}\,(E_b - E_s)\,W\,\mathrm{d}y \\ &\quad + \varepsilon_{sc}\,W \left(\int_0^{x_d} E_{yL}\ \mathrm{d}x - \int_0^{x_d + \mathrm{d}x_d} E_{yR}\ \mathrm{d}x \right). \end{aligned} \tag{10.69}$$

In (10.69), one lets $E_b = 0$ because the bottom of the volume is inside the neutral region and neglects the infinitesimal portion (from x_d to $x_d + \mathrm{d}x_d$) of the last integral; observing that $E_{yL} - E_{yR} = -(\partial E/\partial y)\,\mathrm{d}y$ and dividing both sides by $(W\,\mathrm{d}y)$ yield

$$Q_{sc} = -\varepsilon_{sc}\,E_s - \varepsilon_{sc} \int_0^{x_d} \frac{\partial E}{\partial y}\ \mathrm{d}x. \tag{10.70}$$

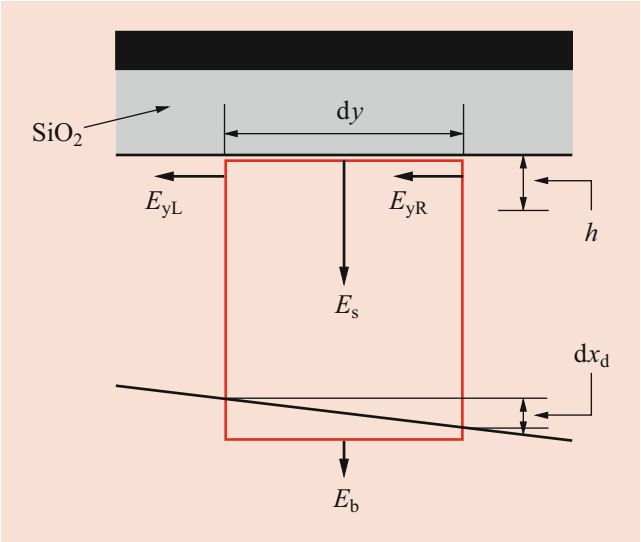

Fig. 10.17 The red line is the intersection with the x, y plane of the volume used for the application of the Gauss theorem, Eq. (10.69). Symbols $E_s, \ldots$ indicate the vertical or horizontal components of the electric field. Symbol h qualitatively indicates the thickness of the inversion layer (the scales of the drawing are not realistic)

Neglecting again the contribution of $\mathrm{d}x_\mathrm{d}$, and remembering that a p-type substrate is considered, one finds for the bulk charge per unit area the relation $Q_\mathrm{b} = -q\,N_\mathrm{A}\,x_\mathrm{d}$. Finally, the expression of $\mathrm{d}\varphi_\mathrm{n}$ is taken from (10.96) and reads

$$\mathrm{d}\varphi_\mathrm{n} = \left[1 + \frac{k_\mathrm{B}\,T}{q}\,\frac{2\,r^2\,\left(V'_\mathrm{GB} - \varphi_\mathrm{s}\right) + k_\mathrm{B}\,T/q}{r^2\,\left(V'_\mathrm{GB} - \varphi_\mathrm{s}\right)^2 - k_\mathrm{B}\,T\,\varphi_\mathrm{s}/q}\right]\,\mathrm{d}\varphi_\mathrm{s},$$
$$r = \frac{1}{\sqrt{2}}\,\frac{\varepsilon_\mathrm{ox}}{\varepsilon_\mathrm{sc}}\,\frac{L_\mathrm{A}}{t_\mathrm{ox}}, \qquad (10.71)$$

with $\varphi_\mathrm{s}(y) = \varphi(x = 0, y)$. The relation between φ_n and φ_s given by (10.71) applies, at each position y, in the depletion, weak-inversion, and strong-inversion cases, that are the working conditions of interest.

10.7.1 Gradual-Channel Approximation

To complete the calculation of (10.67), one exploits the inequality $|\partial E_\mathrm{x}/\partial x| \gg |\partial E_\mathrm{y}/\partial y|$ to reduce the Poisson equation to a one-dimensional form (the details are in Sect. 10.13.1); in this way, each elementary portion of the channel (like $\mathrm{d}y$ in Figs. 10.16 or 10.17) is treated like an MOS capacitor having $\varphi_\mathrm{s}(y)$ as surface potential, and (10.70) reduces to $Q_\mathrm{sc} = -\varepsilon_\mathrm{sc}\,E_\mathrm{s}$. This simplification is designated with *gradual-channel approximation* (GCA).

Next, one describes each elementary MOS capacitor using the full-depletion and ASCE approximations; in other terms, the inversion charge is approximated as a layer at $x = 0^+$, so that the volume charge is due only to the ionized dopants, which contribute to the bulk charge Q_b with a term proportional to $\sqrt{\varphi_\mathrm{s}}$ like in equilibrium. In this way, the inversion-layer charge per unit area at any position y in the channel is given by (10.29), namely,

$$Q_\mathrm{i} = -C_\mathrm{ox}\,\left[\left(V'_\mathrm{GB} - \varphi_\mathrm{s}\right) - \gamma\,\sqrt{\varphi_\mathrm{s}}\right] < 0\,, \qquad (10.72)$$

and (10.67) becomes

$$I = -\beta\,\int_{\varphi_\mathrm{s}(0)}^{\varphi_\mathrm{s}(L)}\,\left[\left(V'_\mathrm{GB} - \varphi_\mathrm{s}\right) - \gamma\,\sqrt{\varphi_\mathrm{s}}\right]\,\frac{\mathrm{d}\varphi_\mathrm{n}}{\mathrm{d}\varphi_\mathrm{s}}\,\mathrm{d}\varphi_\mathrm{s},$$
$$\beta = \frac{W}{L}\,\mu_\mathrm{e}\,C_\mathrm{ox}\,, \qquad (10.73)$$

where the units of β are $[\beta] = \mathrm{A\ V^{-2}}$. The above expression, where $\mathrm{d}\varphi_\mathrm{n}/\mathrm{d}\varphi_\mathrm{s}$ is given by (10.71), applies to the depletion, weak-inversion, and strong-inversion regimes. The integration limits in (10.73) are obtained numerically as shown in Sect. 10.7.3, and, being $V_\mathrm{DS} > 0$, it is found $\varphi_\mathrm{s}(L) > \varphi_\mathrm{s}(0)$; as the integrand is negative, it follows $I < 0$, whence $I_\mathrm{D} = -I$ due to the reference chosen for I_D (Fig. 10.16).

Despite the unwieldy appearance, (10.73) can be integrated analytically; the result is shown in Sect. 10.7.3. Prior to that, it is convenient to illustrate an approximation commonly used for the device description, which consists in neglecting the second term in brackets in (10.71), namely, in letting $\mathrm{d}\varphi_\mathrm{n} \simeq \mathrm{d}\varphi_\mathrm{s}$. The approximation provides an analytic expression for the integration limits, which read (Sect. 10.7.3)

$$\varphi_\mathrm{s}(0) = V_\mathrm{SB} + 2\,\varphi_\mathrm{F}\,, \qquad \varphi_\mathrm{s}(L) = V_\mathrm{DB} + 2\,\varphi_\mathrm{F}\,; \qquad (10.74)$$

on the other hand, it restricts the applicability of the result to the strong-inversion regime only. The approximate expression of I_D reads

$$I_\mathrm{D} = \beta\,\int_{V_\mathrm{SB}+2\,\varphi_\mathrm{F}}^{V_\mathrm{DB}+2\,\varphi_\mathrm{F}}\,\left[\left(V'_\mathrm{GB} - \varphi_\mathrm{s}\right) - \gamma\,\sqrt{\varphi_\mathrm{s}}\right]\,\mathrm{d}\varphi_\mathrm{s}\,; \qquad (10.75)$$

it is used in Sect. 10.7.2 to discuss some features of the n-channel device and in Sect. 10.8, after suitable modifications, for the p-channel device.

Before concluding this section, it is worth noting that the application of GCA is not limited to MOSFETs; in fact, it is a widely used method for finding an approximate solution of the Poisson equation when the geometry and bias configuration of the device are such that the variation of the electric field in the direction of the channel is much weaker than in the other directions. Formally, the approximation consists in eliminating a part of the Laplacian operator, in such a way as to leave a differential relation for one variable (or a separable operator for some variables), whereas the dependence on the remaining variables becomes algebraic.

10.7.2 Differential Conductances and Drain Current, n-Channel

The simplified expression of the drain current of the *n*-channel MOSFET, given by (10.75), is a relation of the form $I_D = I_D(V_{GB}, V_{DB}, V_{SB})$, with $V_{GB} = V'_{GB} + V_{FB}$. From it, the *differential conductances* of the device are readily calculated as the derivatives with respect to the voltages. In circuit applications, it is more convenient to refer the applied voltages to the source contact instead of the bulk contact; this is easily accomplished by the transformation

$$V_{DS} = V_{DB} - V_{SB} > 0\,, \qquad V_{GS} = V_{GB} - V_{SB}\,,$$
$$V_{BS} = -V_{SB} \leq 0\,. \tag{10.76}$$

Then, the *drain conductance* g_D (also called *output conductance*, g_o) is defined as

$$g_D = \left(\frac{\partial I_D}{\partial V_{DB}}\right)_{V_{SB}, V_{GB}} = \left(\frac{\partial I_D}{\partial V_{DS}}\right)_{V_{BS}, V_{GS}}\,, \tag{10.77}$$

namely, from (10.75),

$$g_D = \beta \left[\left(V'_{GB} - V_{DB} - 2\,\varphi_F\right) - \gamma \sqrt{V_{DB} + 2\,\varphi_F}\right]; \tag{10.78}$$

then, using (10.74) and (10.29), one finds

$$g_D = \beta \left[\left(V'_{GB} - \varphi_s(L)\right) - \gamma \sqrt{\varphi_s(L)}\right] = \frac{W}{L}\,\mu_e\,\left[-Q_i(L)\right]\,, \tag{10.79}$$

showing that g_D is proportional to the inversion charge per unit area at the drain end of the channel. In (10.79), it is $Q_i(L) \leq 0$; the zero of $Q_i(L)$ corresponds to the value of $\varphi_s(L)$ obtained from (10.28) and is indicated with φ_s^{sat} (*saturation surface potential*). Combining (10.74) with (10.76) provides the *saturation voltage* in the bulk and source references, respectively:

$$V_{DB}^{sat} = \varphi_s^{sat} - 2\,\varphi_F\,, \qquad V_{DS}^{sat} = V_{DB}^{sat} - V_{SB}\,. \tag{10.80}$$

Correspondingly, the *saturation current* is $I_D^{sat} = I_D(V_{DS}^{sat}, V_{GS})$. The right-hand side of (10.78) becomes negative if a value of V_{DS} larger than V_{DS}^{sat} is used; this unphysical result shows that the approximation leading to (10.75) is not applicable for $V_{DS} > V_{DS}^{sat}$. An important limiting case of (10.78) is

$$g_D(V_{DS} \to 0) = \beta \left[\left(V'_{GB} - V_{SB} - 2\,\varphi_F\right) - \gamma \sqrt{V_{SB} + 2\,\varphi_F}\right], \tag{10.81}$$

or, using (10.76),

$$g_D(V_{DS} \to 0) = \beta\,\left(V_{GS} - V_T\right)\,,$$

$$V_T = V_{FB} + 2\,\varphi_F + \gamma\,\sqrt{2\,\varphi_F - V_{BS}} \tag{10.82}$$

with $V_{BS} \leq 0$. The above defines the *threshold voltage* $V_T = V_T(V_{BS})$; the dependence of V_T on V_{BS} is the *body effect*. Near $V_{DS} = 0$, the current-voltage characteristics reduce to $I_D = \beta\,(V_{GS} - V_T)\,V_{DS}$, namely, to straight lines whose slope, for a given V_{BS}, is prescribed by V_{GS}; for a larger V_{DS}, the slope of the $I_D = I_D(V_{DS})$ curves decreases, to eventually vanish at $V_{DS} = V_{DS}^{sat}$. Since I_D is non-negative, the theory outlined here applies as long as $\beta\,(V_{GS} - V_T) \geq 0$; thanks to this observation, it is possible to better specify the condition of a well-formed channel: from the formal standpoint, such a condition is $V_{GS} > V_T$.

Integrating (10.75) yields $I_D = I'_D - I''_D$, where I'_D is the integral of $\beta\,(V'_{GB} - \varphi_s)$, which reads

$$I'_D = \beta \left[(V_{GS} - V_{FB} - 2\,\varphi_F)\,V_{DS} - \frac{1}{2}\,V_{DS}^2\right], \tag{10.83}$$

and I''_D is the integral of $\beta\,\gamma\,\sqrt{\varphi_s}$,

$$I''_D = \beta\,\frac{2}{3}\,\gamma\,\left[(V_{DS} + 2\,\varphi_F - V_{BS})^{3/2} - (2\,\varphi_F - V_{BS})^{3/2}\right]. \tag{10.84}$$

Comparisons with experiments show that the model $I_D = I'_D - I''_D$, based on (10.83) and (10.84), gives a fair description of I_D up to V_{DS}^{sat}; as shown by the derivation above, this is essentially due to the fact that in this region, the electric field along the channel is small. Beyond saturation, the model is not consistent with the experiments: the terms with a negative sign produce a negative slope g_D, whereas the experiments show that for $V_{DS} > V_{DS}^{sat}$, the current tends to saturate. This explains why the model based on (10.75) is presented in a regional form: given V_{GS} and V_{BS}, the model separates, first, the *on* condition $V_{GS} > V_T$ from the *off* condition $V_{GS} \leq V_T$; second, the *on* condition is further separated into the *linear region* $0 < V_{DS} \leq V_{DS}^{sat}$, where the expression $I_D = I'_D - I''_D$ derived above is used, and the *saturation region* $V_{DS} > V_{DS}^{sat}$; in the latter, the model lets $I_D = I_D^{sat}$. Finally, in the *off* region, one sets $I_D = 0$. It is worth adding that the designation *linear* is due to the behavior of g_D near the origin; the term is used to describe the characteristics up to V_{DS}^{sat} despite the fact that near saturation the curves are not linear any more.

Depending on the materials, V_{FB} may have either sign; it follows that V_T, given by (10.82), may have either sign as well (in a p-type substrate, instead, it is always $2\,\varphi_F = (k_B\,T/q)\,\log(p_{p0}/n_{p0}) > 0$, and vice versa). One must then distinguish two types of n-channel MOSFETs, the *enhancement type*, having $V_T(V_{BS} = 0) > 0$, and the *depletion type*, having $V_T(V_{BS} = 0) < 0$. To obtain a well-formed channel in the enhancement type, one must set $V_{GS} > V_T > 0$, while $V_{GS} = 0$ corresponds to the *off* condition; in the depletion type, instead, a well-formed channel is present when V_{GS}=0,

whereas the *off* condition is achieved with $V_{GS} \leq V_T < 0$. For a given V_{BS}, the $I_D = I_D(V_{DS})$ curves corresponding to different values of V_{GS} are called *output characteristics*; other types of characteristics are also used: for instance, the *transfer characteristics* are the $I_D = I_D(V_{GS})$ curves drawn using V_{BS} as a parameter and letting $V_{DS} = \text{const}$, with a value of V_{DS} small enough to let the limiting case (10.82) hold.

Besides the drain conductance (10.77), two more differential conductances are defined in a MOSFET: the first one is the *transconductance*

$$g_m = \left(\frac{\partial I_D}{\partial V_{GB}}\right)_{V_{SB},V_{DB}} = \left(\frac{\partial I_D}{\partial V_{GS}}\right)_{V_{DS},V_{BS}} = \beta\, V_{DS}\,, \tag{10.85}$$

and the second one is the *bulk transconductance*

$$g_B = \left(\frac{\partial I_D}{\partial V_{BS}}\right)_{V_{DS},V_{GS}} = -\left(\frac{\partial I''_D}{\partial V_{BS}}\right)_{V_{DS}}. \tag{10.86}$$

The small-signal circuit of an n-channel MOSFET is shown in Fig. 10.18, with v_{DS}, v_{GS}, and v_{BS} indicating the small-signal voltages; it holds at low frequencies only because it derives from the steady-state model. The gate and bulk contacts are left open because the corresponding currents are zero; as a consequence, $i_D = i_S$ is the only non-zero small-signal current of the circuit. The small-signal relation reads

$$i_D = g_D\, v_{DS} + g_m\, v_{GS} + g_B\, v_{BS}\,, \tag{10.87}$$

and describes three parallel branches as shown in the figure.

The body effect mentioned above is an inconvenience, as it introduces a complicated dependence of I_D on V_{BS}, which must be accounted for in the circuit design; the effect is suppressed by letting $V_{BS} = 0$, namely, by shorting the bulk and source contacts, which reduces the original four-contact device to a three-contact device (letting $V_{BS} = 0$ also makes g_B to vanish). This solution is adopted whenever the circuit architecture allows for it.

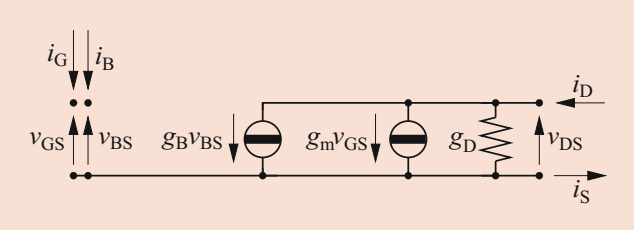

Fig. 10.18 Low-frequency, small-signal circuit of an n-channel MOSFET. (After [2])

Linear-Parabolic Model, n-Channel

In simplified circuit analyses, the term I''_D is expressed as $I''_D \simeq \beta\,\gamma\,\sqrt{2\,\varphi_F - V_{BS}}\,V_{DS}$, this providing a simplified model called *linear-parabolic model*. The approximation consists in replacing $\sqrt{\varphi_s}$ in (10.75) with $\sqrt{2\,\varphi_F - V_{BS}}$; this is equivalent to assuming that the width of the depleted region is constant along the channel and equal to the value taken at source. The expression of the current simplifies to

$$I_D \simeq \beta\,[(V_{GS} - V_T)\,V_{DS} - V_{DS}^2/2]\,, \tag{10.88}$$

with V_T still given by (10.82). In turn, from (10.88), the drain conductance becomes

$$g_D \simeq \beta\,(V_{GS} - V_T - V_{DS})\,, \tag{10.89}$$

whence

$$V_{DS}^{sat} = V_{GS} - V_T. \tag{10.90}$$

The transconductance g_m is the same as in the general case. In the linear-parabolic model, the drain current may also be written $I_D \simeq \beta\,(V_{DS}^{sat}\,V_{DS} - V_{DS}^2/2)$, with V_{DS}^{sat} given by (10.90). Thus,

$$I_D^{sat} \simeq \beta\left[\left(V_{DS}^{sat}\right)^2 - \frac{1}{2}\left(V_{DS}^{sat}\right)^2\right] = \frac{1}{2}\,\beta\,(V_{GS} - V_T)^2\,. \tag{10.91}$$

Finally, the expressions for the saturation region become

$$I_D = I_D^{sat}\,, \qquad g_D \simeq 0\,, \qquad g_m \simeq \beta\,(V_{GS} - V_T)\,. \tag{10.92}$$

The output characteristics of an n-channel MOSFET obtained from the linear-parabolic model are exemplified in Fig. 10.19, using $V_T = 1$ V and $\beta = 0.3$ A V^{-2}. The dashed curve represents (10.91). The symbol of the enhancement-type device is shown in Fig. 10.20 (other symbols are also used in the literature).

10.7.3 MOSFET Theory Including the Subthreshold Current

The results of Sect. 10.13.1 are readily exploited to calculate the general expression (10.73) of the drain current; using the normalized potentials, the expression reads

$$I_D = \beta\left(\frac{k_B\,T}{q}\right)^2 \int_{u_s(0)}^{u_s(L)} \left[\left(u'_{GB} - u_s\right) - (1/r)\,\sqrt{u_s}\right] \frac{d\chi_n}{du_s}\,du_s\,, \tag{10.93}$$

with $u'_{GB} = q\,V'_{GB}/(k_B\,T)$ and $\chi_n = u_n - u_F$. Remembering that the accumulation condition is excluded and that, at each channel position y, it is $E_{sx} = -Q_{sc}/\varepsilon_{sc}$, one recasts (10.169) as

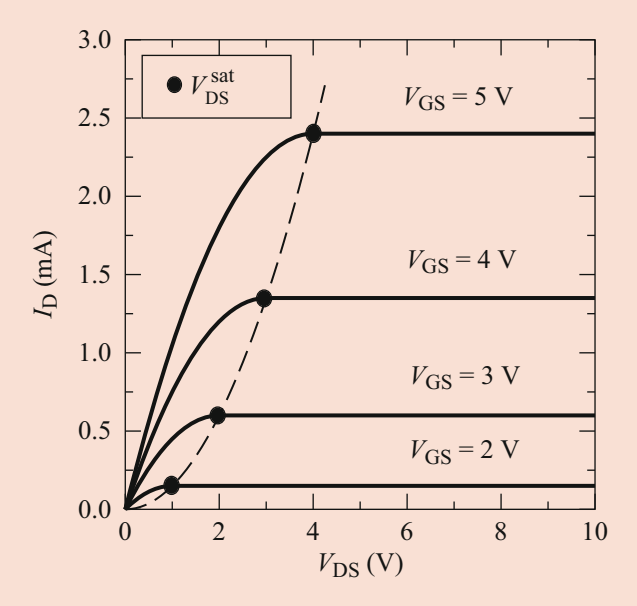

Fig. 10.19 Output characteristics of an n-type MOSFET obtained from the linear-parabolic model, with $V_T = 1$ V and $\beta = 0.3$ A V^{-2}. The dashed curve represents (10.91). (After [2])

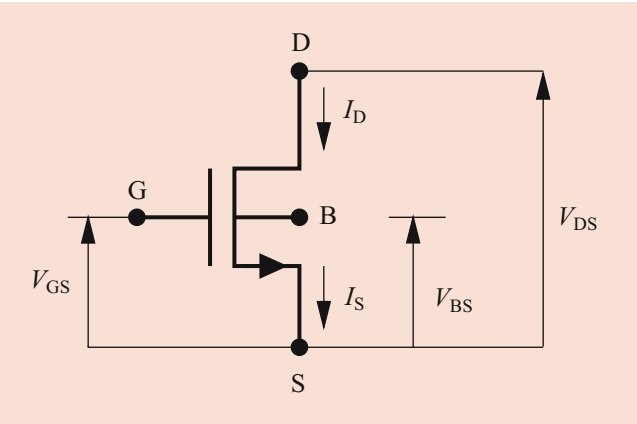

Fig. 10.20 Symbol of the n-channel MOSFET of the enhancement type. (After [2])

$$r^2\,\left(u'_{GB}-u_s\right)^2=\exp(-\chi_n-2\,u_F)\,\left[\exp(u_s)-1\right]+u_s,$$
$$r=\frac{1}{\sqrt{2}}\,\frac{\varepsilon_{ox}}{\varepsilon_{sc}}\,\frac{L_A}{t_{ox}} \tag{10.94}$$

(from (10.26), one notes that $r\,\gamma = \sqrt{k_B\,T/q}$). Observing that when u_s exceeds a few thermal units one can neglect the unity, the $\chi_n = \chi_n(u_s)$ relation in (10.94) simplifies to

$$\chi_n = u_s - 2\,u_F - \log\left[r^2\,\left(u'_{GB}-u_s\right)^2-u_s\right]. \tag{10.95}$$

The integration limits of (10.93) are found by numerically inverting (10.95) after letting $\chi_n(0) = q\,V_{SB}/(k_B\,T)$ and $\chi_n(L) = q\,V_{DB}/(k_B\,T)$; factor $\mathrm{d}\chi_n/\mathrm{d}u_s$ in the integrand of (10.93) is conveniently expressed as

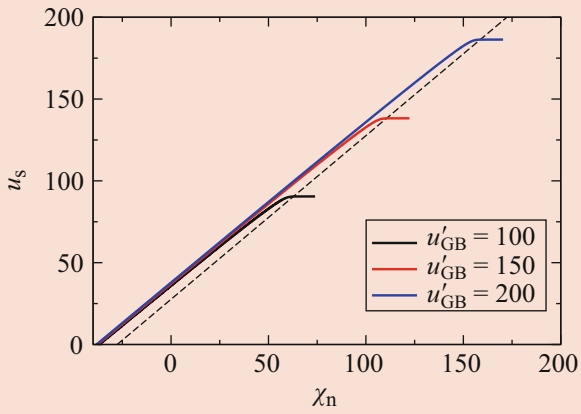

Fig. 10.21 The $u_s = u_s(\chi_n)$ relation (10.95) with u'_{GB} as a parameter, using a dopant concentration $N_A = 10^{16}$ cm^{-3} ($2\,u_F \simeq 27.6$), is compared with the $u_s = \chi_n + 2\,u_F$ approximation (*dashed line*). (After [2])

$$\frac{\mathrm{d}\chi_n}{\mathrm{d}u_s}=1+\frac{2\,r^2\,\left(u'_{GB}-u_s\right)+1}{r^2\,\left(u'_{GB}-u_s\right)^2-u_s}. \tag{10.96}$$

As mentioned in Sect. 10.7, (10.93) applies to all working conditions with the exception of accumulation and, therefore, incorporates the subthreshold current in the analysis; inequality $\mathrm{d}\chi_n/\mathrm{d}u_s \neq 1$ in (10.96) indicates that the transport is not uniquely of the drift type. Also, (10.96) shows that I_D is made of two contributions: the first one comes from the unity at the right-hand side of (10.96) and is similar to the current $I'_D - I''_D$ derived in Sect. 10.7.2, the only difference being that the integration limits must be calculated numerically from (10.95) instead of being $V_{SB} + 2\,\varphi_F$ and $V_{DB} + 2\,\varphi_F$. The remaining contribution to the current is due to the second term at the right-hand side of (10.96); its analytical calculation, a little more elaborate, is provided below (Sect. 10.7.3).

The $u_s = u_s(\chi_n)$ relation given by (10.95) is shown in Fig. 10.21 with u'_{GB} as parameter and is compared with the approximate form $\chi_n = u_s + 2\,u_F$ (dashed line). The approximation is good as long as u_s is smaller than the lower zero of the logarithm argument in (10.95). Then, u_s saturates at the value corresponding to such a zero; this shows that (10.93) provides a smooth transition from the linear to the saturation region: when V_{DB} is such that $\chi_n(L) = q\,V_{DB}/(k_B\,T)$ enters the saturation region, the upper limit $u_s(L)$ of the integral (10.93) is pinned to the saturation value; as a consequence, the current does not increase any more from that value of V_{DB} on.

General Form of the MOSFET Current

As mentioned above, a part of the integral (10.73) derives from the first term (i.e., the unity) at the right-hand side of (10.93) and reads

$$I'_{\mathrm{D}} - I''_{\mathrm{D}} = \beta\ (k_{\mathrm{B}}\,T/q)^2 \left[\left(u'_{\mathrm{GB}}\,u_{\mathrm{s}} - u_{\mathrm{s}}^2/2\right) - (2/3)\,(1/g)\,u_{\mathrm{s}}^{3/2}\right]_{u_{\mathrm{s}}(0)}^{u_{\mathrm{s}}(L)}. \tag{10.97}$$

As for the second term in (10.96), the zeros of the denominator are found to be $u_{\mathrm{s}}^{\pm} = u'_{\mathrm{GB}} + (1 \pm \sqrt{1 + 4\,r^2\,u'_{\mathrm{GB}}})/(2\,r^2)$, so that (10.96) becomes

$$\frac{\mathrm{d}\chi_{\mathrm{n}}}{\mathrm{d}u_{\mathrm{s}}} - 1 = \frac{1}{u_{\mathrm{s}}^{+} - u_{\mathrm{s}}} + \frac{1}{u_{\mathrm{s}}^{-} - u_{\mathrm{s}}}, \qquad u_{\mathrm{s}} < u_{\mathrm{s}}^{-} < u_{\mathrm{s}}^{+}. \tag{10.98}$$

The latter diverges when $u_{\mathrm{s}} \to u_{\mathrm{s}}^{-}$; however, this zero is canceled by another zero belonging to the other factor in (10.93), so that the integrand related to the second term of the current reads

$$Y(u_{\mathrm{s}}) = \left[\left(u'_{\mathrm{GB}} - u_{\mathrm{s}}\right) - \frac{1}{r}\sqrt{u_{\mathrm{s}}}\right]\left(\frac{\mathrm{d}\chi_{\mathrm{n}}}{\mathrm{d}u_{\mathrm{s}}} - 1\right) = 2\,\frac{r\left(u'_{\mathrm{GB}} - u_{\mathrm{s}}\right) + 1/(2\,r)}{r\left(u'_{\mathrm{GB}} - u_{\mathrm{s}}\right) + \sqrt{u_{\mathrm{s}}}}. \tag{10.99}$$

If u_{s}^{-} is replaced into the right-hand side of (10.99), no divergence occurs. After a short manipulation, one finds $Y(u_{\mathrm{s}}) = 2 - 2\,[\sqrt{u_{\mathrm{s}}} - 1/(2\,r)]/[r\,(u'_{\mathrm{GB}} - u_{\mathrm{s}}) + \sqrt{u_{\mathrm{s}}}]$ which, multiplying by $\mathrm{d}u_{\mathrm{s}}$ and letting $w = \sqrt{u_{\mathrm{s}}} - 1/(2\,r)$, provides

$$Y(w) = \left(w + \frac{1}{2\,r}\right)\left(4 + \frac{2/r}{k + w} - \frac{2/r}{k - w}\right)\mathrm{d}w, \qquad k^2 = u'_{\mathrm{GB}} + \frac{1}{4\,r^2}, \tag{10.100}$$

whose integration is elementary.

Subthreshold Approximation

The theory outlined in Sect. 10.7.3 disposes of the hypothesis of a strong-inversion regime at each point of the channel; depending on the values of χ_{n} and u'_{GB}, at a chosen position y in the channel, the condition may hold or not (in the latter case, one speaks of *subthreshold condition* at y). If V_{DB} and V_{SB} are such that the whole channel is in the subthreshold condition, expression (10.93) of the drain current simplifies to

$$I_{\mathrm{D}} \simeq \beta\,\frac{\exp(u_{\mathrm{s}}^{-} - 2\,u_{\mathrm{F}})}{q^2/(k_{\mathrm{B}}\,T)^2}\,\frac{\exp[-\chi_{\mathrm{n}}(0)] - \exp[-\chi_{\mathrm{n}}(L)]}{\omega - 1}, \tag{10.101}$$

with $\omega = (1 + 4\,r^2\,u'_{\mathrm{GB}})^{1/2}$ and $u'_{\mathrm{GB}} - u_{\mathrm{s}}^{-} = (\omega - 1)/(2\,r^2)$. The derivation of (10.101) is based on the observation that in this working condition, the channel is everywhere near saturation; one then calculates (10.93) by letting $u_{\mathrm{s}}(0) \simeq u_{\mathrm{s}}^{-}$ and assuming that u_{s} varies little along the channel, so that the integral is approximated as the product of the integrand calculated at $u_{\mathrm{s}}(0)$ times the integration interval $u_{\mathrm{s}}(L) - u_{\mathrm{s}}(0)$. The latter is determined from (10.95) written in the form

$$r^2\,\left(u'_{\mathrm{GB}} - u_{\mathrm{s}}\right)^2 - u_{\mathrm{s}} - \exp(u_{\mathrm{s}} - 2\,u_{\mathrm{F}} - \chi_{\mathrm{n}}) = 0, \tag{10.102}$$

where the exponential is small because in saturation it is $\chi_{\mathrm{n}} > u_{\mathrm{s}} - 2\,u_{\mathrm{F}}$; for the same reason, the exponential slowly varies along the channel, so one fixes $u_{\mathrm{s}} = u_{\mathrm{s}}^{-}$ in it and solves (10.102) for $u_{\mathrm{s}} - u'_{\mathrm{GB}}$; discarding the solution with the positive sign, and expanding the square root to first order, yields $u_{\mathrm{s}} \simeq u_{\mathrm{s}}^{-} - (1/\omega)\,\exp(u_{\mathrm{s}}^{-} - 2\,u_{\mathrm{F}} - \chi_{\mathrm{n}})$, whence

$$u_{\mathrm{s}}(L) - u_{\mathrm{s}}(0) \simeq \frac{\exp[-\chi_{\mathrm{n}}(0)] - \exp[-\chi_{\mathrm{n}}(L)]}{\omega\,\exp(2\,u_{\mathrm{F}} - u_{\mathrm{s}}^{-})}, \tag{10.103}$$

with $\chi_{\mathrm{n}}(0) = q\,V_{\mathrm{SB}}/(k_{\mathrm{B}}\,T)$ and $\chi\,(L) = q\,V_{\mathrm{DB}}/(k_{\mathrm{B}}\,T)$. The analysis is completed by calculating the integrand of (10.93) after letting $u_{\mathrm{s}} = u_{\mathrm{s}}(0) = u_{\mathrm{s}}^{-}$. The first part of the integrand derives from the first term (i.e., the unity) at the right-hand side of (10.93); it is found by inspection that this part vanishes for $u_{\mathrm{s}} = u_{\mathrm{s}}^{-}$. Thus, the remaining part is $Y(u_{\mathrm{s}}^{-})$ (compare with (10.99)); observing that $\sqrt{u_{\mathrm{s}}^{-}} = r\,(u'_{\mathrm{GB}} - u_{\mathrm{s}}^{-})$, one finds $Y(u_{\mathrm{s}}^{-}) = \omega/(\omega - 1)$, whence (10.101) ensues.

This result expressed by (10.101) is important because it provides the $I_{\mathrm{D}}(V_{\mathrm{GB}})$ dependence below threshold, namely, when the channel is about to transit from the *off* to the *on* condition; this dependence must be strong in order to make the device reliable as a switch. The strongest dependence of (10.101) on u'_{GB} is the exponential one embedded in u_{s}^{-} so that, when the other voltages are kept fixed, the subthreshold current reads $I_{\mathrm{D}} \simeq \text{const} \times \exp[q\,V_{\mathrm{GB}}/(k_{\mathrm{B}}\,T)]$. In fact, in the subthreshold condition, the experimental $\log(I_{\mathrm{D}})$ vs. V_{GB} relation is to a good approximation a straight line; the *subthreshold swing* (indicated with S or SS) is defined as

$$S = \frac{\mathrm{d}V_{\mathrm{GB}}}{\mathrm{d}\log_{10}(I_{\mathrm{D}})} = \frac{k_{\mathrm{B}}\,T}{q}\,\log(10)\,\frac{\mathrm{d}u'_{\mathrm{GB}}}{\mathrm{d}\log(I_{\mathrm{D}})}, \tag{10.104}$$

and is evaluated from (10.101) by inverting the derivative of $\log(I_{\mathrm{D}}) = u_{\mathrm{s}}^{-} - \log(\omega - 1) + \text{const}$ with respect to u'_{GB}, with $u_{\mathrm{s}}^{-}(u'_{\mathrm{GB}})$ and $\omega(u'_{\mathrm{GB}})$ defined above. One finds

$$S = \frac{k_{\mathrm{B}}\,T}{q}\,\log(10)\,\frac{\mathrm{d}u'_{\mathrm{GB}}}{\mathrm{d}u_{\mathrm{s}}^{-}}\,\frac{\mathrm{d}u_{\mathrm{s}}^{-}}{\mathrm{d}\log(I_{\mathrm{D}})} \tag{10.105}$$

where, after neglecting the weaker term $\log(\omega - 1)$, the last derivative equals unity. The other derivative is expressed in

compact form by considering that in the subthreshold condition, it is $Q_{sc} \simeq Q_b$, with Q_b the bulk charge per unit area, so that $Q_b \simeq -C_{ox}\,(V'_{GB} - \varphi_s)$ and $C_{sc} \simeq -\mathrm{d}Q_b/\mathrm{d}\varphi_s = C_b$, with C_b the depletion capacitance per unit area. Combining the two above yields $V'_{GB} = \varphi_s - Q_b/C_{ox}$ whence, using again the relation $u_s \simeq u_s^-$,

$$\frac{\mathrm{d}u'_{GB}}{\mathrm{d}u_s^-} = 1 + \frac{C_b}{C_{ox}}, \qquad S = \frac{k_B\,T}{q}\,\log(10)\,\left(1 + \frac{C_b}{C_{ox}}\right). \tag{10.106}$$

The extension of the above calculation to the case of short-channel MOSFETs is shown in [17]. From the above result, it follows that $(k_B\,T/q)\,\log(10)\,(1 + C_b/C_{ox})$ is the variation ΔV_{GB} that makes I_D to vary by a factor 10; if $C_b \ll C_{ox}$, at room temperature, it is $\Delta V_{GB} \simeq 60$ mV.

The definition of subthreshold swing is not limited to the MOS transistor, but applies in general to the devices where a conductive channel is controlled by a gate. The value of 60 mV per decade calculated from (10.106) is the minimum (i.e., the most favorable one); in real devices, S is larger (i.e., worse).

10.8 p-Channel MOSFET: Current-Voltage Characteristics

The structure of the p-*channel* MOSFET is dual to that of the n-channel type; with reference to Fig. 10.16, the cross-section is obtained by exchanging the "p" and "n" letters. As the source-bulk and drain-bulk junctions are never forward biased, it is $V_{SB} \le 0$, $V_{DB} \le 0$, and $V_{SB} - V_{DB} = V_{SD} > 0$. It is assumed that a layer of holes is present at each point of the channel, this realizing the condition of a well-formed channel. The current I_S flows from the source to the drain contact (Fig. 10.22); following the same reasoning as that leading to (10.61), one finds for the channel current (compare also with (10.63), (10.64), and (10.65))

$$\begin{aligned} I &= \int_{z=0}^{W}\int_{x=0}^{x_d} \mathbf{J}_p \cdot \mathbf{j}\;\mathrm{d}x\;\mathrm{d}z = W\int_0^{x_d} J_{py}\;\mathrm{d}x \\ &= -W\,\frac{\mathrm{d}\varphi_p}{\mathrm{d}y}\int_0^{x_d} q\,\mu_p\,p\;\mathrm{d}x. \end{aligned} \tag{10.107}$$

$$\begin{aligned} &I = -W\,\frac{\mathrm{d}\varphi_p}{\mathrm{d}y}\,\mu_h(y)\,Q_i(y), \quad Q_i = \int_0^{x_d} q\,p\;\mathrm{d}x, \\ &\mu_h = \frac{\int_0^{x_d} q\,\mu_p\,p\;\mathrm{d}x}{\int_0^{x_d} q\,p\;\mathrm{d}x}, \end{aligned} \tag{10.108}$$

where $Q_i(y) > 0$ is the inversion-layer charge per unit area and $\mu_h(y) > 0$ the effective hole mobility at position y in the channel. Integrating over the channel,

$$\int_0^L I\;\mathrm{d}y = L\,I = W\int_{\varphi_p(L)}^{\varphi_p(0)} \mu_h(\varphi_p)\,Q_i(\varphi_p)\;\mathrm{d}\varphi_p \tag{10.109}$$

(compare with (10.66)), and, considering that the dependence of μ_h on y is weak (Sect. 10.13.1),

$$I = \frac{W}{L}\,\mu_h\int_{\varphi_p(L)}^{\varphi_p(0)} Q_i(\varphi_p)\;\mathrm{d}\varphi_p \tag{10.110}$$

(compare with (10.67)). Using the same approximation as that leading to (10.75) for the n-channel device yields $\mathrm{d}\varphi_p \simeq \mathrm{d}\varphi_s$, whence

$$\varphi_s(0) = V_{SB} + 2\,\varphi_F, \qquad \varphi_s(L) = V_{DB} + 2\,\varphi_F, \tag{10.111}$$

so that (10.110) becomes

$$I = \frac{W}{L}\,\mu_h\int_{V_{DB}+2\,\varphi_F}^{V_{SB}+2\,\varphi_F} Q_i(\varphi_s)\;\mathrm{d}\varphi_s, \tag{10.112}$$

with

$$Q_i = C_{ox}\left[\left(-V'_{GB} + \varphi_s\right) - \gamma\,\sqrt{-\varphi_s}\right] > 0, \tag{10.113}$$

and

$$V'_{GB} = V_{GB} - V_{FB}, \qquad \gamma = \frac{\sqrt{2\,\varepsilon_{sc}\,q\,n_{n0}}}{C_{ox}}. \tag{10.114}$$

Being $V_{SB} + 2\,\varphi_F > V_{DB} + 2\,\varphi_F$ and $Q_i > 0$, one finds $I > 0$, whence $I_S = I$ due to the reference chosen for the source current (Fig. 10.22). In conclusion (compare with (10.73)),

$$\begin{aligned} &I_S = \beta\int_{V_{DB}+2\,\varphi_F}^{V_{SB}+2\,\varphi_F}\left[\left(-V'_{GB} + \varphi_s\right) - \gamma\,\sqrt{-\varphi_s}\right]\mathrm{d}\varphi_s, \\ &\beta = \frac{W}{L}\,\mu_h\,C_{ox}. \end{aligned} \tag{10.115}$$

10.8.1 Differential Conductances and Drain Current, p-Channel

To calculate the differential conductances, it is convenient to use the source contact as a voltage reference; the transformations read

$$\begin{aligned} &V_{SD} = V_{SB} - V_{DB} > 0, \qquad V_{SG} = V_{SB} - V_{GB}, \\ &V_{SB} = -V_{BS} \le 0. \end{aligned} \tag{10.116}$$

The *source conductance*, or *output conductance*, is given by

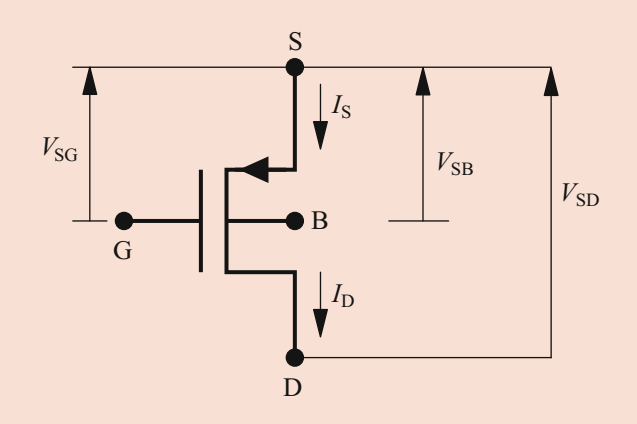

Fig. 10.22 Symbol of the p-channel MOSFET of the enhancement type. (After [2])

$$g_S = \left(\frac{\partial I_S}{\partial V_{BS}}\right)_{V_{BD},V_{BG}} = \left(\frac{\partial I_S}{\partial V_{SD}}\right)_{V_{BD},V_{GD}}, \qquad (10.117)$$

whence

$$g_S = \beta\left[\left(-V'_{GB} + V_{SB} + 2\,\varphi_F\right) - \gamma\sqrt{-V_{SB} - 2\,\varphi_F}\right] = \frac{W}{L}\,\mu_h\,Q_i(0). \qquad (10.118)$$

Letting $g_S = 0$ yields the *saturation surface potential* (compare with (10.28))

$$\sqrt{-\varphi_s^{sat}} = \sqrt{-V'_{GB} + (\gamma/2)^2} + \gamma/2\,; \qquad (10.119)$$

the *saturation voltage* in the bulk and source references is then found to be

$$V_{SB}^{sat} = \varphi_s^{sat} - 2\,\varphi_F\,, \qquad V_{SD}^{sat} = V_{SB}^{sat} - V_{DB}\,, \qquad (10.120)$$

respectively, whence the *saturation current* $I_S^{sat} = I_S(V_{SD}^{sat}, V_{SG})$. The limit of the source conductance for $V_{SB} \to V_{DB}$, or $V_{SD} \to 0$, is

$$g_S(V_{SD} \to 0) = \beta\,(V_{SG} - V_T)\,,$$
$$V_T = -V_{FB} - 2\,\varphi_F + \gamma\sqrt{V_{BS} - 2\,\varphi_F}\,, \qquad (10.121)$$

with $V'_{GB} = V_{GB} - V_{FB}$ and $V_{BS} \geq 0$. The $V_T = V_T(V_{BS})$ voltage defined in (10.121) is the *threshold voltage* of the p-channel MOSFET; the condition of a well-formed channel in a p-channel MOSFET is $V_{SG} > V_T$.

Integrating of (10.115) yields $I_S = I'_S - I''_S$, with

$$I'_S = \beta\left[\left(V_{SG} + V_{FB} + 2\,\varphi_F\right)\,V_{SD} - \frac{1}{2}\,V_{SD}^2\right] \qquad (10.122)$$

and

$$I''_S = \beta\,\frac{2}{3}\,\gamma\,\left[(V_{SD} - 2\,\varphi_F + V_{BS})^{3/2} - (-2\,\varphi_F + V_{BS})^{3/2}\right]. \qquad (10.123)$$

Given V_{SG} and V_{BS}, the regional model separates the *on* condition $V_{SG} > V_T$ from the *off* condition $V_{SG} \leq V_T$; the *on* condition is further separated into the *linear region* $0 < V_{SD} \leq V_{SD}^{sat}$, where the source current is described by the $I_S = I'_S - I''_S$ model worked out above, and the *saturation region* $V_{SD} > V_{SD}^{sat}$, where the regional model lets $I_S = I_S^{sat}$. Finally, in the *off* condition, the model lets $I_S = 0$.

The *enhancement-type* p-channel transistors have $V_T > 0$, so that a gate voltage $V_{SG} > V_T > 0$ is necessary to achieve the condition of a well-formed channel, whereas the transistor is in the *off* condition when $V_{SG} = 0$; the *depletion-type* transistors have $V_T < 0$, so that the condition of a well-formed channel is already present when $V_{SG} = 0$, whereas a gate voltage $V_{SG} \leq V_T < 0$ is necessary to put the device in the *off* condition.

The *output characteristics* of the p-channel MOSFET are the $I_S = I_S(V_{SD})$ curves corresponding to different values of V_{SG}, for a given bulk-source voltage V_{BS}; the *transfer characteristics* are the $I_S = I_S(V_{SG})$ curves drawn using V_{BS} as a parameter and letting $V_{SD} = \text{const}$, with a value of V_{SD} small enough to let the limiting case (10.121) hold. The *transconductance* of the p-channel MOSFET is given by

$$g_m = \left(\frac{\partial I_S}{\partial V_{BG}}\right)_{V_{BS},V_{BD}} = \left(\frac{\partial I_S}{\partial V_{SG}}\right)_{V_{SD},V_{SB}} = \beta\,V_{SD}\,, \qquad (10.124)$$

and the *bulk transconductance* is given by

$$g_B = \left(\frac{\partial I_S}{\partial V_{SB}}\right)_{V_{SD},V_{SG}} = -\left(\frac{\partial I''_S}{\partial V_{BS}}\right)_{V_{SD}}. \qquad (10.125)$$

Like in the n-channel device, the body effect is suppressed by letting $V_{BS} = 0$; this is done whenever the architecture of the circuit makes it possible.

Linear-Parabolic Model, p-Channel

The expression of the current in a p-channel MOSFET is simplified by letting $I''_S \simeq \beta\,\gamma\,\sqrt{V_{BS} - 2\,\varphi_F}\,V_{SD}$, this yielding the *linear-parabolic model*. The reasoning is the same as in the n-channel MOSFET. The expression of the current becomes

$$I_S \simeq \beta\,[(V_{SG} - V_T)\,V_{SD} - V_{SD}^2/2]\,, \qquad (10.126)$$

with V_T still given by (10.121). In turn, from (10.126), the source conductance becomes

$$g_S \simeq \beta\,(V_{SG} - V_T - V_{SD})\,, \qquad (10.127)$$

whence

$$V_{SD}^{sat} = V_{SG} - V_T. \tag{10.128}$$

The transconductance g_m is the same as in the general case. Note that the linear-parabolic expression of the drain current may be recast as $I_S \simeq \beta\,(V_{SD}^{sat}\,V_{SD} - V_{SD}^2/2)$, with V_{SD}^{sat} given by (10.128). As a consequence,

$$I_S^{sat} \simeq \beta\left[\left(V_{SD}^{sat}\right)^2 - \frac{1}{2}\left(V_{SD}^{sat}\right)^2\right] = \frac{1}{2}\beta\,(V_{SG} - V_T)^2\,. \tag{10.129}$$

The linear-parabolic model then yields for the saturation region

$$I_S = I_S^{sat}\,, \qquad g_S \simeq 0\,, \qquad g_m \simeq \beta\,(V_{SG} - V_T)\,. \tag{10.130}$$

10.9 Saturation of the Drift Velocity

The MOSFET theory worked out so far is based on the assumption of a constant effective mobility μ_e along the channel. Actually, the drift velocity v_d of the carriers is proportional to the electric field E only for relatively small values of the latter and tends to saturate when E increases above a critical value of the order of 5×10^4 V cm^{-1}. A widely accepted model of the $v_d(E)$ relation dates back to the 1960s of the last century [18] and reads

$$v_d = \frac{\mu_e\,E}{\left[1 + (\mu_e\,E/v^{sat})^m\right]^{1/m}}\,, \tag{10.131}$$

where μ_e is the small-field carrier mobility, v^{sat} the saturation velocity of the carriers, and m an empirical parameter equal to 2 for electrons and approximately 1 for holes. For electric-field values $E \ll E_c = v^{sat}/\mu_e$, the drift velocity is proportional to E, while, in the opposite limit, $v_d \simeq v^{sat}$. The form of (10.131) suggests that the MOSFET drain current may be expressed heuristically as

$$I_D = \frac{I_D^{lin}}{\left[1 + \left(I_D^{lin}/I_D^{sat}\right)^m\right]^{1/m}}\,, \tag{10.132}$$

with

$$I_D^{lin} = \beta\,(V_{GS} - V_T)\,V_{DS}\,, \qquad I_D^{sat} = W\,C_{ox}\,(V_{GS} - V_T - V^{sat})\,v^{sat}. \tag{10.133}$$

In (10.133), I_D^{lin} is the drain current in the linear region, I_D^{sat} is the saturation current, and V^{sat} is the saturation voltage, i.e., the voltage value beyond which carriers move at saturated velocity. It is worth noting that, from the experimental standpoint, V^{sat} is an ill-defined parameter for two reasons: first, the drain current approaches saturation smoothly; next, the finite output conductance due to the short-channel effects does not allow for a clear identification of the saturation voltage. Even from the theoretical standpoint, it should be remembered that the second of (10.133) is based on the gradual-channel approximation (Sect. 10.7.1), which is not entirely valid at the saturation point due to the occurrence of two-dimensional effects near the drain. The intercept of I_D^{lin} with I_D^{sat} occurs at a voltage V_A such that

$$\beta\,(V_{GS} - V_T)\,V_A = W\,C_{ox}\,(V_{GS} - V_T - V^{sat})\,v^{sat}\,, \tag{10.134}$$

which establishes a relation between V_A and V^{sat}. On the other hand, for a long-channel MOSFET, (10.134) reduces to $\beta\,(V_{GS} - V_T)\,V_A = \beta\,(V_{GS} - V_T)^2/2$, whence

$$V_A = (V_{GS} - V_T)/2 = V^{sat}/2\,, \tag{10.135}$$

where the last equality is found by observing that for a long-channel device, V^{sat} identifies with V_{DS}^{sat} of (10.90). To proceed, one assumes that relation (10.135) between V_A and V^{sat} holds in general and not just for long-channel MOSFETs. Replacing (10.135) into (10.134) yields the following expression for V_A:

$$V_A = \frac{V_{GS} - V_T}{2 + \alpha\,(V_{GS} - V_T)}\,, \qquad \alpha = \frac{\mu_e}{v^{sat}\,L}. \tag{10.136}$$

It is easily found that when $\alpha\,(V_{GS} - V_T) \ll 2$, which occurs in long-channel MOSFETs and/or small values of $V_{GS} - V_T$, (10.136) becomes equivalent to (10.135). In the opposite limit, instead, V_A tends to saturate to $1/\alpha$. Using the first of (10.133) and the left-hand side of (10.134) yields $I_D^{lin}/I_D^{sat} = V_{DS}/V_A$; the drain current (10.132) then becomes

$$I_D = \beta\,\frac{(V_{GS} - V_T)\,V_{DS}}{\left[1 + (V_{DS}/V_A)^m\right]^{1/m}}\,, \tag{10.137}$$

which holds in both the linear and saturation regions, with V_A expressed by (10.136), and tends smoothly to the saturation current given by

$$I_D^{sat} = \beta\,\frac{(V_{GS} - V_T)^2}{2 + \alpha\,(V_{GS} - V_T)}. \tag{10.138}$$

Again, the impact of the saturated drift velocity becomes important when $\alpha\,(V_{GS} - V_T) \gg 2$, which typically occurs in short-channel MOSFETs at relatively large driving voltages. Under the above conditions, the growth of the drain current is no longer quadratic but, rather, linear with $V_{GS} - V_T$. Assuming by way of example $\mu_e = 200$ cm^2/(V s), $v^{sat} = 10^7$ cm/s, and $L = 100$ nm, corresponding to $\alpha = 2$ V^{-1}, the saturation current I_D^{sat} is halved at $V_{GS} - V_T = 1$ V with respect to the constant-mobility value $\beta\,(V_{GS} - V_T)^2/2$.

Figure 10.23 compares the output characteristics resulting from the linear-parabolic model (10.88), which assumes con-

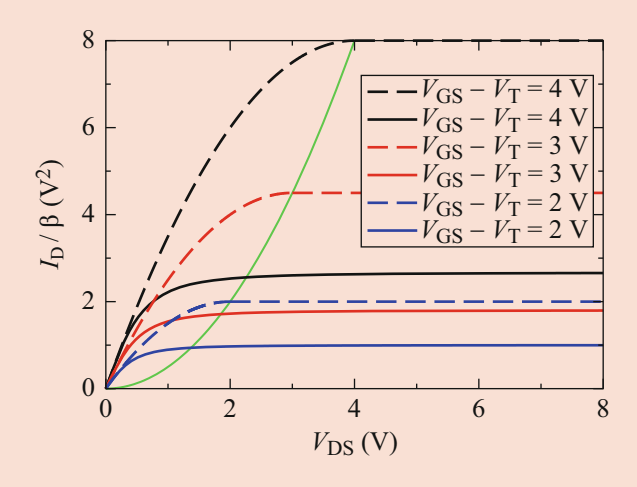

Fig. 10.23 The continuous lines have been obtained from (10.137) letting $\alpha = 1$ and $n = 2$. The dashed lines have been obtained from the linear-parabolic model (10.88). Curves corresponding to the same value of $V_{GS} - V_T$ are drawn in the same color. The green curve envelopes the saturation points of the dashed lines (compare with Fig. 10.19)

stant mobility along the channel, with those of the present model, accounting for the saturation of the drift velocity, and quantifies the strong discrepancies between the two. In order to check the model against experimental data, however, two more aspects must be taken into account. First, it is necessary to model the effective carrier mobility μ_e; next, the drain-induced barrier lowering (DIBL), i.e., the sensitivity of threshold to the drain voltage, must be taken into account. These issues are briefly discussed in Sect. 10.9.1.

10.9.1 Effective Mobility and Drain-Induced Barrier Lowering

The low-field mobility in MOSFET channels was widely investigated in the past. It was found to be essentially independent of channel doping and to follow a universal curve if plotted against the *effective normal field* E_{eff} [19–21]. This fundamental property was first demonstrated in [19] for n-channel MOSFETs and was later confirmed and extended to p-channel devices in [20,21]. More specifically, it was found that the room-temperature carrier mobility is mainly influenced by acoustic-phonon scattering at low normal fields and by surface-roughness scattering at the largest fields. The latter scattering effect turns out to depend on crystal orientation and exhibits different behaviors for electrons and holes. Therefore, different mobility models must be used for the two carrier types. The electron effective mobility μ_{ne} reads

$$\mu_{ne} = \frac{\mu_{n0}}{1 + \theta_{n1} E_{eff}^{0.3} + \theta_{n2} E_{eff}^{2}}, \qquad (10.139)$$

where the effective normal field is given by

$$E_{eff} = (Q_b + Q_i/2)/\varepsilon_{sc} = C_{ox} \left[(V_{GS} + V_T)/2 - (\Phi_{ms} + 2\varphi_F)\right]/\varepsilon_{sc}, \qquad (10.140)$$

Φ_{ms} being the metal-semiconductor work function difference. In turn, the hole effective mobility μ_{pe} reads

$$\mu_{pe} = \frac{\mu_{p0}}{1 + \theta_{p1} E_{eff}^{0.3} + \theta_{p2} E_{eff}}, \qquad (10.141)$$

with

$$E_{eff} = (Q_b + Q_i/3)/\varepsilon_{sc} = C_{ox} \left[|V_{GS} + V_T|/3 + (\Phi_{ms} + 2\varphi_F)\right]/\varepsilon_{sc}. \qquad (10.142)$$

In (10.139) and (10.141), θ_{n1}, θ_{n2}, θ_{p1}, and θ_{p2} are empirical parameters, whose units are such as to make the denominators of (10.139) and (10.141) dimensionless. It is worth noting that terms $\theta_{n1} E_{eff}^{0.3}$ and $\theta_{n2} E_{eff}^{2}$ in (10.139) account for acoustic-phonon and surface-roughness scattering, respectively, and so do the corresponding terms $\theta_{p1} E_{eff}^{0.3}$ and $\theta_{p2} E_{eff}$ in (10.141). These equations show that the surface-roughness dependence of the inverse mobility on the effective normal field is quadratic for electrons and linear for holes. Another important difference between electrons and holes appears in (10.140) and (10.142): the definition of effective normal field within the inversion layer given by the first of (10.140) is consistent with physical intuition; in contrast, the use of $Q_i/3$ rather than $Q_i/2$ in the first of (10.142) is just an empirical choice which gives the best fitting to experimental data [20,21].

The next point to be considered is drain-induced barrier lowering. In this case, the threshold change with drain voltage is approximately linear, i.e.,

$$V_{Tn} = V_{Tn}^{(0)} - \eta_n V_{DS}, \qquad V_{Tp} = V_{Tp}^{(0)} - \eta_p V_{SD}, \qquad (10.143)$$

where η_n and η_p depend on the gate length and are typically expressed in mV/V; for a good device design, they should be as small as possible. Figure 10.24 compares the model (10.137), supplemented with the first of (10.143), with the experimental output characteristics of an n-channel MOSFET having a gate length $L = 130$ nm, an oxide thickness $t_{ox} = 2$ nm, and a nominal threshold voltage $V_{Tn}^{(0)} = 315$ mV. The model fits the experimental curves nicely.

It is worth adding that the model shown here contains a minimal number of parameters; most of them are physical or geometrical parameters, e.g., Φ_{ms}, φ_F, ε_{ox}, ε_{sc}, v^{sat}, W, L, and t_{ox}, and their values are kept fixed. The parameters adjusted for a best fit are those related with mobility and DIBL, namely, μ_{n0}, θ_{n1}, θ_{n2}, η_n, and the like for holes. The mobility parameters are, to some extent, process dependent

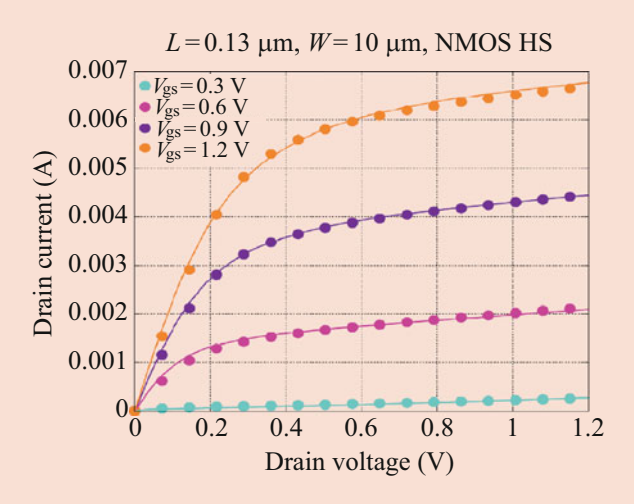

Fig. 10.24 Comparison of the model of (10.137) with experiments. The details about the device are given in the text

and must be determined from a best fit of the device under examination; in turn, the drain-induced barrier lowering factors η_n and η_p depend on two-dimensional effects that are not treated in this context.

The drain conductance g_D and transconductance g_m are derived from (10.137); considering by way of example the n-channel device, one uses definitions (10.77, 10.85) to find

$$g_D = \beta \frac{V_{GS} - V_T}{[1 + (V_{DS}/V_A)^m]^{1+1/m}}, \tag{10.144}$$

whose $V_{DS} \ll V_A$ limit coincides with (10.82). The form of g_D in the other limiting case, $V_{DS} \gg V_A$, is $g_D \simeq \beta (V_{GS} - V_T) (V_A/V_{DS})^{m+1}$ and vanishes when V_{DS} becomes very large. The expression of the transconductance g_m is somewhat unwieldy and is not reported here; its $V_{DS} \ll V_A$ limit coincides with (10.85), whereas the form of the other limiting case, $V_{DS} \gg V_A$, is

$$g_m \simeq \beta V_A \left[1 + \frac{2}{2 + \alpha (V_{GS} - V_T)}\right]. \tag{10.145}$$

10.10 Charge-Transfer Devices

The development of solid-state sensors has intensively been pursued since the late 1960s of the last century, due to the advantages of this class of devices over the then-standard cathode-ray tubes, specifically, (a) low bias voltages and small power absorption; (b) reliability, durability, and compactness; (c) immunity from e.m. fields; and (d) low noise even at moderate illumination levels. Another advantage must be mentioned, related to the architecture of color cameras for video applications: in a cathode-ray camera, it is necessary to guarantee, besides a precise alignment of three tubes (respectively, sensing the red, green, and blue colors), also a perfect – and constant in time – alignment of three electron beams. In a solid-state camera, instead, the transformation of the video signal into a discrete sequence, along with the application of a single clock signal to three sensors, automatically synchronizes the signals associated with the color components; therefore, only the alignment of the three sensors must be cared for.

The first implementations of solid-state optical sensors were made by assembling in matrix form a number of independently addressable elementary sensors; however, this architecture is inadequate, because a separate addressing entails:

1. High output capacitance due to the address lines.
2. Spurious coupling among the signals, still due to the address lines.
3. Lack of uniformity, impossible to avoid, due to the fact that each signal is read at a different output.

Consequences of the above are a modest signal-to-noise ratio, and the presence of fixed patterns in the output signal, due to the lack of uniformity. Such patterns cannot be eliminated by filtering.

A breakthrough came from the introduction of the charge-transfer device (CTD), which is the object of the next paragraphs. The name of the device derives from its capability of transferring a charge packet, in a controlled manner, from the potential-energy well underneath a gate to the well underneath a neighboring gate. The two most important CTD architectures, both able to eliminate the inadequacies listed above, are the Charge-Coupled Device (CCD), described in Sect. 10.10.1, and the Charge-Injection Device (CID), described in Sect. 10.10.3. Some applications are illustrated in Sect. 10.11 and, finally, the performance of image sensors is briefly discussed in Sect. 10.12.

10.10.1 Charge-Coupled Devices

To describe the functioning of a Charge-Coupled Device (CCD) it is convenient to start with a pair of MOS capacitors placed side by side, like those shown in Fig. 10.25. The two gates are labeled 1 and 2, respectively, and the corresponding voltages are indicated with Φ_1 and Φ_2 (in this context the gate voltages are referred to as *phases*). The description of each capacitor is the same as that given in Sect. 10.4 with reference to the photocapacitor; it is assumed that the substrate is of the p-type and that the phases are periodically switched between the flat-band voltage (indicated here with V_L) and another voltage (indicated with V_H) that, in the

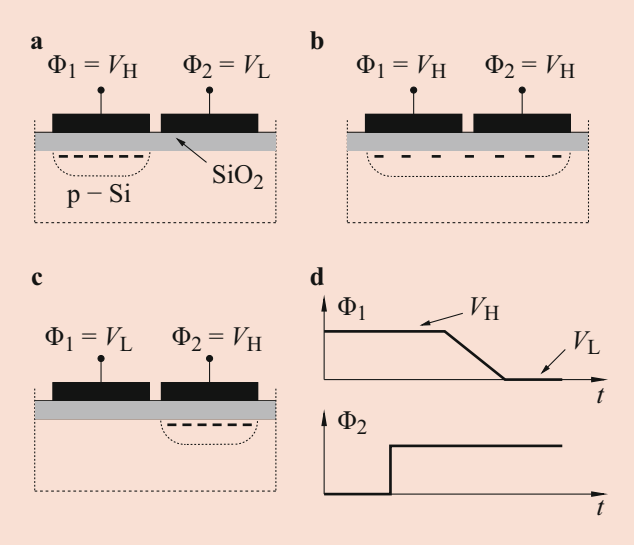

Fig. 10.25 Cross-section of a pair of MOS capacitors forming the basic element of a CCD: parts (**a**-**c**) illustrate the charge-transfer mechanism, part (**d**) sketches the form of the phases

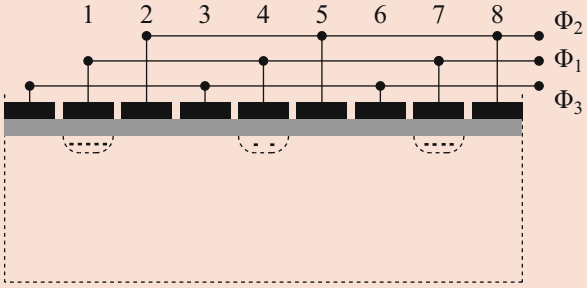

Fig. 10.26 A portion of a three-phase CCD

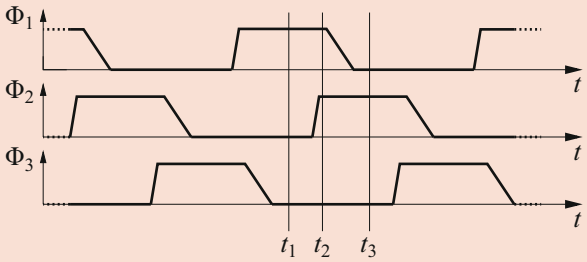

Fig. 10.27 Time dependence of the three phases of the CCD shown in Fig. 10.26

steady-state condition, corresponds to strong inversion. Voltage V_H produces a potential-energy well in the semiconductor region which is underneath gate 1 near the interface with the insulator; an inversion layer is present at the interface, with a charge per unit area that in this context represents a signal; in turn, Φ_2 is kept at V_L (part (a) of Fig. 10.25). If, at a later time, Φ_2 is brought from V_L to V_H, another well forms underneath gate 2; due to the proximity of the two gates, the two wells merge and form a single well in which the charge originally present under gate 1 distributes uniformly (part (b) of the figure). If, then, Φ_1 is gradually brought to V_L, the charge that is still under gate 1 is pushed by the electric field into the well of gate 2 (part (c)). Globally, the result is the transfer of a mobile-charge packet from capacitor 1 to capacitor 2; the transfer is controlled in space by the geometry of the electrodes and in time by the form of the phases (the latter is sketched in part (d) of Fig. 10.25).

The principle of charge transfer illustrated above is easily extended to a succession of equal capacitors, close to each other, whose gates are biased by a three-phase system of voltages (*clock*). This succession of capacitors is the *three-phase CCD*; a portion of it is shown in Fig. 10.26, and the time dependence of the three phases is shown in Fig. 10.27.

With reference to the figures, it is easily found that, at time t_1, being $\Phi_1 = V_H$ and $\Phi_2 = \Phi_3 = V_L$, the charge packets are placed under gates 1, 4, and 7, respectively; at time t_2, being $\Phi_1 = \Phi_2 = V_H$ and $\Phi_3 = V_L$, the charge packets equally distribute under the pairs of gates (1, 2), (4, 5), and (7, 8); at time t_3, being $\Phi_1 = \Phi_3 = V_L$ and $\Phi_2 = V_H$, the transfer of the charge packets under gates 2, 5, and 8 is completed; and so on.

The above description shows that in a three-phase CCD, the elementary cell of the device is made of three capacitors and that the charge packets perform three transfers in a clock period T. It is easily understood that the three-phase architecture is necessary to ensure the one-directional transfer of the packets (from left to right in the examples); architectures featuring cells made of four capacitors have also been implemented. One may wonder whether a two-phase architecture is feasible; the answer is obviously in the negative for symmetric electrodes: in this case, in fact, when $\Phi_1 = \Phi_2 = V_H$, the charge packets would mix, and the information associated with them would be lost. If, instead, a suitable asymmetry of the electrodes is introduced, able to force the one-directional transfer of the packets, the two-phase architecture is feasible (details about the CCD architectures are found, e.g., in [22, 23]).

In the CCD described in Figs. 10.25 and 10.26, the charge packets are placed at the semiconductor-insulator interface; for this reason, the device is also called "surface-channel CCD" (SCCD); by adding a suitable epitaxial layer (here an n-type layer grown over the p-type substrate), it is possible to place the charge packets far from the insulator interface: this implementation, called "buried-channel CCD" (BCCD), although more complicated from the technological viewpoint, provides a better transfer efficiency with respect to SCCD (transfer efficiency is discussed in Sect. 10.10.2).

A CCD as a whole is made of three sections: an input section in which an electric or optical signal is sampled and transformed into a sequence of charge packets; a transfer section, a portion of which has been described above; and an output section, in which the charge packets are converted back into a sampled electric signal. Observing that the CCD is intrinsically an analog delay line carrying a sampled signal, it is possible to exploit the device for realizing analog filters. Another application derives from the idea of considering a well full (empty) of electrons as representative of the logic level 1 (0): in this way, the CCD may be used as a shift register (serial memory). Still another application considers the CCD as a device able to transfer optically generated charge packets into a single output section; this makes the realization of image sensors possible. Some of these applications are briefly addressed in Sect. 10.11.

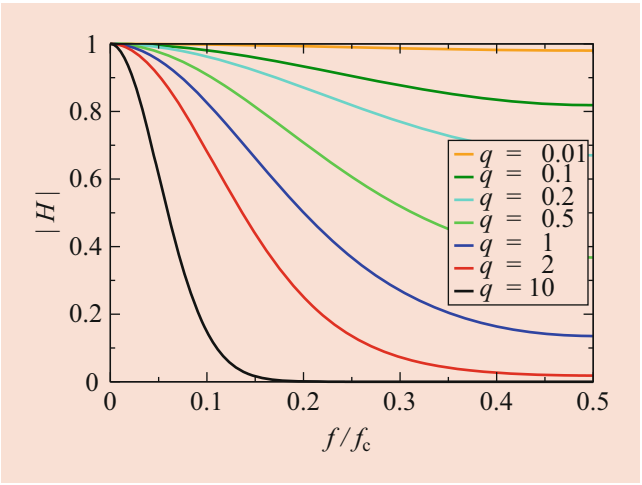

Fig. 10.28 Transfer function (10.150) in terms of f/f_c for different values of parameter $q = N\,p\,\varepsilon$

10.10.2 Transfer Efficiency

Due to the limited time available for the charge packet to leave a well and transfer into the next, some electrons are left behind and eventually mix with the new packet entering the well; this produces a degradation of the quality of the signal. Another degradation mechanism, typical of SCCDs, is that some electrons may temporarily be trapped in the surface states, to be subsequently released into the incoming packet. The fraction ε of electrons left behind for any reason, in a single transfer, is called *transfer inefficiency*; typical figures are $\varepsilon = 10^{-4}$ in SCCDs and $\varepsilon = 10^{-5}$ in BCCDs. Letting p be the number of phases, the inefficiency associated with a full-cell transfer is $p\,\varepsilon$, and the charge present at time t_n in the kth cell reads [24]

$$Q_k(t_n) = (1 - p\,\varepsilon)\,Q_{k-1}(t_{n-1}) + p\,\varepsilon\,Q_k(t_{n-1}). \quad (10.146)$$

The impulse response associated with the transfer from the $(k-1)$th to the kth cell is

$$\begin{aligned} h_k(t_n) &= (1 - p\,\varepsilon)\,(p\,\varepsilon)^{n-1}\,, \quad n > 0\,; \\ h_k(t_n) &= 0\,, \quad n \le 0\,, \end{aligned} \quad (10.147)$$

whose discrete Fourier transform reads [25, p. 257–262]

$$\begin{aligned} F_k(\mathrm{i}\,\omega) &= \sum_{n=1}^{\infty} (1 - p\,\varepsilon)\,(p\,\varepsilon)^{n-1} \exp(-\mathrm{i}\,\omega\,n\,T) \\ &= \frac{(1 - p\,\varepsilon)\,\exp(-\mathrm{i}\,\omega\,T)}{1 - p\,\varepsilon\,\exp(-\mathrm{i}\,\omega\,T)}. \end{aligned} \quad (10.148)$$

For an N-cell device, the full transfer function is $H(\mathrm{i}\,\omega) = [F_k(\mathrm{i}\,\omega)]^N$, namely, using the approximation $(1-\theta)^N = \exp[N\,\log(1-\theta)] \simeq \exp(-N\,\theta)$ holding for $|\theta| \ll 1$,

$$\begin{aligned} H(\mathrm{i}\,\omega) &\simeq \exp(-\mathrm{i}\,\omega\,N\,T)\,\exp\{-q\,[1 - \exp(-\mathrm{i}\,\omega\,T)]\}, \\ q &= N\,p\,\varepsilon. \end{aligned} \quad (10.149)$$

Letting $f_c = 1/T$ be the clock frequency, the modulus of (10.149) reads

$$|H| = \exp\{-q\,[1 - \cos(\omega\,T)]\} = \exp\{-q\,[1 - \cos(2\,\pi\,f/f_c)]\}. \quad (10.150)$$

The form of $|H|$ obtained from (10.150) is shown in Fig. 10.28 for different values of q. When q increases, the transfer function quickly deteriorates, introducing a strong attenuation in the spectral components near $f_c/2$. Remembering Shannon's sampling theorem, such a frequency represents the maximum extension allowed for the spectrum of the input signal.

10.10.3 Charge-Injection Devices

A schematic cross-section of the elementary cell of a charge-injection device (CID) is shown in Fig. 10.29a. An image sensor of the CID type is made of an array of identical cells; in turn, each cell is made of a pair of MOS photocapacitors, whose gate voltages are indicated with V_r and V_c, respectively; like in Sect. 10.10.1, a p-type substrate is assumed, and the two possible levels of gate voltages are indicated with V_H and V_L. During the integration time, one or both gate voltages are kept at V_H, so that a potential-energy well is available to collect the optically generated charge; by way of example, in Fig. 10.29, it is $V_c = V_H$ and $V_r = V_L$. The reading of the integrated charge is carried out by setting both gates to V_L; in this way, the charge is injected through the substrate into the bulk contact B and then brought to the output section of the array.

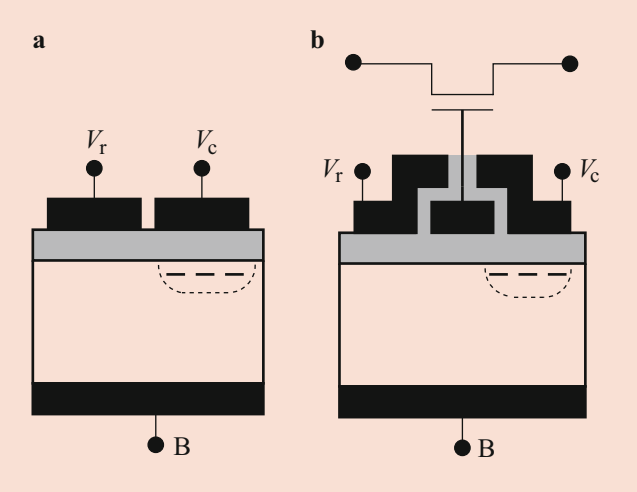

Fig. 10.29 (**a**) Elementary cell of a CID; the two photocapacitors are subjected to independent gate voltages V_r and V_c. (**b**) The same cell with the addition of a floating gate between the two gates; the connection of the floating gate to the gate of an MOS transistor is shown as an example of charge reading

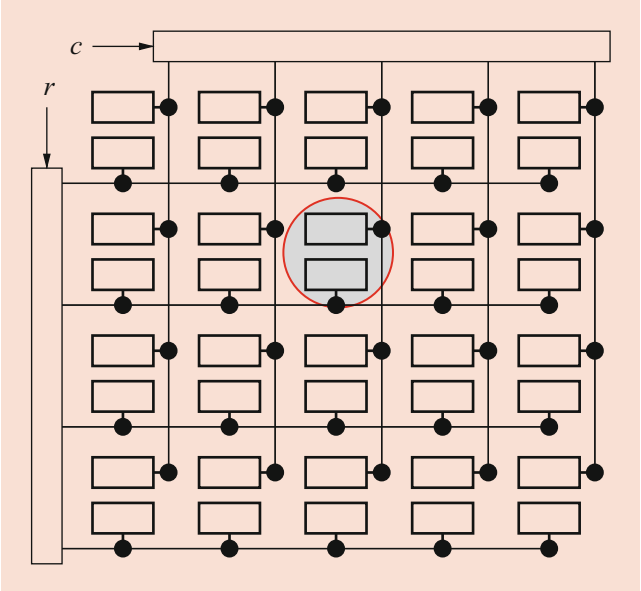

Fig. 10.30 Top view of a CID array. The reading of the marked cell is described in the text

Besides the injection into the substrate, another operation is possible in the CID cell, namely, the right-to-left transfer of a charge packet or vice versa. This is accomplished in the same manner as in a CCD: assume, for instance, that a packet is stored under the right gate, so that $V_c = V_H$ and $V_r = V_L$; first, V_r is brought to V_H, this making the charge to equally distribute under the two gates; finally, V_c is brought to V_L, this completing the transfer. If the packet is initially stored under the left gate, the left-to-right transfer is accomplished by the sequence $V_c \rightarrow V_H$, $V_r \rightarrow V_L$. The transfer feature of the CID cell makes it possible to separately read each cell of the array, in any order. This is easily understood by examining a top view of the array (Fig. 10.30); to read the charged stored, e.g., in the cell marked with a circle, it suffices to operate on the column control c and the row control r: the V_c voltage of the column to which the marked cell belongs is set to V_L, and the V_r voltage of the row of the marked cell is also set to V_L; all remaining columns and rows are set to V_H. In this way, each cell apart from the marked one has at least one gate set at V_H, so that the charge packet either remains under the same gate, or transfers into the other one, or distributes between the two; in contrast, both gates of the marked cell are set to V_L, so the charge is injected into the bulk.

Image sensors using CIDs have demonstrated very good performance and provided a valid alternative to CCDs. It is worth adding that some CIDs, instead of reading the packets by injecting them into the bulk, adopt a reading scheme based on the floating gate. The structure of a CID with the floating gate is shown in Fig. 10.29b; in the figure, the floating gate is connected to the gate of an MOS transistor to show an example of how to detect the variations in the floating-gate voltage without perturbing the operation of the CID (the voltage-charge relation of the floating gate is derived in Sect. 10.10.4). Being non-destructive, the reading based on the floating gate can be carried out repeatedly, with beneficial effects in terms of noise reduction. In low-temperature experiments, the reading of an image has been performed more than 30,000 times without any appreciable degradation; this corresponds to the average loss of less than one electron per reading [26].

10.10.4 Floating-Gate Operation

The analysis of the floating-gate operation is carried out following the theory of the MOS capacitor of Sects. 10.1, 10.2, and 10.3. The symbols used here are visible in Fig. 10.31, where Q_x are charges per unit area and C_x capacitances per unit area; in essence, the device is based on the structure of the MOS capacitor, to which another metal-insulator pair of layers is added. As the state of the intermediate capacitor C_L and so the value of its gate voltage V'_F are determined by electrostatic induction, the metal layer between C_U and C_L is termed *floating gate*; this layer is accessed via a zero-admittance line, in order to detect the voltage V'_F without perturbing the working conditions of the device.

As usual, $V'_G = V_G - V_{FB}$, with V_{FB} the flat-band voltage, indicates the potential difference between the external gate and the semiconductor bulk; similarly, $V'_F = V_F - V_{FB}$ indicates the potential difference between the floating gate and the same bulk (V_G and V_F are referred, instead, to the bulk contact). A p-type substrate is considered; remembering

that the range of gate voltages to be used here is such that the depletion, weak-inversion, or strong-inversion regimes hold, the simplified expression (10.29) of the inversion-layer charge applies,

$$Q_\mathrm{i} = -C_\mathrm{L}\left(V'_\mathrm{F} - \varphi_\mathrm{s} - \gamma\sqrt{\varphi_\mathrm{s}}\right), \qquad \varphi_\mathrm{s} \geq 0. \tag{10.151}$$

If no net charge is present in the floating gate, it is $Q_\mathrm{U} = Q_\mathrm{L}$, whence

$$C_\mathrm{U}\left(V'_\mathrm{G} - V'_\mathrm{F}\right) = \frac{C_\mathrm{U}\,C_\mathrm{L}}{C_\mathrm{U} + C_\mathrm{L}}\left(V'_\mathrm{G} - \varphi_\mathrm{s}\right). \tag{10.152}$$

Solving (10.152) for φ_s or $V'_\mathrm{F} - \varphi_\mathrm{s}$ after letting $r = C_\mathrm{U}/C_\mathrm{L}$ yields $\varphi_\mathrm{s} = (1+r)\,V'_\mathrm{F} - r\,V'_\mathrm{G}$ and $V'_\mathrm{F} - \varphi_\mathrm{s} = r\left(V'_\mathrm{G} - V'_\mathrm{F}\right)$. As the above expressions hold only for $\varphi_\mathrm{s} \geq 0$, it follows $r\,V'_\mathrm{G}/(1+r) \leq V'_\mathrm{F} \leq V'_\mathrm{G}$; replacing the expressions into (10.151) yields the relation between the inversion-layer charge and the floating-gate voltage,

$$-\frac{Q_\mathrm{i}}{C_\mathrm{L}\,V'_\mathrm{G}} = r\,(1 - V'_\mathrm{F}/V'_\mathrm{G}) - \alpha\sqrt{(1+r)\,V'_\mathrm{F}/V'_\mathrm{G} - r},$$
$$\alpha = \frac{\gamma}{\sqrt{V'_\mathrm{G}}}, \tag{10.153}$$

which is shown in Fig. 10.32 for different values of r and α. The curves show that with $\alpha = 0.01$, the $Q_\mathrm{i}(V'_\mathrm{F})$ relation exhibits good linearity; the linearity is still fair for $\alpha = 0.2$, which is a more realistic value in modern technologies. It is worth observing that a similar procedure is feasible also when some charge per unit area is stored in the floating gate, e.g., $Q_\mathrm{L} - Q_\mathrm{U} = Q_0 \neq 0$; in this case, letting $q_0 = Q_0/(C_\mathrm{L}\,V'_\mathrm{G})$, (10.153) is replaced with

$$-\frac{Q_\mathrm{i}}{C_\mathrm{L}\,V'_\mathrm{G}} = r\,(1 - V'_\mathrm{F}/V'_\mathrm{G}) + q_0 - \alpha\sqrt{(1+r)\,V'_\mathrm{F}/V'_\mathrm{G} - r - q_0}. \tag{10.154}$$

10.11 Applications of CCDs

Among the applications mentioned in Sect. 10.10.1, those related to the implementation of memories or analog filters have been attempted in the early 1970s of the last century, but have soon been superseded by more efficient architectures. The realization of image sensors, instead, has been more successful, although other architectures eventually proved more efficient also in this field (an example is the CID matrix illustrated in Sect. 10.10.3). The scheme for realizing an analog filter is briefly illustrated in Sect. 10.11.1, while typical implementations of image sensors using CCDs are described in some detail in Sect. 10.11.2.

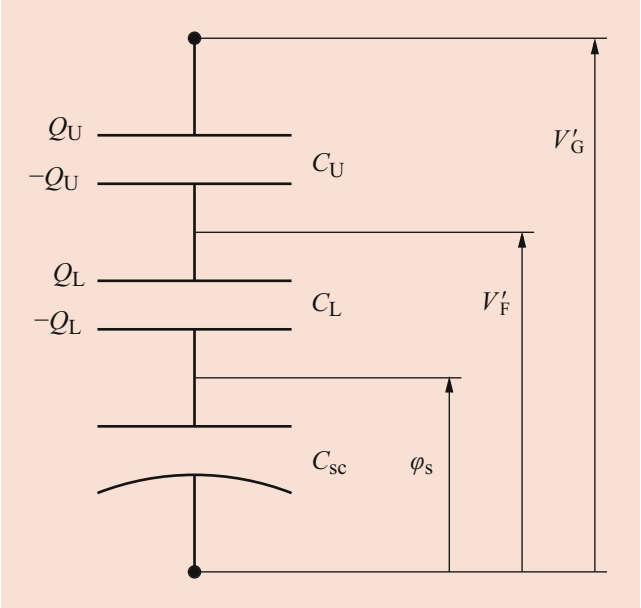

Fig. 10.31 Equivalent circuit of the floating-gate scheme based on an MOS capacitor. The lower plate of the semiconductor capacitance C_sc is bent to indicate that this capacitance is nonlinear

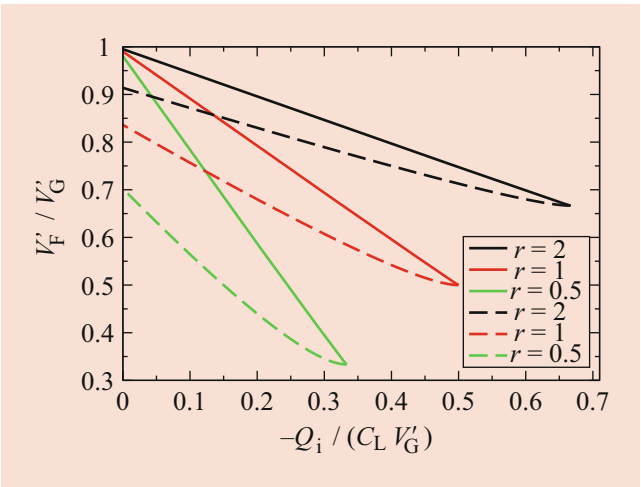

Fig. 10.32 The floating-gate voltage as a function of the inversion-layer charge for different values of $r = C_\mathrm{U}/C_\mathrm{L}$. All curves fulfill the constraint $V'_\mathrm{F}/V'_\mathrm{G} \geq r/(r+1)$. Parameter α has been fixed to 0.01 (*continuous lines*) or 0.2 (*dashed lines*)

10.11.1 Applications to Analog Filtering

As mentioned in Sect. 10.10.1, the realization of an analog filter with a CCD is based on the observation that the device is an analog delay line carrying a sampled signal; the goal is to implement with it a prescribed transfer function $H(\omega)$ acting on the input signal $w(t)$ of the CCD. It can be shown that, if one succeeds in performing a non-destructive reading of the samples, a suitable linear combination of the samples provides a convolution of the input signal with the antitrans-

form $h(t)$ of $H(\omega)$; the antitransform depends only on the coefficients of the combination, which are easily controlled. In this way, it is possible to construct the transfer function sought. This application of CCDs has been the first, and very elegant, example of realization of a filter within the integrated-circuit technology. The main reason why it has not been pursued further is the insufficient attenuation in the stopband.

The input function $w(t)$ is transformed by the input section of the filter into a sequence of charge packets whose size depends linearly on the input signal itself (some indications about the linearity of input sections are given in Sect. 10.12.2); it follows that the charge packets may be considered as samples of w taken at different times 0, T, $2T$, and so on, with T the clock period. The filtering operation is based on the properties of the Fourier transform,

$$W(\omega) = \mathscr{F}w = \int_{-\infty}^{+\infty} w(t)\, \exp(-\mathrm{i}\,\omega\, t)\, \mathrm{d}t\,, \qquad (10.155)$$

and of the convolution integral describing the output signal $u(t)$,

$$u(t) = h(t) * w(t) = \frac{1}{2\,\pi} \int_{-\infty}^{+\infty} h(t')\, w(t-t')\, \mathrm{d}t' = \mathscr{F}^{-1}(H\, W), \qquad (10.156)$$

with $H(\omega) = \mathscr{F}h$ the transfer function of the filter. For the physical realizability of H, it must be $h(t') = 0$ for $t' < 0$, whence $\int_{-\infty}^{+\infty}$ of (10.156) must be replaced with $\int_{0}^{+\infty}$. Observing that the discrete form of (10.156) is

$$u(t) = \frac{1}{2\,\pi} \sum_{k=0}^{\infty} h(t'_k)\, w(t-t'_k)\, T \simeq \sum_{k=0}^{n} a_k\, w(t-k\,T)\,, \qquad (10.157)$$

with $t'_k = k\,T$ and $a_k = h(t'_k)\, T/(2\,\pi)$, the issue is using a CCD to construct the last expression on the right in (10.157). The procedure is understood with the aid of Fig. 10.33, showing that the signal is sampled at the end of each cell, so that the time distance between two neighboring samples is the clock period T. To avoid deteriorating the signal, the sampling operation must be performed in a non-destructive way; this is achieved by the floating-gate scheme illustrated in Sect. 10.10.4 which renders, for each cell, a voltage $w(t-k\,T)$ that depends linearly on the charge of the packet that has crossed the cell. Then, each sampled signal is given an amplification equal to a_k, and, finally, the amplified voltages are added up to form the output signal $u(t)$. It is manifestly inconvenient to associate an amplifier to each cell; this is avoided by observing that (10.157) can be recast as

$$u(t) = \sum_{k=0}^{n} a_k\, w(t-k\,T) = a_{\mathrm{M}} \sum_{k=0}^{n} \frac{a_k}{a_{\mathrm{M}}}\, w(t-k\,T),$$

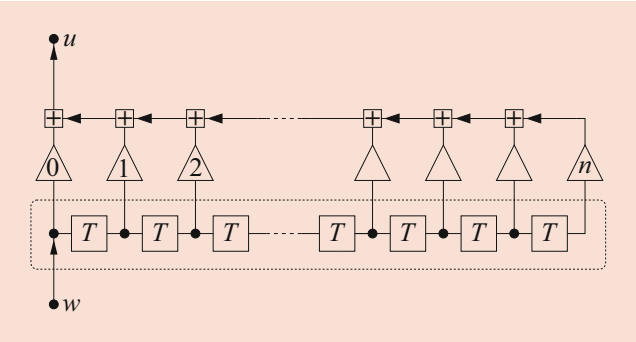

Fig. 10.33 Scheme of the analog filter using a delay line. The CCD is inside the dashed line, with the squares indicating the cells; the charge packets travel from left to right (input and output sections not shown). The triangles represent the amplifications a_k of (10.157) and (10.158)

$$a_{\mathrm{M}} = \max(a_k)\,, \qquad (10.158)$$

so that the problem reduces to implementing n attenuations $0 \le a_k/a_{\mathrm{M}} \le 1$ and a single amplification with gain a_{M}. Achieving the attenuations is relatively easy: it suffices in fact to shorten the width of the kth floating gate ($k = 1, \ldots, n$) from the original value W to $a_k\, W/a_{\mathrm{M}}$, so that only the fraction a_k/a_{M} of the packet that has traveled across the kth cell is detected. The shortening of the floating-gate widths is achieved with a single mask during the fabrication process.

10.11.2 Applications to Optical Sensing

Image sensors based on CCDs belong to two main categories: linear sensors and two-dimensional sensors. The most efficient organizations of the linear sensors are shown in Fig. 10.34; both types are made of a one-dimensional array of MOS photocapacitors, but differ in the method with which the charge packets are transferred to the output section. For simplicity, the oblique arrows visible in Fig. 10.34, which sketch the incoming light, are drawn only on some locations of the sensors; obviously, the radiation impinges everywhere on the sensor surface.

Considering a three-phase organization like that shown in Fig. 10.26, in the linear sensor indicated with (a) in Fig. 10.34, the phases are kept fixed in time during the integration period; one of them, say, Φ_1, is kept at V_{H}, so that the potential-energy wells of the corresponding photocapacitors integrate the optically generated charge. Phases Φ_2 and Φ_3 are kept at V_{L} to prevent the generated packets from mixing. At the end of the integration period, the clock is operated, and the charge packets are transferred along the CCD (here from left to right) and brought to the output section (sketched by the triangle in the figure). This organization is simple, but has the disadvantage that, during

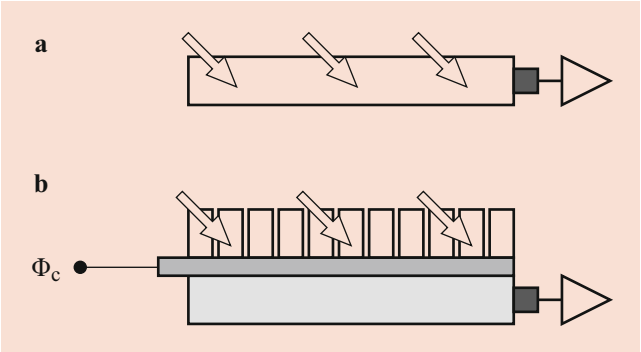

Fig. 10.34 Top view of the two typical organizations of linear image sensors using CCDs

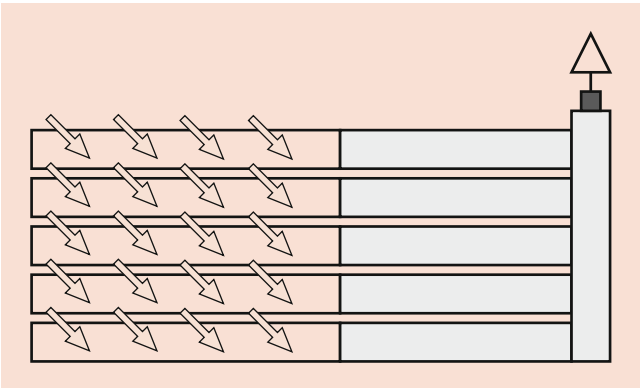

Fig. 10.35 Top view of a frame-transfer image sensor using CCDs

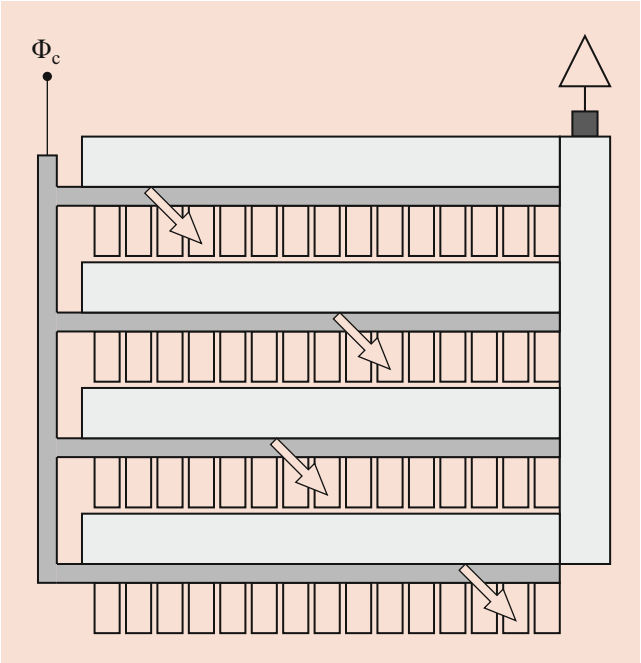

Fig. 10.36 Top view of a line-transfer image sensor using CCDs

the transfer of the packets to the output section, the impinging light keeps generating new charges: the latter add up to the transiting packets and degrade the quality of the image. To minimize the effect, it is necessary to use a high clock frequency.

A more effective solution is shown in part (b) of Fig. 10.34; here, the array of photocapacitors (the white rectangles in the figure) integrates the charge until the integration period is complete; then, by applying a signal Φ_c to the longitudinal gate (the dark-gray strip), the packets are transferred in parallel into the CCD below, which is screened from the radiation by a protective coating. The CCD transfers the packets to the output section. This organization, although more complicated than that of (a) and more onerous in terms of area occupancy, has the advantages of eliminating the spurious generation and of providing a duty cycle practically equal to 100%; moreover, it is less demanding as far as the clock frequency is concerned, because the transfer of the charge packets to the output section takes place during the integration period.

Array image sensors based on CCDs are essentially two-dimensional replicas of the architectures illustrated above. The array corresponding to case (a) of Fig. 10.34 is shown in Fig. 10.35 and is termed *frame-transfer sensor*. At the end of the integration period, the charge packets present in the integration area (the white part on the left) are transferred into the storage area (the gray part); the portion of each CCD belonging to the storage area is screened from the radiation by a protective coating. Then, the charge packets at the right end of the storage area are transferred into the vertical CCD, which finally transfers the packets (in the bottom-up direction) into the output section. To achieve this, the clock frequency of the vertical CCD is a multiple of that of the horizontal ones, the multiplicative factor being the number of rows of the array; in summary, the reading operation introduces a parallel-to-series conversion of the order of the packets.

The array corresponding to case (b) of Fig. 10.34 is shown in Fig. 10.36 and is termed *line-transfer sensor*. At the end of the integration period, a suitable signal Φ_c is applied to the common gate, and the charge packets integrated in each of the one-dimensional arrays of photocapacitors are transferred in parallel into the corresponding CCD, which is screened from the radiation. Then, the horizontal CCDs transfer the packets (left to right) into the vertical CCD, which in turn transfers them (bottom-up) into the output section. Also in this case, the clock frequency of the vertical CCD is a multiple of that of the horizontal ones, and a parallel-to-series conversion of the order of packets takes place.

The advantages or disadvantages of the two implementations of Figs. 10.35 and 10.36 are the same as in the one-dimensional case described earlier. It is worth adding that the frame-transfer scheme provides an easy and elegant solution

to the problem of video interlacing, present in some types of displays. It suffices in fact to control the clock in such a way that, from one integration period to the next, the gates subjected to V_H are swapped with those subjected to V_L; besides solving the interlacing problem, this method practically doubles the spatial frequency of the sampling, this improving the resolution of the image. The gate swapping is not possible, instead, in the line-transfer scheme; considering this aspect, it is found that the performance of the two schemes is substantially the same for a given area of the sensor.

Before concluding the paragraph, it is important to mention a different architecture for imagers, the active-pixel sensor (APS), in which each individual photodetector is supplemented with one or more active devices used as amplifiers; in the typical implementation based on the MOS technology, the amplifier is of the CMOS type. An early and detailed comparison between the performance of CCD and APS imagers is carried out in [27], with a shorter section devoted to CIDs.

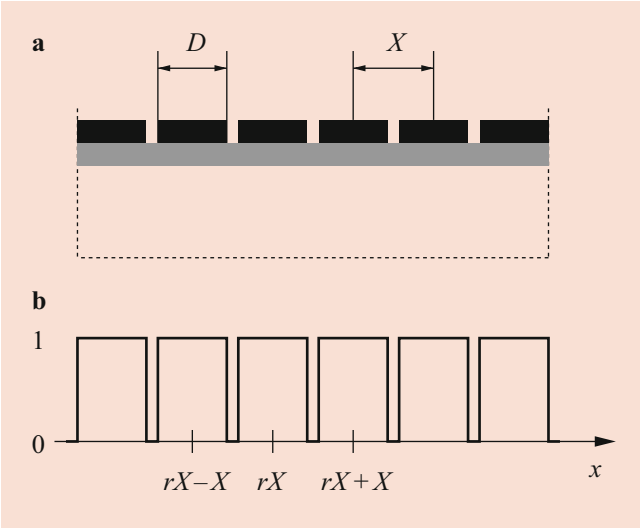

Fig. 10.37 (**a**) Cross-section of a linear image sensor and (**b**) corresponding sampling function

10.12 Performances of Image Sensors

The first part of this section addresses a fundamental aspect of image sensors, namely, spatial resolution; the second part briefly illustrates other aspects, still related to the image-sensor performances: dynamics, linearity, *blooming* effect, spectral responsivity, and sensitivity.

10.12.1 Spatial Resolution

A fundamental property of an image sensor is spatial resolution. Considering for simplicity a linear sensor (Fig. 10.37a), it is readily understood that the device performs a spatial sampling of the image, whose period X is the distance between the midpoints of the individual sensors; due to Shannon's theorem, the maximum spatial frequency that can be resolved is $f_M = 1/(2X)$. When a signal $n(x)$ is sampled with a series of pulses δ of frequency $f_0 = 1/X = 2f_M$, the spectrum of $n(x)$ is replicated periodically with the same frequency f_0; as a consequence, the frequencies of the spectrum of $n(x)$ that are larger than f_M are reflected into the bandwidth and, therefore, cannot be eliminated by filtering. The effect, termed *aliasing*, is shown in Fig. 10.38. In image sensors, the effect is made more complicated by two factors:

(i) The sampling function is not a series of δ pulses; to first order one may describe it as a square wave (Fig. 10.37b).
(ii) The output signal is not the product of the input signal and the sampling function but, rather, the integral of this product.

Basing on the considerations above, the analysis of the sampling operation is carried out by observing that, here, $n(x)$ is the number of charges generated per unit length during the integration period; it follows that the signal associated with the rth elementary sensor is the total charge present in it, given by

$$q\,s(rX) = q\int_{x_-}^{x_+} n(x)\,\mathrm{d}x\,, \qquad x_\pm = rX \pm D/2. \quad (10.159)$$

The output of the image sensor is therefore the discrete sequence $s(rX)$, whose spectrum is calculated following [28]. If $N(k)$ is the Fourier transform of $n(x)$, with $k = 2\pi f$, from (10.159), one obtains

$$s(rX) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} N(k)\,H(k)\,\exp(\mathrm{i}\,k\,rX)\,\mathrm{d}k\,, \quad (10.160)$$

with $H(k) = D\,\sin(kD/2)/(kD/2)$. Letting $W(k) = N(k)\,H(k)$, and parting the integration interval into segments of length $2\pi/X$ after defining $k_\pm = (2m \pm 1)\,\pi/X$, one obtains

$$\begin{aligned} s(rX) &= \sum_{m=-\infty}^{+\infty}\int_{k_-}^{k_+} W(k)\,\frac{\exp(\mathrm{i}\,k\,rX)}{2\pi}\,\mathrm{d}k \\ &= \frac{X}{2\pi}\int_{-\pi/X}^{+\pi/X} S(k)\,\exp(\mathrm{i}\,k\,rX)\,\mathrm{d}k\,, \end{aligned}$$

$$S(k) = \frac{1}{X}\sum_{m=-\infty}^{+\infty} W(k + m\,2\pi/X). \quad (10.161)$$

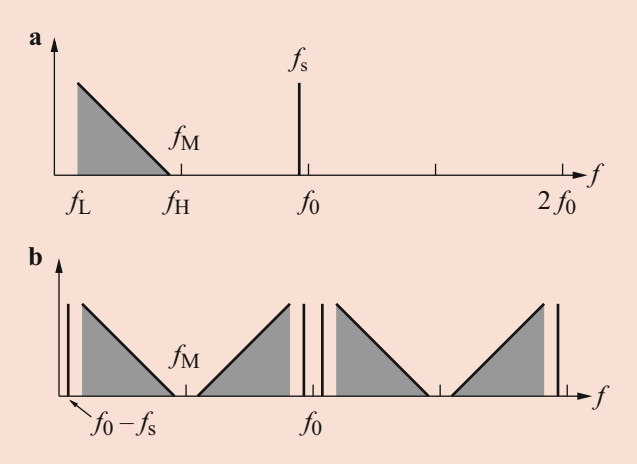

Fig. 10.38 Example of aliasing. The gray area in (**a**) is the spectrum of the input signal, ranging from f_L to f_H; the line at f_s in (**a**) is a spurious signal. The sampling duplicates the input signal producing the signal shown in (**b**), where the line at $f_0 - f_s$ is one of the duplicates of the spurious signal of (**a**): this duplicate cannot be eliminated by filtering because it belongs to the $[0, f_M]$ band

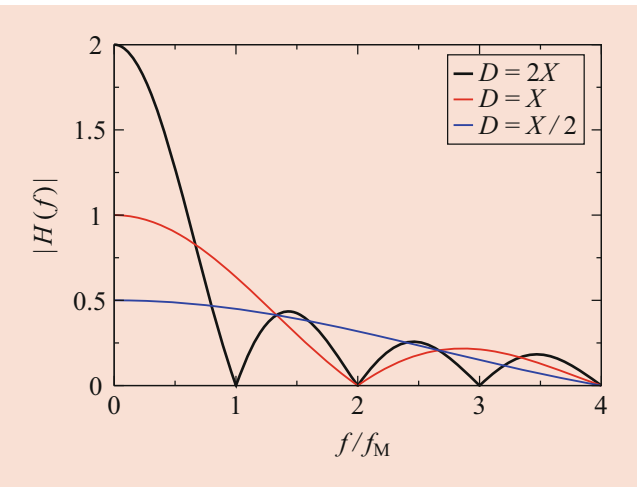

Fig. 10.39 Modulus of H drawn as a function of f/f_M, using different ratios D/X in (10.162)

In conclusion, the spectrum S of the output signal is still periodic with frequency $f_0 = 1/X$, and, therefore, aliasing may occur. Another issue is that the portion of spectrum located around harmonic $mf_0 = 2\,mf_M$ is multiplied by the transfer function

$$H = \frac{D}{X}\,\frac{\sin(\pi\,Df)}{\pi\,Df} = \frac{D}{X}\,\sin\left(\frac{\pi}{2}\,\frac{D}{X}\,\frac{f}{f_M}\right) \Big/ \left(\frac{\pi}{2}\,\frac{D}{X}\,\frac{f}{f_M}\right), \tag{10.162}$$

with $2\,m - 1 \le f/f_M \le 2\,m + 1$. The modulus of (10.162) is drawn in Fig. 10.39 for different ratios D/X. Given that the minimum of X (whence the resolution) is prescribed by the technological process, one must select the D/X ratio in such a way as to obtain the best tradeoff between elimination of aliasing and degradation of contrast; in fact, increasing D/X attenuates the frequencies larger than f_M but, at the same time, eliminates the upper part of the signal spectrum, and vice versa. Considering, for instance, the Nyquist limit $f = f_M$, one finds that the transfer function reduces to $2/\pi = 64\%$ for $D = X$, while it reduces to $\sqrt{2}/\pi = 45\%$ for $D = X/2$ and to zero for $D = 2X$ (the odd-looking condition $D > X$ occurs, for instance, in a frame-transfer device working in the interlaced format). In some applications like commercial television, some loss of contrast is preferable because aliasing produces disturbing effects on the image (*moiré fringes*); in other applications, where the operator is trained to analyze the contents of an image when disturbances are present, it is preferable to accept the presence of moiré fringes to keep that maximum amount of information.

With reference to the pattern noise, it is important to cite [29], which provides a clear description of the characterization methods for noise sources in CCD or CMOS cameras. The paper analyzes the issue from both viewpoints of theory and experiment; Figs. 10.3 and 10.8 of it show measures of nonlinearities and, respectively, compare a number of contributions to noise in CCDs.

10.12.2 Miscellany

The next paragraphs briefly address some other issues related to architecture and performances of CTDs. The interested reader may refer to the original papers. The architecture of the input circuit of a CCD depends on the application. For imaging applications (considering a case in which the CCD is not the sensor itself), the input device consists of a photocapacitor with a semi-transparent gate (typically made of heavily doped polycrystalline silicon). At the end of the integration period, a suitable clock operation transfers the charge packet into the CCD. When the input signal is of the electric type, the input circuit is made of an n^+-p junction and of a pair of electrodes. Different schemes may be adopted to operate the input circuit [30].

The purpose of the output circuit is revealing the charge packet; possible architectures are based on the floating gate, whose functioning is described in Sect. 10.10.4, or, alternatively, on an MOS transistor kept in the *off* condition. This architecture is termed *floating diffusion* because the junction of the MOS transistor nearest to the CCD is floating [31].

Dynamics and Linearity

In a CCD, dynamics is essentially dictated by the maximum signal-to-noise ratio. The analysis of noise is carried out in detail in [32–35]. As for the signal amplitude, the latter is given by the amount of charge within each potential-energy well; for given values of V_H and V_L, the ratio between the

maximum charge of the packet in a SCCD and in a BCCD is $r = 1 + (d/t_{ox})\,(\varepsilon_{ox}/\varepsilon_{sc})$, with t_{ox} the oxide thickness, d the epitaxial-layer thickness, and ε_{ox} and ε_{sc} the permittivities of the oxide and semiconductor, respectively. From the viewpoint of signal amplitude, SCCDs are preferable.

Linearity of CCDs depends on the performance of the input and output circuits. In optical applications, linearity is rather good, typically of the order of 0.3%, and is limited by the nonlinearity of the depletion-region capacitance present in the circuits. When, instead, the charge is injected electrically, linearity is more strongly affected by the architecture of the input circuit; optimal values of second-harmonic attenuation that have been achieved are in the $40 \div 45$ dB range [36]. An analysis of linearity in CIDs is given in [37], where the model and a number of experimental results on these devices are provided; both the destructive and non-destructive reading schemes are considered.

Blooming

All image sensors exhibit, to some degree, the *blooming* effect, which consists in an apparent increase in size of an object whose luminous intensity saturates the device. In CCD sensors, the phenomenon is due to the excessive charge generation occurring in some of the potential-energy wells: the excess charge diffuses laterally into the neighboring wells and produces the apparent enlargement of the object. In a two-dimensional sensor, charges diffuse preferably into the wells belonging to the same channel; thus, a highly illuminated spot produces a bright stripe in the output image. An effective method for eliminating blooming consists in absorbing the excess charges by interspersing conductive areas among the channels; in some implementations, the voltage of the conductive areas is externally controlled.

In CID sensors, the effect of lateral diffusion of the charge is relatively unimportant, because the excess charges are drained by the *p-n* junction formed by the epitaxial layer and the substrate; however, another type of blooming exists in CIDs, which produces stripes similar to those of CCDs. The phenomenon occurs when reading, e.g., a column where a saturated element is present: when another element of the same column is read, the charge of the saturated element transfers into the other gate of the same CID cell, and the excess part of it is injected into the substrate; the effects of the excess charges add up in the output circuit and produce a bright stripe in the column being read. The blooming effect in CIDs is fully eliminated by the non-destructive reading using a floating gate (Sect. 10.10.4).

Spectral Responsivity, Sensitivity, and Recent Developments

The spectral response of an image sensor is the ratio between the number of charges collected at the output circuit per unit time and the optical power density impinging on the sensor at a given frequency. This quantity depends on the optical properties of the semiconductor; in silicon, using back illumination and anti-reflecting coatings, a spectral response near the theoretical limit has been reached in the visible and near-infrared ranges [38]. When front illumination is used, the spectral response is negatively influenced by reflection at the surface and absorption by the polysilicon electrodes. To limit these drawbacks, thin electrodes and anti-reflecting coatings are used; yet, a fraction of the radiation is absorbed by polysilicon at small wavelengths (blue range). Also, multiple reflections at the Si-SiO_2 interfaces produce interferences, this introducing a non-negligible dependence of the spectral response on the layer's thickness.

A new family of back-illuminated CCD, with a very low dopant concentration to achieve depletion regions in the range $[200, 300]\,\mu$m, is presented in [39]. The devices have been used within the Supernova Cosmology Project. Among the reported modeling aspects are the theory of the absorption coefficient for energies below 2.5 eV, accounting for the effect of phonons, and a section devoted to the analysis of spatial resolution. Among the experimental issues are the quantum-efficiency measurements and the pictures of the Dumbbell Nebula, taken with the new type of CCD and compared with those taken with commercial CCDs. An ample description of the state of the art of CCD and CMOS sensors is given in [40]; details are given about the scaling trend of the CCD technology and the improvement in sensitivity; the evolution of the fabrication processes is also analyzed.

An application of CCDs as registers, to the purpose of analyzing the noise associated with the injection of extremely small charge packets, is presented in [41], where the interesting possibility of X-ray detection using CCDs is described. The transfer inefficiency ε of a novel implementation of CCDs is the focus of [42] (transfer inefficiency is defined in Sect. 10.10.2), where a model for ε is discussed and a comparison of the latter with a set of measurements is given; the relative importance of the fringing field and of charge trapping is discussed for both SCCDs and BCCDs. Schemes for response-time optimization in CCD imagers are addressed in [43]. Architectures of imagers combining photodiodes as active area and CCDs as transfer registers have shown able to strongly improve resolution; an example of a 35 mm chip with a 4.5 μm photodiode and a maximum operation speed of 60 MHz is given in [44]. To date, the most recent contribution to the subject is [45].

10.13 Appendix

This appendix illustrates a number of important aspects that were not accommodated in the main part of chapter lest their presence interrupted the fluidness of the presentation.

10.13.1 The Poisson Equation in the MOSFET Channel

To tackle the Poisson equation in non-equilibrium, it is convenient to use the quasi-Fermi potentials φ_n and φ_p, whose normalized form is $u_n = q\,\varphi_n/(k_B\,T)$ and $u_p = q\,\varphi_p/(k_B\,T)$; the carrier concentrations read $n = n_i\,\exp(u - u_n)$ and $p = n_i\,\exp(u_p - u)$, respectively. In equilibrium, $u_n, u_p \to u_F$, with u_F the normalized Fermi potential; one defines

$$\chi_n = u_n - u_F\,, \qquad \chi_p = u_p - u_F\,, \tag{10.163}$$

so that

$$n = n_{p0}\,\exp(u - \chi_n)\,, \qquad p = p_{p0}\,\exp(\chi_p - u)\,, \tag{10.164}$$

with $\chi_n, \chi_p \to 0$ in equilibrium. In non-equilibrium, at any position y in the channel, it is $\lim_{x\to\infty} \chi_n, \chi_p = 0$ as observed in Sect. 10.7, whence $\varphi_n, \varphi_p \to \varphi_F$ when x increases. Considering an n-channel MOSFET (Sect. 10.7), the charge density in the semiconductor reads $\rho = q\,[p_{p0}\,\exp(\chi_p - u) - n_{p0}\,\exp(u - \chi_n) - N_A]$, with $\lim_{x\to\infty} \rho(x, y) = 0$. Using the limiting values of χ_n and χ_p and the boundary conditions on u (shown below) yields $N_A = p_{p0} - n_{p0}$; it follows

$$\rho = -q\,p_{p0}\,A(u, \chi_n, \chi_p)\,, \quad A = \frac{n_i^2}{N_A^2}\,[\exp(u - \chi_n) - 1] + 1 - \exp(\chi_p - u) \tag{10.165}$$

with $n_i^2/N_A^2 = \exp(-2\,u_F) \ll 1$ (compare with (10.3)), and the Poisson equation reads

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = \frac{1}{L_A^2}\,A\,, \tag{10.166}$$

with $L_A^2 = \varepsilon_{sc}\,k_B\,T/(q^2\,p_{p0})$. Also, it is $u = u(x, y)$, $\chi_n = \chi_n(y)$, and $\chi_p = \chi_p(y)$ (the latter two relations hold because the x-component of the current density is zero). The boundary conditions for u with respect to x are $u(\infty, y) = 0$, $u'(\infty, y) = 0$ due to the charge neutrality of the bulk region; in practice, u and u' vanish at the end $x_d(y)$ of the depletion width.

If the channel is well formed, one simplifies (10.166) by noting that the modulus of $\partial E_x/\partial x = -\partial^2 u/\partial x^2$ is large, because E_x changes from E_{sx} (which is also large because it forces the strong-inversion condition at the surface) to zero in the short distance $x_d(y)$. In contrast, for relatively low values of V_{DS} and in long-channel MOSFETs, the y-dependence of E_{sy} (and also of E_{sx}) on y is weak, whence $\partial E_y/\partial y = -\partial^2 u/\partial y^2$ is small at the semiconductor-insulator interface. In conclusion, (10.166) is approximated as

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \simeq \frac{\mathrm{d}^2 u}{\mathrm{d}x^2} = \frac{1}{L_A^2}\,A. \tag{10.167}$$

where the dependence of A on y is of the parametric type. From this point on, the solution procedure becomes the same as in equilibrium (Sect. 10.1.1) and provides $[q\,E_{sx}/(k_B\,T)]^2 = (2/L_A^2)\,F^2$, with

$$F^2 = \{\exp(-\chi_n - 2\,u_F)\,[\exp(u_s) - 1]\} - \{\exp(\chi_p)\,[1 - \exp(-u_s)]\} + \{[1 - \exp(-2\,u_F)]\,u_s\}\,. \tag{10.168}$$

The first, second, and third terms in braces of (10.168) derive from the concentration of electrons, holes, and dopants, respectively; like in the equilibrium case, the flat-band condition $u_s = 0$ corresponds to $F = 0$ (note that the derivation of (10.168) entails a multiplication by $\mathrm{d}u/\mathrm{d}x$ of both sides of $\mathrm{d}^2u/\mathrm{d}x^2 = A/L_A^2$, which is acceptable if χ_n and χ_p are such that $\mathrm{d}u/\mathrm{d}x$ never vanishes). When the accumulation regime is excluded, the contribution of the holes is negligible, and, using also $\exp(-2\,u_F) \ll 1$, a simpler form of (10.168) is found, applicable in the depletion, weak-inversion, and strong-inversion regimes:

$$F^2 = \exp(-\chi_n - 2\,u_F)\,[\exp(u_s) - 1] + u_s\,, \qquad u_s(y) \geq 0. \tag{10.169}$$

In this case, it is $F^2 \geq 0$ for any χ_n, still with $F = 0$ when $u_s = 0$. In strong inversion, the electron charge (proportional to $\exp(u_s) - 1$ in (10.169)) dominates, corresponding to positive values of $u_s - \chi_n - 2\,u_F$; thus, the onset of the strong-inversion condition is identified by $u_s = \chi_n + 2\,u_F$ or, using the definition (10.163) of χ_n,

$$u_s = u_n + u_F\,, \qquad 0 \leq y \leq L. \tag{10.170}$$

Relation $u_s = \chi_n + 2\,u_F$ is coherent with the definition of threshold of the MOS capacitor (Table 10.1), corresponding here to $\chi_n = 0$. Also, as shown in [1, Sect. 10-2] and in Sect. 10.7.3, specifying $u_s = \chi_n + 2\,u_F$ at the source and drain ends of the channel provides the integration limits (10.74).

10.13.2 Inversion-Layer Charge and Mobility Degradation

In the simplified model (10.75) for the drain current worked out in Sect. 10.7.1, when $V_{DS} \to V_{DS}^{sat}$, the inversion-layer charge Q_i vanishes at the drain end of the channel. Considering that the MOSFET current is carried by the inversion-layer charge, the vanishing of the latter occurring at the drain end of the channel when $V_{DS} \to V_{DS}^{sat}$ may seem an oddity. However, it is important to remember that a number of approximations are necessary to reach the result expressed by (10.83) and

(10.84); such approximations make the theory applicable only in the linear region and in the condition of a well-formed channel.

When $V_{DS} \to V_{DS}^{sat}$, the vertical component of the electric field at the interface, E_{sx}, is made weaker by the interplay between the voltages applied to the gate electrode and to the nearby drain electrode; for this reason, at the drain end of the channel, the flow lines of $\mathbf{J}_n$ do not keep close to the interface any longer, but spread into the substrate, this decreasing the carrier density. The phenomenon is better understood with the aid of Fig. 10.40, where the linear-parabolic model is used with, e.g., $V_T = 0.5$, $V_S = 0$, $V_{GS} = 1.5$, and $V_{DS} = 2$ V. As $V_{DS}^{sat} = 1$ V, the saturation condition $V_{DS} > V_{DS}^{sat} = 1$ holds. Along the dash-dotted line enclosed in the right oval, the direction of the electric field is that shown in the vector diagram in the upper-right part of the figure; in particular, the vertical component of the field at the position marked by the vertical dashed line points upward. As a consequence, the channel electrons are repelled downward, and the flow lines of the current density detach from the interface. On the source end of the channel, instead, the vertical component of the field points downward. By continuity, a position within the channel exists where, in saturation, the vertical component of the field vanishes; such a position (not shown in the figure) is called *inversion point*. Also, the large component of the electric field along the y direction, which exists within the space-charge region of the reverse-biased drain junction, makes the average velocity of the carriers to increase at the drain end of the channel; as the total current is constant, a further decrease in the carrier concentration occurs. The two effects briefly illustrated above are not accounted for by the simplified model and require a more elaborate approach in which the two-dimensional structure of the electric field is accounted for.

Another comment is useful, this time related to the *off* condition. When $V_{GS} \to V_T$, the current of a real device does not actually vanish; in fact, a current (called *subthreshold current*), due to the carriers present in the channel in the weak-inversion condition, flows for $V_{GS} < V_T$. Also in this case, a more elaborate theory is necessary, showing that the subthreshold current vanishes exponentially as V_{GS} decreases (Sect. 10.7.3).

It is worth concluding this appendix by commenting the simplification used in (10.67), where the effective electron mobility μ_e is assumed to be independent of the position y along the channel. The factors that affect mobility in a MOSFET are collisions with phonons, ionized impurities, and semiconductor-oxide interface; in macroscopic models, the electron mobility $\mu_n(x, y)$ is made to depend on the lattice temperature T, concentration of ionized impurities N_A, and x-component of the electric field $E_x(x, y)$. The first two parameters, T and N_A, do not introduce a dependence on position because they are themselves constant. The x-dependence

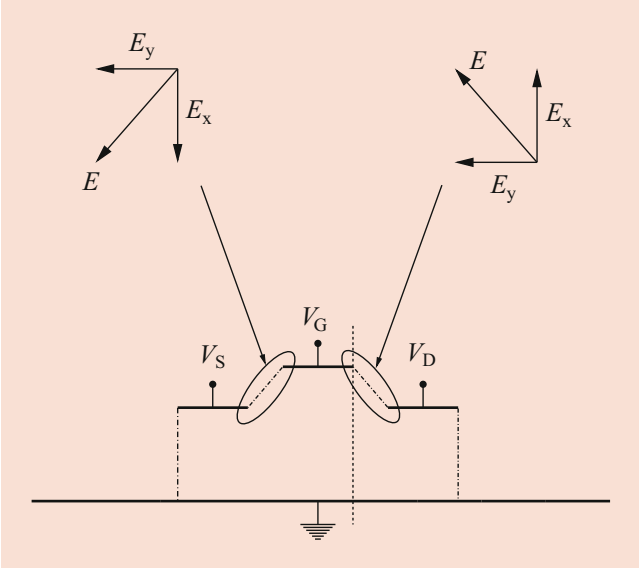

Fig. 10.40 Illustration of the electric-field components at the channel ends in the saturation condition (after [2])

of E_x is absorbed by the integral (10.64) that defines μ_e; it follows that the average mobility depends on y because E_x does. Such a dependence, in turn, is relatively weak in the strong-inversion condition as remarked in Sect. 10.13.1. Therefore, the dependence of μ_e on position is considered negligible.

10.13.3 Exact Charge Partitioning in the MOS Capacitor

In treating the MOS capacitor, the charge distribution has been so far approximated with (10.29), which is applicable whenever accumulation is excluded (Sect. 10.3, with reference to the p-type substrate). The same approximation has then been used for treating the MOSFET. A more precise analysis is possible, which avoids partitioning the semiconductor volume into regions; it is based on the integral expression (10.12) of the semiconductor charge per unit area, in which the individual charge contributions are considered. In the analysis, care must be taken to avoid possible divergences due to the artifact of an infinite extent of the integration domain. In fact, the integral as a whole,

$$Q_{sc} = \int_0^\infty q\,(p - n - N_A)\;\mathrm{d}x = \int_0^\infty q\,[(p - p_{p0}) - (n - n_{p0})]\;\mathrm{d}x\,, \tag{10.171}$$

converges (see below), while the integral of N_A alone obviously diverges. In a p-type substrate, (10.5) holds, with the negative sign because accumulation is excluded; in turn, the charge density reads $\rho = -q\,p_{p0}\,A(u)$, with A given by (10.3); changing the integration variable in (10.171) by let-

ting $\mathrm{d}x = \mathrm{d}u/u' = -L_\mathrm{A}\,\mathrm{d}u/(\sqrt{2}\,F)$, and using the integration limits $u(0) = u_\mathrm{s}$ and $u(\infty) = 0$, yields

$$Q_\mathrm{sc} = -Q_\mathrm{sc}^{(1)} \int_0^{u_\mathrm{s}} \frac{A(u)}{2\,F(u)}\,\mathrm{d}u\,, \tag{10.172}$$

with $Q_\mathrm{sc}^{(1)}$ given by (10.25). The asymptotic condition in the x coordinate corresponds to $u \to 0$; it is easily found that the $u \to 0$ limit of A/F is finite, whence the integral converges. Similarly, if one replaces A with $(n_\mathrm{i}^2/N_\mathrm{A}^2)\,[\exp(u) - 1]$ or, separately, with $1 - \exp(-u)$, the corresponding integrals converge; when the normalization is eliminated, these terms (whose sum is A) correspond to $n - n_\mathrm{p0}$ and $N_\mathrm{A} - p$, respectively. Considering that in the depletion, weak-inversion, and strong-inversion regimes it is $n \gg n_\mathrm{p0}$ and $N_\mathrm{A} \gg p$ in the channel region, one lets

$$Q_\mathrm{i} = -Q_\mathrm{sc}^{(1)}\,\exp(-2\,u_\mathrm{F}) \int_0^{u_\mathrm{s}} \frac{\exp(u) - 1}{2\,F(u)}\,\mathrm{d}u\,,$$

$$\exp(-2\,u_\mathrm{F}) = \frac{n_\mathrm{i}^2}{N_\mathrm{A}^2}\,, \tag{10.173}$$

$$Q_\mathrm{b} = -Q_\mathrm{sc}^{(1)} \int_0^{u_\mathrm{s}} \frac{1 - \exp(-u)}{2\,F(u)}\,\mathrm{d}u. \tag{10.174}$$

These definitions fulfill $Q_\mathrm{sc} = Q_\mathrm{i} + Q_\mathrm{b}$ and yield a more precise charge partitioning in the MOS capacitor, avoiding at the same time the complicacy of placing the neutrality condition at a finite distance. The same analysis applies to the n-type substrate. Although relations (10.173) and (10.174) cannot be integrated analytically, their sum (10.172) is integrable: combining (10.25) with (10.172) yields in fact

$$F(u_\mathrm{s}) = \int_0^{u_\mathrm{s}} \frac{A(u)}{2\,F(u)}\,\mathrm{d}u\,, \tag{10.175}$$

which can also be found through a direct calculation. Using (10.173) and (10.174), it is possible to check the accuracy of the approximations of Sect. 10.3; as shown in [46], when accumulation is excluded, the approximations are sufficiently accurate and can also be extended to the non-equilibrium case (Sect. 10.7.3).

10.13.4 Scaling Rules for MOSFETs

The integrated circuits (ICs) have been introduced in the 1960s; since then, their storage capacity, computing power, and speed have increased exponentially. It has been observed that the number of transistors in an integrated circuit approximately doubles every 2 years (*Moore law*); it is therefore possible to identify "generations" of the IC technology, also referred to as *nodes*: each node is defined by the value of a characteristic length (typically the *half-pitch*, i.e., half the distance between contacts in a DRAM array). The exponential growth in the number of elementary devices in the chip, and, consequently, its augmented performance, derives from the continuous decrease, from one generation to the next, in the radius of the elementary devices and from the parallel increase in the radius of the chip; such improvements, in turn, are due to the steady refinement in the resolution and quality of the fabrication processes. Also, smaller devices absorb less power; in parallel, the clever circuit design made possible by complexity helps in keeping the consumption of the whole chip low. Another advantage is that, when the size of a transistor decreases, its switching time decreases as well.

If the applied voltages are left unchanged from one generation to the next, the decrease in size of a device makes the electric field in its interior to increase; this may eventually give rise to, e.g., junction breakdown due to avalanche or gate-oxide breakdown; to prevent these phenomena, it is then necessary to modify the applied voltages: the schemes by which this goal is obtained are known as *scaling rules*. Different classes of scaling rules exist, and, among them, those in which the electric field in the new-generation device is kept equal to that of the old-generation one are called *constant-field scaling rules*. No matter what class is adopted, for implementing a scaling rule, it is necessary to investigate the behavior of the Poisson equation $-\varepsilon\,\nabla^2\varphi = \rho$ under scaling; the equation, in fact, describes the spatial dependence of the electric field (it is assumed that new-generation devices are made of the same material as the old ones, so permittivity does not change). The device shrinking is described as a variable transformation, from the old-generation to the new-generation set, involving spatial coordinates and electric potential; namely, $x_i^\mathrm{old} \leftarrow x_i^\mathrm{new} = x_i^\mathrm{old}/\lambda$, with $\lambda > 1$ the coordinate scaling factor, and $\varphi^\mathrm{old} \leftarrow \varphi^\mathrm{new} = \varphi^\mathrm{old}/\kappa$, with $\kappa > 1$ the scaling factor of the potential. For the moment, one assumes that λ and κ are independent from each other; this scheme is the most general one and is known as *generalized scaling theory* [47]. The electric-potential transformation does not involve the interfaces between different materials (e.g., contact-semiconductor interfaces); the work-function differences, in fact, do not scale and are dealt with separately. Transforming the Poisson equation yields

$$-\varepsilon \sum_{i=1}^{3} \frac{\mathrm{d}^2(\varphi^\mathrm{old}/\kappa)}{\mathrm{d}(x_i^\mathrm{old}/\lambda)^2} = \rho^\mathrm{new}. \tag{10.176}$$

In order to map the electric potential of the new-generation device over that of the old-generation one (assuming that the boundary conditions are scaled correctly), one must take $\rho^\mathrm{new} = \rho^\mathrm{old}\,\lambda^2/\kappa$. In turn, the electric-field components transform as

$$E_i^{\text{new}} = -\frac{\partial(\varphi^{\text{old}}/\kappa)}{\partial(x_i^{\text{old}}/\lambda)} = \frac{\lambda}{\kappa} E_i^{\text{old}}. \tag{10.177}$$

From (10.177), one finds that the generalized theory yields the constant-field scaling rules when $\kappa = \lambda = x_i^{\text{old}}/x_i^{\text{new}}$; as a consequence, the charge density scales as $\rho^{\text{new}} = \lambda\,\rho^{\text{old}}$. The above relation is obviously fulfilled in insulators ($\rho_{\text{ox}} \simeq 0$) while, in principle, is not fulfilled in a semiconductor, where $\rho = q\,(p - n + N)$, because p and n do not scale. On the other hand, in the standard operating conditions of a device, the semiconductor can be parted (Sect. 10.1.2) into neutral regions, where $\rho \simeq 0$, and space-charge regions, where $\rho = q\,(p - n + N) \simeq q\,N$; therefore, the scaling rule is fulfilled if

$$N^{\text{new}} = \lambda\,N^{\text{old}}\,. \tag{10.178}$$

A very successful application of the scaling rules pertains to the MOS technology; their application to the case of an n-channel transistor is shown in the following. The linear-parabolic model (Sect. 10.7.2) yields for the drain current

$$I_{\text{D}} = \beta\,[(V_{\text{GS}} - V_{\text{T}})\,V_{\text{DS}} - V_{\text{DS}}^2/2]\,, \qquad \beta = \frac{W}{L}\,\mu_{\text{e}}\,\frac{\varepsilon_{\text{ox}}}{t_{\text{ox}}}\,; \tag{10.179}$$

one may argue that (10.179), where the contact voltages appear, involves interfaces between the semiconductor and other materials; however, if one assumes that the contacts are made of the same material, it is found that the non-scalable constants are eliminated because V_{GS} and V_{DS} are in fact voltage differences. The only exception is V_{T}, which is non-scalable; its effect is made less important by taking $V_{\text{GS}} \gg |V_{\text{T}}|$. To summarize, the term in brackets of (10.179) is the square of a scalable voltage. As for the scaling of β, permittivity does not change, while the geometrical factor scales like $W^{\text{new}}/(L^{\text{new}}\,t_{\text{ox}}^{\text{new}}) = \lambda\,W^{\text{old}}/(L^{\text{old}}\,t_{\text{ox}}^{\text{old}})$. Finally, mobility may suffer some degradation due to the increase in the doping concentration dictated by (10.178) (some indications about mobility modeling are in Sect. 10.9.1); neglecting for the moment this phenomenon, and using symbol V_X to collectively indicate the voltages in (10.179), yields

$$I_{\text{D}}^{\text{new}} = \text{const} \times \frac{\left(V_X^{\text{new}}\right)^2}{t_{\text{ox}}^{\text{new}}} = \text{const} \times \frac{\left(V_X^{\text{old}}/\lambda\right)^2}{t_{\text{ox}}^{\text{old}}/\lambda} = \frac{I_{\text{D}}^{\text{old}}}{\lambda}\,. \tag{10.180}$$

The power dissipation in an MOS transistor occurs at the source-drain port (Sect. 10.7); the scaling behavior of the power P dissipated by a single transistor is

$$P^{\text{new}} = V_{\text{DS}}^{\text{new}}\,I_{\text{D}}^{\text{new}} = \frac{V_{\text{DS}}^{\text{old}}}{\lambda}\,\frac{I_{\text{D}}^{\text{old}}}{\lambda} = \frac{P^{\text{old}}}{\lambda^2}\,. \tag{10.181}$$

From the viewpoint of circuit design, it is important to determine the power $\tilde{P}$ dissipated per unit area of the chip; if the number of transistors per unit area is ζ, then in a planar technology, it is $\zeta^{\text{new}} = \lambda^2\,\zeta^{\text{old}}$; the latter expression, combined with (10.181), yields

$$\tilde{P}^{\text{new}} = \zeta^{\text{new}}\,P^{\text{new}} = \lambda^2\,\zeta^{\text{old}}\,\frac{P^{\text{old}}}{\lambda^2} = \zeta^{\text{old}}\,P^{\text{old}} = \tilde{P}^{\text{old}}\,, \tag{10.182}$$

that is, $\tilde{P}$ is invariant under the constant-field scaling. This is a fundamental result, because it shows that a suitable choice of the scaling rules allows the designer to concentrate a larger number of devices in the same area without producing an excessive heat. Another advantage of smaller transistors is that their switching time is shorter. Using the CMOS architecture by way of example, consider the charging or discharging process of the capacitive load that represents the fan-out. Letting A be the capacitor area, and considering a linear capacitor for simplicity, one finds $C^{\text{new}} = \varepsilon_{\text{ox}}\,A^{\text{new}}/t_{\text{ox}}^{\text{new}} = \varepsilon_{\text{ox}}\,(A^{\text{old}}/\lambda^2)/(t_{\text{ox}}^{\text{old}}/\lambda) = C^{\text{old}}/\lambda$. In both charging and discharging processes, current I is the drain (source) current of an MOS transistor, whose scaling rule is (10.180); the circuit equation is $I = C\,\mathrm{d}V/\mathrm{d}t$, in which the scaling factors of V and I cancel each other. With these premises, one finds

$$\mathrm{d}t^{\text{new}} = C^{\text{new}}\,\frac{\mathrm{d}V^{\text{new}}}{I^{\text{new}}} = \frac{C^{\text{old}}}{\lambda}\,\frac{\mathrm{d}V^{\text{old}}}{I^{\text{old}}} = \frac{\mathrm{d}t^{\text{old}}}{\lambda}\,, \tag{10.183}$$

namely, within the constant-field scaling rules, the scaling factor of time is the same as that of lengths.

As mentioned before, the current-voltage characteristics of the devices embed non-scalable quantities, typically due to the presence of interfaces; the problem is not restricted to the device boundaries: for instance, the electric field in a reverse-biased, abrupt p-n junction reads

$$E_0 = -\sqrt{\frac{2\,q}{\varepsilon_{\text{sc}}}\,\frac{\psi_0 - V}{1/N_{\text{D}} + 1/N_{\text{A}}}}\,, \qquad \psi_0 = \frac{k_{\text{B}}\,T}{q}\,\log\left(\frac{N_{\text{D}}\,N_{\text{A}}}{n_{\text{i}}^2}\right), \tag{10.184}$$

where ψ_0 increases under scaling by the additive term $(2\,k_{\text{B}}\,T/q)\,\log\lambda$; only when $|V| \gg \psi_0$, the scaling factors of V and $1/N_{\text{D}} + 1/N_{\text{A}}$ compensate each other and make E_0 invariant under scaling. Another example is the threshold voltage given, e.g., in an n-channel transistor by (10.82); it embeds the Fermi potential $\varphi_{\text{F}} = (k_{\text{B}}\,T/q)\,\log(N_{\text{D}}/n_{\text{i}})$, the work-function difference at the interface between bulk contact and semiconductor (through the flat-band voltage, Sect. 10.3.1), and, possibly, the fixed oxide charge and the surface-state charge.

It is expected that the miniaturization of the present device architecture will attain the end, brought about by fundamental physical limits; for instance, when the insulator becomes too thin, dielectric breakdown or leakage due to tunneling becomes inevitable: for these reasons, in advanced devices, silicon dioxide is being replaced with high-k dielectrics. Another limit made worse by miniaturization is

statistical variability; for instance, implanting a dopant with a 6×10^{18} cm^{-3} concentration into a channel whose size is $40 \times 20 \times 20$ nm^3 yields about 100 implanted atoms, so that treating the dopant profile as a continuous function becomes unrealistic. In turn, practical problems are related to the (exponentially increasing) cost of investments necessary to pass from one generation to the next and from the increasing complexity of the circuit design: the latter issue is in fact tackled by means of advanced techniques for automatic design and of sophisticated models describing each phase of the design (detailed information about device modeling is found in Part IV of this Handbook).

Abstract

Electrostatic doping is widely emerging as an alternative approach to overcome the limitations of traditional chemical doping to provide high charge carrier densities in nanometer-scale semiconductor devices. In this chapter (this work is partly based on Gupta et al. (IEEE Trans Electron Devices 64(8):3044–3055, 2017) and has been expanded with latest insights and developments), various reported approaches on electrostatic doping and related device architectures in different material systems are discussed. It is shown that for the induced electrostatic doping, the role of the metal workfunction, specific semiconductor properties (i.e., electron affinity and energy bandgap), the applied electric field, and the interplay between them are important. The effect of interface traps on the induced charge is also highlighted. In addition, both the performance benefits and major bottlenecks of electrostatic doping for potential future CMOS technology are discussed.

11.1 Introduction

For device dimensions of only several nanometers, conventional chemical (or impurity) doping [1] faces several challenges. In practice it is difficult to form junctions with extremely high doping gradients (e.g., a few nm/decade) [2, 3], especially important for tunnel field-effect transistors (TFETs) realized in ultrathin semiconductor bodies (UTBs) [4, 5]. Moreover, in case of nanometer-scale semiconductor bodies, such as nanowires, doping levels above their solid solubility limit would be required for obtaining sufficiently low body and contact resistances, while accurate control of the doping type, level, and spatial distribution in such nanostructures is also challenging because of their complex growth dynamics and geometrical constraints [6, 7]. In addition, variability induced by random (chemical) doping fluctuation has been the major concern for manufacturing high yield nanometer-scale devices and circuits [8–10].

It appears that for any nanometer-scaled device, the requirement of having a high carrier density along with unintentional, and possibly undesired, ionized dopants in its active semiconductor body points toward impurity-free doping solutions, such as electrostatic doping.

Other than geometrical aspects, electrostatic doping has a strong potential for various alternative emerging material systems as well.

For example, in wide bandgap semiconductors, such as gallium-nitride (GaN), silicon-carbide (SiC), and zinc-oxide (ZnO), chemical doping employed for specific p-type (GaN, SiC) or n-type (ZnO) regions remains difficult. This can be attributed to the deep donor or acceptor levels or dopant passivation via complex formation [11–14].

It is also not straightforward to adopt chemical doping for realizing electronic switches in other types of semiconductor

materials, such as carbon nanotubes (CNTs) and emerging two-dimensional (2-D) materials (graphene, phosphorene, silicene, and transition metal dichalcogenides (TMDs) [15, 16]. For example, tunnel field-effect transistors (TFETs) and 2-D materials (or a combination of those) are potentially attractive for beyond-CMOS (complementary metal oxide semiconductor) devices for their sub-thermal subthreshold slope [17]. However, there are still several technological hurdles left to reach their full potential since realizing highly doped junctions with a steep profile combined with a low defect density, essential for an efficient tunneling process [16, 18], is difficult.

Consequently, in recent years various approaches have been proposed to control the charge carrier density by other means than chemical doping. In many of these approaches, electrostatic interaction between the semiconductor and a different material at the interface, in most cases a metal or a metallic compound, governs the carrier density. Such approaches are therefore referred to as "electrostatic doping".

Device examples based on these approaches are manifold: Schottky barrier (SB) metal-oxide-semiconductor field-effect transistors (MOSFETs) [19, 20], charge plasma (CP)-based ultra-thin body (UTB) devices [21–24], reconfigurable UTB devices such as silicon (Si) nanowire FETs [25–27] and fully depleted silicon-on-insulator (FD-SOI) devices [28, 29], FETs based on graphene [30–33], CNT [34–36] and 2-D materials [37, 38], and electron-hole bilayer based TFETs [39–41]. Electrostatic doping potentially offers well-controlled, possibly ultra-sharp, carrier density profiles with a reduced defect density and therefore could be an attractive alternative to conventional chemical doping for a broad range of electron devices.

In this chapter an overview of various device concepts based on electrostatic doping (ED) is presented and is organized as follows. First, in Sect. 11.2 several ED approaches are summarized which are subdivided into three categories based on the nature of the underlying electrostatics. Thereafter, various types of electrostatically doped devices are discussed focussing on the electrostatics for different types of metal-semiconductor systems. Further, in Sect. 11.3 the performance of potential electrostatically doped devices for future CMOS technology is discussed, and the major challenges and possible drawbacks of the ED techniques are addressed. Finally, in Sect. 11.4 a summary is given.

11.2 The Concept of Electrostatic Doping

As a replacement for conventional chemical doping, electrostatic doping (ED) can generally be considered as a technique to induce charge carriers (electrons or holes) in a semiconductor material resulting from the band alignment near its interface with another (semi)conducting material. This chapter focusses on metal (or metallic compound)-induced ED; other heterostructure-based doping like polarization doping, e.g., in III-nitrides [42], is beyond the scope of this chapter. However, some alternative approaches are discussed in Sect. 11.3.

The carrier concentration in the close vicinity of a metal-semiconductor (MS) interface is largely controlled by the electrostatic condition at that interface, rather than by the chemical impurities as for the case of conventional chemical doping. This interfacial electrostatic condition, which influences the band alignment, is a strong function of the metal workfunction (ϕ_M), the semiconductor's energy bandgap (E_G), and its electron affinity (χ_S) or alternatively the semiconductor workfunction (ϕ_S). In addition, the applied electric field, if any, also influences the electrostatic properties near the interface.

The ED approaches can be subdivided into three categories: (1) Schottky barrier-based devices, (2) workfunction-induced doping, and (3) bias-induced doping. In the following subsections, these ED approaches, as applied to different devices and material systems, are discussed.

11.2.1 Schottky Barrier-Based Devices

In Schottky barrier (SB)-based devices, the current is limited by one or more Schottky contacts. The physics of a Schottky barrier formed at the MS interface has been thoroughly described in good reference books [1, 43].

An SB with height $q\phi_B$ is obtained when $\phi_M > \phi_S$ for an n-type semiconductor (Fig. 11.1a) and $\phi_M < \phi_S$ for a p-type semiconductor, where q is the elementary charge.

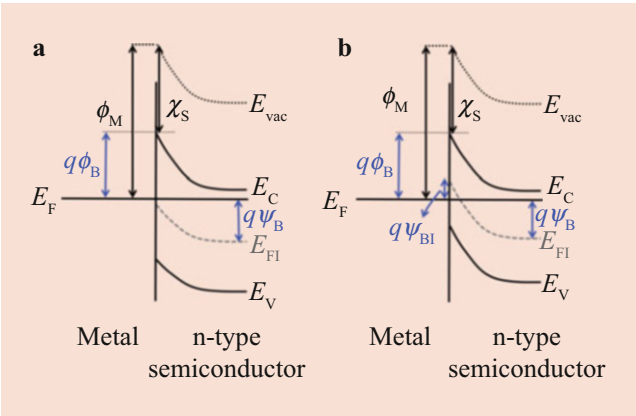

Fig. 11.1 Schematic energy band diagrams for (**a**) a traditional n-type Schottky contact where a depletion layer is formed at the MS interface and (**b**) an n-type Schottky contact with large MS workfunction difference. The excessive band-bending near the interface results in hole inversion in an n-type semiconductor. Consequently, a shallow p-n junction is formed near the MS interface. Similarly, electron inversion could be obtained for Schottky contacts on a p-type semiconductor

The Schottky barrier height (SBH) at the MS interface, $q\phi_B$, equals $(\phi_M - \chi_S)$ for an n-type and $(E_G - \phi_M + \chi_S)$ for a p-type semiconductor. There is a fundamental difference in the operation of SB devices from (chemically doped) p-n junction devices. In case of SB devices, the MS interface, hence ϕ_B, fully controls the majority unipolar current [43]. The electron or hole current flow in SB devices is governed by thermionic emission over the barrier and (thermionic) field emission through the barrier contrary to p-n junction-based devices, where transport mechanisms such as drift-diffusion and band-to-band tunneling (BTBT) will determine the current.

For an ideal unipolar Schottky type operation, the band bending at the MS interface is such that, for example, in an n-type semiconductor, the intrinsic Fermi level E_{Fi} lies below the Fermi level E_F which means that $\phi_B \leq u_T \cdot \ln(N_C/n_i)$. Here N_C represents the conduction band effective density of states, n_i is the intrinsic carrier concentration, and u_T is the thermal voltage ($= kT/q$, where k is the Boltzmann constant and T is the temperature). Excessive band bending at the MS interface on the other hand may result in an electrostatically doped p-n junction type operation as discussed in Sect. 11.2.2.

Therefore, for a unipolar Schottky type operation at the MS interface ($x = 0$) holds that

$$(E_C - E_F)|_{x=0} = q\phi_B \leq kT \cdot \ln\left(\frac{N_C}{n_i}\right) \tag{11.1}$$

for an n-type semiconductor, and

$$(E_F - E_V)|_{x=0} = q\phi_B \leq kT \cdot \ln\left(\frac{N_V}{n_i}\right) \tag{11.2}$$

for a p-type semiconductor. E_C and E_V are the conduction and valence band edges, respectively, and N_V represents the valence band effective density of states. The terms $kT{\cdot}\ln(N_C/n_i)$ and $kT{\cdot}\ln(N_V/n_i)$ are approximately equal to $E_G/2$ for most semiconductor materials.

Next, several examples of SB devices are discussed which could be interesting for future CMOS but also for electro-optical devices.

Schottky Barrier (SB) MOSFETs

In 1966 Nishi [44] first proposed to replace chemically doped source/drain regions in conventional MOSFETs with metal. In 1968 Lepselter and Sze [19] reported for the first time the realization of an Si p-type MOSFET (pMOS), in which the source/drain regions were formed by platinum-silicide (PtSi). Thereafter, a series of developments resulted in the metal source/drain region SB-MOSFET technology (Fig. 11.2a) where basically chemically doped source/drain regions in conventional MOSFETs have been replaced with metal, typically silicide.

During the SB-MOSFET operation, charge carriers are injected from the metal into the semiconductor channel through

thermionic(-field) emission as in a Schottky diode. However, in the former, the gate potential can be used to tune the effective barrier height and width further, as illustrated in Fig. 11.3a, b. SB-MOSFET technology potentially offers several benefits for sub-30-nm scaling, such as a low parasitic source/drain resistance, sharp junctions (needed for down-scaling), better control over the off-state leakage current, suppressed parasitic bipolar action, and that along with low thermal budget processing [20]. Further, as required for CMOS technology, SB-PMOS and SB-NMOS devices can be realized by adopting mid-gap silicides. In addition, SB-FINFETs were realized featuring a 6 mV/dec subthreshold swing at room temperature [46]. The SB-MOSFET concept has also been widely adopted in CNTs [35, 36, 47] partly because chemical doping is not straightforward there. For an elaborate review on SB-MOSFET technology, refer to [20].

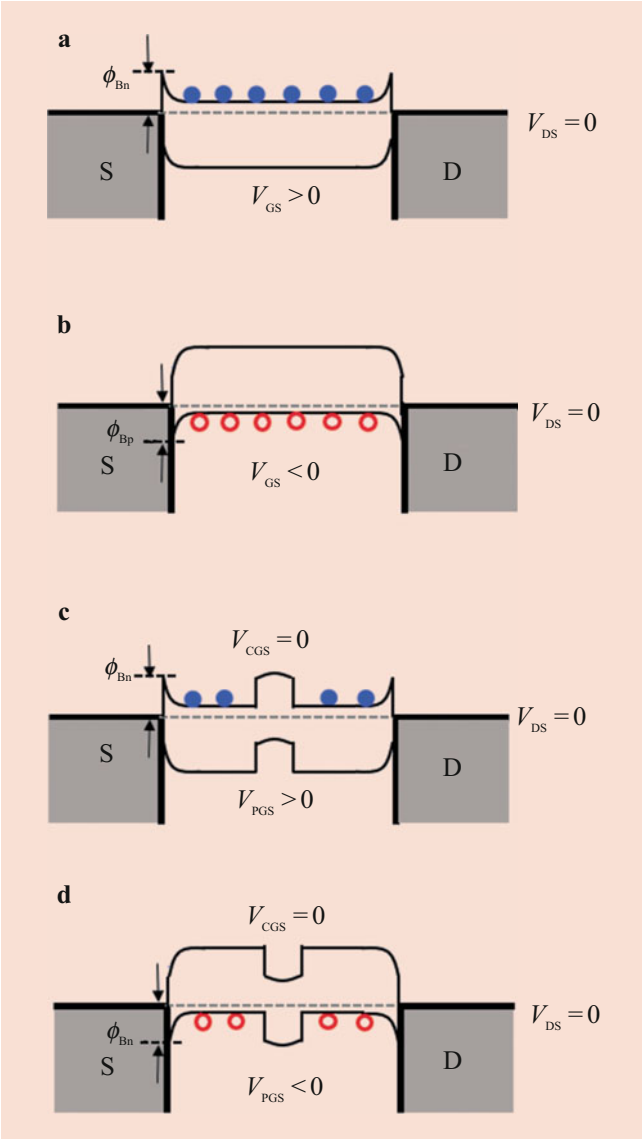

Fig. 11.3 The schematic energy band diagram of an Si-based SB-MOSFET [20] (Fig. 11.2a) for (**a**) n-type operation ($V_{GS} > 0$ V) and (**b**) p-type operation ($V_{GS} < 0$ V). Also, the schematic energy band diagram of an Si Nanowire-based reconfigurable SB-MOSFET [27] (Fig. 11.2c) for (**c**) n-type operation ($V_{PGS} > 0$ V) and (**d**) p-type operation ($V_{PGS} < 0$ V). V_{PGS} and V_{CGS} denote the polarity gate and control gate bias, respectively. An electron channel is formed for a positive $V_{(P)GS}$, while a hole channel is formed for a negative $V_{(P)GS}$. The V_{CGS} controls the current through the channel. Filled circles represent electrons; open circles represent holes

Reconfigurable SB-MOSFETs

Typically, the $I_D - V_{GS}$ (drain current – gate-source voltage) characteristics in symmetric SB-MOSFETs reach relatively high currents for both negative and positive V_{GS}. This effect, the so-called ambipolar effect, is caused by a gate modulated SB junction tunneling current. It is obviously not desirable, and therefore it should be suppressed.

There are several ways to suppress this ambipolarity. For example, Fig. 11.2b shows a device schematic of a nanowire (NW) SB MOSFET that exhibited ambipolar characteristics [45] with a symmetric SB source and drain. Its ambipolarity was successfully suppressed by the introduction of an additional terminal, referred to as the polarity gate (Fig. 11.2c, d).

Interestingly, however, this additional terminal also offers a new degree of freedom in the device. The device can be operated both as an n-type and a p-type MOSFET by modulating this polarity gate: a reconfigurable FET operation is obtained in which the polarity of conduction can be controlled [25–27, 48]. Basically, in these reconfigurable, or polarity controlled, devices, the conduction through the channel is controlled by a so-called control gate, while the other gate (i.e., polarity gate) controls the polarity of conduction; see Fig. 11.3c, d.

SB Electro-optical Devices

Misewich et al. [49] demonstrated polarized infrared light emission from a CNT SB-MOSFET structure as illustrated in Fig. 11.4a. The simultaneous injection of electrons and holes at the source and drain Schottky barrier junctions resulted in radiative recombination and thus light emission. The gate electrode was biased such that $V_{GS} > 0$ but $V_{GS} < V_{DS}$. In this way band bending was formed in the opposite direction at source and drain electrodes which facilitated simultaneous injection of electrons and holes at those source and drain electrodes, respectively, via narrow tunneling barriers, as shown in Fig. 11.4b.

SB contacts have also been utilized to collect photo-generated carriers in solar cells [50]. SB-based solar cells are interesting as they can be realized using only a single type (n or p type) of chemical doping unlike conventional p-i-n type cells which require both a p-type and n-type region to function. Other than in conventional Si-based material, the SB-based solar cell has also been demonstrated in CNTs [51], cadmium sulfide (CdS) [52], and molybdenum disulfide

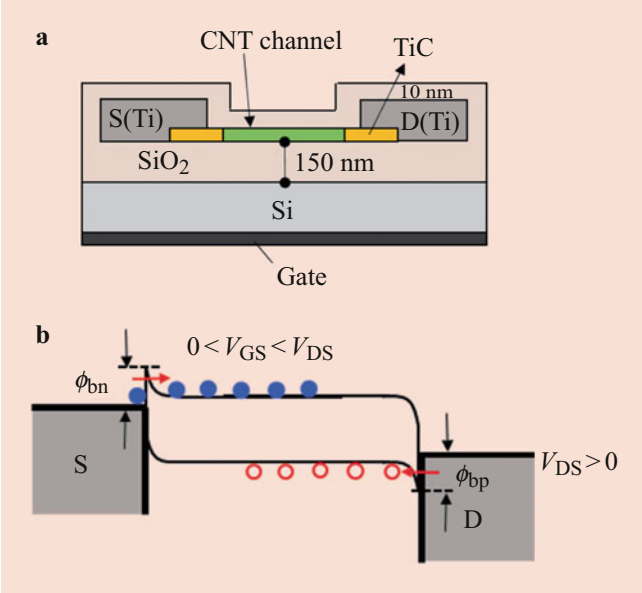

Fig. 11.4 CNT SB light emitting FET, schematic of (**a**) device cross section (**b**) energy band diagram. Electrons are injected in the CNT channel at the source electrode, while holes are injected from the drain electrode into the channel [49]

(MoS_2) [53]. In addition, an SB-based solar cell has been demonstrated in the GaInN/GaN material system without any p-type doping [54, 55].

The actual SBH for electrons (ϕ_{Bn}) and for holes (ϕ_{Bp}) at the MS junction is determined by the choice of the electrode metal. For conventional SB-FETs, unipolar operation ($\phi_{Bn} \neq \phi_{Bp}$) is desirable, while for polarity controlled SB-MOSFETs and light emitting devices [49], for instance, ambipolar operation ($\phi_{Bn} \approx \phi_{Bp}$) is interesting to adopt. Importantly, for the devices described so far, the SBH limits the current.

11.2.2 Workfunction-Induced Doping

The Nobel laureates Brattain and Bardeen [56] first reported bipolar-like current amplification in a Schottky point-contact transistor realized in n-type bulk germanium (Ge). It is believed that this amplification was attributed to a thin layer of p-type conductivity induced near the surface of the Ge via the Schottky point-contact. The formation of that layer could be explained as workfunction-induced doping or metal-induced doping.

Some years later, Bradley [57] proposed the surface-barrier transistor in which a p-type inversion layer was formed by metal-induced doping via both the emitter and collector electrode, while an ohmic contact was formed with the base electrode. This non-planar transistor was realized [58] in uniform n-type Ge without any chemically doped p-n junctions. Functional circuits with such transistors were realized as well [59]. Since then there have not been many reports specifically on this surface-barrier transistor.

However, later on many reports actually followed Brattain and Bardeen's "scaled point-contact transistor" concept as discussed further in this section.

In this section the basic theory of workfunction-induced doping in one dimensional (1-D) Schottky contacts is discussed. Thereafter, the electrostatics of 2-D gated Schottky contacts is discussed, which is important for future CMOS devices such as electrostatically doped TFETs.

1-D Schottky-Based Devices

Similar to the formation of a gate-induced inversion layer in MOSFETs, excessive band bending near the MS interface could ultimately also result in strong inversion, as illustrated in Fig. 11.1b. Such an MS junction will then show a bipolar-type conduction behavior different from the otherwise traditionally formed unipolar Schottky diode, which could be interesting for, e.g., tunnel devices.

As in a MOS capacitor [1], the onset of strong inversion can be defined when the inversion charge density equals the background doping concentration (i.e., donor concentration N_D for n-type and acceptor concentration N_A for p-type) of the semiconductor. From this definition the conditions for its occurrence can be derived.

In case of an n-type semiconductor, shown in Fig. 11.1b, strong inversion at the interface occurs when E_F lies below the E_{Fi} with an energy difference equal to $q\psi_{BI} \geq q\psi_B$, where $q\psi_B = kT \cdot \ln(N_D/n_i)$. The last term is governed by the relative position of E_F from E_{Fi} in the bulk region as defined by the background doping. This results in an SBH at the interface of $\phi_B \geq u_T \cdot \ln(N_C/n_i) + \psi_B$. Consequently, for strong inversion and thus more effective bipolar-type behavior, the following conditions hold.

For the SBH in an n-type semiconductor

$$\phi_B = (\phi_M - \chi_S)/q \geq u_T \cdot \ln\left(\frac{N_D}{n_i}\right) + u_T \cdot \ln\left(\frac{N_C}{n_i}\right), \quad (11.3)$$

and that in a p-type semiconductor

$$\phi_B = (E_G - \phi_M + \chi_S)/q \geq u_T \cdot \ln\left(\frac{N_A}{n_i}\right) + u_T \cdot \ln\left(\frac{N_V}{n_i}\right). \quad (11.4)$$

For the hole density at the MS interface in n-type semiconductors holds that

$$p = n_i \cdot \exp\left(-\frac{\psi_{BI}}{u_T}\right) = n_i \cdot \exp\left(\frac{\phi_B - E_G/2q}{u_T}\right)\sqrt{\frac{N_V}{N_C}}. \quad (11.5)$$

Likewise, for the electron concentration in p-type semiconductors

$$n = n_i \cdot \exp\left(\frac{\psi_{BI}}{u_T}\right) = n_i \cdot \exp\left(\frac{\phi_B - E_G/2q}{u_T}\right)\sqrt{\frac{N_C}{N_V}}. \quad (11.6)$$

For Eqs. (11.5) and (11.6) the semiclassical Boltzmann approximation has been used, assuming $n \ll N_C$ or $p \ll N_V$.

Hence, charge carriers of opposite polarity from the background doping can be induced near the interface of a 1-D Schottky contact provided that a suitable ϕ_M, that governs ϕ_B, is chosen. In this way an ultra-shallow p-n junction near the MS interface is formed where drift-diffusion, or possibly even band-to-band tunneling (BTBT), processes govern the current, which is different from conventional SB-based counterparts where ideally ϕ_B solely controls the charge carrier emission.

In case of an intrinsic semiconductor where $\psi_B = 0$, Eqs. (11.3) and (11.4) reduce to the following equations for p-type doping:

$$\phi_M \geq \chi_S + \frac{E_G}{2}, \quad (11.7)$$

and n-type doping:

$$\phi_M \leq \chi_S + \frac{E_G}{2}. \quad (11.8)$$

In other words, by adopting metals with a different workfunction from that of the semiconductor, it is possible to make an intrinsic semiconductor locally p-type or n-type. The position of the intrinsic Fermi level E_{Fi} is essentially described by the term $\chi_S + (E_G/2)$, i.e., the workfunction ϕ_S of the intrinsic semiconductor.

Earlier, Wittmer [60, 61] reported high barrier vertical Schottky diodes using silicided contacts on bulk n-type Si and analyzed their conduction mechanisms. Such a high ϕ_B, in case of iridium-silicide (IrSi) ~0.982 V, would result in inversion charge. Despite such high SBH, the author concluded that thermionic emission was the main mechanism for the current flow.

In [62] high barrier vertical Schottky diodes were realized by depositing aluminum (Al) on top of a p-type Si substrate with a bottom ohmic contact, for which the extracted SBH was $\phi_B = 0.77$ V. The basic idea was to experimentally verify whether the device characteristics show bipolar-type behavior instead of conventional unipolar characteristics. For this reason reference Schottky diodes were realized by depositing Al on top of an n-type Si substrate, offering a $\phi_B = 0.53$ V. The ϕ_B value of 0.77 V is not high enough for having an dominant bipolar-type behavior, but it was considered to be sufficient for the objective. Technology computer-aided design (TCAD) simulations predicted that when using thick substrates, the (minority) diffusion current and the thermionic emission current can reach equally high levels for higher ϕ_B. Moreover, the simulation results highlighted that the bipolar-type behavior hence diffusion becomes dominant for smaller dimensions, as would be the case in UTB devices, or at elevated temperatures [62]. It is therefore likely that the use of relatively thick substrates and moderate temperature range (200 K $\leq T \leq$ 300 K) in the experiments of Wittmer [60, 61] could have led to the conclusion that thermionic emission was the main mechanism.

In [62] the approach was different from that reported in [60, 61]. One of the methods to determine the bipolar effectiveness of the devices used in [62] was the so-called two-diode electrical test method [63,64]. This method makes it possible to distinguish the operation of a (Schottky-like) ultra-shallow p-n junction diode from that of a conventional Schottky diode. The experimental outcome of [62] indicated indeed that the minority carrier injection in the Al/p-Si diode is important unlike its low barrier counterpart. In addition, from the carefully designed hexagonal Schottky diodes, infrared electroluminescence experiments were carried out. The high barrier Schottky diode showed a faint glow of infrared light emission, while for its low barrier counterpart, this could not be observed, reconfirming that there is more minority charge in the former because of the higher electron emitter efficiency.

TCAD-based simulation studies have been reported before where such 1-D Schottky based p-n junctions were proposed to be utilized in a vertical Si bipolar junction transistor (BJT) structure [65] and in a gallium-arsenide (GaAs) tunnel diode [66]. For the latter, however, Fermi-Dirac statistics were applied, and therefore in principle Eqs. (11.5) and (11.6) do not hold. Nonetheless, this does not change the fact that for an effective bipolar-type behavior, a suitable ϕ_M is required.

Gated Schottky-Based Ultrathin-Body Devices

In this section, the ED concept is discussed for devices in which a dielectric layer is placed between the metal and a fully depleted (FD) semiconductor ultrathin-body [67]. In such a FD-UTB device, the depletion charge can be practically ignored. Note that for clarity sake, a long device structure is considered so that 1-D electrostatics can be used for the discussion.

Figure 11.5 shows a schematic cross section of such a gated Schottky-based FD-UTB device which is similar to an FD 2-D MOSFET. In such an FD-UTB device, assuming ideal interfaces, the potential drop in direction perpendicular to the gate electrode can be written as

$$V_{GB} = V_{ox} + \psi_s + \phi_M/q - \chi_S/q - (E_C - E_{Fi})/q \quad (11.9)$$

where V_{GB} is the applied potential difference between the gate and semiconductor body, V_{ox} is the potential drop across the oxide, and ψ_s is the surface potential, i.e., the Fermi-level shift from its intrinsic position.

Equation (11.9) can be simplified by considering not too high carrier concentrations ($n, p \ll N_C, N_V$), resulting in

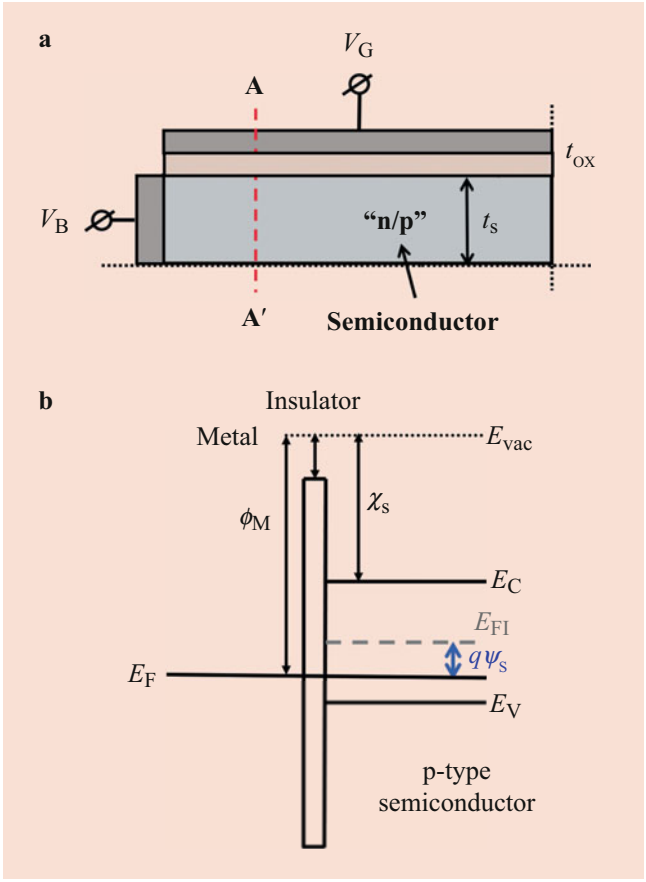

Fig. 11.5 (**a**) Schematic cross-section of a UTB device with a 2-D gated Schottky contact for workfunction or bias-induced electrostatic doping. (**b**) The energy band diagram of a p-type formed region perpendicular to the gate along the red dashed line

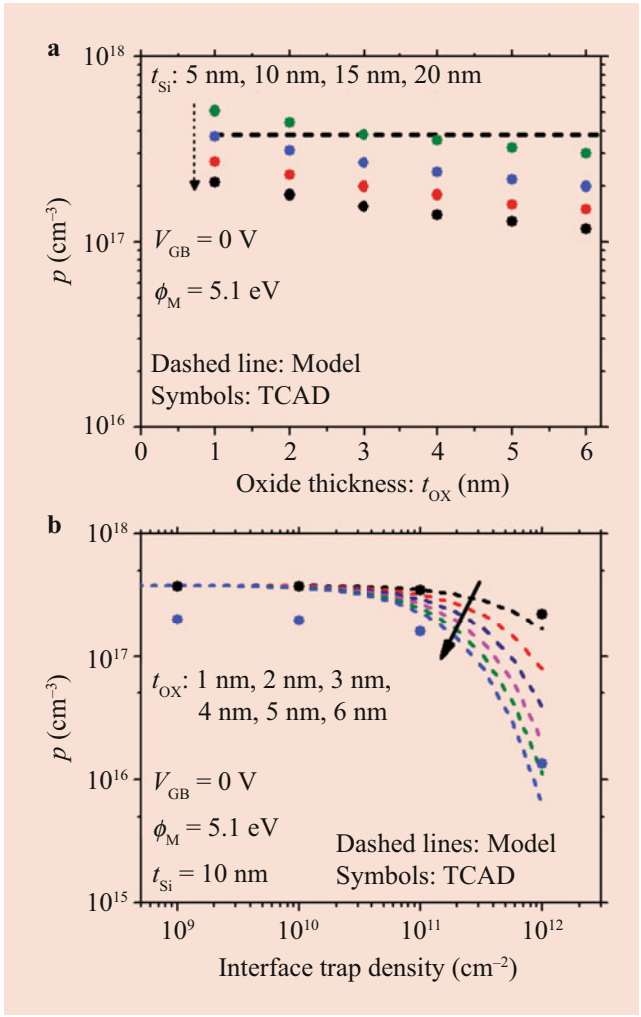

Fig. 11.6 Induced surface hole density for an Si/SiO_2 gated Schottky structure (see Fig. 11.5) with $\phi_M = 5.1$ eV as a function of the (**a**) oxide thickness with ideal interfaces and (**b**) the interface trap density [70]. A uniform distribution of both donor and acceptor traps across the bandgap [1] has been considered in the TCAD simulations [68], and the carrier density was extracted at a lateral distance of 0.5 µm from the Schottky sidewall contact

$V_{ox} \approx 0$ in an FD-UTB device, and by focussing on pure workfunction-induced doping which implies that $V_{GB} = 0$.

For this case it can be stated that

$$\psi_s = (E_{Fi} - E_F)/q = \chi_S/q - \phi_M/q - u_T \cdot \ln\left(\frac{n_i}{N_C}\right). \quad (11.10)$$

It is clear that Eq. (11.10) is the condition for workfunction-induced doping in a gated Schottky-based FD-UTB device which is equivalent to Eq. (11.7) for p-type doping ($\psi_s < 0$) and to Eq. (11.8) for n-type doping ($\psi_s > 0$). Similar to the p-n junction formation in a 1-D Schottky contact, the induced surface charge concentration can be expressed as

$$p = n_i \exp\left(\frac{-\psi_s}{u_T}\right), \quad (11.11)$$

for the hole density and for the electron density

$$n = n_i \exp\left(\frac{\psi_s}{u_T}\right). \quad (11.12)$$

In Fig. 11.6a the induced surface hole density against the oxide thickness is depicted for an Si/SiO_2 gated Schottky structure (Fig. 11.5) for $\phi_M = 5.1$ eV. According to Eq. (11.10) the induced hole density in FD-UTB devices does not depend on the insulator and semiconductor thicknesses as $V_{ox} \approx 0$ is assumed here. However, TCAD simulations [68] show different results, which can be attributed to a finite V_{ox} (~30 mV at $t_{ox} = 6$ nm and $t_S = 10$ nm) caused by a relatively high surface charge density. For studying physical trends, the model is still useful though. For obtaining more accurate results, a numerical model need to be derived [69], perhaps one that even includes quantum confinement in case of UTB layer thicknesses of less than the Broglie wavelength

(for Si this corresponds to ∼15 nm), which is not part of this discussion.

By including the effect of the interface trap charge (Q_{it}), Eq. (11.10) can be modified as

$$\psi_s = \chi_S/q - \phi_M/q - u_T \cdot \ln\left(\frac{n_i}{N_C}\right) + \left(\frac{Q_{it}}{C_{ox}}\right), \quad (11.13)$$

where $C_{ox} = \varepsilon_{ox}/t_{ox}$ is the areal oxide capacitance. In Eq. (11.13) a uniform interface trap density is assumed, i.e., $Q_{it} = -C_{it}\psi_s$, with $C_{it} = q^2 D_{it}$ represents the areal interface trap capacitance, and D_{it} is the interface trap density [1].

After rearranging Eq. (11.13), the following condition for the workfunction-induced doping that includes the effect of interface states is obtained:

$$\psi_s = \frac{\left(\chi_S/q - \phi_M/q - u_T \cdot \ln\left(\frac{n_i}{N_C}\right)\right) \cdot C_{ox}}{(C_{it} + C_{ox})}. \quad (11.14)$$

The condition for induced electrostatic doping in a gated Schottky device including interface trap charge is basically described by Eqs. (11.11), (11.12), and (11.14). Hence, the ED effect is adversely affected by a higher interface trap density, and therefore process control is essential. Figure 11.6b shows the induced charge concentration plotted against the interface trap density using Eq. (11.14). As can be seen, the interface traps affect the ED more strongly for a larger oxide thickness: the surface hole density is reduced by a maximum of two orders in magnitude when the trap density is increased to $10^{12}/cm^2$ for an oxide thickness of 6 nm.

Charge Plasma Devices

One example of a gated Schotty device is the so-called charge plasma (CP) p-n junction diode as proposed by Hueting et al. [21, 22], shown in Fig. 11.7. The CP diode comprises a gated anode and a gated cathode with metals of a different (preferably extreme) workfunction ϕ_M. Both the anode and cathode also form sidewall contacts with the intrinsic or (unintentionally) doped semiconductor body. The basic idea is by introducing two different workfunction metals; a bipolar-type behavior in the semiconductor body can be obtained, as in a conventional (chemically doped) p-n junction. Depending on the values of the workfunctions, the rectification (or "effectiveness" of the bipolar-type behavior) of the CP diode can be improved. During operation the device is in abundance of charge carriers, hence the name "charge plasma".

For obtaining a relatively high rectification according to Eqs. (11.11) and (11.14) for the anode region, a high ϕ_M is required, while the opposite holds for the cathode region.

At a first glance, the energy band diagram of a CP diode along the lateral direction depicted in Fig. 11.7, obtained from 2-D TCAD simulations, is similar to that of a conventional p-n junction. However, there are some key

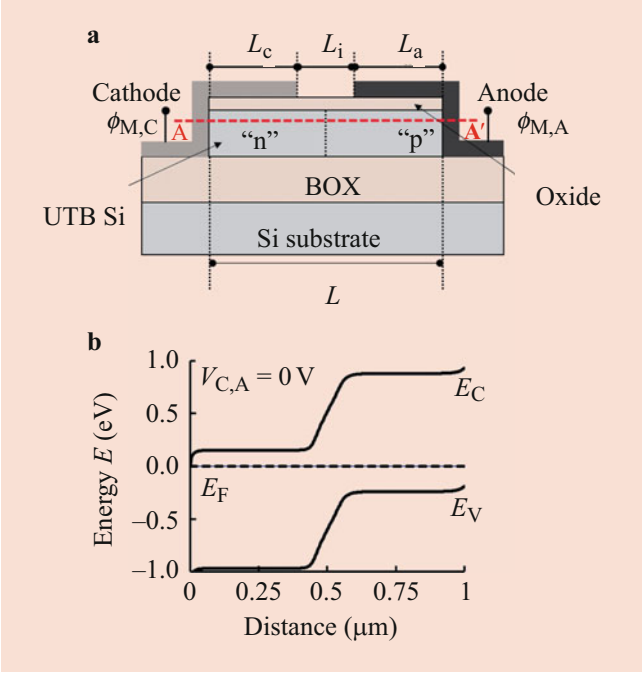

Fig. 11.7 (**a**) Schematic cross section of the CP p-n diode and (**b**) its energy band diagram along the dotted red line at equilibrium. $\phi_{M,C}$ = 4.17 eV and $\phi_{M,A}$ = 5.1 eV are cathode and anode metal workfunctions, respectively. L_c and L_a denote cathode and anode gate lengths, respectively. L_i denotes the length of the intrinsic region, i.e., the gap between the two electrodes. The thickness of UTB Si (t_{Si}) is 20 nm, and gate oxide thickness (t_{ox}) is 5 nm [21]

differences [34]. One difference is that the quasi-neutral regions of the CP diode are formed by the gates, unlike in a conventional p-n junction where the donor and acceptor ions form the space charge region. In addition, the lateral configuration shows a linear potential distribution in the intrinsic gap region because of the absence of impurities, instead of a parabolic potential profile in the conventional counterpart. For the latter the built-in electric field is formed by fixed donor or acceptor ions near the junction to balance drift and diffusion components at equilibrium. There is also a built-in field in the CP diode, but that is primarily formed by the workfunction difference at the edges of the gated regions. The band bending at the sidewall contacts is attributed to the 2-D fringe field-effect. Note that analytically derived $I-V$ models for the CP diode, based on drift-diffusion, also reproduced the $I-V$ characteristics of the CP diode obtained from TCAD simulations [71].

For the realization of the CP diode [22], palladium (Pd) was adopted for the anode electrode and erbium (Er) for the cathode. Good rectifying behavior was obtained, showing an on/off-current ratio of $\sim 10^7$ (on-current taken at $V_D = 1$ V forward bias) and room temperature, combined with a low leakage current of 1 fA/μm. Figure 11.8a shows experimental $I-V$ characteristics of various fabricated CP diodes with different anode/cathode metal combinations. From the ex-

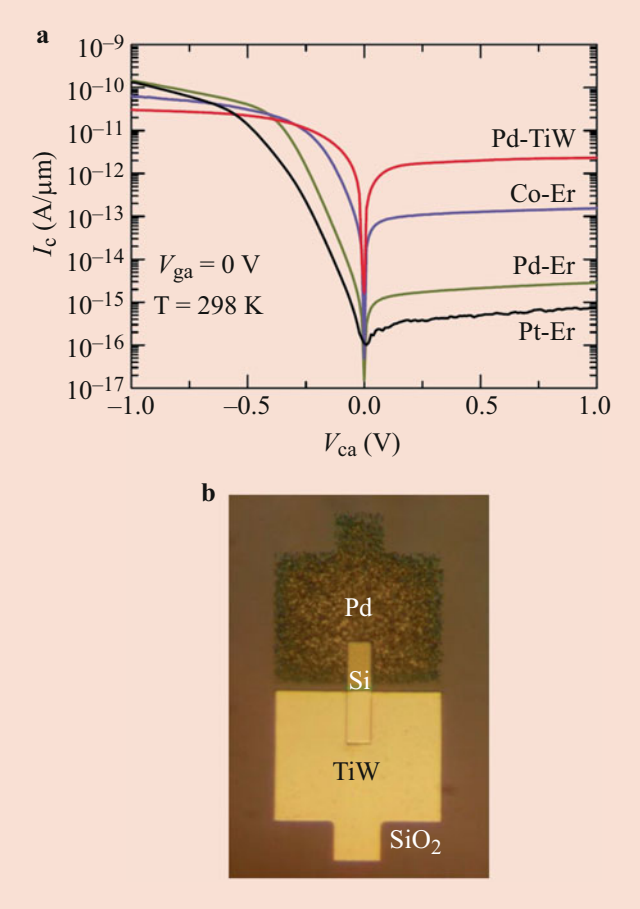

Fig. 11.8 (**a**) $I_c - V_{ca}$ characteristics for various valence and conduction level metal combinations Pt−Er, Pd−Er, Co−Er, and Pd−TiW on either side of silicon. $L_a = L_c = 0.9\,\mu m$, $L_i = 3\,\mu m$ (see Fig. 11.7). The substrate potential (V_{ga}) was kept at 0 V. (**b**) Top view of a realized CP diode showing the effect of placing a wafer with high workfunction (Pd) and low workfunction (TiW) metal islands in a chemical etching solution. The combination of the metals with the solution formed an electrolyte cell which resulted in the corrosion of highest workfunction (Pd) metal [22]

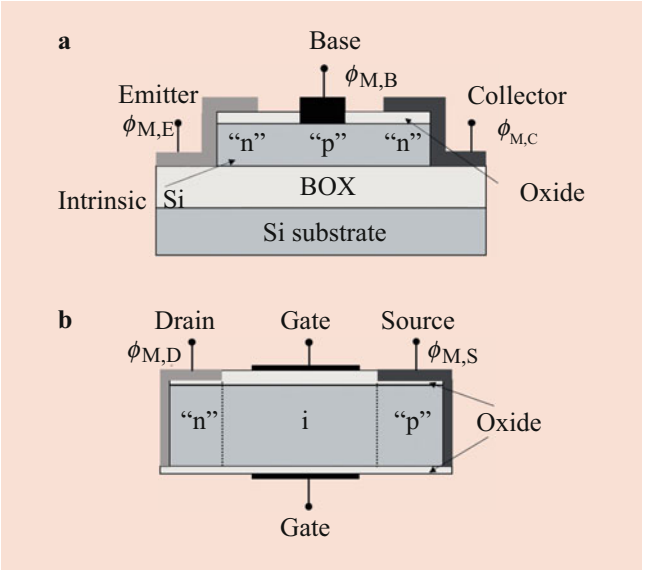

Fig. 11.9 Schematic cross section of the CP based (**a**) Lateral BJT [23], (**b**) TFET [24]. The "n" and "p" indicate electrostatically doped regions

perimental observations, it can be concluded that the hole and electron current are equally important for the CP diode: the total current increases when the anode workfunction is reduced by replacing platinum (Pt) with Pd or cobalt (Co), or conversely, the cathode workfunction is increased by replacing Er with titanium-tungsten (TiW). In the same experimental work [22], MOSFET characteristics were obtained with a symmetric gated anode/cathode electrode structure where the substrate was used as a back gate.

The charge plasma concept has been extended to other types of devices. Kumar and Nadda [23] proposed and investigated the charge plasma-based lateral bipolar junction transistor (BJT) incorporating electrostatically doped regions in the emitter, base, and collector regions of a conventional BJT using metals with different workfunctions, as shown in Fig. 11.9a. The authors proposed to use hafnium (Hf) ($\phi_{M,E} = 3.9\,eV$) for the emitter, Pt ($\phi_{M,B} = 5.65\,eV$) for the base, and Al ($\phi_{M,C} = 4.28\,eV$) for the collector electrode, resulting in an n^+-p-n configuration. This 2-D TCAD simulation study shows device characteristics similar to that of the conventional chemically doped counterpart but with improved current gain.

Another, high potential, charge plasma-based device is the doping-less TFET, proposed by Kumar and Janardhanan [24]; see Fig. 11.9b. Similar to the CP-BJT, in this TFET electrostatically doped regions were incorporated by employing metals with a different workfunction: Hf for the n-type drain and Pt for the p-type source. The performance of this charge plasma-based TFET was found to be similar to the conventionally doped TFET with the same device geometry.

Unfortunately, so far most of these charge plasma-based architectures have not been experimentally verified. Table 11.1 summarizes other proposed charge plasma devices reported in the literature. Interestingly, similar ideas for electrostatically doped graphene via metal electrodes have also been reported [30–33, 72–74].

11.2.3 Bias-Induced Doping

For the electrostatics at the MS interface, hence the charge in the UTB, the externally applied electric field is also important. Even though this appears to be similar to the conventional field-effect, one important different aspect should be taken under consideration. In conventional FETs the charge carriers originate from (chemically) doped semiconductor regions (i.e., source/drain regions) in close vicinity of a chan-

nel, whereas in case of the electrostatically doped concept, the charge carriers originate from metal electrodes directly contacting the semiconductor body. These metal electrodes are not necessarily forming a gate, but they are important as a source of charge carriers. Refer to the gate region shown in Fig. 11.5. For this type of ED, i.e., the bias-induced doping, similar conditions apply compared to the workfunction-induced doping (Eq. 11.10), though a non-zero V_{GB} term should be accounted for

$$\psi_s = V_{GB} + \chi_S/q - \phi_M/q - u_T \cdot \ln\left(\frac{n_i}{N_C}\right). \tag{11.15}$$

Using a non-zero V_{ox} term in Eq. (11.9), similar relations can be obtained for a bulk or partially depleted semiconductor device. The workfunction difference $(\phi_M - \phi_S)/q$ actually corresponds to the term $(\chi_S/q - \phi_M/q - u_T \cdot \ln(n_i/N_C))$, which is zero for a purely bias-induced doping. In this case it is clear that a positive V_{GB} will induce n-type doping, while a negative V_{GB} will induce p-type doping. Furthermore, the effect of interface traps can be included as well

$$\psi_s = V_{GB} + \chi_S/q - \phi_M/q - u_T \cdot \ln\left(\frac{n_i}{N_C}\right) + \left(\frac{Q_{it} + Q_{inv}}{C_{ox}}\right), \tag{11.16}$$

where Q_{inv} is the areal mobile inversion charge. Again, it can be concluded that the interface traps affect the ED effect: both the gate and interface traps control the mobile charge. Note that earlier modeling work on I–V characteristics of asymmetric double-gate (DG) devices [69] could be used for modeling bias-induced doping including interface traps.

Importantly, for devices based on bias-induced doping, side metal contacts with a midgap (or solely p- or n-type) workfunction or doped regions are needed for a successful operation. Alternatively, the charge carriers could also be supplied via thermal generation but that will only work for narrow bandgap semiconductors ($\lesssim$1 eV).

For a simultaneous formation of p-type and n-type charged regions in a semiconductor body via an externally applied field, a double (or multiple) gate UTB device could be employed. By biasing two gates with opposite polarities, electrons and holes can be simultaneously generated in a semiconductor body as expressed by Eqs. (11.15) and (11.16). The relative position of those gates will then play an important role [34,39], as discussed in the next section.

Lateral p-n Junction

For the first time, bias-induced electrostatic doping was experimentally demonstrated in a CNT system [34] where a lateral p-n junction diode was formed adopting a split gate configuration as shown in Fig. 11.10. An n-type doping of the CNT channel region adjacent to the first gate electrode was obtained by biasing this electrode with a positive voltage with respect to the CNT body. Similarly, a negative voltage with respect to the CNT body at a second gate resulted in a p-type doping. As a result, an electrostatically doped lateral p-n junction diode was formed in the CNT channel. The fabricated device showed rectifying characteristics with an ideality factor close to one. In addition, biasing both gate electrodes with the same polarity resulted in either an n-channel or a p-channel FET. BTBT was also observed in CNTs [75] basically demonstrating an electrostatically doped p-n junction tunnel diode, which laid the foundation for the CNT-TFET.

Also experiments have been reported showing the strong potential of bias-induced doping in an advanced and mature FD-SOI process [28,29] that also includes a unique back gate feature. The authors demonstrated for the first time that their reconfigurable device can be transformed into multiple (i.e.,

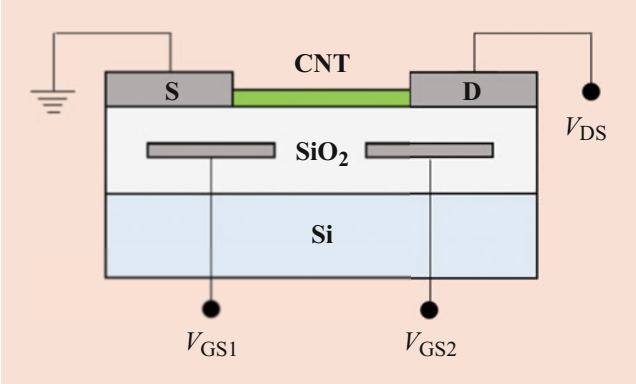

Fig. 11.10 Schematic cross section of the CNT p-n diode [34]. The split gate configuration was used to electrostatically induce a lateral p-n junction. Biasing $V_{GS1} < 0$ would give a p-type region in the adjacent CNT channel, and $V_{GS2} > 0$ would result in an n-type region

nine) types of devices with different functionalities, such as virtual diodes, TFETs, p-i-n diodes, and band-modulation FETs. Their device structure had a five terminal configuration, among which two back gates and a single (front) gate. The authors even went further: they experimentally demonstrated an electrostatically doped Esaki diode at low temperatures ($T = 77$ K) in the same FD-SOI process [76]. As stated earlier (though with a focus on FETs) [77], the authors emphasized that their work could open a new route toward reconfigurable circuits, but they also highlighted that this feature could be interesting for device or layer characterization.

Vertical p-n Junction: Electron-Hole Bilayer (EHB)

Another type of a potentially attractive device configuration is the bias-induced electron-hole bilayer (EHB) formed by two vertically faced gates with an opposite bias polarity, as illustrated in Fig. 11.11. As a first demonstration, a double-gate (DG) SiO_2/Si/SiO_2 structure with a 22 nm thick silicon layer was realized [78, 79].

This structure is interesting for, e.g., tunnel FETs [39, 40] but in some semiconductor material systems for light-emitting devices as well [80], though there are different requirements. For example, in tunnel FETs a relatively narrow overlap between an ultra-high electron and hole density profile in the semiconductor body is required that should be strongly controlled by the gate. For light-emitting devices on the other hand, a relatively wide overlap between moderately to high electron and hole density profiles is needed.

The performance of the EHB concept strongly depends on the thickness of the semiconductor body. For example, for a relatively thick semiconductor with a partially depleted channel, there is no electrostatic coupling between the metal gates, and therefore at both sides of the body, the bias-induced charge near each gate can be described with Eq. (11.15) (for $n, p \ll N_c, N_v$). For an FD-UTB configuration with a double

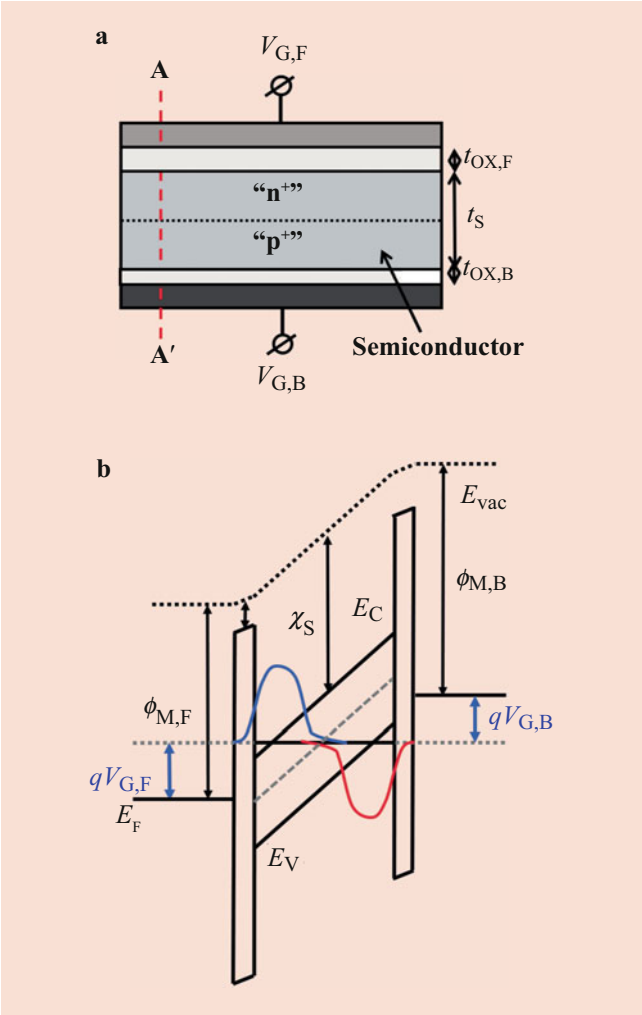

Fig. 11.11 (**a**) A schematic cross section of the electron-hole bilayer (EHB) concept. (**b**) The energy band diagram perpendicular to the gates along the red dashed line indicated in the left figure. By enforcing a bias with an opposite polarity between the top and bottom gate, a tunnel junction can be formed. The wave function curves represent the electron (**a**) and hole (**b**) distribution in the EHB structure for illustration purposes

asymmetric gate structure however, the electrostatic coupling between the gates needs to be taken care of. Following the early work of Lim and Fossum [81] and assuming a not too high charge carrier concentration, for a coupled EHB double gate structure, the following relation for the vertical electric field in the semiconductor body can be derived:

$$\mathcal{E}_s = \frac{(V_{G,F} - V_{G,B}) - (\phi_{M,F} - \phi_{M,B})}{\frac{\varepsilon_S}{\varepsilon_{ox}}(t_{ox,F} + t_{ox,B}) + t_S}, \tag{11.17}$$

and for the surface potentials at both interfaces

$$\psi_{s,F/B} = V_{G,F/B} \mp \frac{\varepsilon_S \mathcal{E}_s}{C_{ox,F/B}} - \Delta\phi_{M,F/B}, \tag{11.18}$$

where the subscripts F and B refer to the front and back of the structure, respectively. $\Delta\phi_{M,F/B}$ is the gate-body workfunction difference, and $C_{ox,F/B}$ is the areal oxide capacitance; t_{ox} and t_S are the oxide and semiconductor thickness, respectively. In Fig. 11.12a $\mathcal{E}_s$ is plotted as a function of the semiconductor body thickness t_S for an $HfO_2/Si/HfO_2$ EHB structure, also showing that Eq. (11.17) is in good agreement with the TCAD simulations [68]. Semi-classically, $\psi_{s,F} > 0$ results in an induced electron channel at the front gate electrode with density $n = n_i \exp(\psi_{s,F}/u_T)$ (refer to Eq. (11.12)). Similarly, if $\psi_{s,B} < 0$ a hole density near the back gate electrode at the interface is formed according to $p = n_i \exp(-\psi_{s,B}/u_T)$. It is however rather difficult to obtain closed form solutions for $\psi_{s,F}$ and $\psi_{s,B}$. Moreover, quantum effects should also be included as this will change this picture [82] as qualitatively shown in Fig. 11.12b using TCAD simulation. The effect of fixed or interface charge can also be included which obviously counteracts the ED effect [70].

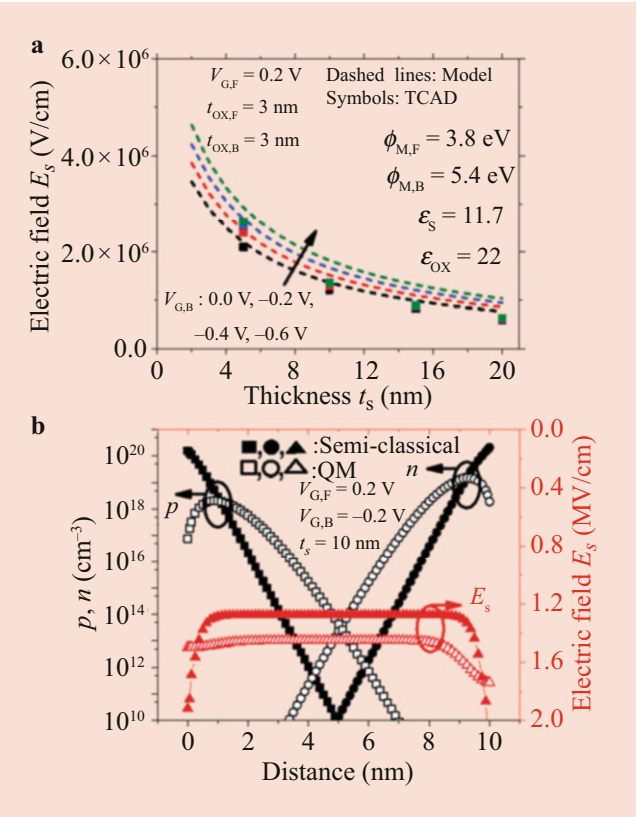

Fig. 11.12 (**a**) The vertical electric field in the $HfO_2/Si/HfO_2$ EHB structure (refer to Fig. 11.11) for various semiconductor body thicknesses. Quantum mechanical (QM) effects have not been taken into account both in the model (Eq. 11.17) and TCAD simulation [68]. (**b**) TCAD simulation of charge carrier distribution and electric field profile in the vertical direction along the red dashed line of Fig. 11.11 with $t_s = 10$ nm and $V_{G,F} = 0.2$ V and $V_{G,B} = -0.2$ V. TCAD simulation of the induced electron and hole bilayer at vertically opposite interfaces of a dual gate structure is shown using both semi-classical (using Poisson only) and QM (density-gradient model [83]) approaches. The detailed quantitative calibration of the QM model in TCAD was not the focus of this work

Lattanzio et al. [39,40] proposed a DG TFET based on the EHB concept and adopted TCAD simulations to investigate the device behavior. They reported the formation of a vertical EH bilayer in the UTB device by asymmetrically biasing the opposite gates. Eventually for a specific front-back gate bias difference (~0.1 to 0.5 V), the drain current was shown to increase via the BTBT mechanism of charge carriers in the EHB p-n junction [82]. In this case the direction of tunneling is parallel to the gate field, i.e., line tunneling [85]. Because of the relatively large tunneling surface area and a stronger electrostatic control over both n-type and p-type regions in the subthreshold region, this results in a higher on-state tunneling current compared to, e.g., the doping-less TFET [24]. The effectiveness of such an EHB formation however has been debated [41, 86]. Experimentally realized EHB-TFET structures have been reported [41] for which the trade-off between the applied field (or electrostatic doping) and quantum confinement was discussed. According to this work, the condition to have both an efficient BTBT and the formation of the EHB cannot be simultaneously satisfied.

However, so far only a single semiconductor layer in the UTB region of the EHB-TFET has been considered. This ED-quantum-confinement trade-off could be broken, for example, by employing heterostructures in the UTB region in which a broken gap in the energy band diagram has been formed. Elaborate TCAD simulations on InAs/GaSb EHB-TFETs [87, 88] have shown that in fact due to quantum confinement the broken gap at the InAs/GaSb interface closes, i.e., becomes staggered, improving the BTBT behavior which results in extreme steep-subthreshold slopes.

11.3 Electrostatic Doping Approaches: Discussion

Table 11.1 summarizes and classifies various electrostatically doped device concepts. Based on this literature survey, it can be concluded that a high carrier density of both p- and n-type (~10^{18} – 10^{20} cm^{-3}) can be formed by ED in nanometer-scale (i.e., UTB) devices, particularly for narrow bandgap semiconductors. Figure 11.13 shows the induced charge carrier concentration using Eqs. (11.10), (11.11), and (11.12) for gated Schottky regions in the CP-UTB device (refer to Fig. 11.5) for various semiconductor materials. Note that an experimental effective charge carrier density of ~10^{19} cm^{-3} in electrostatically doped Si nanowire devices has been reported [77].

For most semiconductor materials, a high electron density in their UTB can be obtained relatively easy, by adopting a suitable workfunction for the gate electrode such that

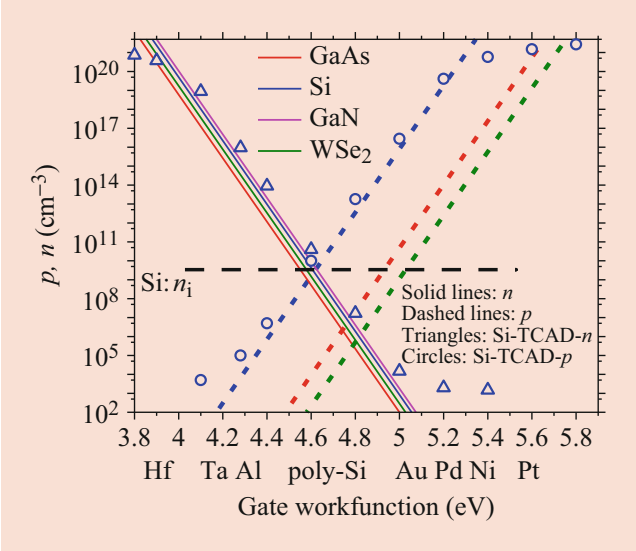

Fig. 11.13 Calculated induced carrier concentration (Eq. (11.10)) in "n" and "p" type gated Schottky regions of the CP diode structure (refer to Fig. 11.7) with a varying workfunction of the gate electrode. The calculation is performed for different semiconductor channel materials (Si ($E_g = 1.12$ eV, $\chi_s = 4.07$ eV), GaAs ($E_g = 1.42$ eV, $\chi_s = 4.07$ eV), GaN ($E_g = 3.39$ eV, $\chi_s = 4.1$ eV), WSe_2 ($E_g = 1.56$ eV, $\chi_s = 4.03$ eV) [84]) in the UTB device. TCAD simulation (symbols) for Si shows good agreement with the model. In both the model and TCAD simulations, ideal interfaces have been assumed

Eq. (11.8) is fulfilled. For electrons the electrostatic doping is governed by the electron affinity of the semiconductor body and the metal workfunction, and in practice there are many conventional metals or pure metal elements available to fulfill this [1, 43, 104]. The range of workfunctions of pure metal elements varies roughly between 2.14 eV Cesium (Cs) and 5.65 eV for Platinum (Pt).

However, to obtain a high hole density in UTB devices is for some, particularly wide bandgap, semiconductor materials more difficult. This can be attributed to the fact that the semiconductor bandgap plays an important role here; see Eq. (11.7). For obtaining a sufficiently high hole density metals with workfunctions, above 5.65 eV are needed, and those do not exist in the form of a pure elemental metal. Alternatively, other materials than traditional metals could be employed for this.

MoO_x has been reported [105, 106] to be a semiconductor with a wide bandgap (~3.3 eV). However, because of possible internal oxygen vacancies, which could arise in case of evaporated films ($x < 3$), defect band formation occurs near its conduction band which imparts it high conductivity. Provided that a layer thicknesses of less than 20 nm is used, MoO_x can be considered as a metal with a workfunction varying between ~5.5 to 6.6 eV [107]. This material has been applied for Si solar cells [105, 106] as a "hole selective" layer but could possibly be implemented with other semiconductor materials as well.

There have been reports in using MoO_x for transistors as well. Other than the mostly reported n-type MoS_2 device [102], recently a p-type MoS_2 transistor [103] was demonstrated with an I_{on}/I_{off} ratio of 10^4 employing a Schottky contact with a high workfunction MoO_x for efficient hole injection.

Either way, for this kind of alternative materials, more research is needed.

In the following the potential of electrostatic doping for future CMOS is discussed and compared with chemical doping. This also includes the possible drawbacks that go along with it.

11.3.1 Potential ED Devices for Future CMOS

Out of many various electrostatically doped devices that have been reported so far, there are three types that appear to be the most promising for future CMOS: (1) the SB-MOSFET, (2) the reconfigurable FET, and (3) the TFET.

In this category, so far the SB-MOSFET has been the most experimentally investigated device. A detailed review has been reported [20] that elaborated on the competitiveness of this device concept for ultimately scaled CMOS. The SB-MOSFET offers improved performance in terms of the off-current (I_{off}) and elimination of the parasitic bipolar action, in addition to its technology benefits in terms of scalability to sub-30-nm gate lengths and lower temperature processing along with less lithography steps. The low parasitic source/drain resistance (that represents ~1% of its total resistance) of the SB-MOSFET also makes it attractive for high-speed analog applications. The incorporation of metal source/drain regions in UTB SB-MOSFETs helps in reducing the parasitics, and it is claimed [108] that for relatively low SBHs, those devices get better performance than conventional MOSFETs. In addition, the SB-MOSFET concept has been experimentally demonstrated in alternative materials like CNTs but also in different geometries such as nanowires and FinFETs. Albeit that the SBH in the SB-PMOS and NMOS devices needs to be further optimized from view point of improved I_{on} and I_{off} to become CMOS competitive. Barrier height lowering techniques such as the implementation of a thin interfacial layer are being explored but are challenging from process integration view point [20].

Because of its tunable functionality, the reconfigurable nanowire FET (RFET) [26, 77] is also conceptually attractive for future CMOS. The performance of various RFETs has been experimentally demonstrated, and their operation in logic circuit applications has been evaluated in [77]. In addition to the polarity control, for low-power CMOS, it is important to have a symmetric transfer characteristic for both n-type and p-type FET operation. This could be obtained by fine-tuning the metal workfunctions in the devices. The I_{off} in the RFET can be suppressed by its extra gate, i.e., the control

gate [26], which is especially important for narrow bandgap channel materials for which high leakage currents form a big concern.

In their RFET-based CMOS inverter, the same authors [77] extracted a propagation delay of 35 ps at $V_{DD} = 5\,V$ which could be further optimized. They also demonstrated a reconfigurable NAND/NOR logic operation with a lower amount of FETs than would have been required for the same functionality in conventional CMOS [77]. It is clear that the RFET concept is not only limited to nanowires. Provided an efficient electrostatic control, it can be adopted to any other low-dimensional (preferably CMOS compatible) material, such as FD-SOI [109]. However, in the high-level RFET-based CMOS circuitry managing, a large amount of programming gate signals could become too complex and hence could be a concern.

Generally, the TFET has been considered to be the potential candidate for future low-power CMOS switches [4, 5]. And particularly for this type of device, doping control is the key. ED therefore offers an potential solution. Although mainly based on TCAD simulation studies, novel electrostatically doped TFET concepts such as the CP-TFET [24] and the EHB-TFET [110] have been reported to be competitive to conventionally doped counterparts, and those could therefore be interesting for future CMOS. For example, Lattanzio et al. [110] concluded from their calculations that Ge-based EHB-TFETs outperform doped DG-TFETs in terms of intrinsic delay. They estimated that the intrinsic delay for a single EHB device was less than 1 ns at $V_{DD} = 0.25\,V$ with a theoretically maximum operating frequency of 1.39 GHz. Also, other types of EHB-TFETs, such as the InAs/GaSb EHB-TFET [87,88], have a high potential because of the predicted extreme subthreshold slopes. On the other hand, many technological challenges will then have to be overcome.

Cristoloveanu et al. [28, 29] demonstrated one essential feature of ED: tunable transformation of device functionality. For the first time they reported a reconfigurable TFET and even a band-modulation FET obtained from a single five terminal electron device realized in a mature FD-SOI process. If carefully optimized, such a reconfigurable TFET could open a new route toward low-power reconfigurable CMOS circuits, although, as stated before, such a reconfigurable circuit could eventually become too complex, especially when multiple back gates are used. The same research group also recently presented an overview about this work [111].

Other recently proposed electrostatically doped TFET designs [38,98] also offer distinct advantages. Ilatikhameneh et al. [38] proposed to enhance the field in a lateral electrostatically doped tunnel junction using low-κ dielectric spacers in between high-κ dielectrics in the gated regions. The device performance of such a dielectric engineered TFET (DE-TFET) is also less sensitive to the gate dimensions compared to previously discussed electrostatically doped TFETs [24, 84].

Pan and Chui [98] proposed to adopt a gate design in their electrostatically doped TFET structure that comprises two different metal workfunction electrodes which are physically and electrically shorted. They highlighted that, unlike in their proposed gate design, the minimal tunneling width of previous TFET designs is limited by the lithography resolution of the inter-gate spacing. They also claimed that their design overcomes the limitations of bias-induced quantum confinement effects which could have a counteracting effect on the device performance as in the EHB-TFET [82]. On the other hand, it could be technologically challenging to obtain the essential feature in this design, an abrupt transition between the gate metals (i.e., metal heterojunction) by preventing metal intermixing, in addition to avoiding workfunction pinning.

Then there is also a wide span of choice in materials. Transistors based on 2-D materials such as transition-metal dichalcogenides (TMDs) [37, 84, 102, 103] and graphene [33, 74] are interesting candidates for future low-power and high-speed CMOS [16]. In this class of materials, ED is the most applied doping technique. The key challenge for the technology development here however is to obtain an MS interface with a low contact resistance.

In summary, provided that the quality of all interfaces has been taken care of, the performance of electrostatically doped devices could be highly competitive with chemically doped devices. On the other hand, more extensive experimental research is needed to confirm whether ED could ultimately replace chemical doping in mainstream CMOS technology. Nevertheless, the ED techniques is the potential solution for alternative materials such as graphene, CNTs, TMDs, and nanowires, where chemical doping faces a big challenge. Particularly innovative device concepts such as EHB-TFETs and reconfigurable devices, which could not be realized using chemical doping, have a strong potential which could open a new route toward future CMOS technology.

11.3.2 ED: Limitations and Drawbacks

Although ED appears to be very promising, there are still some limitations and drawbacks from a technology perspective that need to be considered when adopting it for device applications.

First, for adopting the ED concept in new device designs, generally ideal MS contacts or interfaces have been considered. However, many experimental data indicate that the observed "effective" workfunctions on various MS systems deviate from their bulk values. Consequently, the linear relationship between ϕ_B and ϕ_M may not always be valid [43]. The assumption of an ideal, abrupt, and non-reactive MS interface does not hold in practice. The possible chemical reaction between a metal and a semiconductor, interdiffusion, and the presence of interface dipoles cause a differently observed ϕ_B than that predicted from the ideal Schottky-Mott relation [112] where ϕ_B has a linear relationship with

ϕ_M. In that respect, the detailed review on the physics and chemistry of SBHs at MS interfaces reported by Tung [113] is interesting, among which its overview of various strategies for modifying ϕ_B. For example, the review paper describes that by an insertion of a thin ($\approx$2 nm) interfacial layer at the MS interface, chemical interdiffusion is avoided and that it also decouples the electron states in the semiconductor from the influence of the metal [43]. Typically, the ϕ_B obtained from such an metal-insulator-semiconductor (MIS) system shows a much stronger dependence on the metal workfunction than an MS interface without an intentionally grown interfacial layer [113, 114]. Such a thin interfacial layer could therefore be a solution for the realization of workfunction-induced electrostatically doped devices [115]. Since most electrostatically doped devices can be realized via low temperature processing, the metastability of the thin interfacial layer is not of a major concern. For future 2-D electronics on the other hand, the formation of a van der Waals MS contact [116] has a strong potential. In such an MS contact an atomically flat metal thin film is laminated onto a 2-D material, so that there is no direct chemical bonding. This creates an MS interface essentially free from defects and Fermi-level pinning. In this way the ideal Schottky-Mott relation can be obtained.

Second, the local workfunction variation of a metal layer could be a concern [117, 118], particularly for metal nitride gates like titanium-nitride (TiN) [119] caused by their polycrystalline nature. This could be deteriorating the effectiveness and uniformity of workfunction-induced doping and may induce device variability.

Third, during wet processing of electrostatically doped devices, the incorporation of different metals in galvanic contact may lead to corrosion [22]. Therefore rather than wet etching, alternative metal patterning approaches are recommended, such as dry etching, damascene, or lift-off.

Fourth, the effect of geometrical scaling in electrostatically doped devices may be different from chemically doped counterparts [37]. Atomistic simulations of such an electrostatically doped 2-D material transistor showed a different behavior from devices with the same EOT (equivalent oxide thickness) for a wide span of physical oxide thicknesses. Therefore, a new scaling theory and design guidelines were proposed [37] for such electrostatically doped devices where the actual physical oxide/dielectric thickness is more critical. The authors proposed to employ ultra-thin wide bandgap oxides for the gate dielectric for obtaining both an optimized ED and suppressed gate leakage.

Fifth, for wide bandgap semiconductors such as GaN with $E_G = 3.4$ eV and electron affinity $\chi_S = 4.1$ eV, the condition for the workfunction-induced n-type doping, i.e., $\phi_M < (\chi_S + E_G/2)$, can be satisfied with a lower workfunction metal like Al. However, for p-type ED in GaN a workfunction higher than 5.8 eV (see Fig. 11.13) would be required, which is not realistic. A possible solution to this problem could be the bias-induced doping approach with a metal having a reasonably high workfunction and polarization doping or to employ alternative materials such as MoO_x (or a combination of those).

Further, generally in any material system, for the optimal performance of an electrostatically doped device, a minimal lateral spacing between the gates is desired [37] which is mainly limited by the lithographic resolution. For wide bandgap materials, this forms a more critical aspect as the highly resistive intrinsic gap between the two electrostatically doped regions could lead to a reduced I_{on} and high turn-on voltages. As discussed earlier, Pan and Chui [98] proposed to overcome this limitation in their new electrostatically doped TFET design making use of a gate electrode comprising two different metal workfunction electrodes. Such ideas can be explored for other electrostatically doped devices as well.

Finally, interface traps could counteract the electrostatic (doping) control as discussed before. For gate dielectrics this remains to be an issue and can only be carefully controlled in a mature technological process. For forming contacts however, incorporating a thin interfacial layer is a potential solution to minimize the effect of interface traps on induced charge [113, 115].

11.4 Conclusion

Electrostatic doping offers an alternative solution to chemical doping in nanometer-scale devices, irrespective of the type of material systems ranging from ultrathin-body bulk semiconductors to carbon nanotubes, graphene, and other 2-D semiconductors.

It can be concluded that for an effective electrostatic doping, several physical parameters, and the interplay between them, play a key role: (1) the metal workfunction, (2) the energy bandgap and the electron affinity of the semiconductor material, and (3) the applied bias. From the literature and the developed physical understanding, it can be concluded that the electrostatic doping techniques can be adopted to induce high charge carrier concentrations, in particular for forming n-type doping, in active ultrathin-body devices. For obtaining high p-type doping levels, generally this technique is more effective for narrow bandgap ($\lessapprox$1.1 eV) semiconductors.

The relatively low temperature processing with a fewer lithography steps makes electrostatic doping attractive as well. Electrostatically doped devices, especially SB-MOSFETs, reconfigurable devices, and TFETs, offer a great potential for future CMOS. However, many of these device architectures, in particular TFETs, are based on TCAD simulation studies. Consequently, much more experimental research is needed in evaluating the true merit of these device ideas in alternative material systems and innovative device concepts for future CMOS.

In addition, the current major limitations of the electrostatic doping techniques are the presence of interface traps, the local metal workfunction variation, processing with multiple metals, and to some extent the applicability to wide bandgap materials. These need to be extensively addressed to meet the expectations for future CMOS technology.

Acknowledgments This work was partly supported by the NWO Domain Applied and Engineering Sciences (TTW), the Netherlands (OTP 2014, under Project 13145.)

The authors would like to thank Jurriaan Schmitz, Sander Smits, and Satadal Dutta for critically reading the original work [70] upon which this work is based. Bijoy Rajasekharan and Rob Wolters are kindly acknowledged for fruitful discussions and the fabrication of the charge plasma diode.

Dr. Raymond J.E. Hueting obtained his master (cum laude) and his Ph.D. in electrical engineering from Delft University, the Netherlands in 1992 and 1997, respectively. He then joined Philips (locations Nijmegen, Eindhoven and Leuven) to work on power and RF device modelling, design and characterization. In 2004 he joined the University of Twente (UT) and has been an associate professor since 2011. His main interests are physics and technology of power semiconductor devices, CMOS, electro-optical devices, and packaging.

He (co-)authored over 100 scientific papers and holds 35 US patents. He is a recipient of the Philips Research invention ("dovo") award (bronze medal). He is (co-)inventor of various devices, such as the charge-plasma diode, the piezoelectric field-effect transistor as a steep-subthreshold switch, and the optocoupler in commercial CMOS. He is an IEEE Senior Member, and has been a technical program committee member of the ISPSD, the ESSDERC and EDTM conferences.

Dr. Gaurav Gupta received the B.Tech. degree in electrical engineering from IIT (BHU) Varanasi, Varanasi, India, in 2008, the M.Sc. degree from The University of Manchester, Manchester, U.K., in 2009 and the Ph.D. degree in semiconductor devices from University of Twente, The Netherlands in 2020. He joined Hitachi Energy (formerly ABB Semiconductors), Switzerland in 2020 where he has been involved in research and development of high-power semiconductor devices such as Si-IGBTs. His current research interests include semiconductor device physics, novel high power semiconductor devices and light-emitting devices.

Planar MOSFETs and Their Application to IC Design

Abstract

Planar MOSFETs are widely recognized as key drivers of the semiconductor industry. This chapter presents analytical models and useful charts for IC design using the most advanced planar MOSFET technological nodes. After a brief review of the progress in MOSFET architectures, the state-of-the-art UTBB FDSOI technology advantages are compiled, and some important designer needs are reminded. The main physical ingredients involved in the MOSFET strong inversion operation are reviewed and generalized to the UTBB FDSOI transistors with a particular focus on the back-gate voltage impact. For better insight into the weak inversion and moderate inversion regimes, both the low-frequency g_m/I_D FoM and the high-frequency y_m/I_D FoM are presented. A modeling of the UTBB FDSOI MOSFET is proposed for low-frequency and high-frequency operations and compared to measurements considering distributed effects in both the gate and the channel. The results show excellent agreement across all regimes of operation including very low bias conditions and up to 110 GHz. Finally, an LNA circuit first-cut sizing procedure using presented charts is proposed for an expected operation at 35 GHz.

UTBB FDSOI · MOSFET · Drain current · gm/ID · Analog design

12.1 Introduction

The metal-oxide-semiconductor field-effect transistor (MOSFET) is by far the most used semiconductor device in analog and digital integrated circuits (ICs). In digital ICs including logic and memory, the MOSFET is mainly used as a switch (i.e., ON state when gate voltage is high and OFF state when gate voltage is low) or a logic gate in order to execute Boolean logic operation, while it is used as a transconductance for signal amplification and conversion in analog ICs. Silicon technologies have been driven for years by downscaling the MOSFET dimensions dictated by the high-performance integrated digital circuits [1]. Recently, further reduction of MOSFET dimensions has

M. Rudan et al. (eds.), *Springer Handbook of Semiconductor Devices*, https://doi.org/10.1007/978-3-030-79827-7_12

become critical due to intrinsic limitations such as short-channel effects (SCEs). To overcome these challenges, the semiconductor industry has developed successful strategies such as the use of new materials and revolutionary device architectures, including planar double-gate (DG) ultra-thin body and box (UTBB) fully depleted (FD) silicon-on-insulator (SOI) MOSFET, vertical DG FinFET, and multiple-gate (MG) MOSFET [2–4].

With the aggressive downscaling of the MOSFET, it has become gradually more subtle to understand the key device physical parameters entering in the drain current model. Analytical models using first-order parameters (e.g., mobility, saturation velocity, etc.) and invariant charts help IC designers in their hand calculations to gain insight into the device operation prior to the necessary SPICE simulations using compact models. In this chapter, after a brief history of the MOSFET architecture in Sect. 12.2, a drain current model using first-order parameters in planar MOSFETs operating in the strong inversion (SI) regime is presented in Sect.12.3. In Sect.12.4, the g_m over I_D charts are presented and generalized to all the frequency spectrum for analog applications. Low- and high-frequency non-quasi-static (NQS) models are also proposed. Application of planar MOSFETs is exemplified in Sect.12.5 by the paradigmatic case of an LNA analog circuit.

12.2 Planar MOSFET Evolution

In the last five decades, the semiconductor industry was mainly governed by Moore's law with a main focus on scaling IC component geometry gradually down to the nanoscale. Moore's law is mainly about cost reduction, and the economic aspect resulted in electronics widespread. Recently, the downscaling of the planar bulk MOSFET has reached fundamental limits, and new materials and architectures have been developed to overcome SCEs and drain-induced barrier lowering (DIBL).

12.2.1 From Bulk MOSFETs to UTBB FDSOI

In order to increase the gate control over the channel, high-k materials were introduced since 45 nm technology node. This has enhanced the gate capacitance without increasing the tunneling leakage [5]. Additionally, the mobility degradation due to scattering in the channel has been partially compensated by means of mobility enhancement in strained channels [6, 7].

Initially developed for its radiation hardness properties, the SOI technology is one of the first identified solutions to extend Moore's law for MOSFETs [8]. In SOI technology, a silicon layer is used on top of an insulator layer which is in turn put on top of a Si substrate. This layered planar architecture improves performance by considerably reducing parasitic capacitances and reduces power consumption. Thanks to a complete isolation from the substrate, SOI MOSFETs are inherently latch-up resistant. Depending on the thickness of the silicon film on top of the buried oxide layer, two SOI device categories can be defined: the partially depleted SOI with thick silicon film and the fully depleted SOI with thin silicon film. In the partially depleted SOI, only the top part of the silicon film is depleted, while the bottom part is neutral which is commonly called floating body (FB). The FB is causing severe kinks in the output characteristics of the MOSFET, and the partially depleted region is too sensitive to the source and the drain voltage variations. In order to mitigate the FB effects, the silicon film has been thinned down in the fully depleted MOSFET so that the silicon film is fully depleted. A back gate is obtained by thinning the buried oxide in the UTBB FDSOI transistor and by adding an underlying ground plane (GP) underneath the BOX. With this architecture, the influence of the drain electric field on the channel is reduced as the most electrical field lines from the drain terminate on the buried GP. Figure 12.1 summarizes the architecture evolution of the planar MOSFET devices from bulk to UTBB FDSOI.

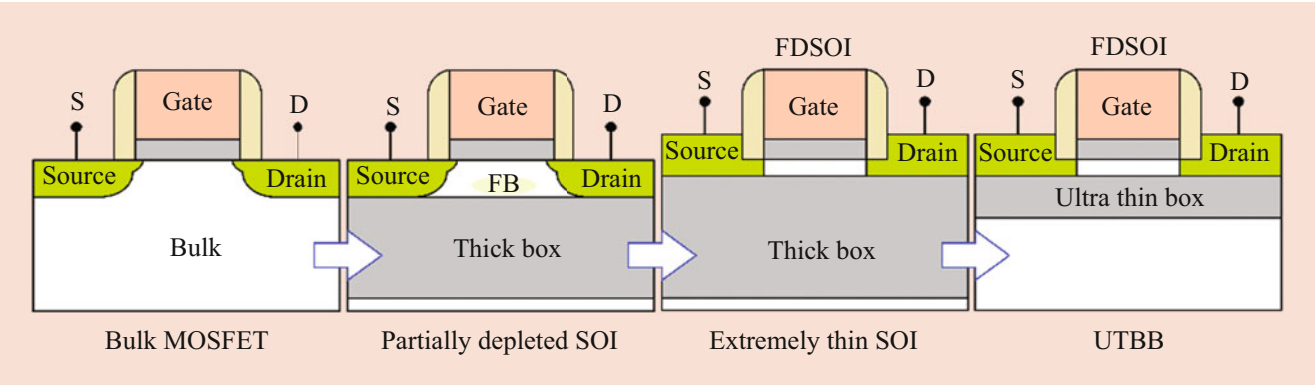

Fig. 12.1 Evolution of planar MOSFET

All enhancement techniques that were used in previous nodes hit their limit when approaching the 20 nm technology node. The mobility degradation due to scattering limited the doping concentration in the channel, and the lattice maximum stress limited the mobility enhancement in strained channels [6, 7]. With the above limitations, novel device architectures with multiple gates such as the UTBB FDSOI described above were foreseen to continue device scaling. The first published work on the double-gate MOSFET [8], shows significant SCE reduction in FDSOI MOSFETs, thanks to the bottom or back gate. With this architecture, the influence of the drain electric field on the channel is reduced. However, the first manufactured double-gate MOSFET was the fully depleted lean-channel transistor (DELTA) which is similar to FinFET but without the top hard mask [9]. The two leading technology contenders, FinFET and UTBB FDSOI, have been adopted and are in mass production today. The two basic differences between UTBB FDSOI and FinFET technologies are the gates and the channel orientation and the two gates' connection. FinFET is basically a 3-D vertical double-gate in which the two gates are connected together. However, in a UTBB FDSOI MOSFET, the two gates are not connected and can be biased differently. Otherwise, FinFET and UTBB FDSOI look the same as depicted in Fig. 12.2.

Other MOSFET architectures were also proposed such as silicon-on-nothing (SON) [10], the tri-gate FET [11], and the gate-all-around FET [12]. The choice of the architecture depends on several criteria, notably the manufacturing complexity and cost, the targeted type of applications and markets, the circuit portability from previous technologies, the circuit area, and the impact of the intrinsic parasitic elements. For instance, in the applications taking advantage of a bias controlled threshold voltage for power control, the independent gate architectures such as UTBB FDSOI are preferred.

Thanks to a thin silicon body, all aforementioned architectures can be fully depleted and consequently have very strong potential for both digital and analog applications [13, 14]. This chapter will focus on the UTBB FDSOI technology solution where the channel(s) mainly lays horizontally.

The UTBB FDSOI MOSFET is considered as a planar low-cost and a straightforward solution to continue shrinking the complementary metal-oxide-semiconductor (CMOS) transistor for low-power and high-speed very-large-scale integration (VLSI) circuits [15]. The advantages of the UTBB FDSOI MOSFETs include steep subthreshold slope (close to the room temperature Boltzmann limit of 60 mV/dec for long channels), thanks to the better control of the channel potential [16], lower DIBL (Fig. 12.3a), low channel doping, and excellent control of short-channel effects (SCE). With a steep subthreshold slope, lower threshold voltages and OFF current are obtained in comparison to bulk. Another considerable advantage of the UTBB FDSOI for design is the fact that same bulk technology design flows are applicable as both technologies are planar [15]. Buried oxide isolation is known to give birth to temperature increase because of self-heating effect [17]; however, thanks to a thinner BOX in the UTBB FDSOI, thermal effects' influence on device parameters is limited in comparison with standard SOI [18]. Similar to SOI devices, UTBB FDSOI MOSFET displays excellent radiation hardness to the detrimental alpha particles, neutrons, and other particles that generate electron-hole pairs after Si penetration [19].

While UTBB FDSOI can provide comparable digital performances with tri-dimensional FinFET [20], the RF behavior of FinFET is however affected by larger parasitic

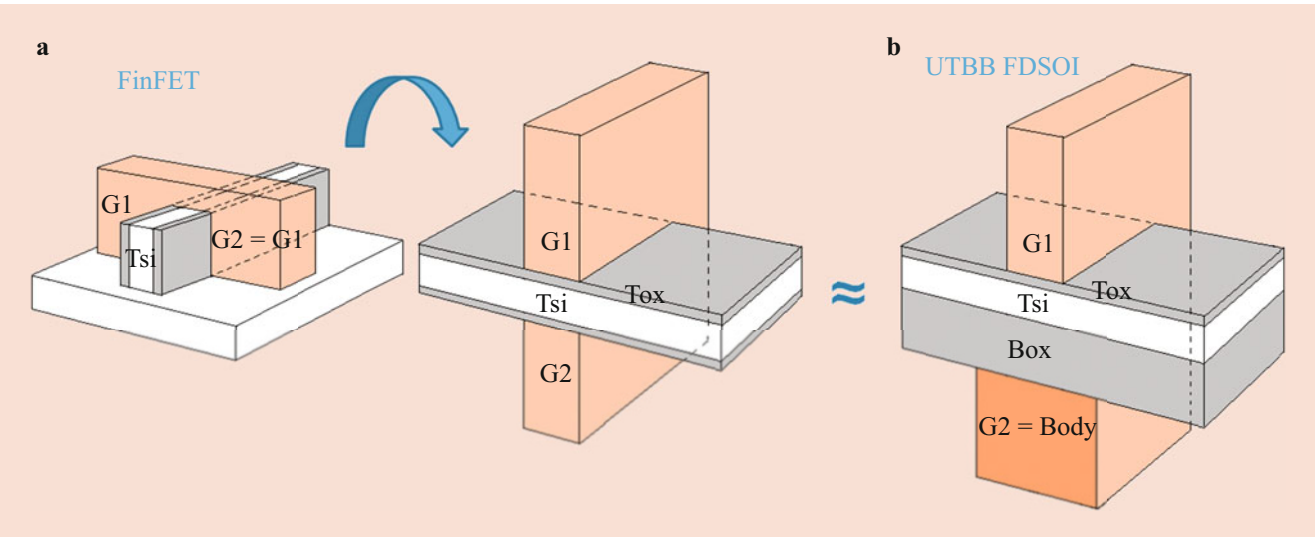

Fig. 12.2 FinFET (**a**) and UTBB FDSOI (**b**) similarity

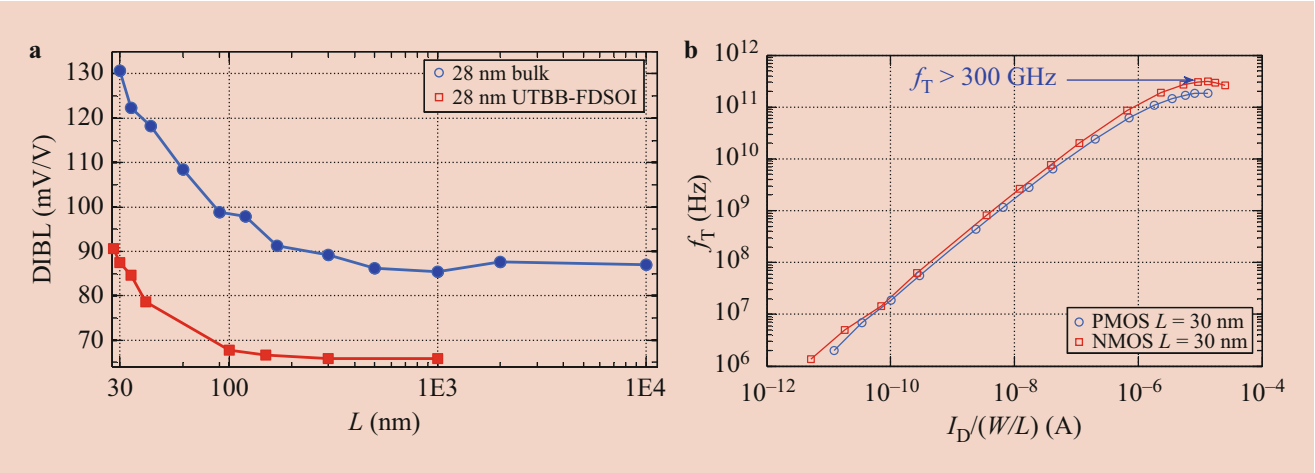

Fig. 12.3 (**a**) Comparison of DIBL between FDSOI and bulk 28 nm technology nodes in saturation ($V_{DS} = 1$ V) and $V_{bG} = 0$ V. (**b**) Measured f_T versus normalized drain current $I_D/(W/L)$ for FDSOI NMOS and PMOS ($L = 30$ nm)

elements [21–24]. The benchmarking of the transit frequency f_T for various state-of-the-art MOSFETs shows that UTBB FDSOI presents higher f_T versus FinFET, thanks to the reduced parasitic resistance and capacitance elements [24]. Moreover, the ITRS (International Technology Roadmap for Semiconductors) expectations are meet by UTBB FDSOI and confirmed experimentally in Fig. 12.3b for NMOS and PMOS devices.

12.2.2 Analog and Digital Design Needs

Circuit simulation using electronic design automation (EDA) tools is essential for IC design. Prototyping and debugging a circuit before the first hardware prototype is undeniably the most cost-effective way of achieving a first-cut design. Therefore, one of the main designer's needs to successfully complete the design is accurate simulations during the final step of verification over process, voltage, and temperature variations. Obviously, the accuracy of these simulations depends on the accuracy of the MOSFET models involved.

The MOSFET models fall into two well-defined categories according to the role in the design flow. The first category is composed of highly accurate, scalable, and continuous compact models suitable for SPICE simulations. The electrical SPICE compact model serves as a bridge between process and circuit design. It is a compact mathematical description of the complex device physics with a trade-off between accuracy and calculation efficiency, but also continuity and numerical robustness as required by SPICE simulators. Compact models are physically based and allow to predict circuit design behavior and performance beyond the measured data used to extract the model. Compact model simulations are nowadays systematically used for IC simulation earlier to an expensive production process. Moreover, compact models are flexible enough to describe MOSFETs fabricated in different foundries. Standard compact models go through extensive qualification within semiconductor foundries and fabless industrials that are organized into an industry consortium, namely, Compact Model Coalition (CMC) [25]. It should be noted that the valuable contributions from universities are key for innovative compact modeling solutions. Several SPICE compact model industry standards coexist, such as the threshold voltage (V_{TH})-based BSIM4 model from UC Berkeley and the surface potential-based PSP model originated from Philips and Pennsylvania State University, as far as bulk MOSFETs are concerned. For UTBB FDSOI MOSFET, several core models have been proposed such as BSIM-IMG and L-UTSOI. A practical modeling approach in the semiconductor industry is the use of sub-circuit build using passive element network on top of core MOSFET models that have been qualified for DC and low-frequency operation. The high-frequency behavior of MOSFETs is captured using additional lumped elements to end up with complex sub-circuits. Lumped elements are commonly added to each MOSFET terminal to account for high-frequency behavior (e.g., gate and substrate passive RC networks). The SPICE compact models will not be thoroughly treated in this chapter.

The chapter will rather focus on the second category of models which consists of simpler models, charts, and equivalent circuits appropriate for hand calculations. Nowadays, SPICE compact models due to the increasing complexity of the transistor physics tend to become difficult to use for both technology prospection by process engineers and device sizing by analog designers. Prior to the lengthy SPICE verifications, simple device models or charts are commonly used in order to predict circuit performance and perform preliminary circuit analysis, despite lower accuracy. Moreover, equivalent

circuits are also useful in order to gain practical insight into the contributors to the small-signal frequency behavior.

12.3 Model for Drain Current and First-Order Parameter Extraction

Modeling plays an increasingly important role in the development of integrated circuits. The accuracy of circuit simulations depends on the quality of the models used to predict the integrated devices' behavior, particularly the omnipresent MOSFET devices. Huge advances have been made in recent years to predict the electrical behavior of MOSFETs taking into account complex physical phenomena. The new miniaturized MOSFETs with novel architectures have made the modeling task more challenging.

Although the intrinsic electrostatic behaviors of the different architectures have been accurately modeled in several commercial standard models, variability and local layout effects are still important challenging issues for semiconductor foundries.

As for the single-gate MOSFET models, compact models for multiple-gate MOSFETs rely on long-channel core on the top of which various physical effects are added such as short-channel effects (SCE), mobility degradation, velocity saturation, and quantum mechanical effect (QME). The 3-D electrostatic behavior of the multiple-gate architectures is generally simplified and modeled using comparable formulations under reasonable assumptions regarding involved geometries [26]. Symmetrical architecture models have been reduced into single-gate-like formulations. Difficulties to model some architectures such as asymmetrical and independent gate MOSFETs have been reported and recently resolved [27, 28]. For instance, multiple threshold voltages and mobilities have been proposed to circumvent the complexity of multiple gate control [29]. In an asymmetric double-gate MOSFET, the resolution of Poisson equation with boundary conditions is not an easy task. Partitioning of inversion charge between source and drain is classically calculated using front interface potential in bulk. However, for asymmetric DG MOSFET where more than one interface is available, the classical way is not relevant.

Yet, the I–V characteristic in SI for multigate MOSFETs is close to the square law derived for early bulk technologies when mobility reduction, velocity saturation, and series resistance have lower impact. It should be noted that for thin silicon body such as the fins in FinFET, the series resistance is high and the current deviates from the ideal square law unless source and drain access is improved.

Even though the simple analytical models are somehow less accurate, they are extremely useful tools for circuit modeling and computer-aided design (CAD) application. These MOSFET models rely on a limited number (typically ten) of physical parameters (often called "first-order parameters"), such as the channel mobility μ, mobility degradation θ, velocity saturation v, and source and drain external resistances.

The aim of this section is to provide a set of simple equations in order to analyze the behavior of the overthreshold drain current in the linear regime but also in the saturation regime.

12.3.1 UTBB FDSOI Device Cross Section

In the UTBB FDSOI technology, MOSFET channel is formed in a thin silicon film separated from the substrate by an oxide film called buried oxide (BOX) as depicted in Fig. 12.4. In 28 nm FDSOI technology from STMicroelectronics, final silicon film is 7 nm thick, and BOX is 25 nm thick after a few process steps [2]. In contrast with the most advanced bulk transistor, the channel of the UTBB FDSOI devices is un-doped, and no pockets of counter-doping are introduced in order to enhance the electrostatic control and to limit the punch-through in the shortest devices.

Figure 12.4 shows a cross section of the device with an emphasis on the access region. This access region tends to have an increasing impact on the drain current [30]. As shown in Fig. 12.4, it is composed not only of the highly doped source and drain region itself (a) but also of the low-doped drain (LDD) region below the spacer (b). Unlike region (a), this latter overlap region (b) depends on gate voltage, and a simple model detailed in [30] can accurately describe the regions (a) and (b) as a series resistance (independent of the channel length) as:

$$R = 2 \cdot R_0 + 2 \cdot \sigma \cdot (V_G - V_{TH})^{-1} \qquad (12.1)$$

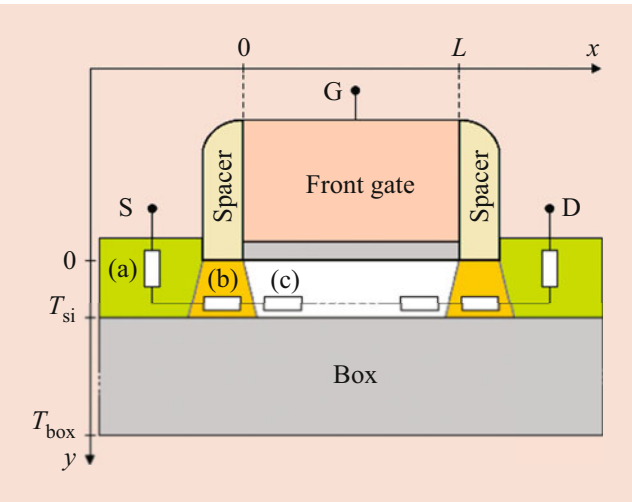

Fig. 12.4 Cross section of the UTBB FDSOI MOSFET with a lumped resistance model

where R_0 and σ are two model parameters whose extraction strategy will be described later.

12.3.2 Drain Current Model

A closed-form exact analytical drain current expression is derived from the Pao and Sah integration [31] and assuming the proportionality between the inversion charge and the gate voltage overdrive. The derived drain current model considers mobility degradation, velocity saturation, and access resistances.

Reference to the Pao and Sah Approach

Region (c) in Fig. 12.4 corresponds to the part of the device where the channel is considered to be homogenous. This part's effective length $L_{\text{eff}} = L - \Delta L$ can be either longer or shorter than the drawn gate length L depending on the source, drain, and LDD architecture. In what follows, for simplicity, we will drop the explicit reference to L_{eff} keeping in mind the meaning of this quantity. Similarly, due to access voltage drop in the (a) and (b) regions, a pseudo source voltage and a pseudo drain voltage have to be considered instead of the external applied voltages.

Above threshold voltage, the current in region (c) can be expressed using the quasi-Fermi level ϕ by:

$$I_{\text{D}} = \frac{W}{L}\int_{\text{S}}^{\text{D}} \partial x \cdot (\mu_{\text{eff}} \cdot Q_{\text{i}}) \cdot \frac{\partial \phi}{\partial x} = \frac{W}{L}\int_{\phi_{\text{s}}}^{\phi_{\text{D}}} \partial \phi \cdot (\mu_{\text{eff}} \cdot Q_{\text{i}}) \tag{12.2}$$

with L the effective channel length, W the MOSFET width, μ_{eff} the effective mobility, and Q_{i} the inversion charge. The integration along the channel direction starts at the position in the channel $x = 0$ corresponding to the pseudo source and ends at the pseudo drain corresponding to $x = L$. Within the Pao and Sah approach, the integral over x is transformed into an integral over the pseudo-Fermi levels, from source to drain. According to (12.2), one needs to express the inversion charge as a function of the gate voltage V_{G} and the channel threshold voltage V_{TH}, (12.2) being valid for $V_{\text{GT}} = (V_{\text{G}} - V_{\text{TH}}) > 0$. For bulk transistors, it is well known that the inversion charge density depends on the oxide capacitance C_{ox} as:

$$Q_{\text{i}} = C_{\text{ox}} \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A) \tag{12.3}$$

where $A = C_{\text{ox}}/(C_{\text{ox}} + C_{\text{d}}) \approx 1$ and C_{d} stands for the depletion capacitance [32]. This expression is also valid for the FDSOI with $V_{\text{bG}} \leq 0$ V (see latter) knowing that an additional inversion charge can appear when the back gate is forward biased (e.g., $V_{\text{bG}} > 0$ V) [33].

Let us first introduce the mobility degradation using the well-known empirical model [32, 34]:

$$\mu_\theta = \mu_0/(1 + |Q_{\text{i}}|/Q_{\text{c}}) = \mu_0/(1 + \theta \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A)) \tag{12.4}$$

where Q_{c} is a "critical" charge from which the mobility starts to decrease and θ is the mobility degradation parameter. It is generally more convenient to use θ instead. The non-saturated current (accounting for the mobility degradation due to vertical field) can be written as:

$$I_{\text{D0}} = \frac{\mu_0 C_{\text{ox}} W}{L}\int_{\phi_{\text{s}}}^{\phi_{\text{D}}} \partial \phi \cdot \frac{(V_{\text{G}} - V_{\text{TH}} - \phi/A)}{(1 + \theta \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A))} \tag{12.5}$$

To evaluate the current, one needs to perform the integration over the pseudo-Fermi levels. This can be done evaluating the integral [32]: $\delta = \int_{\phi_{\text{s}}}^{\phi_{\text{D}}} \partial\phi/\,(1+\theta \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A))$. Using trivial algebra, one can easily re-write the current as:

$$I_{\text{D0}} = \frac{\mu_0 C_{\text{ox}} W}{L} \cdot \frac{V_{\text{DS}}\,(1 - \delta/V_{\text{DS}})}{\theta} \tag{12.6}$$

with $\delta = \frac{A}{\theta} \ln\left[\frac{1+\theta \cdot (V_{\text{G}} - V_{\text{TH}} - V_{\text{S}}/A)}{1+\theta \cdot (V_{\text{G}} - V_{\text{TH}} - V_{\text{D}}/A)}\right]$.

Let us now introduce the saturation velocity in the mobility as:

$$\mu_{\text{eff}} = \mu_\theta / \left(1 + \frac{\mu_\theta}{v^*} \cdot \frac{\partial \phi}{\partial x}\right) \tag{12.7}$$

Using the electrostatic potential ψ and the approximation $F_x = \frac{\partial \psi}{\partial x} \approx \frac{\partial \phi}{\partial x}$, which is well justified in the drift regime, the current writes:

$$I_{\text{D}} = \frac{W}{L}\int_0^{\text{L}} \partial y \frac{\mu_0 C_{\text{ox}} \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A) \cdot \frac{\partial \phi}{\partial y}}{(1 + \theta \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A)) \cdot \left(1 + \frac{\mu}{v^*} \cdot \frac{\partial \phi}{\partial y}\right)} \tag{12.8}$$

which implies that:

$$\begin{aligned} &\frac{W}{L}\int_0^L \partial x \cdot I_{\text{D}} \cdot \left(1 + \frac{\mu}{v^*} \cdot \frac{\partial \phi}{\partial x}\right) \\ &\quad = \frac{W}{L}\int_0^L \partial x \cdot \frac{\mu_0 C_{\text{ox}} \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A) \cdot \frac{\partial \phi}{\partial x}}{(1 + \theta \cdot (V_{\text{G}} - V_{\text{TH}} - \phi/A))} \end{aligned} \tag{12.9}$$

and finally using (12.6):

$$I_{\text{D}} = \frac{I_{\text{D0}}}{\left(1 + \frac{\mu_0}{v^* L}\delta\right)} \tag{12.10}$$

Equation (12.10) is valid below saturation voltage, the value of which can be obtained when the derivative vs V_{DS}

of the current is zero. This can be done analytically for I_{D0}, and it can be shown that whatever the degradation parameter is, the saturation drain voltage is $V_{DSAT} = A.(V_G - V_{TH})$. Some more complex analytical models for V_{DSAT} accounting for the velocity saturation can be found in [32, 35]. However, the general case considering, mobility degradation, velocity saturation, and source and drain resistances are subtler, and in what follows, V_{DSAT} is obtained from the derivative of the drain current which must be done numerically and self-consistently since the voltage drops in the drain and the source resistances also depend on the current.

Saturation Drain Voltage

Figure 12.5 shows that V_{DSAT} as a function of the channel length can increase significantly when series resistances and saturation velocity are accounted for unlike the long-channel case in which $V_{DSAT} = (V_G - V_{TH})$. The behavior is more pronounced at high V_G where drain current is important. The trend can be inversed due to saturation velocity. In that case, neglecting the series resistances, the saturation voltage tends to be zero in the shortest devices [35]. In a more realistic case, when both saturation velocity and external resistances are accounted for, the decrease of V_{DSAT} observed in the shortest devices (due to the saturation velocity) tends to be compensated by the impact of the external resistances, and V_{DSAT} remains closer to $V_G - V_{TH}$ for all channel lengths.

R_{on}-L Model

The drain current expressed with (12.10) is still quite complex, and some simplifications are welcome. The linear regime without external resistance can be simplified as (assuming also $A = 1$):

$$I_D \cdot \frac{L}{W} = \frac{C_{OX} \cdot \mu_0}{(1 + \theta \cdot (V_{GS} - V_{TH} - V_{DS}/2))} (V_{GS} - V_{TH} - V_{DS}/2) \cdot V_{DS} \tag{12.11}$$

Similarly, with the external resistance R, the current writes [32]:

$$I_D = \frac{W}{L} \frac{C_{OX} \cdot \mu_0 \cdot (V_{GS} - V_{TH} - V_{DS}/2) \cdot V_{DS}}{\left(1 + \left(\theta + \frac{R \cdot C_{OX} \cdot \mu_0}{L}\right) \cdot (V_{GS} - V_{TH} - V_{DS}/2)\right)} \tag{12.12}$$

In other words, the resistance can be seen "internally" as a supplementary contribution to the effective mobility degradation parameter.

A simple account for the velocity saturation consists in using the same derivation as in (12.10) (with $\theta = 0$):

$$I_D = \frac{I_{v*=\inf}}{\left(1 + \frac{\mu_0}{v^* L} V_{DS}\right)} \tag{12.13}$$

Additional complexity can be added considering the mobility degradation and recasting the series resistances into θ:

$$I_D = \frac{\frac{W}{L} \frac{C_{OX} \cdot \mu_0 \cdot (V_{GS} - V_{TH} - V_{DS}/2) \cdot V_{DS}}{\left(1 + \left(\theta + \frac{R \cdot C_{OX} \cdot \mu_0}{L}\right) \cdot (V_{GS} - V_{TH} - V_{DS}/2)\right)}}{\left(1 + \frac{\mu_0 \cdot V_{DS}}{v^* L \cdot \left(1 + \left(\theta + \frac{R \cdot C_{OX} \cdot \mu_0}{L}\right) \cdot (V_{GS} - V_{TH} - V_{DS}/2)\right)}\right)} \tag{12.14}$$

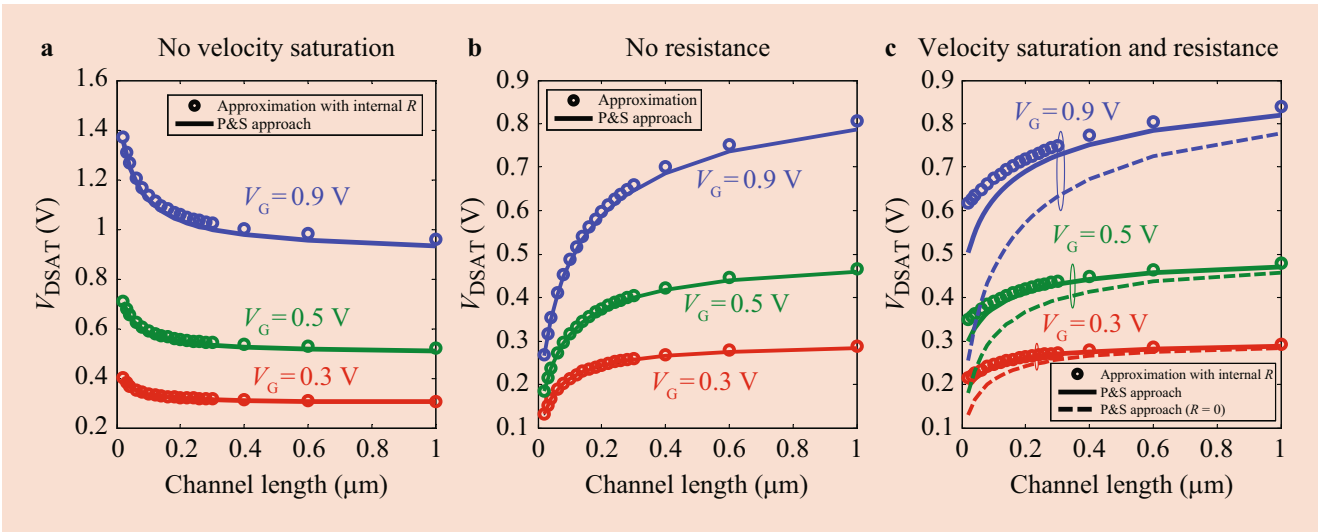

Fig. 12.5 Simulation of the saturation voltage for various V_G (considering for simplicity $V_{TH} = 0$). (**a**) Impact of the series resistances with $R = 100\ \Omega$, (**b**) impact of the velocity saturation with $v = 1e5$ m.s^{-1}, and (**c**) impact of both velocity saturation and series resistance ($v = 1e5$ m.s^{-1}, $R = 100\ \Omega.\mu m$). Solid line: Pao and Sah-based model in (12.10) with $C_{OX} = 0.025$ F.m^{-2}, $\mu_0 = 0.04$ m^2/(V.s), $\sigma = 0\ \Omega.\mu m.V$, and $\theta = 0.15$ V^{-1}. Symbol: a simplified model where series resistance effect is treated as an additional mobility degradation (cf. (12.12))

The saturation drain voltage obtained from the derivative of the drain current vs V_{DS} is shown in Fig. 12.5.

Equation (12.14) allows us to compute the device resistance R_{on} from the inverse of the current and using (12.1) in an explicit and useful way:

$$R_{LIN} = L \cdot \left\{ \frac{1}{\mu_0 C_{OX} (V_{GS} - V_{TH})} + \frac{\theta}{\mu_0 C_{OX}} \right\} + \frac{1}{(V_{GS} - V_{TH})} \cdot \left\{ 2 \cdot \sigma + \frac{V_{DS}}{v^* C_{OX}} \right\} + 2 \cdot R_0 \tag{12.15}$$

As mentioned previously, the simplification consisting in using $V_{DSAT} = V_G - V_{TH}$ is reasonable in practice over a large range of channel lengths and in the saturation regime R_{SAT} writes:

$$R_{SAT} = L \cdot \left\{ \frac{2 \cdot V_{DS}}{\mu_0 C_{OX} (V_{GS} - V_{TH}) \cdot (V_{GS} - V_{TH})} + \frac{\theta \cdot V_{DS}}{\mu_0 C_{OX} \cdot (V_{GS} - V_{TH})} \right\} + \frac{2 \cdot V_{DS}}{(V_G - V_{TH})} \cdot \left\{ \frac{\sigma}{V_{GS} - V_{TH}} + \frac{1}{v^* C_{OX}} \right\} + 2 \cdot R_0 \cdot \frac{V_{DS}}{V_{GS} - V_{TH}} \tag{12.16}$$

Figure 12.6 compares the R_{on} in the linear and saturation regimes calculated using various models. One can notice differences between the predictions of the model using "internal" or "external" resistance. In fact, the approximation consisting in recasting the series resistances into θ can lead to unphysical results since in that case Kirchhoff's law is not satisfied at the source and drain nodes. One notes that this can be even more pronounced in the linear regime due to the presence of the V_{DS} term in the denominator (assuming v^* is not zero).

Despite their simplicity, Eqs. (12.15) and (12.16) allow a useful breakdown of the total resistance splitting the L-dependencies and the V_G-dependencies. Based on these equations, a direct extraction of the first-order model parameters is in principle possible from simple current measurements at various $V_G - V_{TH}$ overdrives. In particular, an effective access resistance can be extracted from the $R_{on} - L$ curve intersect with the Y-axis, while the intrinsic "channel" current and the mobility parameters can be obtained from its slope.

12.3.3 Parameter Extraction from Measurements

The proposed drain current and R_{on} models allow a straightforward extraction of the main physical ingredients, namely, the threshold voltage, the mobility degradation parameter, the access resistance, and the saturation velocity.

The Threshold Voltage Extraction

The determination of threshold voltage from measurements has a long history, and several conflicting definitions and extraction methods are proposed in the literature [36]. In the first series of methods, the threshold voltage is rather a fitting parameter that will depend on the chosen model for the linear and the saturation regimes. Alternatively, the threshold voltage can be extracted from the gate voltage corresponding to the maximum of the gate capacitance derivative. As explained in [37], we have the following relation:

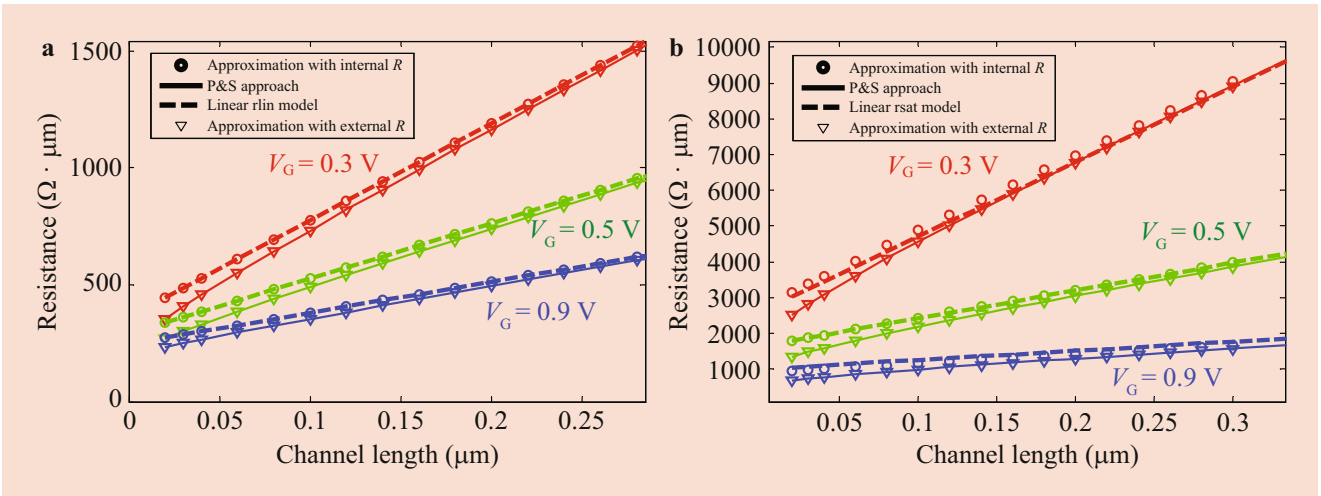

Fig. 12.6 Device resistance R_{on} in the linear ((**a**): $V_{DS} = 0.05$ V) and saturation regimes ((**b**): $V_{DS} = 0.9$ V) for various V_G (considering for simplicity $V_{TH} = 0$). Model described in the text with $C_{OX} = 0.025$ F.m^{-2}, $\mu_0 = 0.04$ m^2/(V.s), $\theta = 0.15$ V^{-1}, $R = 100$ Ω.µm, and $v = 1e5$ m.s^{-1}

$$C_{gc} \equiv \frac{\partial Q_{inv}}{\partial V_{GS}} = \frac{\partial \left(C_{ox} \cdot V_{ox}\right)}{\partial V_{GS}} = C_{ox}\frac{\partial V_{ox}}{\partial V_{GS}} = C_{ox}\frac{\partial \left(V_{GS} - \Psi_s\right)}{\partial V_{GS}} = C_{ox}\left(1 - \frac{\partial \Psi_s}{\partial V_{GS}}\right) \tag{12.17}$$

where Q_{inv}, C_{ox}, V_{ox}, and ψ_s are, respectively, the inversion charge, the oxide capacitance, the oxide voltage drop, and the surface potential. If we derive (12.17) with respect to V_{GS}, we get:

$$\frac{\partial C_{gc}}{\partial V_{GS}} = -C_{ox}\frac{\partial^2 \Psi_s}{\partial V_{GS}^2} \tag{12.18}$$

This quantity maximizes at the inflection point of the surface potential plot with respect to V_{GS} and corresponds to the inversion charge rise.

One other direct extraction of the threshold voltage, which provides comparable results to the *C-V* derivative, is the g_m/I_D derivative method proposed in [38]. The agreement between the two aforementioned methods in bulk is explained using:

$$\frac{\partial \left(\frac{g_m}{I_D}\right)}{\partial V_{GS}} = \frac{1}{U_T}\frac{\partial^2 \Psi_s}{\partial V_{GS}^2} \tag{12.19}$$

In bulk, the g_m/I_D derivative is proportional to the quantity expressed in (12.18) and also determines the inversion charge rise when maximized. It can be noted that in FDSOI devices in which the charge is composed of front and back inversion charges (see latter), some slight discrepancies between these two latter methods can exist.

In Fig. 12.7, the *Y*-function-based, the H-function-based, and the normalized reciprocal H-function (NRH)-based methods [36] are compared to the g_m/I_D derivative-based method for several FDSOI MOSFET lengths. The several methods provide different values in particular for short channels in saturation regime. Thus, inversion level metric based on threshold voltage concept (e.g., gate voltage overdrive $V_{GT} = V_{GS} - V_{TH}$) can be inaccurate as being closely tied to the threshold voltage extraction method.

The Apparent Channel Mobility Degradation and the Access Resistance

The finite number of available sub-bands carrying the current puts a lower fundamental limit to the total drain current. Even in the absence of contact and spreading resistances, the intersect of the R_{ON} (L) plot for $L = 0$ exhibits a finite value, which is often referred to as quantum or "ballistic" resistance [30, 39–44]. The quantum resistance, the value of which does not significantly change with the channel thickness, acts as a series resistance and can be expressed as:

$$R_Q \approx \sqrt{2\pi \cdot m \cdot kT}/\left(q \cdot C_{ox} \cdot \left(V_{GS} - V_{TH}\right)\right) = 2 \cdot \sigma_B \cdot \left(V_{GS} - V_{TH}\right)^{-1} \tag{12.20}$$

with $\sigma_B \approx 8.4$ in silicon N-type MOSFETs. In realistic silicon MOSFETs, featuring spacers and S/D regions, the impact of the quantum resistance on the drain current is nevertheless relatively small. This is shown in Fig. 12.8a–c in which the extracted series resistance values are more than four times larger than the theoretical quantum resistance ones. As shown in [30], the near-spacer/LDD region exhibits a large resistance (that does not depend on L and therefore can be considered as a series resistance in the lumped elements model in Fig. 12.4). We found out that the "apparent" mobility degradation observed in short devices can be inferred from the impact of this V_G-dependent resistance on the device current. The "apparent" channel length dependency of the mobility in nanometric devices has been long discussed [39–45], and some additional scattering mechanisms localized near the LDD junction have been suspected to give rise to an "average" decrease of the mobility (considered as a model parameter) in the shortest devices. We believe that systematic errors in the characterization procedures may also be at the origin of this "apparent" decrease of the mobility.

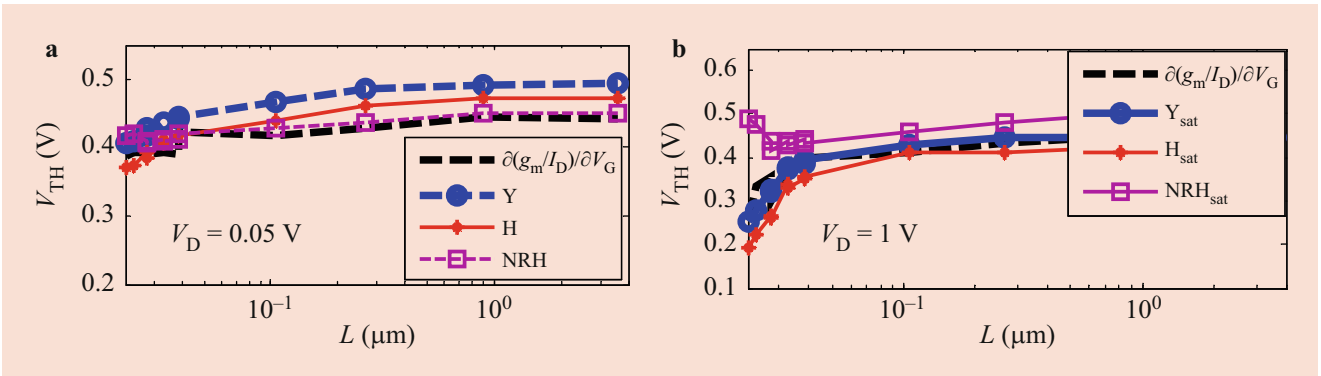

Fig. 12.7 Threshold voltage versus length for NFDSOI devices in linear (V_{DS} = 50 mV) and saturation (V_{DS} = 1 V)

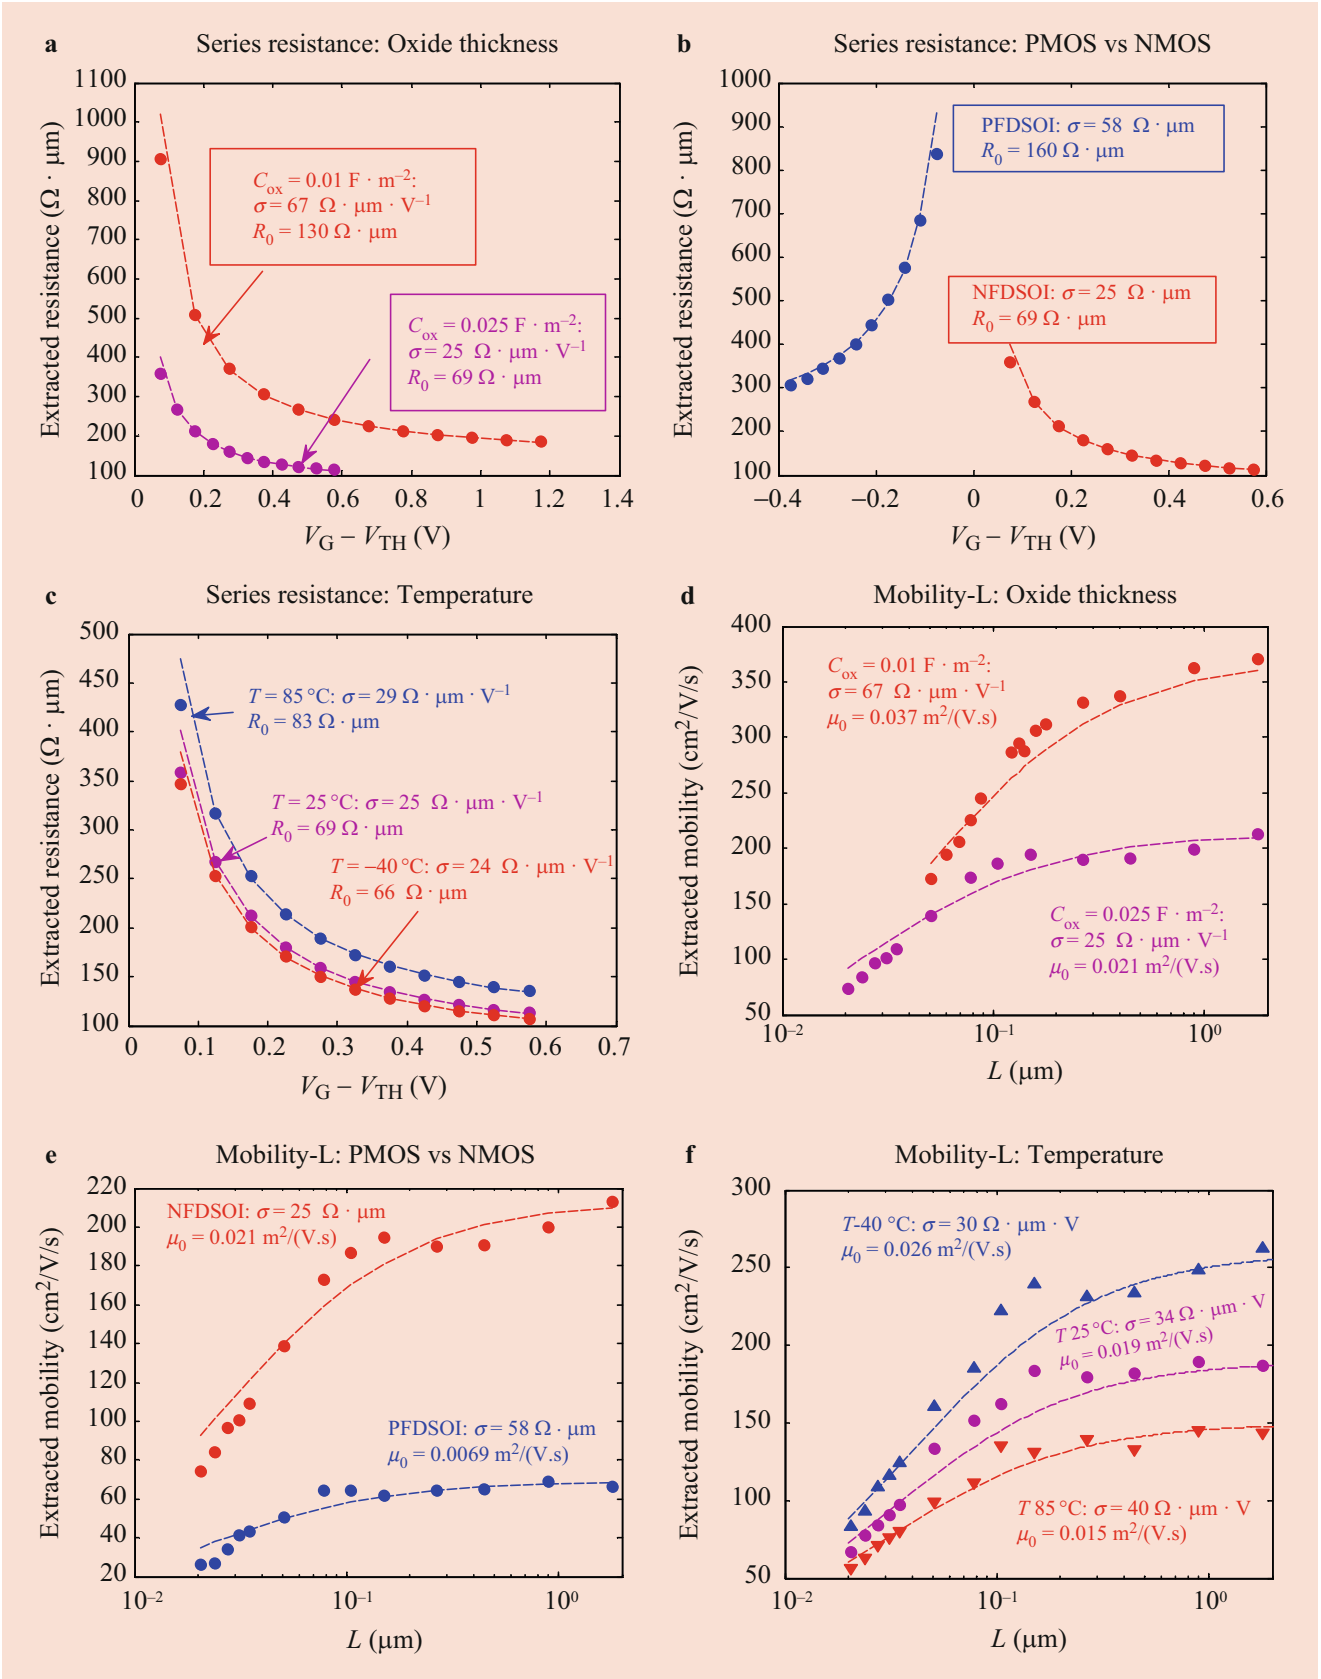

Fig. 12.8 (continued)

In the shortest device, series resistances significantly reduce the drain current, even in the linear regime. Series resistance extraction methods have been extensively discussed in literature [41, 43]. We reported in [30] that the usage of the Y-function [41] can introduce large errors when the resistances are extracted from R_{ON} $(1/\beta_{eff})$ plots. With some algebra, it can be proven that in the linear regime (and considering $L_{eff} = L$), the inverse of the gain factor $\beta_{eff} = \mu_{eff} \cdot C_{ox} \cdot W/L$ extracted from the slope of the Y-function $Y = I_D/\sqrt{g_m} \approx \sqrt{(\beta_{eff}. V_{DS})} \cdot (V_G - V_{TH})$ writes $1/\beta_{eff} = 1/(\mu_0 \cdot C_{ox}. W) \cdot L + 2 \cdot \sigma/W$, where μ_0 is the long-channel mobility. This implies that the extracted effective mobility μ_{eff} becomes L-dependent as $\frac{1}{\mu_{eff}} = \frac{1}{\mu_0} + 2 \cdot \sigma \cdot C_{ox}/L$. The coefficient σ can be significantly larger than σ_B because of the V_G-dependent part of the access resistance. This is shown in Fig. 12.8a–c reporting the series resistance extracted using the $R_{ON}(L)$ intersect with the Y-axis. Also shown is the mobility extracted from Y-function [41]. It can be noted that the apparent mobility degradation is correctly modeled using the σ value extracted from $R_{acc} - V_{GT}$ (please notice that for simplicity, we did not distinguish here the LDD-related threshold voltage from the channel one V_{TH}).

The Pinch-OFF and the Velocity Saturation

Figure 12.9 shows the experimental R_{on}-L together with a linear R_{on}-L model fit in N-type FDSOI MOSFET device at $V_{DS} = 0.05$ V and $V_{DS} = 1$ V for various temperatures. As already mentioned, the channel length corresponds to the gate length L corrected by a small offset ($L_{eff} = L - \Delta L$) [40]. In the most advanced industrial technological nodes, where the channel length is aggressively scaled, the device source and drain architecture is optimized in order to reduce ΔL as much as possible (typically $\Delta L < 1$ nm).

As can be seen, the extracted resistance exhibits a nearly linear behavior versus effective channel length. The observed deviations from the linear model (in particular at high temperature in the saturation regime) can have several origins. This can come from the simplified model for $V_{DSAT} = V_{GT}$ that we have shown to be accurate for long devices only. Additionally, the accuracy of the extracted resistance depends on the gate voltage overdrive accuracy that must be carefully controlled (i.e., the accuracy of the threshold voltage extraction).

In recent technologies, the linear R_{on}-L model shown in Fig. 12.9 seems to be rather a good approximation and has been applied with a relatively good accuracy in P-type FDOSI MOSFET, in thick and thin oxide technologies (see, e.g., Fig. 12.8), but also in 28 nm bulk transistors featuring no pocket implants. However, we would like to mention that the carrier transport has been considered homogeneous along the channel. This is well verified in, e.g., 28 nm UTBB FDSOI devices, but can be untrue in 20 nm UTBB FDSOI technological nodes featuring, e.g., source and drain stressors whose impacts are more pronounced in the shortest devices [20].

Figure 12.10a shows the experimental access resistance extracted from the R_{on}-L Y-axis intercept at V_{DS}=0.05 V and $V_{DS} = 1$ V. A model $\frac{\sigma_{eff}}{(V_G - V_{TH})}$ allows a good fitting of the measurements. According to (12.16), the extracted value of the V_G-dependent part of the access resistance that increases with temperature can be approximated at high gate voltage overdrive by $\sigma_{eff} \approx V_{DS} \cdot \left\{R_0 + \frac{1}{v^* C_{OX}}\right\}$. Considering that the contribution R_0 (extracted using the Y-function method) only varies by 30% on the considered temperature range, this suggests that v^* decreases with temperature.

To gain more insight into the drain current, we can use Eqs. (12.15) and (12.16) and extract from the R_{on}-L slope that can be referred to as the "channel" contribution to the resistance. Figure 12.10b shows this quantity at $V_{DS} = 0.05$ V and $V_{DS} = 1$ V for various temperatures. The "channel" resistance of the short device is compared to the total resistance of the long device. This figure tends to show that the short device current "de-embedded" from its access resistances exhibit the same quadratic V_G-dependent resistance than the long-channel one (in which the access resistances have a much lower impact). We believe that this constitutes an evidence of the fact that the short-channel device is in pinch-off regime in agreement with the measurement of drain current with negative drain voltage showing no saturation of the total current [45].

12.3.4 Do We Need a Quantum Approach for Ultimate Silicon-Based UTBB FDSOI?

Non-equilibrium Green function (NEGF)-based simulations [30] have been performed on 28 nm FDSOI devices, with a view to comparing the results to the classical P&S approach. Figure 12.11a shows the structure as obtained from TCAD (technology computer-aided design) process simulation. NEGF structures have been obtained randomizing the dopant distribution and the interfaces. Figure 12.11b, c shows the charge densities and the quasi-Fermi levels (calculations from the NEGF density are obtained from a fit of a heated

Fig. 12.8 (**a**) to (**c**) Extracted series resistance from R_{on}-L Y-axis intersect. Lines show best fit with a model: $\sigma . V_{GT}{}^{-1} + R_0$. (**d**) to (**f**) Extracted mobility using the Y-function compared to model predictions (see text for details). Measurements in the linear regime ($|V_{DS}| = 0.05$ V) in N-type FDSOI MOSFETs featuring various oxide thicknesses, in N- and P-type MOSFETs, and in N-type FDSOI MOSFET at various temperatures

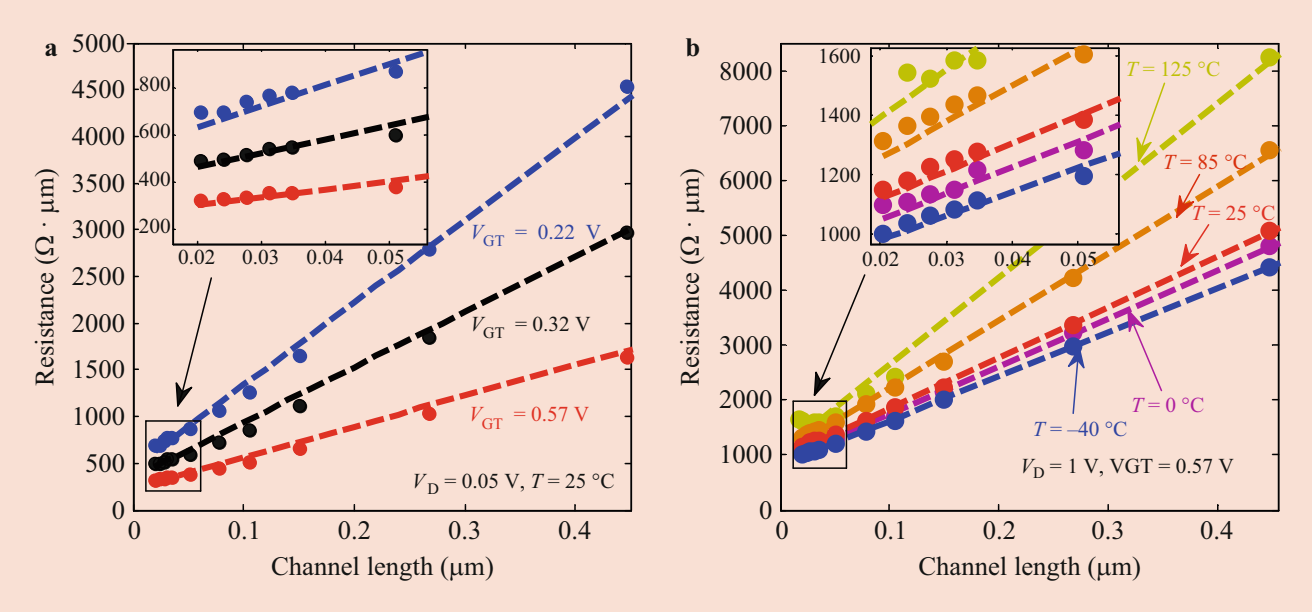

Fig. 12.9 Experimental R_{on}-L and model predictions in the linear (**a**) and saturation (**b**) regimes in a thin oxide FDSOI device: $C_{OX} = 0.025$ F.m^{-2}; $\mu_0 = 0.023$ m^2/(V.s); $\theta = 0.07$ V^{-1}; $R = 50$ Ω.μm; $\sigma = 35$ Ω.μm.V; $\nu = 2.3$e5 m.s^{-1}

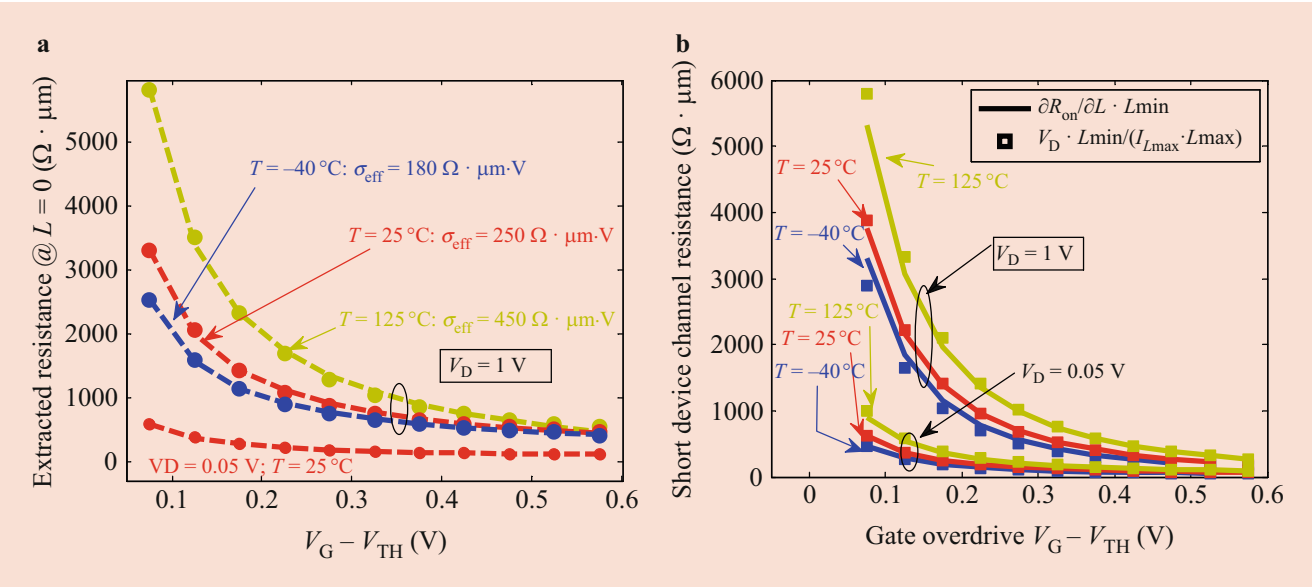

Fig. 12.10 (**a**) Experimental access resistance at $V_{DS} = 0.05$ V and $V_{DS} = 1$ V. (**b**) Experimental channel resistance extracted from the R_{on}-L slope at $V_{DS} = 0.05$ V and $V_{DS} = 1$ V (see text for details)

Maxwellian carrier distribution). It can be noticed that despite some statistical oscillations originated from the random placement of the dopant atoms and the surface roughness, a significant quasi-Fermi level drop in the near-LDD region is observable, while the channel operates in a diffusive regime as testified by the nearly linear voltage drop occurring in this region. Also shown are the computationally less demanding TCAD device simulations within the hydrodynamics approach (see [30] for details).

Figure 12.12 compares R_{on}-L (a) and its interest at $L = 0$ (b) obtained from NEGF. As expected, NEGF results depend on the models and approximations during the simulation. NEGF simulations are performed considering scattering with phonon only including or not the additional scattering mechanisms: surface roughness and remote Coulomb in the high-K gate stack. Additionally, simulations have been performed within the effective mass approximation (EMA) and the two bands' k.p model (featuring non-parabolic band structures).

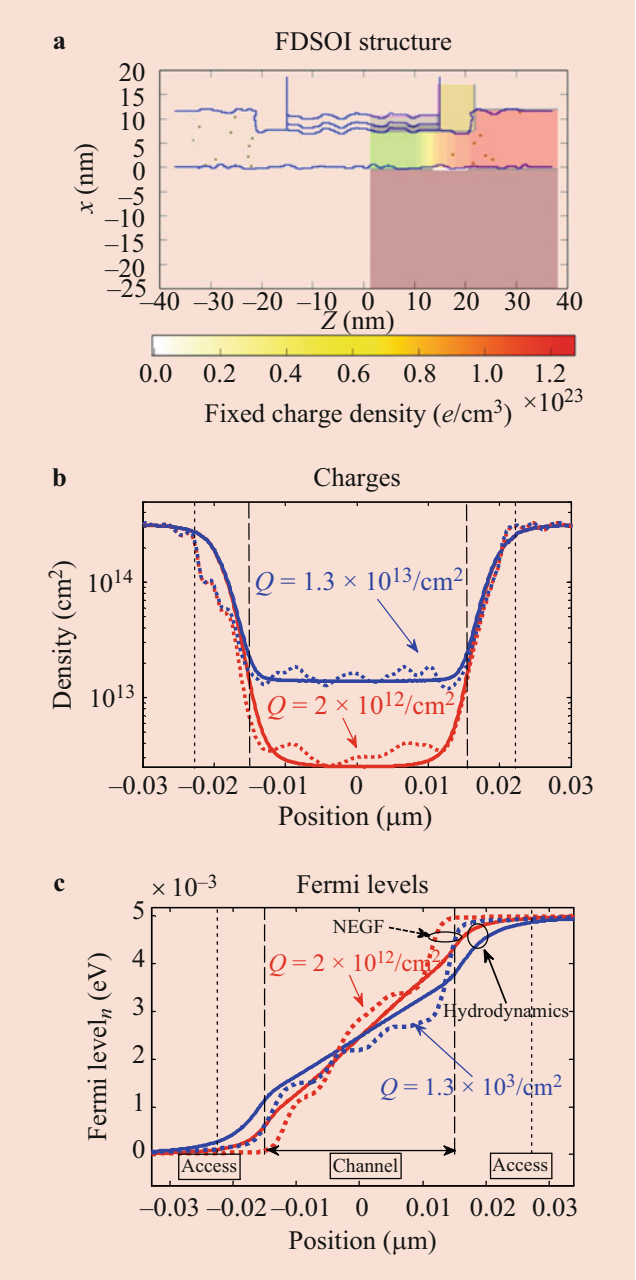

Fig. 12.11 Simplified FDSOI structure (**a**) featuring SiON/HfO2/metal gate with remote Coulomb interfacial charges (QHK = 3e13/cm^2), surface roughness, and discrete LDD dopants. NEGF (dashed) compared to density-gradient-corrected hydrodynamics-based simulations. (**b**) Inversion charges 1.3e13/cm^2 and 2e12/cm^2. (**c**) Quasi-Fermi levels calculated along the channel

We can see in Fig. 12.12 that the mobility μ_0 (as extracted from the R_{on}-L slope) and the σ value (best fit using (12.20)) largely depend on the choice of the models used during the NEGF simulation.

Figure 12.13 compares R_{on}-L predictions using the classical P&S to the NEGF results. The relatively large value of the velocity saturation used in the models can be inferred from the approximations used in the NEGF simulations (EMA and phonon only) which tends to overestimate the velocity saturation.

The classical P&S approach results compare well with the NEGF results, even in the saturation regime. We believe that, in a certain way, for a certain usage, the classical models are able to account for the observed and simulated overthreshold currents in UTBB FDSOI devices. However, some discrepancies can remain and are inevitable. In particular, discrepancy can come from the fact that we have considered the saturation velocity to be constant vs channel length. Saturation velocity overshoot phenomena have been highlighted in a theoretical viewpoint, and experimental results [41] tend to suggest that v^* increases by up to 50% in the shortest devices. Alternatively to classical approaches, the quantum approaches [46, 47] have pointed out that for the shortest devices, one may need quasi-ballistic models. In that case, the current can be expressed at the virtual source injection point, and the saturation of the velocity v^* is interpreted as an "injection" thermal velocity $v_T \approx \sqrt{2 \cdot kT/(\pi \cdot m)} \approx 1.2 \times 10^5$ m/s whose value is close to the saturation velocity in silicon [47]. Although such drain current models lead to similar current equations in saturation, the temperature dependence is different. Indeed, the thermal velocity is expected to increase with temperature, while the saturation velocity is expected to decrease with temperature (as suggested in Fig. 12.10).

12.3.5 Back Biased UTBB FDSOI MOSFET

One major advantage UTBB FDSOI has in comparison to bulk technology is the possibility to control the threshold voltage (V_{TH}) using the back-gate bias voltage as shown in Fig. 12.14 for both N- and P-type MOSFETs with a coupling factor of $\frac{C_{BOX}}{C_{OX}} \sim$ 70–100 mV/1 V for BOX thicknesses of 20–25 nm. The parasitic substrate coupling is avoided in the UTBB FDSOI by the introduction of the ground plane which is a highly doped region underneath the thin BOX [48]. This highly doped layer underneath the BOX opens various possibilities to tune the device threshold voltage (V_{TH}) [49] and extends the usage of the MOSFET back-gate biasing V_{bG} to dynamically optimize the power consumption [50].

Figure 12.15a shows the measured drain current for N-type MOSFET versus the front-gate voltage V_{GS} for various back-gate voltages V_{bG}. The transfer characteristic I_D–V_{GS} significantly shifts toward lower or higher V_{GS} value, but the subthreshold slope is nearly unchanged (cf. Sect. 12.4.2). The increase of V_{bG} is commonly called forward back biasing (FBB), and lowering V_{bG} is called reverse back biasing (RBB). It should be noted that, thanks to a ~25-nm-thick buried oxide, high voltages can be applied to the back gate (typically –10 V to 10 V range without stressing the buried oxide). Figure 12.15b shows the measured front-gate

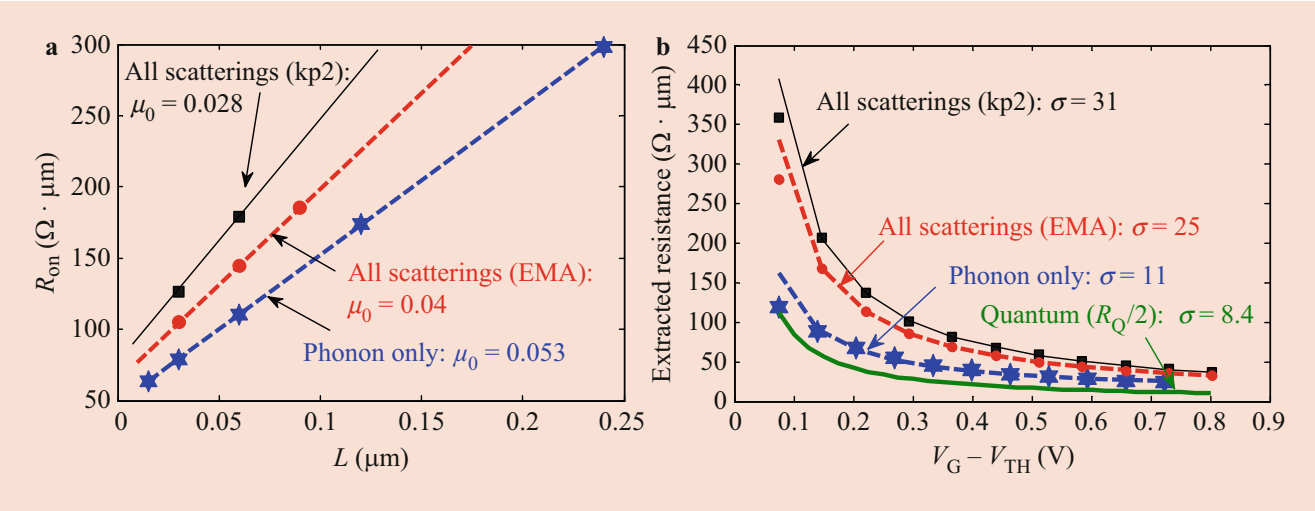

Fig. 12.12 (**a**) Device resistance R_{on} in the linear regime ($V_{DS} = 0.001$ V) for $V_{GT} = 0.8$ V, simulated using various approximations (see text for details). (**b**) Extracted series resistance from R_{on}-LY-axis intersect. Lines show best fit with a model: $\sigma.V_{GT}{}^{-1} + R_0$

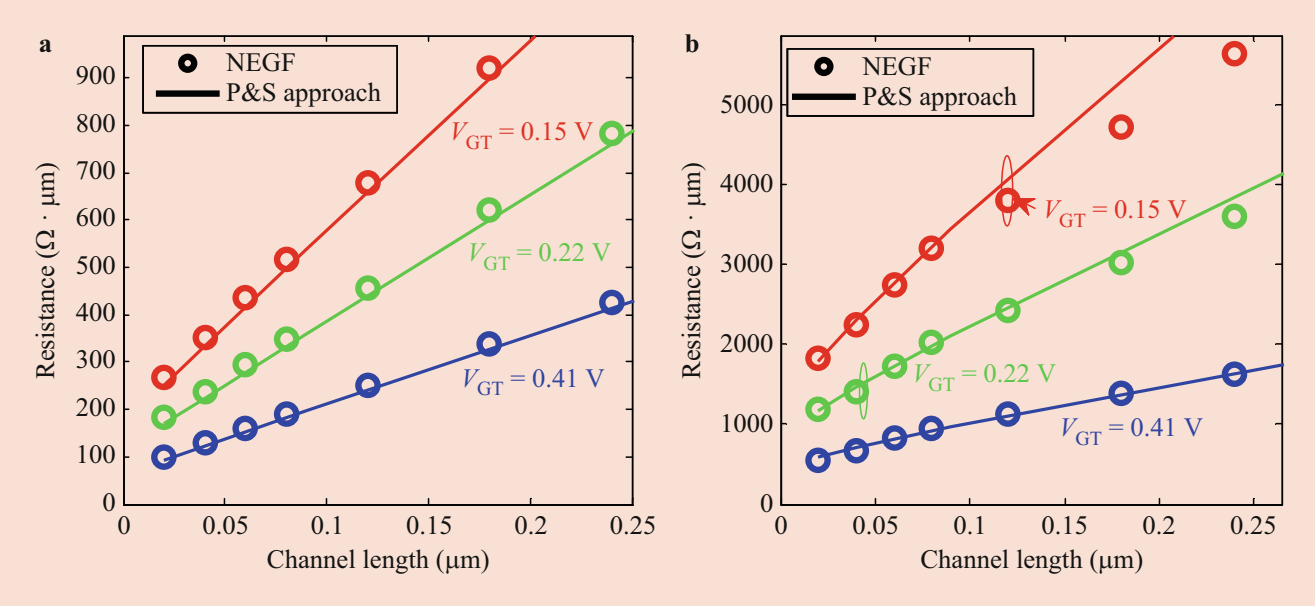

Fig. 12.13 Device resistance R_{on} in the linear ((**a**): $V_{DS} = 0.01$ V) and saturation ((**b**): $V_{DS} = 0.8$ V) regimes for various V_{GT}. Best fit with P&S approach ($C_{OX} = 0.025$ F.m^{-2}; $\mu_0 = 0.069$ m^2/(V.s); $\theta = 0$, $v = 2.1$e5 m/s) using an external overlap resistance model: $R = 0$ Ω.µm, $\sigma = 13$ Ω.µm.V. NEGF simulations within the EMA and with phonon only

to channel capacitance C_{gc} normalized using the front oxide capacitance C_{ox} with respect to the front-gate voltage V_{GS} for various back-gate voltages V_{bG}. A clear change of the capacitance shape can be observed for high back bias. In this case, the inversion charge shifts toward the back oxide for negative gate voltage and gradually shifts back to the front interface when increasing the gate voltage. This situation is depicted in Fig. 12.16 where band diagrams are extracted for an effective surface of $|E_{eff}| \sim 0.65$ MV/cm for at either $V_G = 1$ V and $V_B = 0$ or $V_G = -1$ V and $V_B = 8$ V.

Figure 12.17a shows the extracted threshold voltage (from the maximum of $\frac{\partial\left(\frac{g_m}{I_D}\right)}{\partial V_G}$ with current curves shown in Fig. 12.15). As well known [33], the slope of V_{TH} vs V_{bG} (namely, the coupling factor) changes for high back-gate biasing values. This is due to the back inversion in which the silicon layer capacitance C_{Si} has to be considered:

$\Delta V_{TH} = -\frac{C_{BOX}}{C_{OX}} \cdot \alpha \cdot (V_B)$ with $\alpha = 1$ for front inversion and $\alpha = \frac{C_{OX}+C_{Si}}{C_{Si}}$ for back inversion.

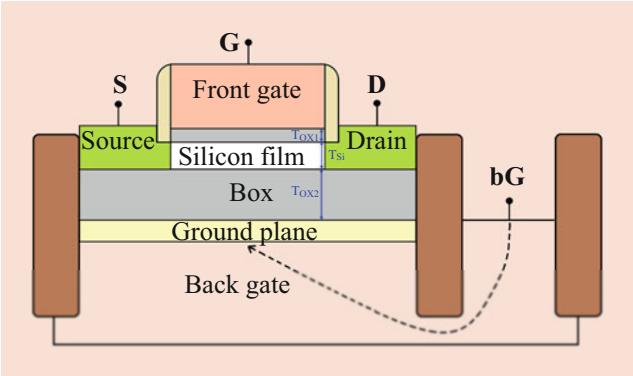

Fig. 12.14 Back biasing in UTBB FDSOI MOSFET

Figure 12.17a shows the inversion charge density (obtained integrating the capacitance curves of Fig. 12.15) as a function of gate voltage. The total inversion charge is composed of the sum of the back and the front inversion charges, and a change of the slope versus V_G is clearly visible in high FBB. Equation (12.3) remains valid provided that we define two threshold voltages for the front and back inversion charges and keeping in mind that the back inversion charge remains constant for $V_G > V_{TH2}$ due to the screening by the front inversion charge.

12.4 MOSFETs in Analog Design

In recent low-power and high-performance circuits such as those implemented in FDSOI for the Internet of Things (IoT) market, one needs to operate MOSFETs from weak inversion (WI) to SI regimes [51]. MOSFET compact models should accurately reproduce transistor behavior in all regions of operation including in WI and MI regimes. Considering only digital figures of merit (FoMs) such as ION and I_{OFF} is not sufficient to assess analog behavior of a MOSFET. Moreover, analog applications such as amplification need accurate prediction of continuous and higher-order MOSFET metrics and FoMs in all levels of inversion. It is worth pointing that moderate inversion region has been found to be a good compromise, while power consumption and speed are valued equally [23, 52, 53]. The MI provides higher transconductance for lower current and still acceptable bandwidth for low-power and low-voltage applications. It is worth noting that all parameters used in the model derivation in (12.10) are fitting parameters extracted in SI regime. Therefore, the derived analytical model in the previous section is very useful when MOSFET channel is strongly inverted and obviously not valid in WI and MI regimes where some analog applications find a valuable trade-off between gain, power consumption, and speed.

For hand calculations, although classical WI exponential law and SI square law models can be carefully used, the transconductance efficiency (g_m/I_D) charts briefly presented hereafter are more convenient to predict UTBB FDSOI MOSFET capability in all levels of inversion. The transconductance efficiency is an interesting figure of merit which can be used to gain insight into the transfer characteristic of a MOSFET for all levels of inversion. It is also defined as the slope of the transfer characteristic in its semi-logarithmic scale as it is expressed as:

$$\frac{g_m}{I_D} = \frac{1}{I_D}\frac{\partial I_D}{\partial V_{GS}} = \frac{\partial \ln I_D}{\partial V_{GS}} \tag{12.21}$$

The transconductance efficiency is used in Fig. 12.18 to compare the efficiency of three generations of planar MOSFET, highlighting at the same time the semiconductor industry smooth transition from bulk to UTBB FDSOI.

The plateau of the g_m/I_D plots (i.e., maximum g_m/I_D) in Fig. 12.18, which represents the WI regime, is inversely proportional to the subthreshold slope. The 28 nm FDSOI technology provides a near-ideal subthreshold slope (1.08) versus 65 nm bulk (1.13) and 28 nm bulk (1.17). The downscaling from 65 nm to 28 nm bulk clearly shows the electrostatic control degradation due to SCEs, which results in higher leakage. Moreover, the SCEs, responsible of the departure from the ideal square law current trend, are worst for bulk technologies as shown in the inset of Fig. 12.18. In particular, the velocity saturation and series resistances are responsible for the decrease of g_m/I_D at high current density and departure from the $\sim 1/\sqrt{I_D}$ trend. The main advantage of 28 nm bulk versus 65 nm bulk is the higher g_m/I_D in SI region, thanks to a higher $C_{ox}.\mu_0$, which results in a higher transconductance efficiency for the same current value (analog and RF applications) and a higher I_{ON} current (digital applications).

12.4.1 Inversion Level Metric

We have seen that the transfer characteristic of a MOSFET is used to extract a threshold voltage of the inversion phenomena taking place in the channel and is generally used to determine the level of the inversion of the MOSFET. In particular, the gate overdrive voltage (i.e., $V_{GT} = V_{GS} - V_{TH}$) is usually taken as a metric for this inversion phenomenon. However, the threshold voltage concept is not accurately defined, and the overdrive voltage loses its physical meaning below threshold (i.e., $V_{GS} - V_{TH} < 0$ V). Therefore, another metric, namely, the inversion coefficient (IC), has been introduced by Vittoz [54] and validated for a double-gate MOSFET in our published work [55]. IC is nothing else than the normalized drain current using the technology current

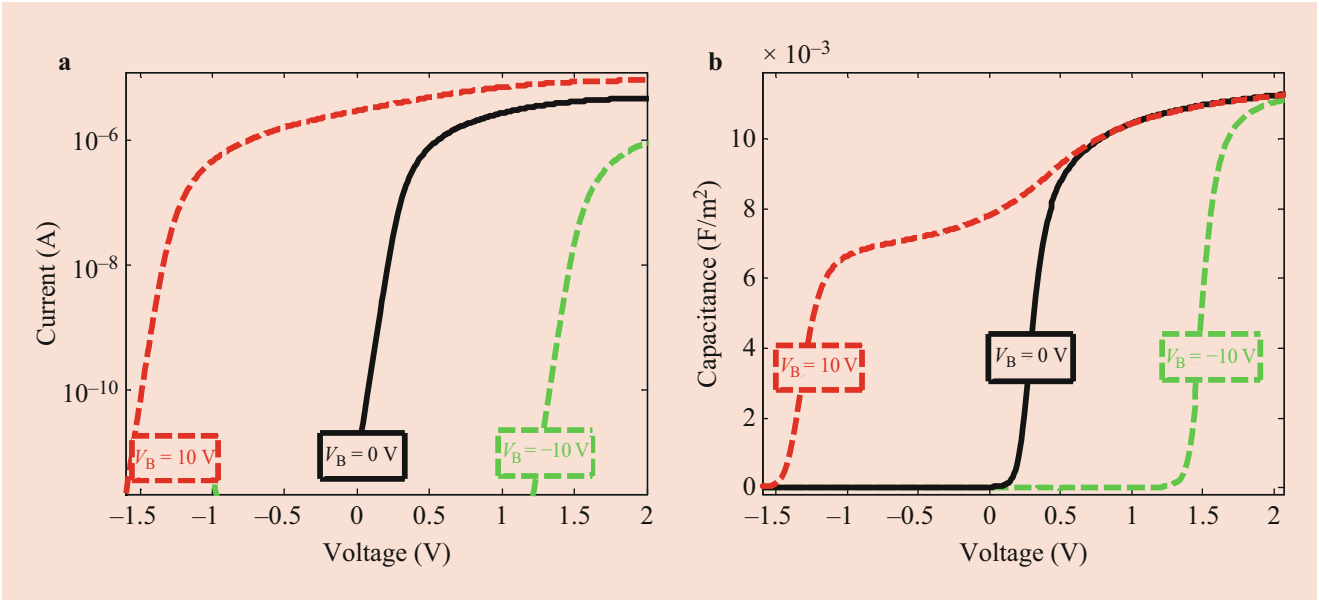

Fig. 12.15 (**a**) Measured and normalized linear drain current $I_D/(W/L)$ versus front-gate voltage V_{GS} for various back-gate voltages V_{bG}. (**b**) Measured and normalized front-gate capacitance versus front-gate voltage for various back-gate voltages. NFDOSI with $L = 10$ µm, $W = 2$ µm. Test structures for capacitance measurements performed on 30 identical devices in parallel

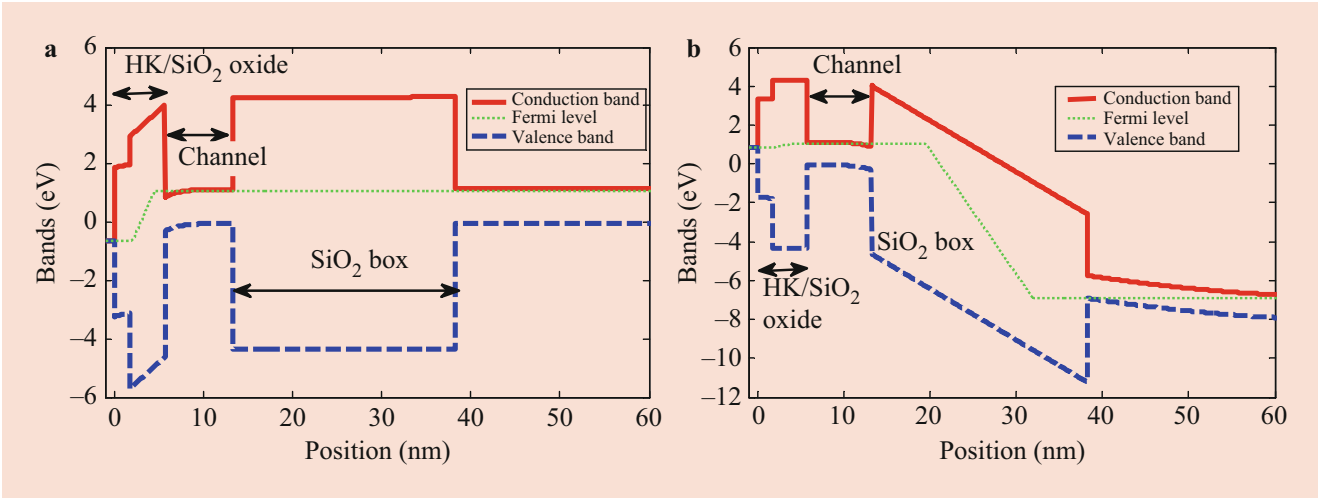

Fig. 12.16 Simulated band diagrams of the thick oxide FDSOI device when (**a**) the back terminal is grounded and (**b**) with 8 V back bias. The effective channel field is +0.652 MV/cm and –0.65 MV/cm, respectively

I_i which is located at the intersection of the WI (i.e., the plateau representing the Boltzmann limit) and the saturation SI square law asymptotes of the g_m/I_D plot versus normalized current $I_\square = I_D \cdot (L/W)$ for a long-channel MOSFET as depicted in Fig. 12.18. The *IC* expression is given as:

$$\mathrm{IC} = \frac{I_\square}{I_i} = \frac{I_D/(W/L)}{I_i} \tag{12.22}$$

Inversion coefficient concept is helpful to easily identify the MOSFET level of inversion from WI to deep SI. Unlike relaxed bulk technologies, in advanced technologies such as FDSOI, MI covers more than two decades of the drain current as depicted in Fig. 12.19a. IC will be used instead of the gate voltage overdrive $V_{GS} - V_{TH}$ while dealing with analog applications in order to cover all levels of inversion including MI.

12.4.2 MOSFET g_m/I_D Invariance

The drain current expression is complex in an asymmetric double-gate MOSFET and cannot be easily used for hand calculations in analog design. However, we have shown that

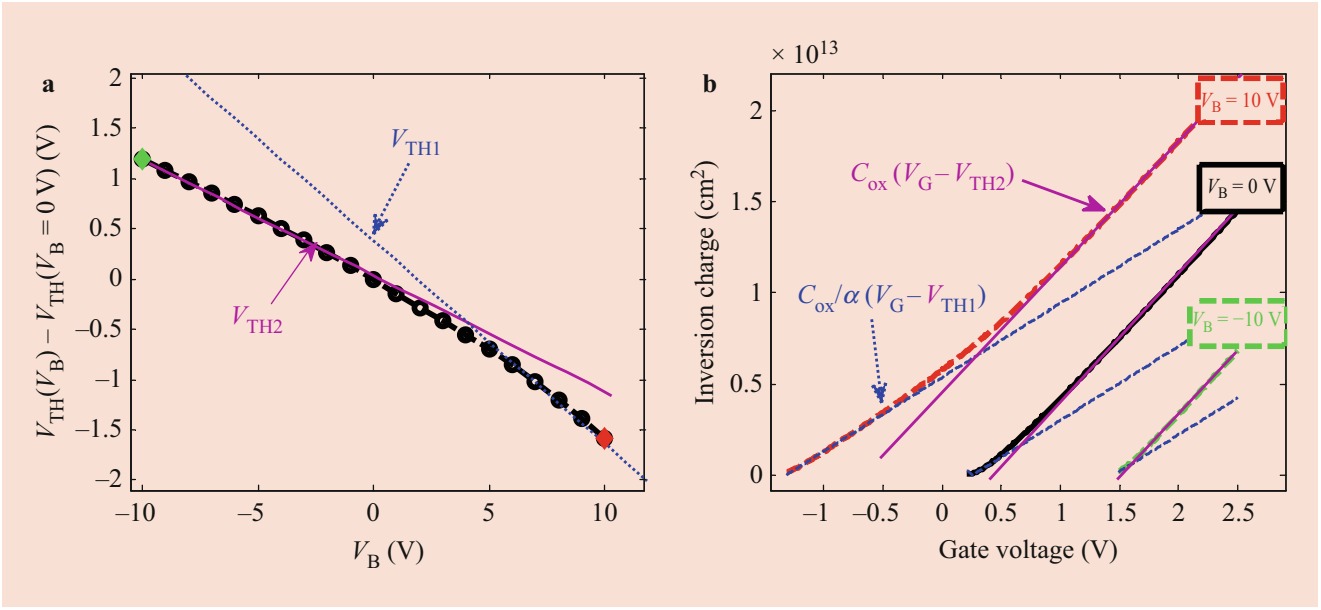

Fig. 12.17 Extracted threshold voltage (**a**) and inversion charge density (**b**). Model with $C_{OX} = 0.0114$ F.m^{-2}; $C_{BOX} = 0.0013$ F.m^{-2}; $C_{SI} = 0.015$ F.m^{-2}

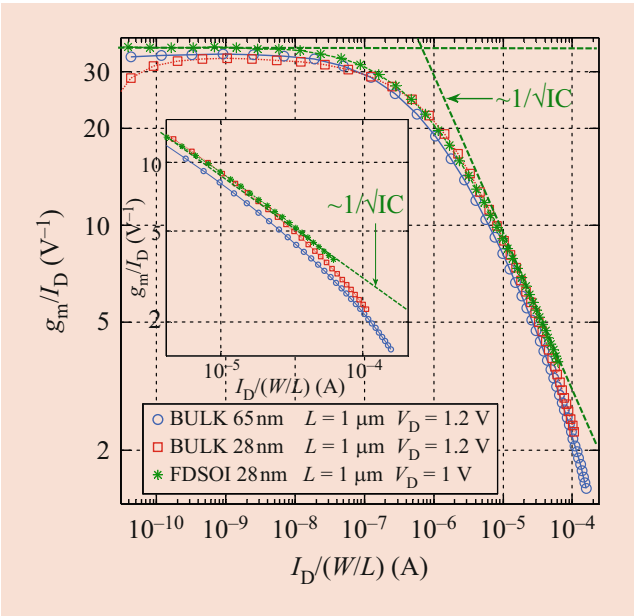

Fig. 12.18 Measured transconductance efficiency g_m/I_D versus normalized drain current $I_D/(W/L)$ for long channels $L = 1$ µm in saturation for bulk 65 nm, bulk 28 nm, and UTBB FDSOI 28 nm planar MOSFETs

a threshold voltage-based approach similar to bulk can be used to get a first insight into the main physical ingredients in SI regime. In MI where the simple models fail or for the case of short channels where complex physical phenomena occur, measured g_m/I_D charts can be used to estimate the analog performance of the device. In particular, the UTBB FDSOI transconductance efficiency charts are shown to be predictable and generally invariant. Indeed, if we plot the front transconductance g_{m1} over the drain current I_D characteristics with respect to IC for various V_{bG} in a log-log scale, we get the interesting invariance property shown in Fig. 12.19 where g_{m1}/I_D is normalized using the thermal voltage U_T and the front-gate slope factor n_1 (i.e., all g_{m1}/I_D plots superpose for various back-gate voltages V_{bG}). This property is assessed in [55] using measurements with respect to geometry, back-gate voltage, temperature, drain to source voltage, and process variations. In SI, all the long-channel plots tend to the square law characteristic which varies as the inverse of the square root of the current as can be predicted using (12.10). For WI, the measured plateau corroborates the exponential law of the drain current with respect to V_{GS}.

As shown in Fig. 12.19 for a long transistor, transconductance efficiency is maximum in weak inversion, decreases rather slowly in moderate inversion, and decreases as the inverse square root of IC in strong inversion. At the onset of strong inversion (i.e., IC = 10), transconductance efficiency is 70% lower than its maximum value.

The g_m/I_D invariance property can be used to predict the transconductance provided that W/L and level of inversion (i.e., IC) are given. Moreover, as a substitute to the analytical drain current model, one can predict drain current provided that W/L, V_{TH}, and gate voltage V_{GS} are provided. This calculation requires an additional chart of IC with respect to the gate voltage overdrive $V_{GS} - V_{TH}$ as shown in Fig. 12.19b, noting that a bijective relation exists between the two inversion metrics. This can allow designers to predict MOSFET DC properties without the need of an analytical model including in MI which is difficult to capture.

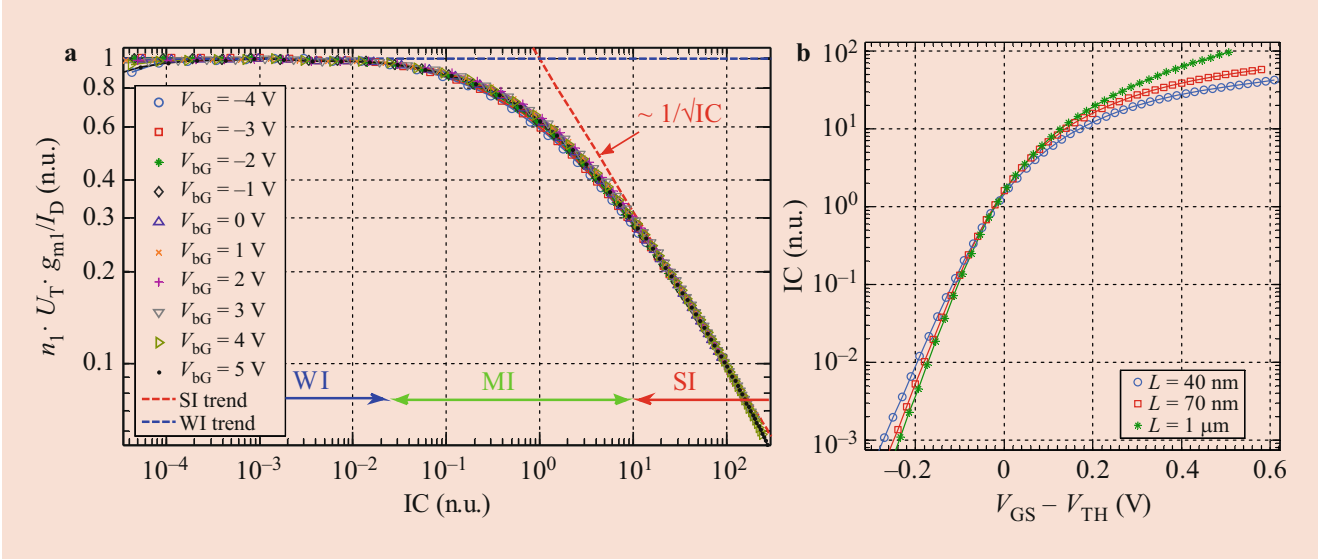

Fig. 12.19 (**a**) Measured and normalized g_{m1} over I_D as a function of the inversion coefficient at different V_{bG} for NMOS ($L = 1$ µm and $W = 1$ µm) in saturation ($V_{DS} = 1$ V) at $T = 25$ °C along with the WI and SI trends. (**b**) Inversion coefficient vs gate voltage overdrive for three lengths $L = 40$ nm, $L = 70$ nm, and $L = 1$ µm

Physical Insight

Both electrostatic and transport contribute to the g_m over I_D characteristic as:

$$\frac{g_m}{I_D} = \frac{\partial \ln I_D}{\partial V_{GS}} = \frac{1}{Q_{inv}} \frac{\partial Q_{inv}}{\partial V_{GS}} + \frac{1}{v} \frac{\partial v}{\partial V_{GS}} \tag{12.23}$$

noting that $I_D = Q_{inv} \cdot v$, where v is the average velocity of the charge carrier. In order to assess the transport contribution to the g_m over I_D characteristic, we propose to use a simple mathematical operation based on (12.23) and given as:

$$\frac{1}{v} \frac{\partial v}{\partial V_{GS}} = \frac{g_m}{I_D} - \frac{1}{Q_{inv}} \frac{\partial Q_{inv}}{\partial V_{GS}} \tag{12.24}$$

The mathematical operation in (12.24) is applied to data obtained from measured transfer characteristics $I_D - V_{GS}$ and gate to channel capacitance characteristics $C_{gc} - V_{GS}$ for various V_{bG} values in linear regime. Inversion charge Q_{inv} is extracted using a careful integration of the $C_{gc} - V_{GS}$ characteristics. The contribution of the transport to the g_m over I_D is finally depicted in Fig. 12.20 with respect to V_{GS} for various back-gate voltages V_{bG}. We clearly observe the impact of the V_{bG} on carrier velocity. The transport quantity $1/v \; \partial v/\partial V_{GS}$ which is equal to the derivative of $\ln(v)$ with respect to V_{GS} has its minimum at higher velocities. Therefore, for intermediate V_{bG} values close to –0.5 V, thanks to the volume inversion strength, the maximum apparent carrier velocity is higher. The term "apparent" stands for the fact that the extracted transport metrics (i.e., carrier velocity or mobility) using drain current characteristic represent an average on all carriers in the silicon film (i.e., in all its volume). Thanks to a lower vertical field, while volume inversion is taking place, more carriers in the Si volume are contributing to the transport, and this is interpreted as being an increase of the mobility at the back interface in various publications such as in Ohata [56] and Rudenko [57]. Although the transport contribution slightly depends on the back-gate voltage V_{bG} and the level of inversion, the impact on the variation of the normalized g_m/I_D plots is negligible.

Short Channels

Figure 12.21a shows normalized transconductance efficiency as a function of IC for different transistor lengths for N-type MOSFET. g_m/I_D is normalized using the slope factor n_1 of the long-channel MOSFET in order to highlight the slope degradation of short channels. Transfer characteristics of short channels also depart from the SI asymptotic trend because of mobility reduction, velocity saturation effects, and series resistance. The deviation from SI trend is more important for N type than P type because of the higher carrier mobility. Transconductance efficiency curves overlay in weak and moderate inversion for the 120 nm to 4 µm range of channel lengths. SI degradation ceases when carrier's velocity saturates completely and a ~1/IC dependence (i.e., linear dependence in $V_{GS} - V_{TH}$) is obtained. An additional degradation with respect to the linear asymptote (~1/IC) occurs when series resistance and mobility degradation add to velocity saturation for short-channel transistors. The long-channel transistor unique chart can be used in weak and moderate inversion to predict transconductance efficiency

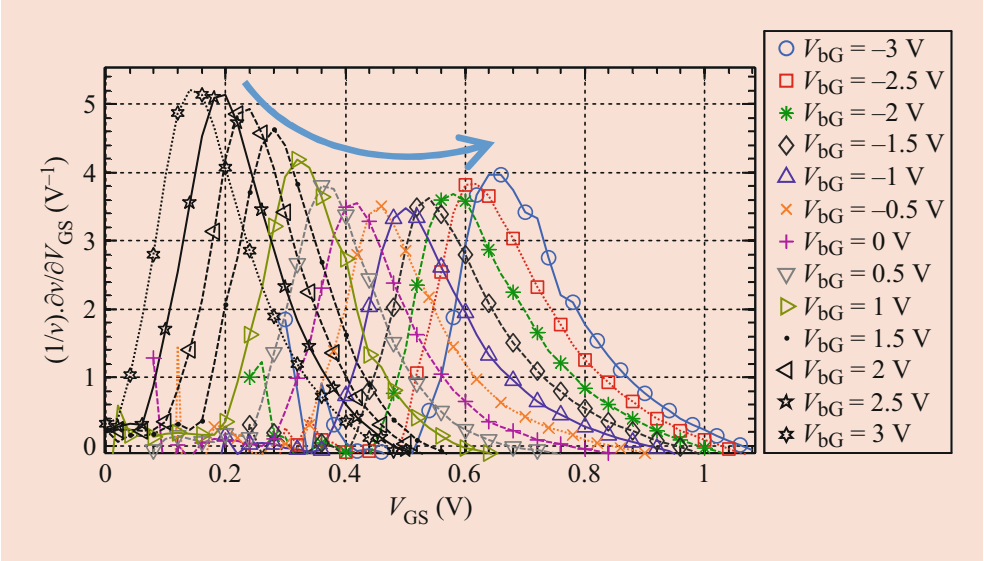

Fig. 12.20 Measurements showing the transport term $\partial \ln(v)/\partial V_{GS}$ versus gate voltage V_{GS} for various V_{bG} values (from –3 V to 3 V) in linear regime ($V_{DS} = 50$ mV)

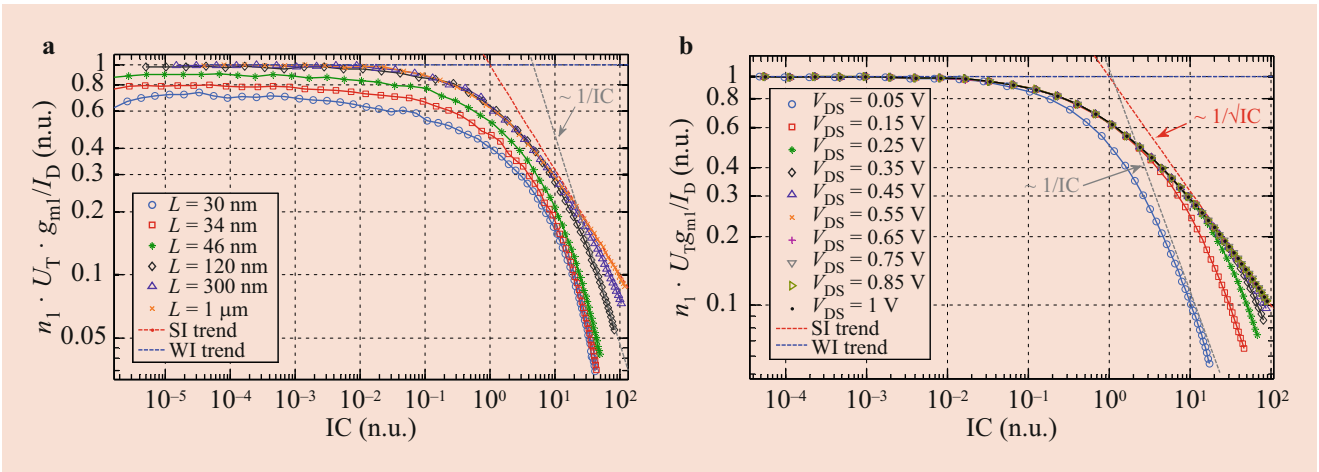

Fig. 12.21 (**a**) Measured and normalized g_{m1} over I_D as a function of the inversion coefficient for different lengths for NMOS ($W = 1$ µm) in saturation ($V_{DS} = 1$ V) at $T = 25$ °C. (**b**) Measured and normalized g_{m1} over I_D as a function of the inversion coefficient for different V_{DS} for NMOS ($W = 1$ µm and $L = 1$ µm) at $T = 25$ °C

for all transistors with a length greater than 120 nm, while error is kept lower than 5%.

Linear Versus Saturation

The g_m/I_D invariance should be considered in priority for saturation regime, and it is worth assessing the limit of drain potential below which the invariant breaks down in the onset of strong inversion. This information is useful in modern low-voltage low-power design since high transconductance efficiency is obtained in moderate inversion with lower drain to source saturation voltage V_{DSAT}. Figure 12.21b shows normalized transconductance efficiency versus IC for different drain to source voltages. In linear regime, the g_{m1}/I_D curve departs from the saturation and strong inversion asymptotic behavior and follows the 1/IC asymptote instead (i.e., linear dependence in $V_{GS} - V_{TH}$) as seen in the previous section. The transconductance efficiency chart defined at $V_{DS} = 1$ V can be used for lower drain to source voltages down to $V_{DS} = 250$ mV in weak and moderate inversion with an error of less than 4%.

The g_m over I_D charts clearly can be beneficial to the hand calculation-based analog design. Other important parameters such as gate-to-drain capacitance C_{gd} can easily be linked to the g_m over I_D through the powerful normalized IC instead of the questionable gate voltage overdrive. Thus, the g_m/I_D as a metric of the transconductance efficiency of the MOSFET can be accurately predicted for all inversion levels at low-frequency operation where transconductance g_m can

be considered as invariant versus frequency. Yet, the g_m/I_D FoM quantitatively favors gain and power consumption at the expense of operation speed. The g_m/I_D FoM can be used in conjunction with other metrics such as the transit frequency f_T in order to consider operation speed. In particular, the new FoM $f_T.g_m/I_D$ introduced in [58] captures decently both the transconductance efficiency and RF performance noting that the maximum value of this RF FoM represents the best trade-off between gain, power consumption, and speed and lays in the MI regime close to the SI onset. The aforementioned FoMs (i.e., g_m/I_D and $f_T.g_m/I_D$) are valid in low frequency and assume the g_m over I_D is invariant with regard to operation frequency.

12.4.3 MOSFET Efficiency at High Frequency

Because of a crowded up to 5 GHz spectrum with many interferers, some applications such as automotive radar started to tackle the mm-Wave spectrum looking for more bandwidth [59]. Other applications are under active investigation and design in mm-Wave spectrum such as low-power portable radars demonstrated in [60] and high data rate wireless USB-like communication prospected in [61]. The nanoscale CMOS device architectures display very high transit frequencies practically beyond the millimeter-wave (mm-Wave) spectrum as shown in Fig. 12.3b and can be clearly used for these mm-Wave applications. To be ready to take full advantage of the advanced nanoscale CMOS devices, the CAD tools must be updated with accurate descriptions of their behavior in all operation conditions including low voltage. Therefore, advanced nanoscale MOSFET models for high-frequency (HF) and low-voltage (LV) applications are required.

The simulation of advanced high-precision mixed-mode analog circuits including A/D converters, switched-capacitor circuits, and RF amplifiers requires accurate device models in a large frequency spectrum including mm-Wave. At high-frequency operation, the input signal may have rise or fall times comparable or smaller than the transit time of the transistor. Most compact models available so far are low-frequency quasi-static operation models with no or simplified high-frequency effects. The quasi-static (QS) operation is defined when an applied small signal varies sufficiently slowly that the carriers in the channel can follow the variation simultaneously.

High-Frequency Distributed Effects

Y-parameters are obtained from *S*-parameters' measurements and usually used to assess the high-frequency behavior of RF devices. An equivalent of the transconductance g_m at high frequency is the mutual transadmittance defined as:

$$y_m = Y_{21} - Y_{12} \tag{12.25}$$

where Y_{21} and Y_{12} are, respectively, the gate-to-drain transadmittance and the drain to gate transadmittance. At low frequency, the imaginary part of the complex y_m tends to zero. Consequently, the modulus or the real part of y_m is equal to the transconductance g_m at low frequency.

Figure 12.22a shows the real part of y_m (denoted Re(y_m)) for a long-channel MOSFET compared with a QS model (e.g., the MOSFET equivalent circuit proposed hereafter) which assumes constant transconductance over frequency. The QS model is clearly valid only up to 1 GHz and does not reproduce the performance degradation (i.e., "transconductance" decrease) at high frequency. Clearly, the real part of y_m decreases beyond a critical frequency F_{crit} that is defined

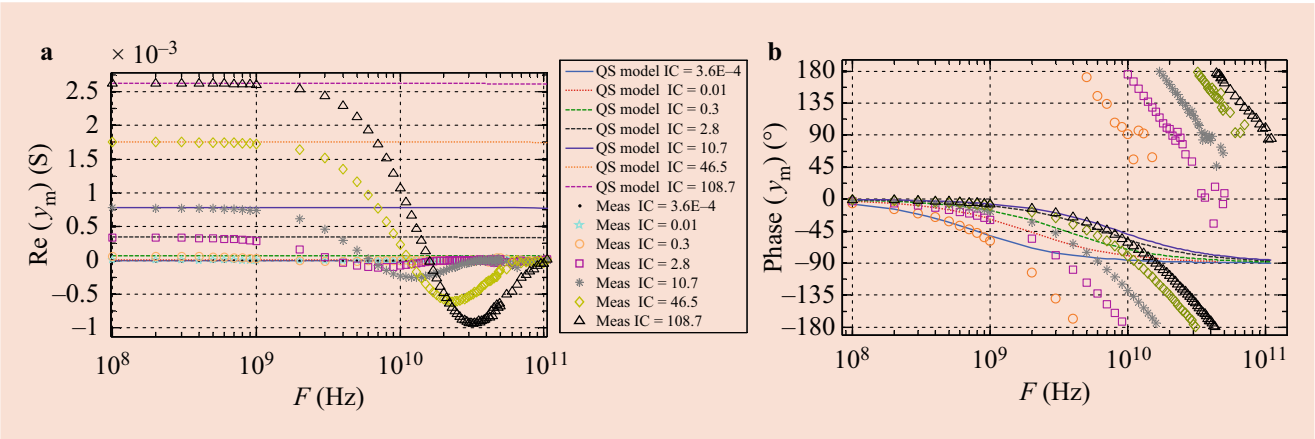

Fig. 12.22 (**a**) The real part of the measured and simulated mutual transadmittance y_m of a long channel $L = 1$ µm for various gate-to-source voltages from WI to SI in saturation ($V_{DS} = 1$ V). (**b**) The phase of the measured and simulated mutual transadmittance y_m of a long channel $L = 1$ µm for various gate-to-source voltages from WI to SI in saturation ($V_{DS} = 1$ V)

hereafter. Moreover, measurements show negative Re(y_m) at high frequency, which means that the phase shift is greater than 90°. This is confirmed in Fig. 12.22b where y_m phase is shown versus frequency. With regard to phase shift, the QS model is valid up to 1 GHz for $V_{GS} = 0.4$ V (i.e., IC = 0.3) and up to 8 GHz for $V_{GS} = 1$ V (i.e., IC = 109). The QS simulation phase tends to −90° for WI and SI, while measurements show a clear antiphase phenomenon (i.e., a difference in phase of 180°). The phase shift decreases faster than the modulus from initial value of zero up to more than 270° (i.e., antiphase 180° + 90° noting that phase continues to decrease even beyond the –180° and discontinuities in the plots are only due to the phase axis unit convention).

The critical frequency F_{crit} clearly depends on V_{GS} and consequently on the channel inversion level. For long-channel devices, the critical frequency is lower for lower inversion levels. However, for short-channel devices, the y_m phase decreases faster for stronger levels of inversion (i.e., F_{crit} is lower for SI) as the higher gate capacitance contributes to a higher signal delay in the gate [62]. The performance degradation at high frequency is observed for all geometries and bias conditions, in particular for long-channel devices. The phase shift of y_m means that the voltage excitation at the gate terminal lags behind the generated current at the drain terminal. This delay is due to the distributed effects that are taking place in the MOSFET structure and that are not modeled in QS compact models. Two distribution effects are competing in a MOSFET structure: (1) the NQS effect occurring in the channel [63] and (2) the longitudinal distribution effect taking place in the gate fingers [64]. The two distribution phenomena are confused in some research works noting that the consequences of the two effects on the Y-parameters are comparable. An enhancement of the model considering the two distributed effects is proposed in the following for high-frequency operation.

Transadmittance Efficiency (Y_m/I_D)

The low-frequency transconductance efficiency (g_m/I_D) is generalized to high frequency. More specifically, the transadmittance efficiency (y_m/I_D) offers a practical insight to help MOSFET performance assessment in all frequency ranges [62]. On top of the harmful impact of the high channel inversion level upon the transconductance efficiency, the trend is amplified due to the distributed effects described above. This impact is shown in Fig. 12.23 which reports the measured transadmittance efficiency modulus and phase versus operation frequency (F) for various inversion levels.

At any frequency, the y_m/I_D FoM defines the gain and phase shift for a given inversion level IC. The evolution of the transadmittance efficiency versus frequency provides a very valuable insight in terms of power performance and efficiency at high frequency in the presence of NQS effects. As shown in Fig. 12.23, at high frequency, the NQS operation degrades the efficiency expected at low frequency and in particular for weak and moderate inversion (IC < 10). The higher efficiency of the moderate and weak inversion modes (i.e., $g_{m1}/I_D > 10$) does not hold anymore beyond $F = 4$ GHz for $L = 1$ µm. Moreover, beyond 13 GHz and unlike low-frequency operation, the SI performs better with regard to the transadmittance efficiency. Plotting the integral of each curve in Fig. 12.23a over the interval [0, F_{NQS}] versus IC where F_{NQS} is an onset frequency of NQS effect (cf. expression in (12.26)), the maximum is found in SI (IC > 10) for $L = 1$ µm, while it is located in MI for $L = 300$ nm and shorter devices. This integral is a FoM for the trade-off between performance, power consumption, and speed and is a general case of the $f_T.g_m/I_D$ FoM which considers f_T as the maximum possible operation frequency.

$$\mathrm{FoM_{HF}} = \int_0^{F_{NQS}} \frac{|y_{mi}|}{I_D} \mathrm{d}F \tag{12.26}$$

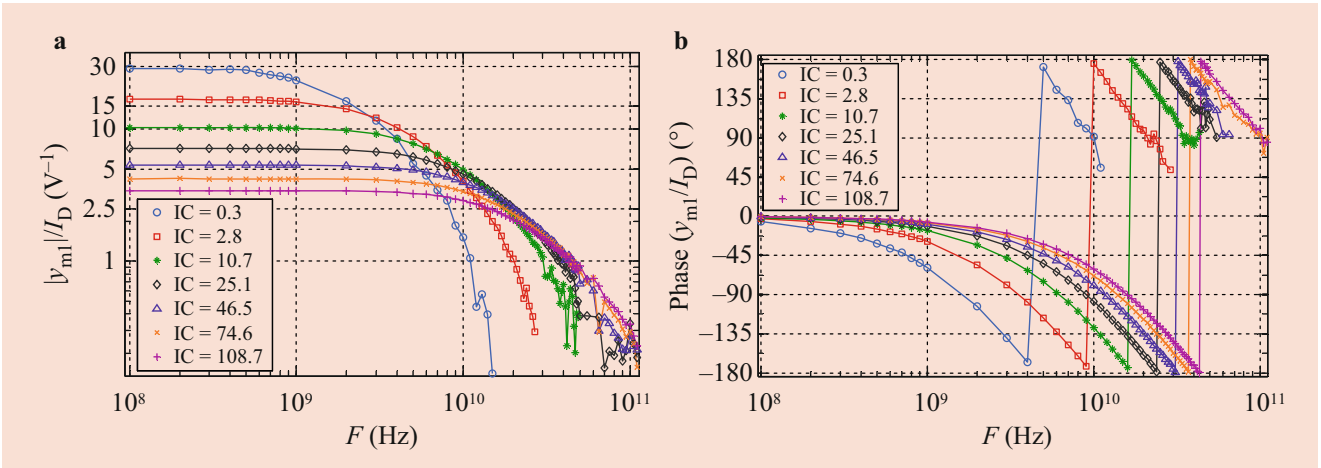

Fig. 12.23 Measured transadmittance efficiency modulus (**a**) and phase (**b**) versus the frequency for different IC for a NMOS ($L = 1$ µm) in saturation ($V_{DS} = 1$ V) and back-gate voltage $V_{bG} = 0$ V

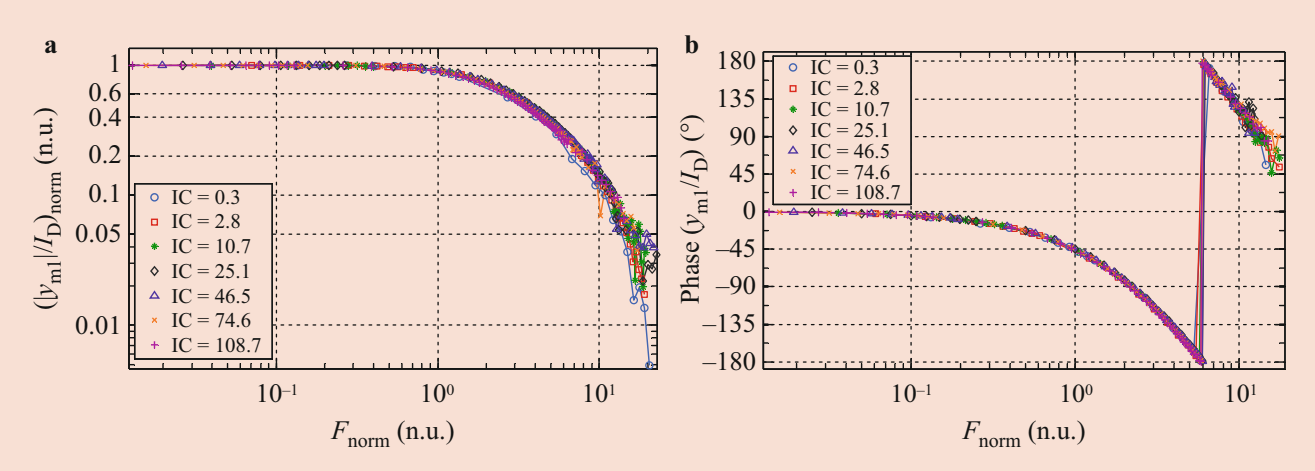

Fig. 12.24 Normalized transadmittance efficiency modulus (**a**) and phase (**b**) versus normalized frequency F_{norm1} at different IC for NMOS ($L = 1$ µm and $W = 1$ µm) in saturation ($V_{DS} = 1$ V) and back-gate voltage $V_{bG} = 0$ V (measurements)

Having a clear definition for the onset frequency of NQS operation is needed to provide a more realistic insight into the high-frequency performance of MOSFETs. Exact small-signal analytical expressions for NQS operation are presented in [63] for single-gate bulk MOSFETs and simplified in [65] to derive a compact model. The critical frequency F_{crit} expression, which corresponds to the first pole of the frequency characteristic of the device, as a function of the inversion coefficient IC is:

$$\mathrm{F_{crit}} = \frac{1}{2\pi}\frac{15}{4}\cdot\frac{\mu_{eff}U_T}{L^2}\cdot\frac{2+6\,\mathrm{IC}+3\sqrt{\mathrm{IC}+\frac{1}{4}}+4\left(\sqrt{\mathrm{IC}+\frac{1}{4}}\right)^3}{1+2\,\mathrm{IC}+3\sqrt{\mathrm{IC}+\frac{1}{4}}} \tag{12.27}$$

$$\approx \frac{15}{4\pi}\times\frac{\mu_{eff}U_T}{L^2}\cdot\sqrt{\mathrm{IC}}\ \text{(in SI)} \tag{12.28}$$

where μ_{eff} and U_T are, respectively, the effective mobility and the thermal voltage. Equation (12.28) approximates (12.27) while neglecting smaller terms in strong inversion, with less than 1% error on F_{crit} for IC > 2. It should be noted that F_{crit} is proportional to the effective mobility and U_T is inversely proportional to the square of gate length and accounts for the dependence of NQS on the inversion coefficient IC. This critical NQS frequency will be used for frequency normalization as in (12.29), while a further normalization of $|y_{m1}|/I_D$ is applied using the low-frequency transconductance efficiency g_{m1}/I_D as in (12.30).

$$F_{norm} = \frac{F}{F_{crit}} \tag{12.29}$$

$$\left(\frac{|y_{m1}|}{I_D}\right)_{norm} = \left(\frac{|y_{m1}|}{I_D}\right)/\left(g_{m1}/I_D\right) \tag{12.30}$$

All normalized moduli plotted in Fig. 12.24a from weak to strong inversion are almost superposed as a result of the frequency normalization in (12.29) and (12.30) (despite the very-high-frequency disturbance of the measurement parasitic elements). The invariance is also evidenced for the phase in Fig. 12.24a up to a phase shift as large as 270°.

If we consider the additional pole due to the gate-distributed effect which is the main cause of the transconductance degradation at high frequency for short MOSFETs, a new normalization frequency is used. The first pole of the gate distribution effect is captured using a simple $R_g.C_g$ model where R_g and C_g are the gate resistance and average gate capacitance, respectively. For a short-channel MOSFET, the normalization taking into account NQS effect and gate distribution effect leads to similar conclusions as for the $L = 1$ µm case [62].

These results are of prime importance for modeling NQS effects in UTBB FDSOI MOSFETs. A simple but powerful analytical model can predict the gate transconductance, magnitude, and phase, during highly non-static operation of the intrinsic channel and in all the regions of operation. Additional normalizations in terms of the inversion coefficient and critical frequency were used to derive a kind of abacus, paving the way to a simple and efficient high-frequency design methodology where device parameters, biasing conditions, and frequency are treated on the same ground.

12.4.4 Small-Signal Equivalent Circuit

High-frequency operation of a MOSFET is closely linked to its bias condition and consequently to its DC operation. The high-frequency QS operation can be seen as an assessment of the multiple derivations of the DC operation, in that it scans a part of the *I*–*V* characteristic and "senses" its variations.

When terminal voltage variations are sufficiently small, the small-signal assumption can be considered, and linear relations between produced current variations and input voltage variations can be used. Consequently, only one derivation of the I–V characteristic is sufficient to predict the behavior of the MOSFET in small-signal assumption. Acceptable prediction of the derivatives of the DC characteristic obviously relies on accurate DC model (e.g., the simple drain current model in (12.10) or the g_m/I_D charts).

In order to allow a simpler access to the different contributors to the small-signal frequency operation, equivalent circuits of the MOSFET devices are usually proposed. For high-frequency operation, the device core model (e.g., a compact model or a lumped small-signal equivalent circuit) is enriched to capture parasitic and distribution effects.

One of the frequently used MOSFET equivalent circuits is the Meyer (1971) one based on reciprocal capacitances (C_{gs}, C_{gd}, and C_{gb}). Besides the problem with the charge conservation, this model is still acceptable for hand calculation with small errors at low-frequency operation. An augmented version of the Meyer model used hereafter to model the UTBB FDSOI MOSFET small-signal equivalent circuit valid in low-frequency operation is depicted in Fig. 12.25. It includes intrinsic MOSFET components such as the front and back transconductances g_{m1} and g_{m2}, respectively, and extrinsic elements such as source and drain series resistances (i.e., R_S and R_D, respectively). Gate-to-source (C_{gs}), gate-to-drain (C_{gd}), and front-to-back-gate (C_{gb}) reciprocal capacitances are also included as shown in Fig. 12.25. By a reciprocal C_{xy} capacitance, we mean that the following condition is verified:

$$\frac{\partial Q_x}{\partial V_y} = \frac{\partial Q_y}{\partial V_x} \tag{12.31}$$

It should be noted that the equivalent circuit elements (i.e., capacitances and resistances) include both intrinsic and extrinsic parts. It is important to distinguish between the intrinsic (denoted by "i") and extrinsic (denoted by "e") contributions that have different origins. The intrinsic part is related to the device itself and mainly useful for channel current modulation, while the extrinsic part is related to parasitic elements unnecessary for the device operation. The extrinsic part can be optimized using proper layout technics such as multi-finger layout but cannot be completely removed. At high-frequency operation, the extrinsic elements gain particular importance and must be carefully modeled. At mm-Wave operation, these parasitic elements can even dominate the device performance. In general, the electrostatic couplings between the MOSFET terminals are not reciprocal, and for the dynamic operation modeling, 16 transcapacitances are required to agree with the charge conservation rule. Recent MOSFET compact models such as L-UTSOI account for the charge conservation, and the 16 transcapacitances are provided as part of the simulators DC operating point (OP) information.

In the MOSFET device, the C_{gd} and C_{dg} capacitances are not reciprocal due to the gate impact on the channel inversion. The modeling of the non-reciprocal C_{gd} and C_{dg} capacitance effect is done by adding an imaginary part C_m to the transconductance g_m (i.e., drawn in parallel to it in the equivalent circuit as shown in Fig. 12.25). The mutual capacitance is defined as [66]:

$$C_m = \frac{\partial Q_d}{\partial V_G} - \frac{\partial Q_g}{\partial V_D} = C_{dg} - C_{gd} \tag{12.32}$$

The mutual capacitance is playing an important role although it is usually neglected for low frequency.

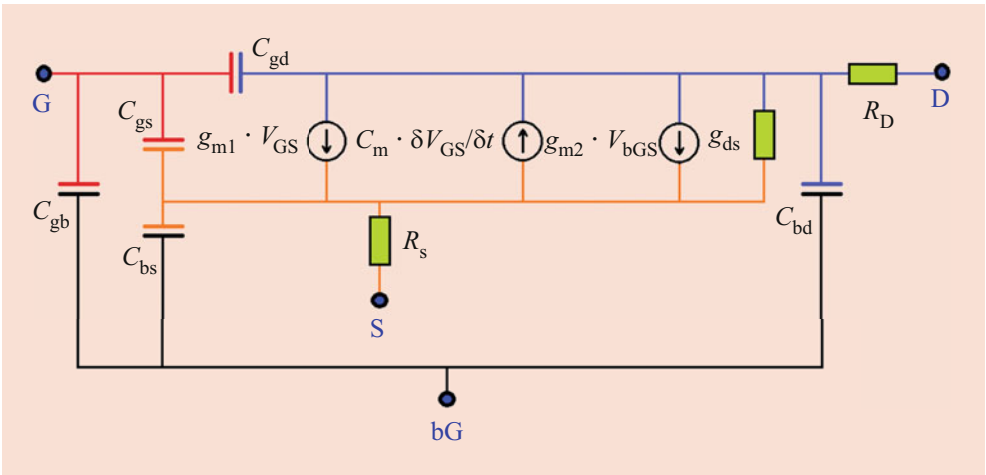

Fig. 12.25 Small-signal equivalent circuit for quasi-static operation of the UTBB FDSOI MOSFET including series resistances R_S and R_D ($C_{gd} = C_{gdi} + C_{gde}$ and $C_{gs} = C_{gsi} + C_{gse}$). C_{sd} is neglected here

All the coupling effects represented in the proposed equivalent circuit in Fig. 12.25 are extracted and validated under QS operation. For high-frequency operation, non-quasi-static effects (e.g., the lateral and longitudinal distribution effects) must be considered and modeled.

12.4.5 High-Frequency Modeling

The small-signal equivalent circuit in Fig. 12.25 is a QS model valid in low-frequency and unable to predict the high-frequency performance degradation due to the distribution effects. This limitation is shown in Fig. 12.22 for a long-channel device. The equivalent circuit parameters are determined using extraction routines applied to low-frequency measured characteristics performed on dedicated DC test structures. Only DC-based extraction leads to RF performance overestimation; therefore, RF extraction is required to multigate real high-frequency performances. The characterization using S-parameter measurements and de-embedding procedures is a method of choice for RF and mm-Wave spectrum operation assessment. S-parameters are practical metrics and are frequently used by microwave engineers and RF designers as the open or short circuit assumptions are not required. Instead, adapted terminations are used. However, S-parameters are generic and generally not practical to gain a deeper insight into the MOSFET physics. The measured S-parameters are transformed into Y-parameters and compared with the simulated counterparts for several inversion levels from WI to SI. Moreover, all equivalent circuit parameters as well as extrinsic elements such as gate resistance can be expressed using Y-parameters and easily evaluated at high frequency.

Gate Resistance

For DC and low-frequency operation, no gate resistance is required as the gate leakage current is very low (i.e., typically lower than 10 nA/μm^2). However, for high-frequency operation, the gate resistance should be considered, noting that high dynamic (AC) current is generated at the gate terminal. Moreover, the gate resistance in series with the gate capacitance will contribute a pole in the transadmittance function, and this will decrease the transadmittance as shown in Fig. 12.23. The gate resistance model accounts for the distributed aspect composed of the contact resistance, the horizontal resistance along the gate finger, and finally the vertical gate stack or interface resistance contributions.

The series and parallel RC-based front-gate network is developed using the pole-zero compensation technique. The gate network thus developed and integrated in the complete non-quasi-static model of Fig. 12.26a is convenient to simulate the gate distribution effect of short channels where the channel NQS effect contribution is multigated. In summary, besides the NQS effect that is modeled hereafter using channel segmentation, the gate-distributed effect can be modeled using series and parallel RC network. In addition to the overlap capacitances included in the core MOSFET model (i.e., in C_{gs} and C_{gd} capacitances), the gate network accounts for the distributed lateral fringing capacitance (i.e., $C_{frwS} + C_{frwD}$ and $C_{frlS} + C_{frlD}$) which is mainly dependent on the MOSFET width (i.e., finger length) [67].

NQS Modeling Using Channel Segmentation

At high-frequency operation, charge carrier's inertia in a long channel limits the device performance and induces admittance and transadmittance phase shifts. The channel can be viewed as a transmission line at high frequency and should be modeled accordingly. An accurate and physically based charge model for NQS effects has been proposed by Sallese [63] based on Bessel functions. Other NQS formulations based on spline collation method are also proposed [68, 69]. However, the proposed models are valid for small-signal analysis only (i.e., no time domain transient) or difficult to efficiently implement on top of the proposed models unless a simplification is used (need of additional nodes). Several simplified NQS models are also proposed in the literature to capture the first order and used in standard models such as the relaxation time approximation (RTA)-based method or the widely used Elmore model [70, 71]. However, these simplified models are only valid up to a maximum of 1 to 2 f_T. The segmentation of the channel proposed in [72] is adapted to the UTBB FDSOI MOSFET architecture and used for NQS modeling. The method is valid for small-signal as well as large-signal analysis, in frequency and time domains. The MOSFET device channel is split into several segments. Each segment is modeled using a compact model such as L-UTSOI or the equivalent QS circuit in Fig. 12.25 which provides comparable results. Only five elements provided accurate results with respect to measurements and chosen as a trade-off between accuracy and computational time. All segments have the same model parameters that represent the core behavior.

In order to model the DIBL effect, two voltage-dependent voltage sources are added in series with the two gate terminals. The DIBL is implemented as a threshold voltage shift. The overlap and fringe capacitances are added on top of the segmented channel and can also be modeled using a sixth parallel MOSFET with a mobility set to zero. The advantage of using a MOSFET shell for parasitic capacitances is the compatibility with the QS compact model parameters in particular the overlap capacitance term. In order to account for the diode formed between the well under

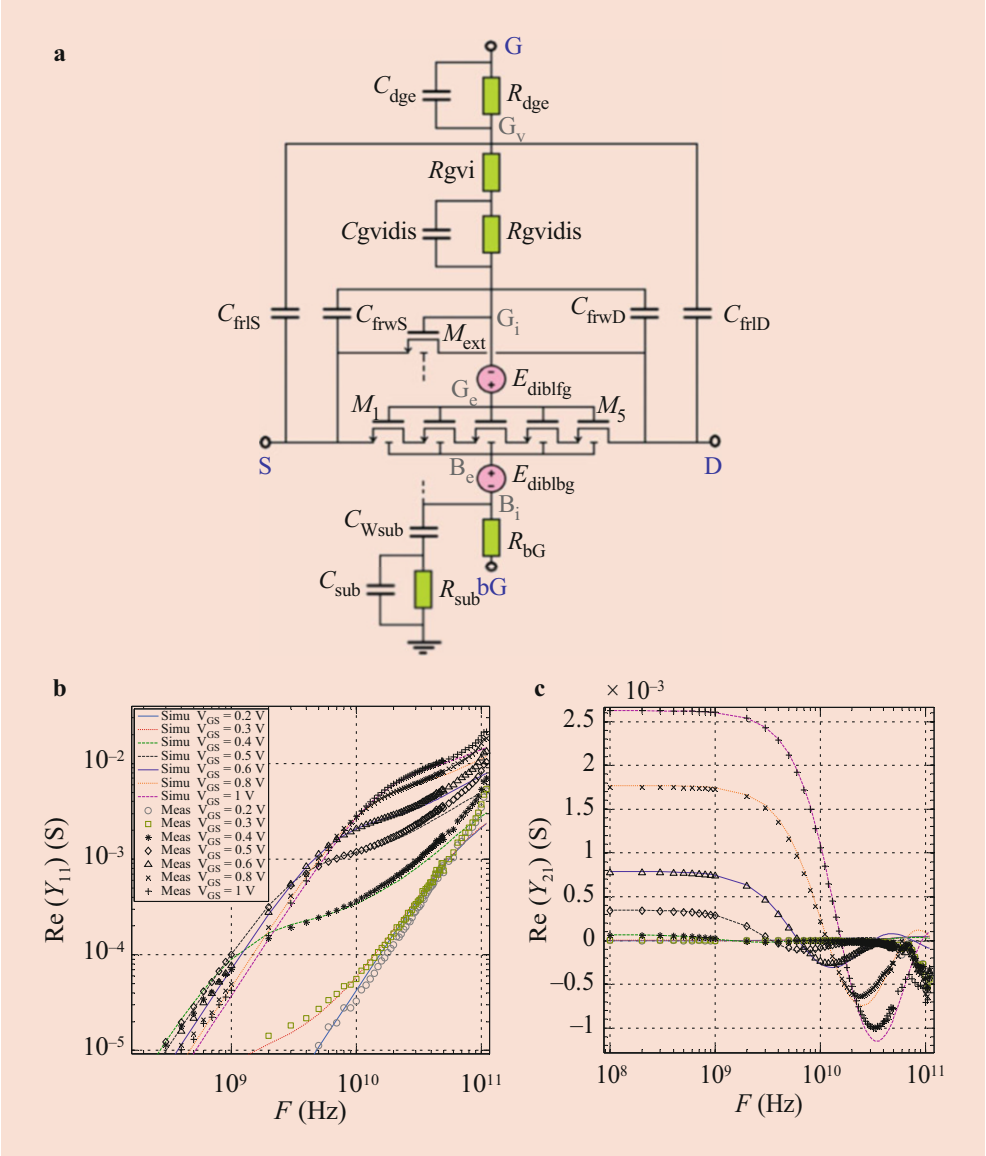

Fig. 12.26 (**a**) Complete non-quasi-static model. Simulation and measurements of the real parts of the input transadmittance Re(Y_{11}) (**b**) and input-to-output transadmittance Re(Y_{21}) (**c**) of 1-μm-long NMOS vs frequency for various gate-to-source voltages from WI to SI in saturation ($V_{DS} = 1$ V)

the BOX and the substrate, a simple lumped circuit is added to the model for the comparison with the measured data. The final proposed non-quasi-static model is shown in Fig. 12.26a along with *Y*-parameters' model-hardware correlation results (Fig. 12.26b, c). The proposed high-frequency non-quasi-static model is well suited for modeling UTBB FDSOI MOSFET operation. Validation conditions include length scaling down to nominal value, a wide frequency range up to 110 GHz, and operation under different channel inversion levels down to low-current and low-voltage regime. An excellent agreement is shown over more than eight decades of current density for DC and four decades for RF and mm-Wave.

12.5 Application Example: LNA Analog Design in MI Regime

The common architecture of mixed analog-digital systems consists of digital processing cores surrounded by A/D and D/A converters, which separate the digital part from the analog blocks. The mixed analog-digital systems are integrated into one IC known as the system-on-a-chip (SoC). The analog part role is to sense and communicate with the external world which is a key and sensitive role. In digital CMOS circuits, static power consumption is mainly

related to the leakage current. However, in analog circuits, biasing current is the main contributor for circuit power consumption. Thus, the devices used in analog blocks need to be permanently biased in the appropriate region. Besides power supply voltage lowering in recent technology nodes, the current budget should be reduced as well.

Several circuit topology-based techniques such as current reuse are proposed in analog design to optimize performance and power consumption [73]. These techniques are out of this chapter scope. Here, the focus will be on another design challenge which is the transistor sizing in MI regime to achieve a good trade-off between speed and low current budget. The RF designer dilemma is to calculate transistor geometry and current in order to get maximum amplification, minimum degradation of the signal-to-noise ratio, and minimum power consumption. The goal is to provide an illustration of an analog design method mainly based on the charts and properties described in previous sections. The UTBB FDSOI MOSFET characteristics are used for first-cut analog sizing method. In particular, the g_m/I_D versus inversion coefficient IC is used to determine the width of the MOSFET, while the transit frequency (f_T) versus IC charts are used for length selection. The design method, using relaxed length and MI regime, provides a valuable trade-off between gain, power consumption, and performance, while MOSFET width is kept reasonably large, and short-channel effects are multigated. An eye is also kept on passive devices' limitations from the very beginning of the sizing flow.

One of the key building blocks in a wireless system is a low-noise amplifier (LNA). The LNA circuit amplifies the input signal with minimum degradation of the signal-to-noise ratio. One of the challenges RF designers face is the simultaneous matching of the noise and the input impedance for the same source impedance. This challenge is beyond the scope of this chapter; therefore, ideal impedance matching is considered here. However, a constraint on the value of the inductors is considered in order to account for integrated inductors with acceptable quality factors.

12.5.1 LNA Circuit Characteristics

One of the most used circuit topologies for an LNA is the narrowband cascode. The cascode transistor is used to isolate the input from the inductive load. In particular, the Miller effect is reduced for the input transistor. However, using a cascode topology leads to a minimal room for drain to source voltage required to set both transistors in saturation. This also corroborates the need for MI operation as V_{DSAT} is lower in this regime. The circuit of the cascode LNA is shown in Fig. 12.27. The transistor M_1 is the input transistor, and M_2 is the cascode transistor. Both transistors are chosen to have the same geometry. Degeneration inductor L_s and input series inductor L_g are used for input impedance matching.

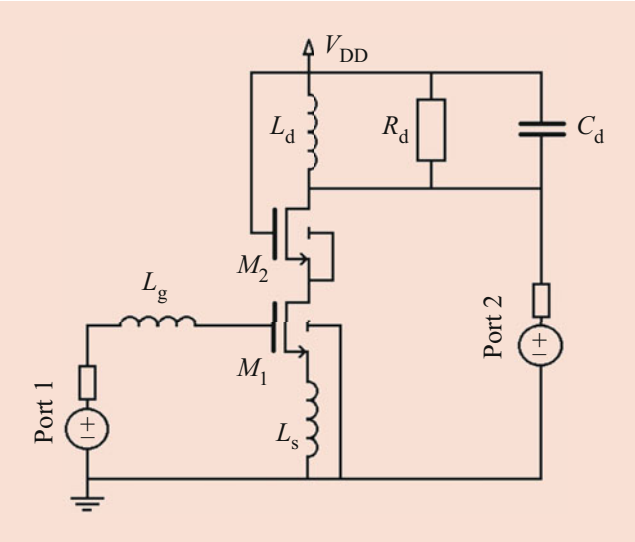

Fig. 12.27 LNA cascode circuit

The following specifications are taken as an example: Drain current is 2 mA, power gain is greater than or equal to 8, operation frequency is $F_0 = 35$ GHz, minimal noise figure NF_{min} is no more than 2 dB, and input impedance is matched for 50 Ω.

In order to size the circuit components and meet the specifications, the following three steps are followed:

12.5.2 Passives-Related Constraints and Length Selection

Inductance values are constrained and chosen within the integrated mm-Wave inductance values [25–100 pH] to favor higher-quality factors Q as in [74]. The real part of the LNA input impedance is mainly tuned using degeneration inductor L_s. The expression of this real part is given in (12.33), provided that M_1 intrinsic conductance influence on input impedance is neglected:

$$\mathrm{Re}\,[Z_{in}] = \frac{g_m L_s}{C_{gs}} \approx 2\pi f_{Ti} L_s \tag{12.33}$$

where C_{gs} and f_{Ti} are the gate-source and intrinsic transit frequency of M_1, respectively. According to the target specification related to impedance matching, the real part of Z_{in} is equal to 50 Ω. Thus, (12.33) links the transit frequency of M_1 to the inductance L_s. If we consider a maximum L_s inductance of 100 pH, M_1 transit frequency f_{Ti} should be greater than 80 GHz.

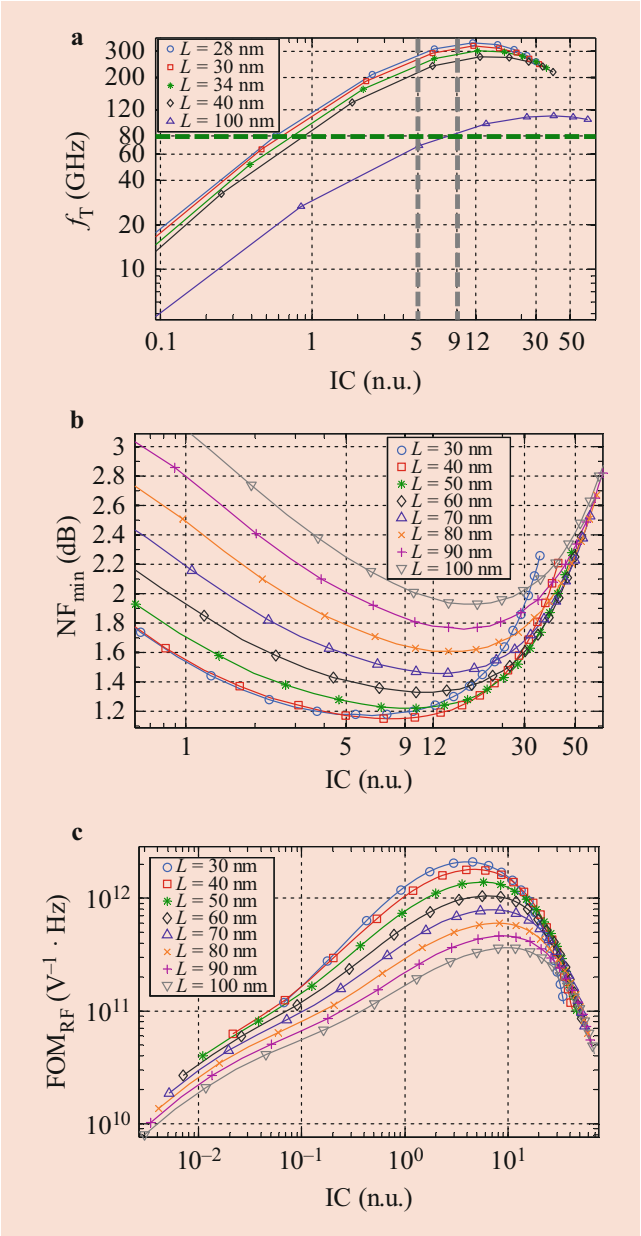

Fig. 12.28 (**a**) Measured f_T versus IC for various MOSFET lengths in saturation ($V_{DS} = 1$ V). (**b**) NF_{MIN} noise figure vs IC for various lengths in saturation. (**c**) FoM_{RF} versus IC for several short-channel lengths

According to Fig. 12.28a, for operation within MI, the MOSFET length that guarantees the required f_T is strictly lower than $L = 100$ nm. To obtain acceptable noise figures and using NF_{min} versus IC charts shown in Fig. 12.28b, length should also be lower than 100 nm. For illustration purpose, we will consider two channel lengths $L = 40$ nm and $L = 70$ nm with acceptable high-frequency performances and less subject to DIBL and mismatch than minimal length (cf. Fig. 12.3).

12.5.3 IC Selection

The maximum value of the RF FoM given in (12.34) and representing the trade-off between gain, high-frequency performance, power consumption, and noise figure is located in the upper part of the MI region for short channels as shown in Fig. 12.28c for several short-channel lengths (i.e., from $L = 30$ nm to 100 nm).

$$\mathrm{FoM_{RF}} = \frac{g_m}{I_D} \cdot \frac{f_T}{\mathrm{NF_{min}}} \tag{12.34}$$

For the selected lengths (i.e., $L = 40$ nm and $L = 70$ nm), FoM_{RF} is maximizing, respectively, at IC = 5 and IC = 9. In general, optimal IC for RF applications lays between IC = 1 and IC = 10.

Knowing the inversion level and length, one can calculate the degeneration inductor L_s based on (12.33). Thus, L_s values of 33 pH and 39 pH for, respectively, $L = 40$ nm and $L = 70$ nm MOSFET-based LNAs are found.

The LNA is designed to operate at $F_0 = 35$ GHz, and consequently, to cancel the input impedance imaginary part at this resonance frequency, the input inductor L_g is tuned with a target value given by [75]:

$$L_g = \frac{1}{(2\pi F_0)^2 \cdot C_{in}} - L_s \tag{12.35}$$

where C_{in} is including the total M_1 gate capacitance C_{gg} and the Miller effect of the gate-drain capacitance (C_{gd}).

12.5.4 Width and V_{GS} Calculations

The width is calculated using the expression (12.36) and the drain current is given by:

$$W = \frac{I_D}{\mathrm{IC} \cdot I_i} \cdot L \tag{12.36}$$

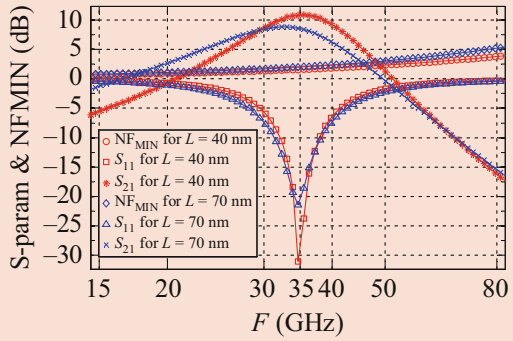
Close width values of 22.8 µm and 22.1 µm are found for, respectively, $L = 40$ nm and $L = 70$ nm based LNA circuits.

The gate voltage overdrive with respect to IC charts shown in Fig. 12.19 (**b**) is used to retrieve the gate-to-source voltage corresponding to the two IC values for each length. The calculated V_{GS} values are, respectively, 0.49 V and 0.55 V.

The results of the above sizing flow are shown in Fig. 12.29 versus frequency and summarized in a table for the operation frequency $F_0 = 35$ GHz.

Power gain is lower for the $L = 70$ nm based LNA because of the higher IC and consequently lower transconductance efficiency. The input impedance matching is acceptable for both LNA circuits. The NF_{min} value is higher for the

a



b

At F_0 = 35 GHz	S_{21}	S_{11}	NF_{min}
LNA (L = 40 nm)	10.9	–31	1.5
LNA (L = 70 nm)	8.6	–21.5	2

Fig. 12.29 (**a**) Power gain S_{21}, input match S_{11}, and minimal noise figure NF_{min} with respect to frequency for two LNA circuits (first with MOSFET length of 40 nm and second with 70 nm). (**b**) Summary table of the two LNA parameters at $F_0 = 35$ GHz

longer-channel-based LNA as expected; however, this can be lowered using optimized layout. The power consumption of both LNAs is 2 mW which is excellent for low-power applications.

The constrained sizing methodology proposed for the LNA at an operating frequency of 35 GHz is based on f_T versus IC measured or simulated curves for the length selection and on the invariance property of the g_m over I_D versus IC charts for the width calculation. The inversion coefficient is fixed to a value where the MOSFET optimum performance is expected, making this analysis dependent only on the channel current and "independent" of the front- and back-gate biases, a great simplification in terms of analysis. The methodology considers the passive components' limitations and thus requires less if not minimal iterations.

12.6 Conclusions

Silicon-based planar MOSFETs have had an impressive impact on our lives. The success was mainly based on the aggressive downscaling dictated by the high-performance integrated digital circuits. This chapter briefly reviews the evolution of the MOSFET architecture from single gate to double gate in the last few decades.

The detrimental SCEs have been controlled by brilliant scientists and creative engineers using new device architectures and new materials. Control of the channel using multiple gates appears to be a straightforward solution. The new architectures such as the UTBB FDSOI presented in this chapter allow for excellent electrostatic control, high level of integration, reduced power consumption, and very high operation frequency.

The extraction of the main physical parameters of the MOSFET, thanks to a simple SI analytical model, allows to gain insight into the device operation. The analytical model is accurate enough to predict the device behavior in SI regime which defines the ON current for digital applications. Analog applications need accurate prediction of the MOSFET performance in all inversion regimes particularly in MI where optimum MOSFET operation is expected. In the case of analog applications, the y_m/I_D charts versus (IC, F) can be used to predict and optimize the MOSFET operation and therefore favor the high-frequency and low-power operation. The simple models and charts presented in this chapter are essential tools for circuit performance prediction and first-order circuit optimization. Yet, the advanced compact models are necessary for final circuit verification over process, voltage, and temperature variations.

With the recent advances in silicon MOSFET technology, IoT network is becoming more of a reality in terms of their widespread use in various aspects of life. Although IoT already brings more capability in our daily life in terms of sensing and communicating using planar MOSFET RF systems, higher performance along with more autonomy is still to be explored. A need of faster and energy-efficient communication between sensors using 5G mobile network, for example, is emphasized by the industry today for a functioning IoT. Therefore, profound skills still have to be developed in the following two key areas: (1) silicon-based CMOS technology usage in mm-Wave spectrum and beyond and (2) transistor operation at lower applied voltages and in lower levels of inversion.

Abstract

According to a recent market survey and forecast on power devices (Fuji Keizai Co., Ltd website. https://www.fuji-keizai.co.jp/, 5 Jun 2019 (in Japanese)), the global device market in 2018 stood at about 3.0 trillion Japanese yen (about 27.3 billion USD); and of this total, SiC (silicon carbide) and GaN (gallium nitride) power devices accounted for slightly less than 41 billion Japanese yen (about 373 million USD), or as little as roughly 1.4% of the silicon power semiconductor device market. Despite numerous reports that SiC and GaN power devices exhibit far better characteristics than silicon power devices, the latter make up by far the largest segment of the power devices market. In the same forecast, by 2030, while the global power device market will grow by about 66% to 4.9 trillion Japanese yen (about 44.9 billion USD), the SiC and GaN power device market will not even make up 12% of the global market. Why would the silicon power device market maintain such a large market segment? Rapid technological advancement in silicon power devices has led to improvement in cost performance, which has dampened the motivation to adopt SiC and GaN power devices. In this chapter, the device structure and design concept of a variety of silicon power devices, and salient features and drawbacks of these devices are analyzed. In addition, it will present a brief history of their development and wrap up the state-of-the-art structures and characteristics of such devices.

13.1 Introduction

Nowadays, there are a wide range of power electronics converters, utilized in vehicles, heavy industry, power supply, and home appliances. These converters, which are indispensable for achieving an energy efficiency society, can be classified into four types such as AC-to-DC, DC-to-DC, DC-to-AC, and AC-to-AC conversions. Power electronics technologies enable the conversion of electrical energy. AC-to-AC conversion is mostly performed by rectifier and inverter circuits connected in series, though there are a few exceptions, such as direct conversion using matrix converters. Hence, converters have usually one DC link, in which the energy is stored temporarily. Based on the DC link, the converters can be further classified into two types, a current source converter and a voltage source converter [2].

In the case of a current source converter, the power devices must have blocking capability in both reverse and forward direction. The reverse blocking capability is achieved by connecting or integrating diodes in series with switching power devices in actual applications, but high forward conducting dissipation must be tolerated in this case. Since the converter is suitable for extremely high-power applications, some high-power converter still utilized symmetrical devices like a gate commutated turn-off thyristor in the current source converter with high power capability. Since a current source converter utilizes inductors to store energy, and operate with an almost constant current in the DC link, the main advantage is fault tolerance in the case of short circuiting.

Voltage source converter, on the other hand, needs a reverse conducting power semiconductor device because it operates inductive loads at the AC terminal. When power semiconductor devices turn off the current, a free-wheeling path is required to avoid generating a high voltage spike, which may lead to destructive device failure. This reverse conducting or free-wheeling operation of the power device can be achieved by connecting or integrating an anti-parallel diode for switching the power devices. Therefore, unlike in the case of current source converter, no additional diode is in series with the power device, and additional forward voltage drop does not take place in the current path of the converter. Therefore, though a voltage source converter requires protection against load short circuiting, it shows more efficiency than current source converter. Therefore, voltage source converter is more popular in modern power electronics applications.

Many kinds of power semiconductor devices have been developed and manufactured thus far, and each device structure exhibits specific advantages. The current power device structures are thyristors, bipolar transistors, metal-oxide-semiconductor field-effect-transistors (MOSFETs), and insulated gate bipolar transistors (IGBTs). Figure 13.1 shows the range of power semiconductor devices and their applications. It is clear from this figure that power devices are required for applications that operate over a wide range of current and voltage levels. In voltage levels of relatively low (<300 V), typical applications are power supply for personal computers and automotive applications. Silicon power MOSFETs give the best performance for the applications due to their low on-resistance and fast switching characteristic. In the case of higher power levels, where the operating voltage is from 600 to 6500 V, typical examples are home appliances, heavy industry utilizing motors, and electric vehicle drives. In silicon power MOSFETs, the on-resistance is so high that the devices cannot be used in these applications, which instead utilize silicon IGBTs. HVDC transmission and power lines are typical examples of applications with extremely high power levels, where the operating voltage is in excess of 6500 V; and here, silicon thyristors still provide the best performance. It is worth noting that silicon MOSFETs and IGBTs are mostly seen in voltage-controlled devices with high voltage current saturation features, in modern power electronics applications. Voltage-controlled operation and high voltage current saturation features are attractive for their easy drive and ability to protect power semiconductors from accidental load short circuiting; therefore, through the utilization of MOSFETs and IGBTs, voltage source converters have been widely used over a broad power range.

An ideal power device must enable to control power to loads without power loss. The delivered power is often controlled by periodically activating the power device. In an ideal power device, the forward voltage drop is zero, leading to no power loss. Likewise, the there is no leakage current in the device during the off-state, leading to no power loss. Moreover, it is assumed that an ideal power device switching between the on-state and off-state in a flash, leading to no power dissipation. MOSFET and IGBT use depends on the required voltage and current levels of the power device in question. Among low-power applications, power supply for battery chargers and electronic ballasts in lighting systems represents a major global market. In automobile applications, many small drives are fed from 12 or 24 V on-board power sources; thus, MOSFETs are most common in these applications. IGBTs are suitable, on the other hand, for medium- and high-power applications, such as consumer and industrial applications that use motors, and electric vehicle drives, with further applications being high-power motor drive in traction for railway cars. The IGBT structure exhibits MOS-bipolar integration, combining the MOSFET physics with the bipolar transistor operation. In IGBT operation, the n-channel (n-ch) MOSFET is utilized to supply the base current for the wide-base pnp bipolar transistor, to be in conductivity modulation of the n-drift region of the MOSFET; thus, IGBT devices can achieve greatly reduced on-resistance. One notable result is that the bipolar transistor structure can be modified to form a wide-base pnp transistor in the IGBT structure, and the

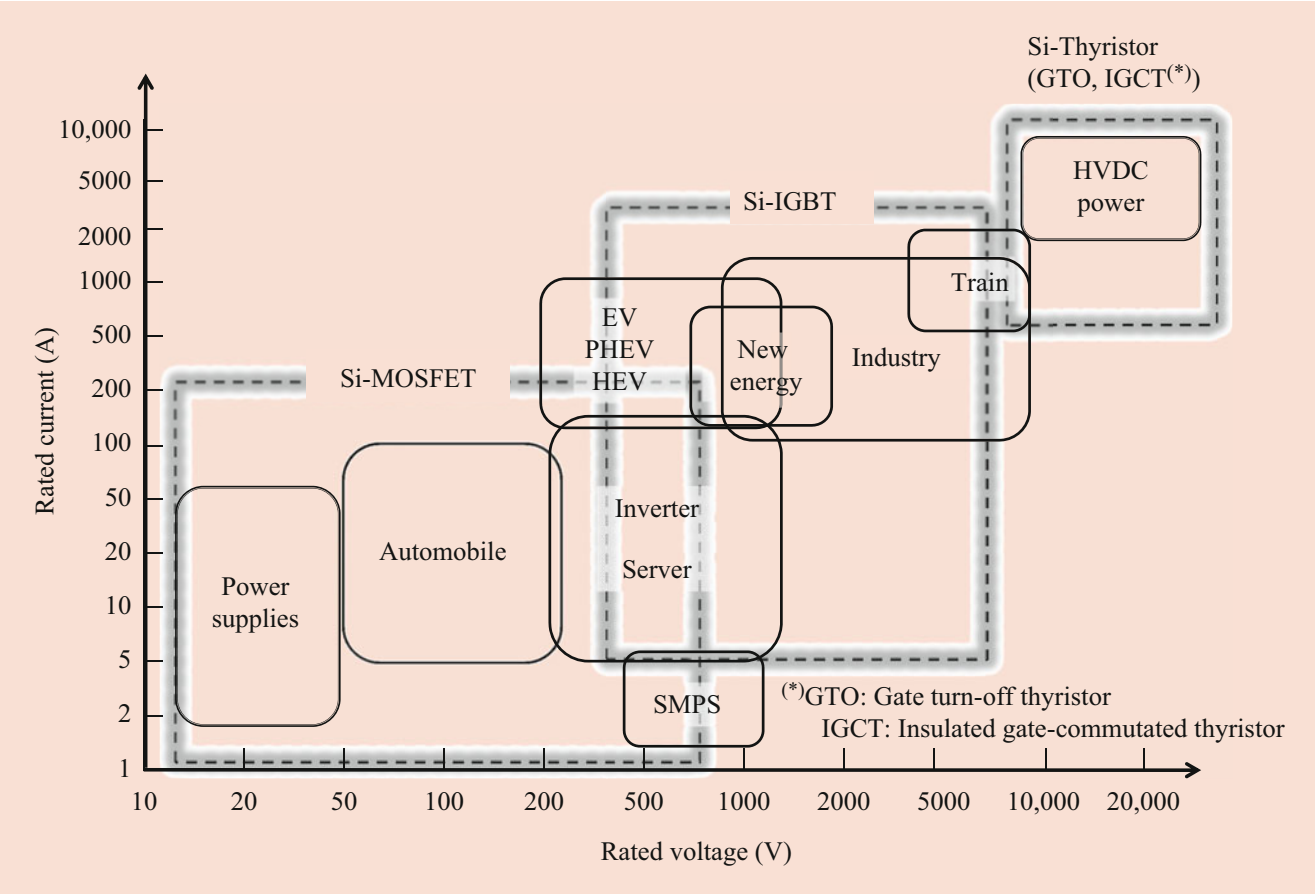

Fig. 13.1 Power semiconductor devices and their applications

withstanding capability of the IGBT can be improved; thus, as aforementioned, many IGBTs with a breakdown voltage of 400–6500 V have been manufactured and utilized in a variety of applications.

In this chapter, the author focuses on the device structure, operation, and design concept of silicon power devices with diodes, MOSFETs, IGBTs, or MOS-gated thyristors and the features of such unipolar and bipolar devices. In addition, it will present a brief history of the devices' development and summarize the state-of-the-art structures and characteristics of silicon MOSFET and IGBT devices.

13.2 Power Metal-Oxide-Semiconductor Field-Effect Transistors (MOSFETs)

Silicon power MOSFETs are power device structures designed to handle high electric power with fast switching characteristics and are widely used in contexts such as switching power supply and DC-DC converters, in the relatively low breakdown voltage region from roughly 20 to 300 V. With the recent development of new structural devices, however, the breakdown voltage range has been expanded to about 700 V and more. Power MOSFETs will continue to play a leading role in supporting high-efficiency operation of power electronic devices, as their element structures evolve.

13.2.1 Power MOSFETs

There have been many unipolar power devices, such as junction field effect transistors (JFETs) and static induction transistors (SITs) [3]; but, these have not been utilized for many power electronics applications because these show a normally on operation. Power MOSFETs can be classified into depletion and enhancement mode types. In a depletion mode MOSFET, the gate threshold voltage V_{th} is below zero volts, the device is normally on, and it cannot block the leakage current at gate voltage $V_{gs} = 0$. In the enhancement mode MOSFET, the gate threshold voltage is positive, the device is normally off, and it blocks the leakage current at $V_{gs} = 0$. In addition, when V_{gs} is set higher than the threshold voltage V_{th}, an inversion layer is formed.

Enhancement mode power MOSFETs are mainly utilized in power electronics because of their normally off characteristics; and n-channel MOSFETs, in particular, are utilized

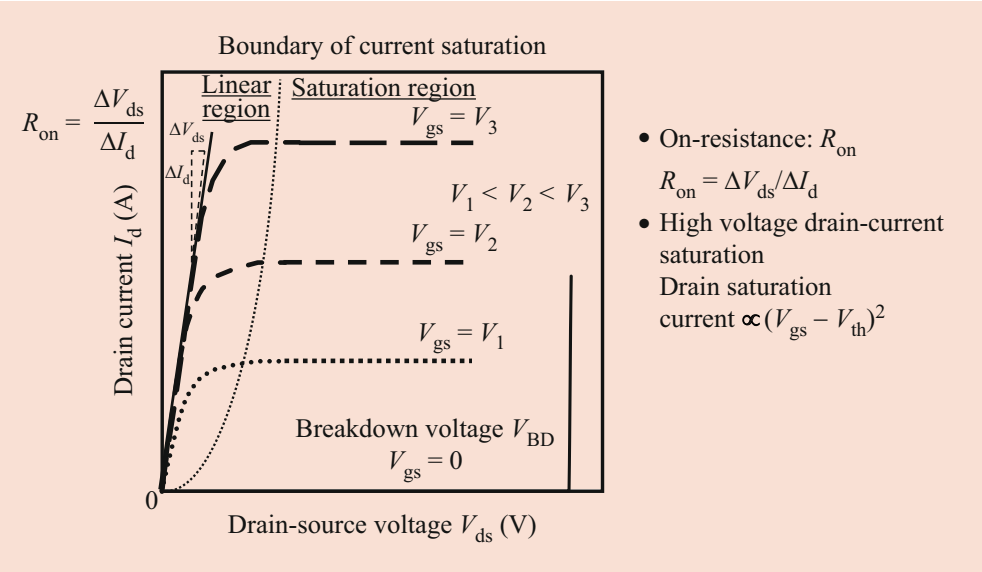

Fig. 13.2 Current and voltage characteristics of typical MOSFET

because the electrons mobility is much higher than holes mobility. The gate threshold voltage V_{th} of a silicon power MOSFET is typically adjusted to between about 2 V and 4 V at room temperature; and power MOSFETs typically exhibit a low on-state voltage drop and a negligible off-state leakage current level. Further, they exhibit power loss during transition between the on- and off-state. The current and voltage characteristics of a typical power MOSFET are shown in Fig. 13.2. We can see that the "breakdown voltage" has a finite level. The typical MOSFET can operate with high current and voltage in the active region; and the device exhibits high voltage drain-current saturation, owing to the pinch-off at the channel, which is especially useful in power electronics applications such as motor controls. The basic structures of silicon power MOSFETs and lateral MOSFETs are shown in Fig. 13.3. Lateral DMOSFET (LDMOSFET) transistors are frequently used in several types of power ICs; however, they have the disadvantage of low current capacity because the current flows mainly through the surface of the n-drift region, which occupies a large part of the semiconductor surface.

When higher power levels must be operated by a semiconductor, vertical MOSFETs (VDMOSFETs) are often employed, with control being achieved by establishing a vertical region for the electric field. As a result, the overall semiconductor region is efficiently used, and the MOSFET surface can be utilized for the striped, square, or hexagonal cells formation. Vertical power MOSFETs were developed in the middle of 1970s, for improved characteristic compared to silicon bipolar power transistors, which suffered from low current gain (or base-to-collector current amplitude factor) when designed to show high blocking voltage. Further, the

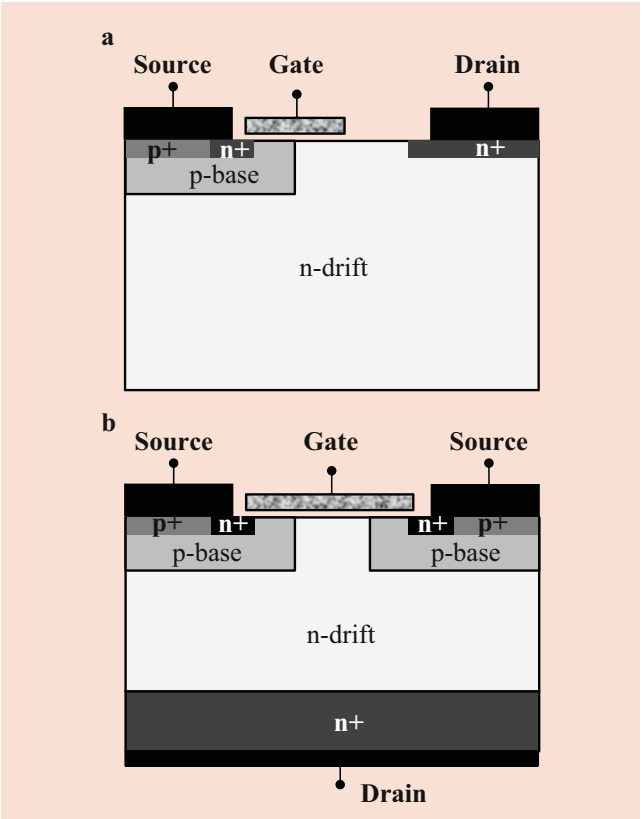

Fig. 13.3 Cross section of (**a**) LDMOSFET and (**b**) VDMOSFET structures

bipolar transistors cannot be switched in high frequency operation, because of the large storage time resulting from the injected and stored charges in the drift regions. So,

replacing current-controlled devices with voltage-controlled varieties was thus attractive from the application point of view. Vertical power MOSFETs are further divided into low breakdown voltage (approximately 200 V or less) and high breakdown voltage (200 V or more) devices.

Three types of MOSFETs (LDMOSFETs, vertical DMOSFETs with low breakdown voltage, and vertical DMOSFETs with high breakdown voltage) were independently developed in pursuit of performance improvement. Two common targets for such improvement are reduction in the drain-source on-resistance and reduction in the gate-source and gate-drain capacitances; with the former aimed at minimizing power loss in the device conduction state, and the latter necessary for reducing power loss during high-speed switching. In addition, efforts are made to ensure breakdown tolerance and reliability.

The power MOSFET was developed with a V-groove structure in which the channel is formed along (111) crystallographic planes [4]. U-groove structures were also designed and fabricated via a similar processing technique. The difference is that, in the fabrication of the U-groove structure, the anisotropic etching process is halted prior to the formation of a V-groove [5]. Improved current spreading and reduced electric fields are advantages of the U-grooved structure. The fabrication process and structure of the U-groove MOSFET differs from those of the UMOSFET and trench MOSFET, described below and in Sect. 13.2.3, respectively. As a next stage, vertical planar double-diffused structures were developed, which achieved a higher packing density than the V-groove and U-groove structures, without the need for a three-dimensional structure. These successful vertical power MOSFETs, created using the double-diffused process, and referred to as vertical DMOSFETs (or VDMOSFETs), were introduced in the market in the 1970s [6]. In them, the p-base and n+ source regions are formed to be self-aligned to the edge of the gate polysilicon layer, utilizing boron and phosphorous (or arsenic) ion implantation followed by the respective annealing and drive-in process. The MOSFET channel is defined by the difference in the lateral diffusion length of the implanted dopants under the gate electrode, and the MOSFET can sustain positive-bias voltage to the drain electrode by the p-n junction of p-base and n-drift layer. The blocking voltage is primarily determined by the doping concentration and thickness of the n-drift layer. Low-voltage MOSFETs have low on-resistance, but the resistance in n-drift layer increases rapidly with the blocking voltage; therefore, the operation of silicon power VDMOSFETs is limited to a blocking voltage of roughly 700 V or less in modern power electronics applications.

To enhance the operational capability of drain current in the VDMOSFET, its components of resistance were reduced through the use of many advanced structural designs involving finer cell dimensions. However, it soon became clear that the devices contained fundamental parasitic resistances that blocked more improvement in reducing the resistance. Thus, during the 1980s, a superior device structure was developed, based on the technology for trench structure that had developed for DRAM (dynamic random access memory). The name "UMOSFET" is derived from the device's gate structure with U-shaped geometry, but the term "trench MOSFET" is also frequently utilized. According to [7], the silicon UMOSFET became commercially available in the late 1980s. The UMOSFET structure can increase channel density significantly and eliminate the contribution of JFET resistance, leading to great enhancement of low-voltage (<200 V) MOSFET performance.

The on-resistance in these devices becomes dominant, due to the high resistance of n-drift region, when the breakdown voltage is designed to exceed about 500 V. In MOSFET with high breakdown voltages, its on-resistance typically exceeds 50 mΩ cm^2 and an on-state voltage drop is more than 1.0 V. To overcome this, IGBTs were born in the 1980s, for use in medium- and high-voltage/current power electronics apparatus. The superior characteristics of IGBTs in medium- and high-voltage applications resulted in MOSFET use focusing on application field with an operation voltage of less than roughly 200 V.

Silicon superjunction (or SJ) MOSFETs, which utilize charge coupling, have enabled an extension of the power MOSFET breakdown voltage to the 600–700 V level; and a heavily doped drift region in the SJ-MOSFET can be utilized, in comparison with the VDMOSFET and UMOSFET. The latter factor enables to reduce resistance in n-drift region resistance greatly in devices capable of sustaining high drain voltage. To achieve a superior charge coupling characteristic, the n-type and p-type drift regions must be in a complete depletion when the drain voltage increases and gets closer to the breakdown voltage, and the SJ design has been attractive in high breakdown voltage devices in excess of 500 V.

13.2.2 The VDMOSFET Structure

Figure 13.3b shows a cross-sectional view of VDMOSFET. A vertical device structure was developed to achieve high operational current capability by placing electrodes on both a top and bottom surfaces of the wafer. Device fabrication begins with an n-epitaxial layer grown on an n+ substrate with high impurity concentration. As aforementioned, the term "VDMOSFET" is derived from its vertical structure, with the p-base and n+ source regions formed by n-type and p-type doping through the same photomask opening, followed by thermal diffusion. The p-base and n+ source regions are self-aligned to the left- and right-hand sides of the gate electrode during ion implantation. The channel is

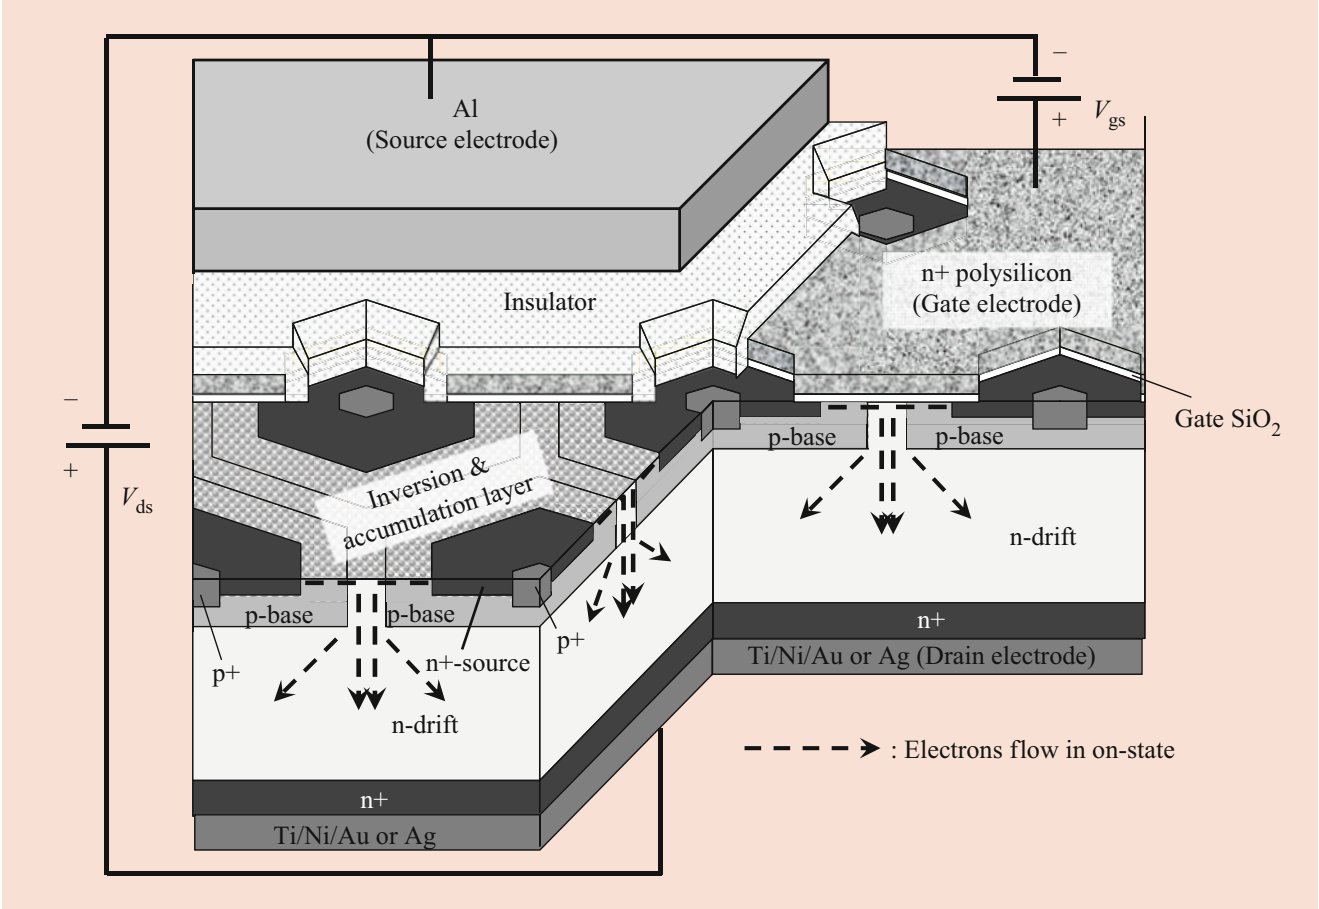

Fig. 13.4 Schematic bird's eye view of VDMOSFET structure in a hexagonal form arranged in a hexagonal pattern

defined by the extension difference in lateral diffusion of the p-base and n+ source regions. The p-base region is connected to the source electrode such that the parasitic npn transistor (n+ source/p-base/n-drift) is completely shorted. To ensure very low resistance in the short region, the doping concentration is increased by adding a p+ implanted region, followed by the thermal diffusion. In addition, an n+ doped polysilicon gate is used to enable the fabrication of devices that allow diffusing the dopants under a gate electrode at high temperatures. The VDMOSFET consists of a MOSFET fabricated on an n-drift region, with the thick n+ substrate, and can sustain a high voltage across the p-n junction of p-base and n-drift region.

A main current must flow through the inversion layer; therefore, a lot of individual cells are formed to extend the width of the MOS channel. Figure 13.4 shows an example. Here, the individual cells are hexagonal and set up in a hexagonal pattern; a design that has been utilized even more effectively in so-called HEXFET structures [8].

Blocking Characteristics

In the off-state, the blocking voltage is sustained by not only the p-n junction of the p-base and n-drift regions, but also the MOS capacitor, consisting of the gate and the drift region. A blocking voltage can be determined when the peak electric field reaches equal to the critical field for breakdown at the reverse biased p-n junction. In this case, it is important that an operation of the parasitic npn bipolar transistor is completely suppressed by the shorted p-base and n+ source regions via the source electrode, as shown in Fig. 13.3. Further, we have to pay attention that a large leakage current could take place if the depletion layer in the p-base region extends and touches the n+ source region (reach-through). To avoid this "reach-through" phenomenon, the thickness and doping concentration of the p-base region must be carefully designed [6].

If the doping is assumed to be uniform on both sides, the positive bias to the drain electrode is sustained by the p-n junction (the p-base/n-drift region), with a triangular-shaped electric field (Fig. 13.5). The peak of electric field is located

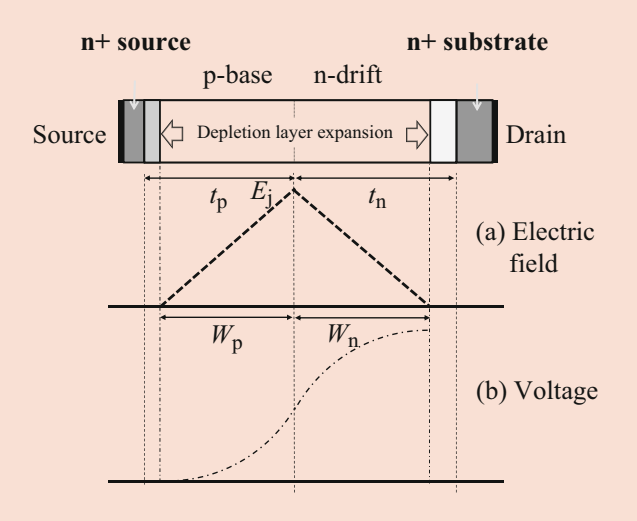

Fig. 13.5 Triangular electric field and voltage distribution at p-base/n-drift junction in a power VDMOSFET structure

at the junction, and the depletion layer width in the p-base region W_p is given by

$$W_p = \frac{\varepsilon_s E_j}{qN_A}, \tag{13.1}$$

where E_j is the maximum field, N_A is the doping density in the p-base region, q is the charge on the electrons, and ε_s is the dielectric constant. The minimum p-base thickness required to prevent the breakdown due to the reach-through can be calculated with the assumption that the E_j at the junction becomes the critical field for breakdown E_c:

$$t_p = \frac{\varepsilon_s E_c}{qN_A}. \tag{13.2}$$

In [6], the minimum thickness of p-base region for silicon power MOSFETs was calculated and compared with that for 4H-SiC MOSFETs; and it was found that the thickness for silicon was roughly six times less than for 4H-SiC, implying that the channel length for silicon MOSFETs is much less than for SiC MOSFETs, leading to decreased on-resistance. Increasing the doping concentration reduces the minimum thickness of the p-base region for preventing the reach-through breakdown; however, the p-base region with the higher doping concentration results in increase of the threshold voltage and decrease of the mobility of the inversion layer.

Assuming that the p-base layer concentration is much higher than the n-drift layer one (see Fig. 13.6), the following equation holds in the p-n junction of the p-base and n-drift layers:

$$\frac{d^2V}{dx} = -\frac{dE}{dx} = -\frac{qN_D}{\varepsilon_{Si}}, \tag{13.3}$$

where $V(x)$ is the voltage distribution in the device, and N_D is the donor concentration in the n-drift layer. This is Poisson's equation for a single-step junction. When this equation is integrated with respect to distance x, to obtain the electric field $E(x)$, based on the boundary condition $E(W_{dep}) = 0$, the electric field $E(x)$ can be expressed as

$$E(x) = -\frac{qN_D}{\varepsilon_{Si}}\left(W_{dep} - x\right), \tag{13.4}$$

where W_{dep} is the depletion layer width. Further, integrating the above equation for x, voltage $V(x)$ can be obtained based on the boundary condition of $V(0) = 0$:

$$V(x) = \frac{qN_D}{\varepsilon_{Si}}\left(W_{dep}x - \frac{x^2}{2}\right). \tag{13.5}$$

When the applied drain voltage V_{ds} is sufficiently high, and the built-in potential of p-n junction is low enough to be ignored, the V_{ds} and depletion layer width W_{dep} can be given by

$$V\left(W_{dep}\right) = V_{ds} = \frac{qN_D W_{dep}^2}{2\varepsilon_{Si}} \tag{13.6}$$

and

$$W_{dep} = \sqrt{\frac{2\varepsilon_{Si}V_{ds}}{qN_D}}. \tag{13.7}$$

Thus, the breakdown voltage V_B of a power MOSFET is given using the depletion layer width $W_{dep,B}$ under the breakdown, as

$$V_B = \frac{E_c \times W_{dep,B}}{2} \tag{13.8}$$

and

$$W_{dep,B} = \sqrt{\frac{2\varepsilon_{Si}V_B}{qN_D}}. \tag{13.9}$$

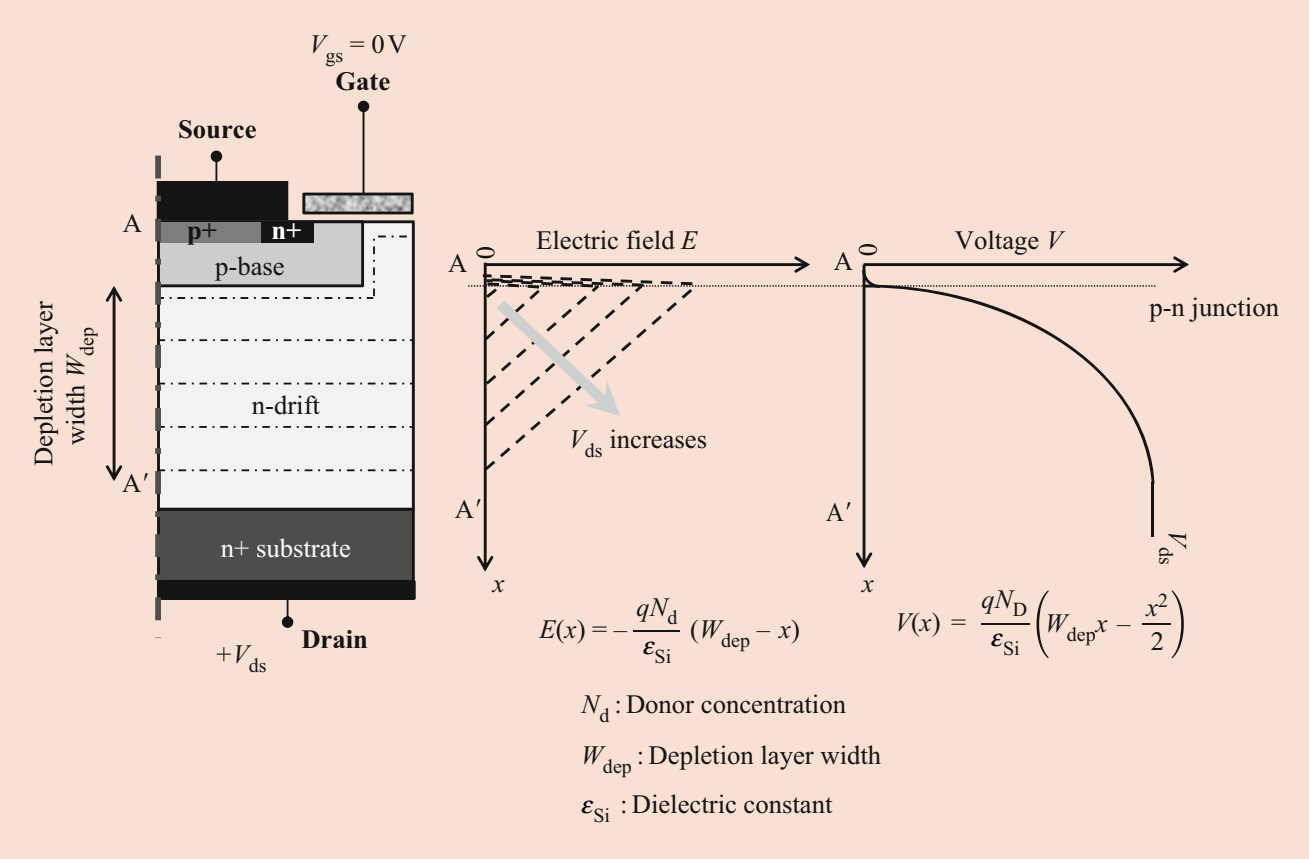

Fig. 13.6 Electric field and voltage distributions and depletion layer expansion in a VDMOSFET forward-blocking state

Using Eqs. 13.8 and 13.9, the breakdown voltage V_B of a power MOSFET is obtained:

$$V_B = \frac{\varepsilon_{Si} E_c^2}{2qN_D}. \tag{13.10}$$

This equation shows that the breakdown voltage V_B is proportional to the reciprocal of the impurity concentration N_D in the n-drift layer; thus, this concentration should be reduced to increase the MOSFET breakdown voltage. However, reducing N_D leads to the increase of on-resistance of the MOSFET, meaning that, in power MOSFETs, the breakdown voltage and on-resistance are in a trade-off relation.

Threshold Voltage

The VDMOSFET threshold voltage is an important design parameter for applications. The threshold voltage must be kept at 1–2 V and more for most power electronics systems, to provide the characteristics of being unaffected against turn-on owing to voltage spikes caused by disturbance signals and noise. At the same time, a high threshold voltage is undesirable, because the voltage for inducing the inversion layer in the MOSFET channel is defined by $V_{gs} - V_{th}$, where V_{gs} is the gate bias and V_{th} is the threshold voltages. In most power electronics systems designed for high-voltage operation, a gate voltage is set of 15 V, meaning that the threshold voltage should be maintained less than 5 V, for example, to obtain a low resistance from the MOSFET channel.

The threshold voltage can be expressed by modeling it as the gate voltage at which the strong inversion layer begins to form in the MOSFET channel. The voltage is given by

$$V_{th} = \frac{\sqrt{4\varepsilon_s kTN_A \ln\left(\frac{N_A}{n_i}\right)}}{C_{ox}} + \frac{2kT}{q}\ln\left(\frac{N_A}{n_i}\right), \tag{13.11}$$

where C_{ox} is the specific capacitance of the oxide in the MOS structure, N_A is the p-base doping concentration, k is Boltzmann's constant, n_i is the intrinsic carrier concentration, and T is the absolute temperature [6]. When there is an effective positive charge in the oxide (Q_{ox}), which is assumed to be located at the metal-oxide interface [6], the threshold voltage shifts to negative and given by

$$\Delta V_{th} = -\frac{Q_{ox}}{C_{ox}} \tag{13.12}$$

In addition, by utilizing highly doped n+ polysilicon as the gate electrode, a further negative threshold voltage shift can be achieved.

The threshold voltage in a VDMOSFET decreases with temperature because of an increase in the n_i. The dependence of the threshold voltage on temperature was analyzed in detail in [6]. According to [6], the threshold voltage varies by a factor of roughly two, over the temperature range of −50 to 200 °C. This threshold voltage decrease at elevated temperatures must be considered in VDMOSFET design.

On-Resistance

The on-resistance of a VDMOSFET is expressed as the total amount of MOSFET channel resistance plus the n-drift region and substrate resistance. The drain current in a VDMOSFET is provided by the positive gate bias, which induces an inversion layer at the surface of the p-base region under the gate electrode, resulting in a formation of electron path from the n+ source to the n+ substrate in a positive drain voltage application. After flowing through the inversion layer, the electrons reach the n- drift region at the upper region of the MOSFET, where they flow through a limited space of JFET region between p-base regions. This constriction of the electron flow through this region increases the JFET resistance considerably, and design optimization such as the width between the p-base regions is required to lower the overall resistance of the MOSFET. Further, the higher doping concentration in the JFET region is typically utilized to increase the conductance for flowing electrons through this section. After transportation through this region, the electrons reach the n-drift region and flows below the p-n junction, and the electrons spread toward the entire n-drift region of the cell. This non-uniform electron transportation in the n-drift region increases the resistance, making the on-resistance of the VDMOSFET greater than the ideal level of on-resistance in the n-drift region; and this increased internal resistance has encouraged the development of trench power MOSFETs and superjunction MOSFETs.

Figure 13.7 shows the VDMOSFET structure. In this figure, components of its internal resistance are also shown [6]. There are eight resistances components and these must be investigated, in order to find the total on-resistance between the source and drain electrodes. The total on-resistance for a VDMOSFET is obtained by totaling these resistances:

$$R_{ON} = R_{CS} + R_{n+} + R_{ch} + R_{acc} + R_{JFET} + R_D + R_{SUB} + R_{CD}. \quad (13.13)$$

The goal is to achieve a minimization of the on-resistance while keeping a specific blocking voltage, and this involves optimizing the device design parameters, such as the doping density, and the thickness and dimensions of each layer and

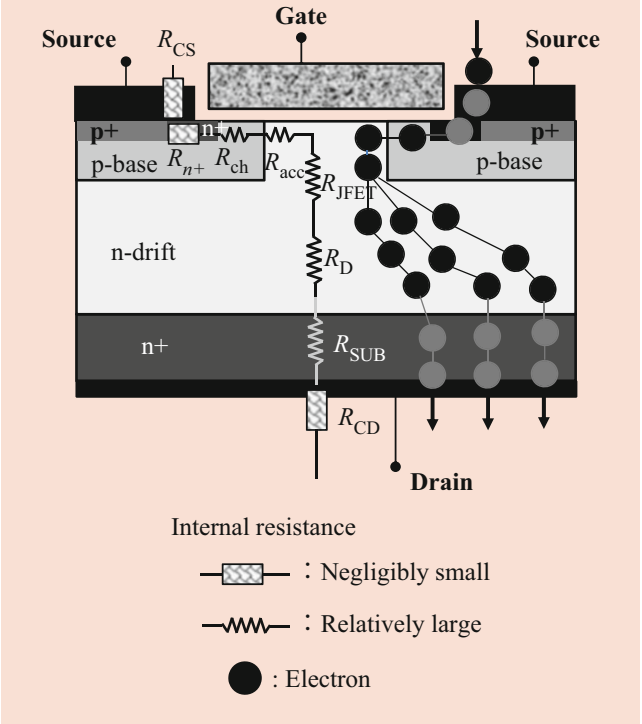

Fig. 13.7 Internal resistances and electron flow path in VDMOSFET structure

region. Further, a comprehensive study must include the two-dimensional effects because of current crowding and field concentration. The former corresponds to the end of the inversion layer as electrons spread into the JFET region and the bottom edge of the JFET region as electrons spread into the n-drift region. Field crowding takes place, in the forward blocking mode, at the corners of the p-n junction of p-base and n-drift region in the vertical transistor cell, and at the edge termination region of the VDMOSFET. These two dimensional effects are commonly analyzed through TCAD (technology computer aided design) device simulations. The pursuit of minimal resistance, minimal area, and keeping the blocking voltage has led to the development of several innovations that have been utilized in modern silicon power MOSFETs; among them, a self-aligning sub-micron MOS channel, a JFET region with higher doping concentration, p-base contacts that are segmented along the three dimensional direction of the stripe cells, and the fine pitch trench-gate structure. The resistances of the source contact (R_{CS}), n+ source region (R_{n+}), and drain contact (R_{CD}) are negligibly small in the VDMOSFET. Figure 13.8 shows the relative contribution of various resistance components in a 30 V and 600 V VDMOSFET with planar gate cells [9]. The resistance of package (R_p) is included in this figure. In MOSFETs with a blocking voltage below 50 V, many attempts are made to minimize the MOSFET channel resistance by improving the

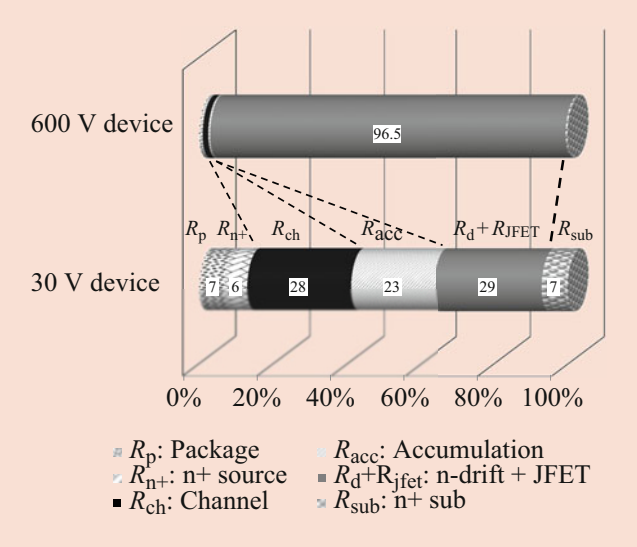

Fig. 13.8 Relative contribution to on resistance in devices of different voltage rating

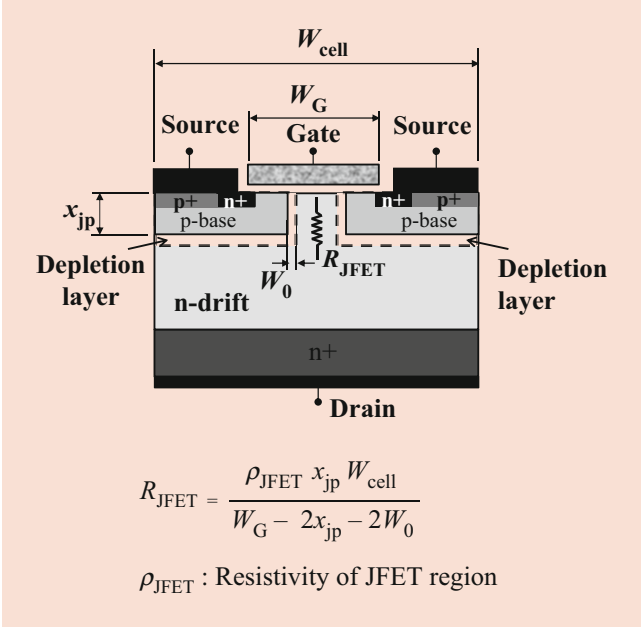

Fig. 13.9 VDMOSFET structure for modeling the JFET resistance

components near the device surface through the cell density enhancement.

The resistance R_D of the n-drift region with low doping concentration is given by

$$R_D = \frac{W_D}{q\mu_n N_D}, \tag{13.14}$$

where W_D is the thickness of the n-drift layer, N_D is the doping concentration of the n-drift region, and μ_n is the electron mobility.

The depletion layer width under the breakdown is expressed by

$$W_{dep,B} = \frac{2V_B}{E_C}, \tag{13.15}$$

where V_B is the breakdown voltage. The doping concentration of the n-drift layer to obtain this breakdown voltage is expressed by

$$N_D = \frac{\varepsilon_s E_C^2}{2qV_B}, \tag{13.16}$$

where q is the charge on the electrons. From these equations, the on-resistance of the n-drift region is calculated:

$$R_D = \frac{4V_B^2}{\varepsilon_s \mu_n E_C^3}. \tag{13.17}$$

The denominator in Eq. 13.17 is usually referred to as Baliga's Figure of Merit for power devices [10], a number showing the effect of the material properties of semiconductor on the resistance of the drift region. If the device is designed for higher voltages, W_D must be set higher and N_D must be lower.

The resistance in the JFET regions is an important component when a MOSFET is designed with fine cell structure. The JFET resistance was modeled using the schema in Fig. 13.9 and is given by [11]

$$R_{JFET} = \frac{\rho_{JFET} x_{jp}\, W_{cell}}{W_G - 2x_{jp} - 2W_0}, \tag{13.18}$$

where ρ_{JFET} is the JFET region resistivity, x_{jp} is the diffusion depth of the p-base region, W_{cell} is the unit cell width of the MOSFET, W_G is the width of the gate electrode, and W_0 is the depletion width at the zero bias. From this equation, it is clear that use of a more heavily doped JFET region (as described above) to reduce ρ_{JFET} and a shallow p-base region to lower the values of x_{jp} is an effective method for improving JFET resistance.

The specific on-resistance in the channel in a VDMOSFET is given by

$$R_{ch} = \frac{L_{ch} W_{cell}}{2\mu_{nch} C_{ox} (V_G - V_{th})}, \tag{13.19}$$

where μ_{nch} is the channel mobility, C_{ox} is the specific capacitance of the MOS, L_{ch} is the channel length, and W_{cell} is the unit cell width. According to [11], for example, in 30 V VDMOSFETs used for power supply applications, when the gate oxide thickness is set at 0.05 μm, the threshold voltage is 2 V, and a channel mobility of 450 cm^2/Vs is assumed, the calculated on-resistance in the channel is 0.245 $m\Omega\ cm^2$ when the gate voltage is set to 10 V (at $W_{cell} = 12\ \mu m$).

Switching Characteristics

Since power MOSFETs are unipolar devices, fast switching can be achieved (unlike in the case of IGBTs), due to the absence of minority carrier accumulation. The switching characteristics of power MOSFETs are strongly dependent on the gate circuit and the kind of connected loads. To activate the devices, the MOS capacitance must be charged by a gate voltage higher than a threshold voltage of V_{th}. To deactivate them, it is necessary to extract the charge accumulated in the MOS capacitance. Therefore, the switching speed of power MOSFETs is characterized by the rapidity with which the MOS capacitance is charged and discharged, and reducing the gate resistance and MOS capacitance is effective for improving the switching characteristics. Figure 13.10 shows the parasitic capacitance in a power MOSFET. The input capacitance C_{iss}, output capacitance C_{oss}, and reverse transfer capacitance C_{rss} are defined as follows:

$$C_{iss} = C_{gs} + C_{gd}, \tag{13.20}$$

$$C_{oss} = C_{gd} + C_{ds}, \tag{13.21}$$

$$C_{rss} = C_{gd}, \tag{13.22}$$

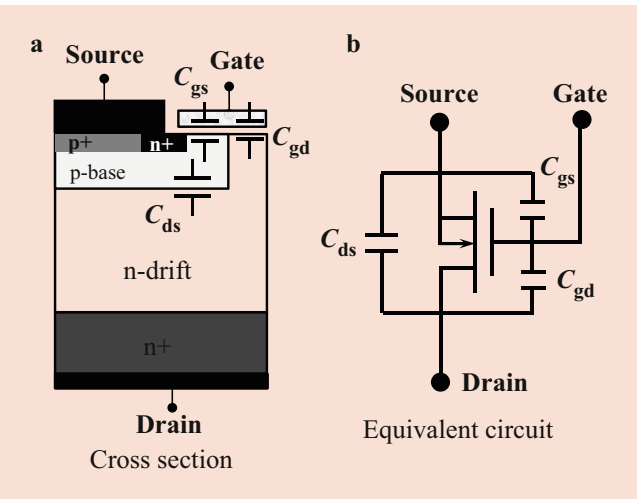

Fig. 13.10 Parasitic capacitance in VDMOSFET structure. (a) Cross section. (b) Equivalent circuit

where C_{gs} is the gate-source capacitance, C_{gd} is the gate-drain capacitance, and C_{ds} is the drain-source capacitance. The C_{iss}, C_{oss}, and C_{rss} have nonlinear characteristics with respect to the drain voltage, and these values increase when a low drain voltage is applied. In power MOSFETs, the gate voltage and drain voltage waveforms are completely opposite to each other; the C_{rss} impedes charging through the C_{iss} by feeding back to the gate voltage waveform; and as a result, the effective capacitance during this switching period increases. Figure 13.11 shows the schematic gate charge waveform when a MOSFET is activated. Initially, the MOSFET is assumed to be in an off-state with a full line voltage of V_{ds} applied across the drain-source electrode. At time zero, the gate current starts to flow in the device. The C_{iss} is charged at a constant rate:

$$\frac{dV_{gs}}{dt} = \frac{I_g}{C_{iss}} = \frac{I_g}{C_{gs} + C_{gd}}, \tag{13.23}$$

where I_g is the gate current. When the drain-source voltage is high, the C_{iss} is similar to the C_{gs}; therefore, the gate current I_g is used for charging the C_{gs} in this initial period. When the V_g reaches the gate threshold voltage V_{th}, the MOSFET operates in its active region and the drain current starts to flow. The drain current I_d in this period can be expressed as

$$I_d = g_m \left(V_{gs} - V_{th}\right), \tag{13.24}$$

where g_m is the transconductance, which is defined by

$$g_m = \frac{\partial I_d}{\partial V_{gs}}. \tag{13.25}$$

When the drain current increases and gets to the load current I_{load}, the drain voltage V_{ds} starts to fall. Thus, the constant gate current discharge of the reverse transfer capacitance (or Miller capacitance) C_{rss} is given by

$$\frac{dV_{ds}}{dt} = -\frac{I_g}{C_{rss}}. \tag{13.26}$$

After this, the C_{rss} increases with decreasing drain voltage V_{ds}. When the drain voltage falls to the level of the on-state voltage, the gate voltage starts to increase, and continues to increase as long as the gate current I_g flows. During this period, dV_{gs}/dt decreases due to the increase in C_{gd}. Figure 13.11 shows that the changes in I_d influence the gate-source charge of Q_{gs} and changes in V_{ds} affect the gate-drain charge of Q_{gd}, so that the reduction of C_{rss} (=C_{gd}) is especially important for improving the switching character-

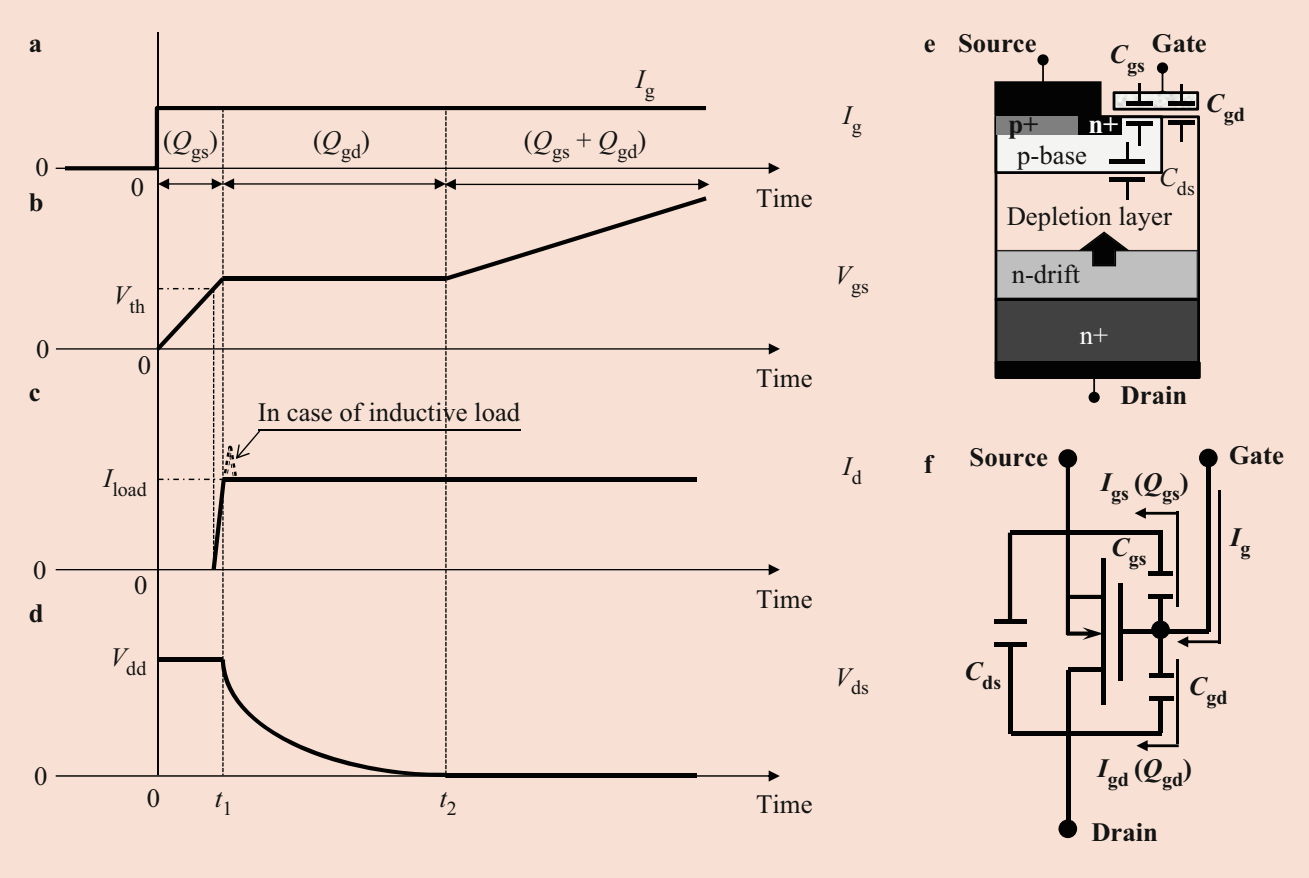

Fig. 13.11 Schematic gate charge waveform at turning on the MOSFET. (**a**) Gate current, (**b**) gate voltage, (**c**) drain current, (**d**) drain voltage, (**e**) depletion layer dynamics (from t_1 to t_2 in (**d**)), and (**f**) gate current flow

istics. The power consumption of the gate drive circuit is expressed by $V_{gs} \times (Q_{gs} + Q_{gd}) \times f$, where f is the switching frequency. When designing gate drive circuits for especially high frequency application, it is very important to minimize the gate charge.

Power MOSFETs are often utilized to control the current in inductive loads for motor control; and their switching operations in such circuits have been analyzed and discussed in several works, such as [6].

The typical circuit configuration is illustrated in Fig. 13.12. The circuit is comprised of the power MOSFET and an inductive load, connected in series with the power source by a free-wheeling diode. The turn-on current and voltage waveforms for an inductive load are shown in Fig. 13.13. With power MOSFET turn-on, the free-wheeling current still flows through the diode. When the gate bias is switched on ("A" in Fig. 13.13), the gate voltage V_{gs} begins to slowly increase due to the capacitance components of the power MOSFET and the connected gate resistance R_g. Since the gate-drain capacitance C_{gd} remains constant owing to the constant drain voltage, the time constant for charging the gate of the power MOSFET is expressed by $R_g \times (C_{gs} + C_{gd})$. Thus, the gate voltage V_{gs} is given by

$$V_{gs}(t) = V_{GS}\left[1 - \exp\left\{-t/R_g\left(C_{gs} + C_{gd}\right)\right\}\right]. \quad (13.27)$$

When the drain-source voltage is high, the C_{iss} $(= C_{gs} + C_{gd})$ is similar to the C_{gs}; therefore, the gate current I_g is used for charging the C_{gs} in this initial period.

The drain current increases while the load is clamped to the source voltage by the conducting free-wheeling diode. When the V_{gs} reaches the threshold voltage V_{th}, the power MOSFET operates in the active region and the drain current starts to flow. In this regime, the MOSFET supports a high drain voltage by expanding the depletion layer in the n- layer ("B" in Fig. 13.13). The drain current density is given by

$$I_d(t) = g_m \times \left(V_{gs}(t) - V_{th}\right) = \frac{\mu_{nch} C_{ox}}{2L_{ch} W_{cell}}\left(V_{gs}(t) - V_{th}\right)^2, \quad (13.28)$$

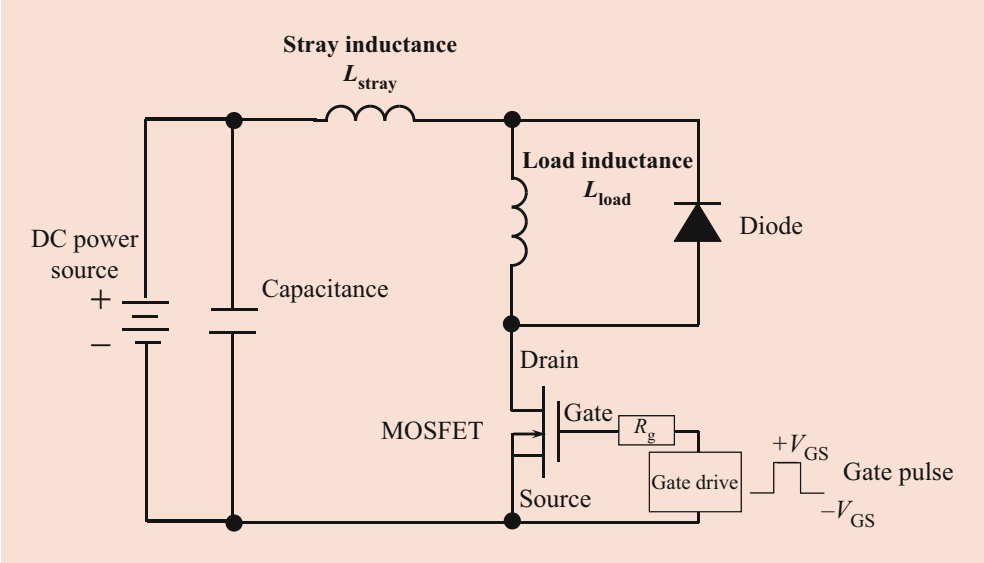

Fig. 13.12 Inductive load circuit configuration

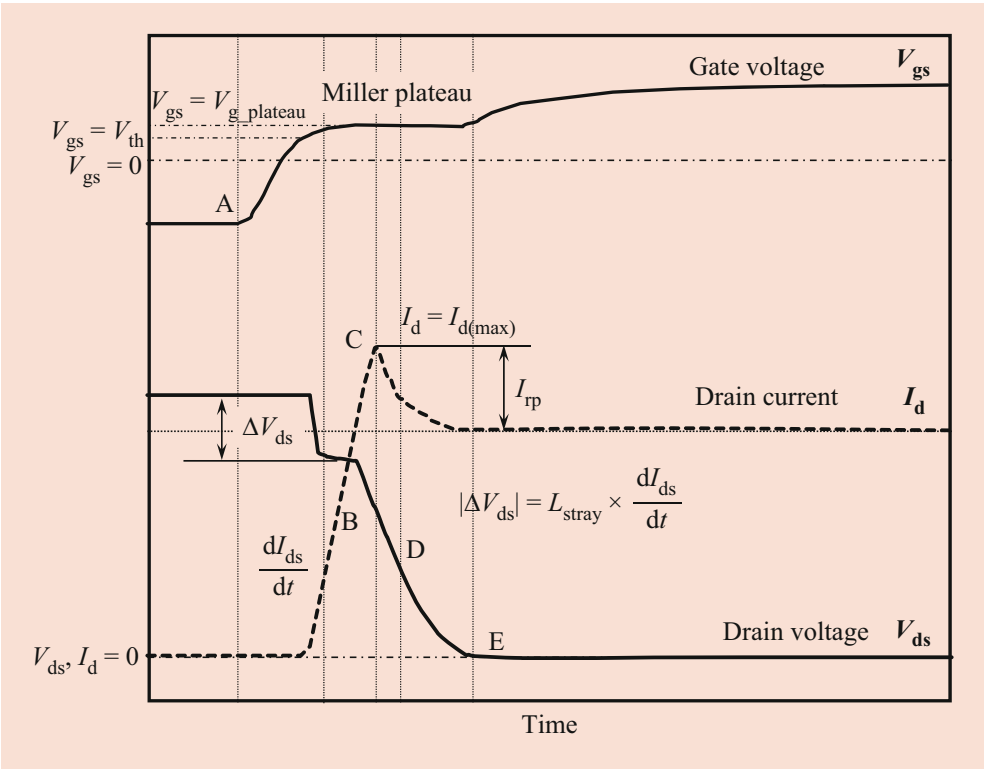

Fig. 13.13 MOSFET turn-on waveforms with an inductive load

where μ_{nch} is the channel mobility, C_{ox} is the specific capacitance of the oxide in the MOS structure, L_{ch} is the channel length, and W_{cell} is the unit cell width. Figure 13.13 shows the drain voltage drop ΔV_{ds} in this period. The voltage drop is caused by a constant increase in the MOSFET drain current (dI/dt), multiplied by the stray inductance L_{stray} in the circuit ($L_{stray} \times dI/dt$). The MOSFET current increases until it reaches the apex $I_{d(max)}$, defined by the total amount of the load current and the peak reverse recovery current in the free-wheeling diode ("C" in Fig. 13.13), and then the drain current is reduced to a load current.

Since the gate voltage V_{gs} is constant during this period, all the gate current I_g is utilized to charge the gate-drain

capacitance $C_{gd}(=C_{rss})$. The gate current I_g in this gate-plateau region is given by

$$I_g(t) = \frac{\left(V_{GS} - V_{g_plateau}\right)}{R_g}. \tag{13.29}$$

From Eq. 13.26, the dV_{ds}/dt is given by

$$\frac{dV_{ds}}{dt} = -\frac{I_g}{C_{rss}} = -\frac{\left(V_{GS} - V_{g_plateau}\right)}{R_g C_{gd}}. \tag{13.30}$$

The drain voltage V_{ds} then starts to fall ("D" in Fig. 13.13), and the voltage continues to fall until it reaches the on-state value ("E" in Fig. 13.13). The gate voltage V_{gs} is constant at $V_{g_plateau}$ during this time, and the gate-drain capacitance increases with the decrease in the V_{ds}. Finally, the gate voltage starts to increase and continues to do so as long as the gate current I_g flows.

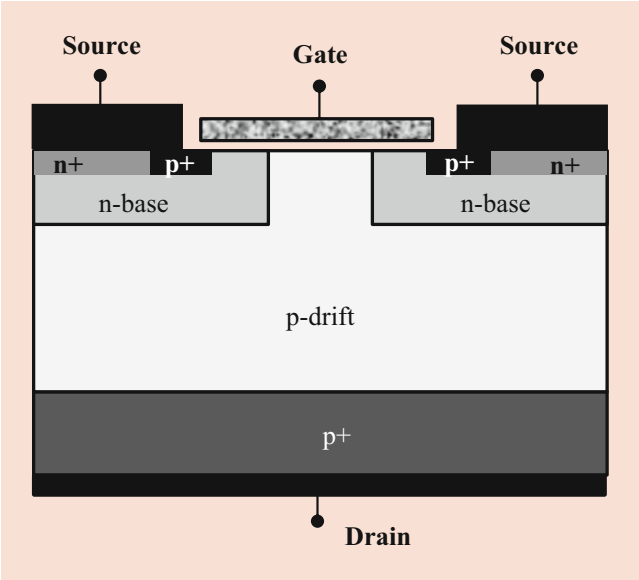

Fig. 13.14 Cross section of p-channel VDMOSFET structure

P-Channel (P-ch) MOSFETs and Their Value for Power Electronics Applications

Figure 13.14 shows the structure of a p-ch VDMOSFET, which can be fabricated simply be reversing the dopant type. The on-resistance increases by a factor of three, compared to the n-ch counterpart, because the channel and bulk mobility of the holes are roughly three times less than that of the electrons. However, when complementary p-ch and n-ch MOSFETs are available, a considerable advantage in circuit simplicity can be achieved in the power electronics field, as in the case of CMOS (complementary MOS) integrated circuits. Figure 13.15 shows leg configuration examples. Figure 13.15a is a commonly utilized leg, consisting of two n-ch MOSFETs (conventional type). In such legs, the reference voltages of the two MOSFETs have different value; hence, two independent gate drive circuits are required to control the MOSFETs. The possible operational states are the following:

(i) MOSFET in upper arm turned on
(ii) MOSFET in lower arm turned on
(iii) MOSFETs in both arms turned off
(iv) MOSFETs in both arms turned on

The last state leads to shoot-through of the DC voltage, and this is forbidden in voltage source inverter circuits, but could take place due to the discrepancy in the signal delay between the two gate control circuits when dead time is not set. That is why dead time with a certain period is required, and it is usually set in advance. Current technologies, such as digital isolators and opto-couplers, can reduce the dead time to roughly 0.1 μs; however, for reliability, the dead time is generally kept at least 1 μs and more in actual power electronics apparatus. An alternative approach to leg driving, instead of the utilization of two independent gate drive circuits, is required to minimize the dead time.

The complementary legs can minimize the dead time beyond the limit of the current technologies by using a p-ch MOSFET. An n-ch MOSFET is activated by the application of positive gate voltage (V_{gs}) and deactivated by the application of negative one to V_{gs}. A p-ch MOSFET, on the other hand, is activated by the application of negative voltage to $V_{gs,}$ and deactivated by applying positive one to V_{gs}. Figure 13.15b shows a complementary leg configuration, similar to the logic inverter circuit in an LSI (large-scale integrated circuit). This configuration has a p-ch MOSFET in the upper arm and an n-ch MOSFET in the lower arm. In the p-ch MOSFET, the reference voltage is the positive side, and in the n-ch MOSFET, the reference voltage is the negative side of the DC voltages. When the gate terminals are not connected with each other, which means that each arm switch operates independently, two gate drive circuits are required, as in the case of conventional leg. The source voltage in a p-ch MOSFET is constant when the device acts as a high-side switch. On the other hand, the source voltage of an n-ch MOSFET utilized as a high-side switch changes between the low side and the input side of the DC bus voltage in the conventional configuration. Therefore, when controlling an n-ch MOSFET, an insulated gate circuit or pulse transformer must be utilized. However, the gate circuit requires an additional power supply, and the transformer can occasionally induce faulty operation. Therefore, the p-ch

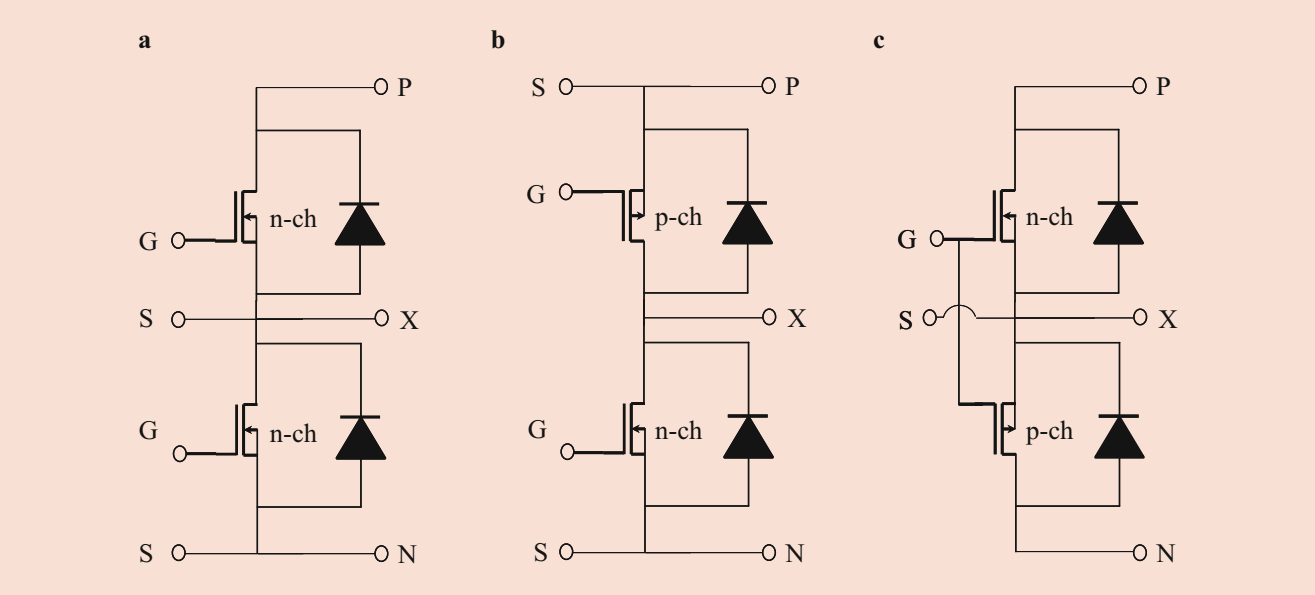

Fig. 13.15 Leg configurations: (**a**) conventional, (**b**) CMOS type, (**c**) source common type

MOSFET has the advantage of enabling reduction in the number of components, and this simplifies the circuit, enhances reliability, and enables a reduction in the size and weight of the overall system.

When the gate terminals are connected with each other, on the other hand, one gate circuit can control both MOSFET, making it possible to reduce the dead time. However, in the CMOS-type configuration, a voltage similar to the DC voltage level could be applied to the gate-source terminals as V_{gs} in the upper arm of the p-ch MOSFET; and in power electrics applications, as the DC voltage level is usually much higher than the rated voltage for V_{gs}, the MOSFET may well not withstand it. In addition, this configuration may experience the shoot-through when the leg state is changed. Therefore, this configuration cannot be used in high voltage power electronics applications. The configuration in Fig. 13.15c has a p-ch MOSFET in the lower arm and an n-ch MOSFET in the upper arm, with a common reference voltage in both MOSFETs, so that one gate circuit can control both MOSFETs in the leg by connecting the gate terminals with each other. In addition, shoot-through hardly occurs, because it is impossible for both MOSFETs to be in the on-state, simultaneously. Therefore, the dead time set in advance can be minimized by employing the gate control circuit. The advantage of minimum dead-time operation in such a complementary topology was confirmed by utilizing the device in a grid-tied inverter of 400 W and switching frequency of 100 kHz and impedance in the grid-connection inductor reduced to 1.5%, which resulted in current THD (total harmonic distortion) of only 2.3% [12].

13.2.3 UMOSFET Structure

In planar VDMOSFETs, the JFET resistance R_{JFET} fundamentally limits the beneficial cell dimension scaling [13]. Specifically, as the polysilicon gate width is reduced below a certain value when shrinking the device cell pitch, an unavoidable increase in the R_{JFET} occurs and the overall device resistance increases. The trench power MOSFET in silicon was developed late in the 1980s [7] via applying the trench process technology primitively developed for DRAMs. In a V-groove trench MOSFET, a channel is formed along the surface of an anisotropically etched groove which forms a 54.7° angle with the surface [13]. To prevent an electric field crowding, the top of the V-grooved etching must be prematurely terminated to form a flat-bottomed groove. Furthermore, since the groove is too wide to refill and planarize, the deposited gate electrode must coat the nonplanar shape, leading to fabrication difficulties such as source metal coverage. Thus, instead of the V-grooved gate structure, a new type of trench MOSFET with a steeper rectangular-shaped groove was proposed [14]. This device utilized a polysilicon gate that, in combination with a steep and wide rectangular groove profile, led to an even larger step height.

A number of technological fabrication innovations, such as planarizing trench refill technology, resulted in the mass production of a trench MOSFET. Figure 13.16 shows a trench or UMOSFET structure, along with its components of internal resistance [6]. The UMOSFET structure can increase the channel density significantly and eliminate the JFET resistance, leading to an enhanced performance of low-voltage (<200 V) power MOSFET. The total on-resistance of a power

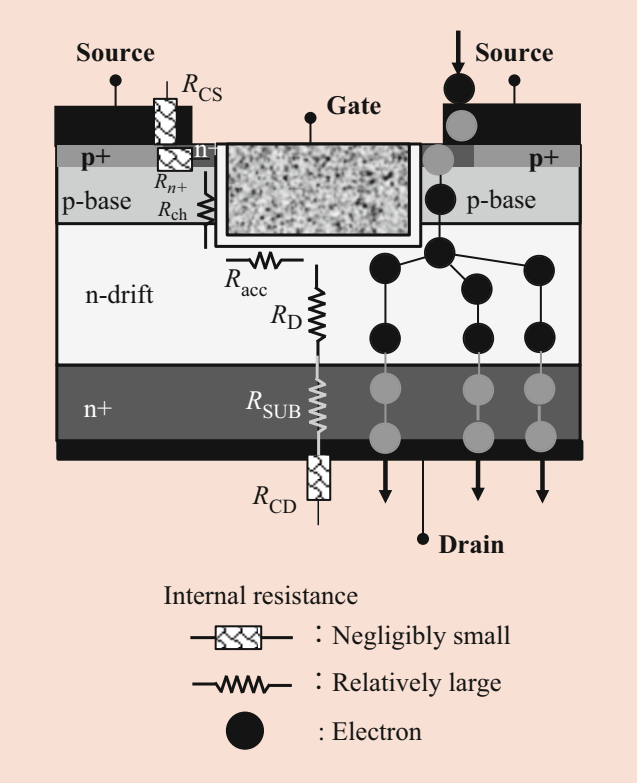

Fig. 13.16 Cross section, internal resistances, and electron flow path in trench MOSFET structure

UMOSFET is obtained by totaling the contributions of all the resistance components:

$$R_{ON} = R_{CS} + R_{n+} + R_{ch} + R_{acc} + R_D + R_{SUB} + R_{CD}. \tag{13.31}$$

Stripe cell surface topology is utilized in power UMOSFETs because of its elimination of the bottom trench corner, which otherwise exhibits high electric field concentrations. Furthermore, by utilizing the stripe cell topology, the surface of trench sidewalls can be oriented in the suitable direction to produce high-quality etched surfaces. In UMOSFETs, the resistances of the source contact (R_{CS}), n+ source region (R_{n+}), and drain contact (R_{CD}) are negligibly small.

The UMOSFET has channels formed on both the vertical sidewalls, and the specific on-resistance in channel is obtained by

$$R_{ch} = \frac{L_{ch} W_{cell}}{2\mu_{nch} C_{ox} \left(V_{gs} - V_{th}\right)}, \tag{13.32}$$

where μ_{nch} is the channel mobility, C_{ox} is the specific capacitance of the MOS, L_{ch} is the channel length, and W_{cell} is the UMOSFET cell width. According to [11], for example, in a 30 V UMOSFET with a cell width (W_{cell}) of 3 μm and gate oxide thickness of 0.05 μm, the calculated on-resistance in channel is 0.057 mΩ cm^2, when a gate voltage is set at 10 V. This value is much less than the channel resistance in the VDMOSFET described above (0.245 mΩ cm^2). The reduction in the channel resistance in the UMOSFET is because of the fourfold enhancement in channel density (W_{cell} ratio: 12 μm/3 μm = 4). The UMOSFET has thus become the main power semiconductor device for low-voltage regions, with reduced on-resistance due to cell structure optimization and finer cell pitch utilization, as a result of the introduction of nano-fabrication technologies. However, the chance of further on-resistance improvement appears to be limited, even when advanced forms of existing technologies are employed.

State-of-the-Art UMOSFETs

The field-plate trench MOSFET [15] is a UMOSFET with a buried electrode, surrounded by a thick insulating film, under the gate electrode of a conventional trench MOSFET, or a split-gate or shielded-gate trench MOSFET, as shown in Fig. 13.17. This structure has recently been reported as suitable for use with low breakdown voltage (about 200 V or less). In conventional low-voltage UMOSFETs, the channel resistance is reduced by reducing the cell pitch; however, this does not reduce the drift layer resistance, resulting in the increase of relative contribution of the drift layer resistance, and this has been a problem for UMOSFETs, even in the low breakdown voltage range. In the field-plate trench structure, on the other hand, the doping concentration in the drift layer can be increased by the field-plate effect of the buried electrode, and the drift layer resistance is thereby reduced. Therefore, along with superjunction technology, much attention has been paid to this structure as a means of extending the limits of silicon MOSFET capability. Since the mesa doping concentration is determined by the mesa width, and the concentration can be increased in roughly inverse proportion to the mesa width, the drift layer resistance can be lowered by pitch shrinkage. In [16], Park et al. reported 60 V class split-gate trench MOSFET fabrication results. The on-resistance in n-drift layer constituted roughly 60% of the overall resistance, even in 60 V class devices; thus, minimization in the on-resistance in the drift region is attractive in this voltage class. The fabricated device exhibited an on-resistance of 10.9 mΩ mm^2, gate charge Q_g of 73.9 nC, and $R_{on} \times Q_g$ of 85 mΩ nC due to its fine field-plate trench structure (the result of chemical mechanical polishing (CMP)) and tungsten plug technology, which enhance its performance compared to devices fabricated using previous-generation technologies (see Table 13.1). Further, this device was utilized in the synchronous rectifier of an isolated-type DC-DC converter and showed high efficiency as well as advantages of the field-plate trench structure, such as low dV_{ds}/dt and low peak drain voltage.

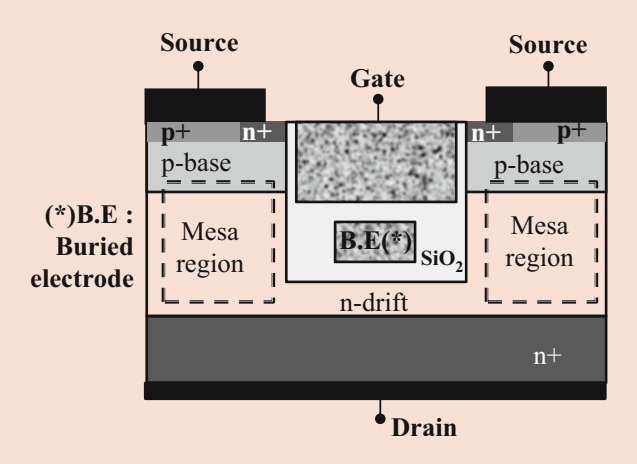

Fig. 13.17 Cross section of field-plate trench MOSFET

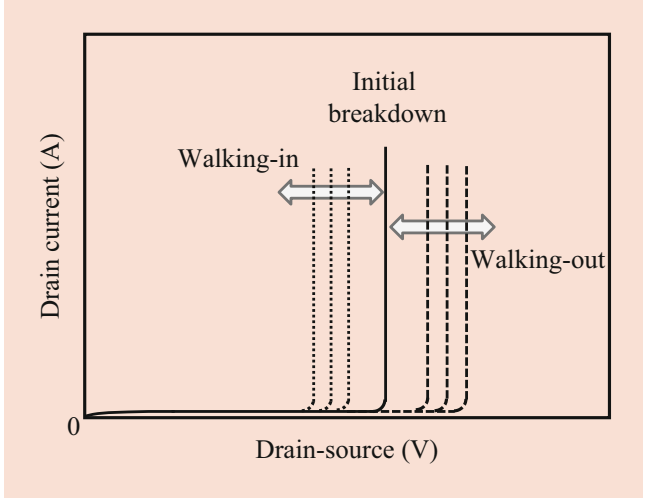

Fig. 13.18 An example of breakdown instability characteristics in trench field plate MOSFET

Table 13.1 Comparison of electrical characteristics (60 V class MOSFETs)

	Split gate trench MOSFET	Conventional device
Specific on resistance (mΩ mm^2)	10.9	17.8
Q_g (nC)	73.9	66
$R_{on} \times Q_g$ (mΩ · nC)	85	145

Another approach to reducing the on-resistance involves increasing the field-plate effect and doping concentration in the mesa. Kobayashi et al. gradually thickened the oxide film in the depth direction of the trench in a so-called multiple stepped oxide field-plate trench MOSFET (MSO-FP-MOSFET) and showed that the longitudinal electric field in the mesa was maintained even at a higher doping concentration than before and that the breakdown voltage could be maintained and the on-resistance reduced [17]. The study confirmed that a breakdown voltage of 114.8 V can be obtained, even with a 1.5 times greater doping concentration in the drift layer with respect to the field-plate trench structure of a conventional 100 V class device, by fabricating a diode TEG (test element group) with the trench structure mentioned above. Based on the device simulation results, it was inferred that this device structure could exhibit an on-resistance of 28.5 mΩ mm^2, 25% lower than the conventional structure. It is strongly expected that the device's on-resistance will continue to be improved in the future, due to miniaturization and refinement of the gate structure in the trench.

On the other hand, as a problem peculiar to this structure when using a Si/SiO_2 interface, there is instability in the breakdown voltage; however, there have been reports of improvement in stability resulting from analysis of this phenomenon and the device design. In the field-plate trench structure that improves the breakdown voltage by using Si/SiO_2, variation in the breakdown voltage due to charge trapping or interface degradation (also termed "walking-in and walking-out"; see Fig. 13.18), which is presumed to be caused by hot carriers during avalanche generation, has been reported in recent years. Yedinak et al. reported that the breakdown voltage is stabilized by lowering the doping concentration in the drift layer of the cell to a level slightly lower than the concentration at which charge balance can be obtained [18]. Hossain et al. noted that the charge balance design, not only of the cell component but also of the termination component, is important for stabilizing the breakdown voltage; and by optimizing the distance between the termination trench and the cell trench, it was confirmed that the breakdown voltage fluctuation could be suppressed [19]. Furthermore, Hossain et al. calculated the charge balance in the termination structure using three-dimensional TCAD simulation and provided a more detailed explanation of this phenomenon [20]. To optimize the charge balance in the cell, Deng et al. performed an analysis based on the integration value of the space charge in the depth direction, and the average space charge, for an element in which the doping concentration in the drift layer changed in the depth direction [21]. The results suggested that it is desirable to use a slightly lower doping concentration in the drift layer, which can nonetheless ensure charge balance, in order to suppress the degradation of breakdown voltage due to the walking-in phenomenon.

Several technologies have been developed for suppressing breakdown voltage fluctuation by optimizing designs such as those described above, but the physical mechanism of breakdown voltage fluctuation continues to be discussed. A common conclusion of the published studies, however, is that there is a high possibility that positive charges are generated at the Si/SiO_2 interface of the trench. Nishiwaki et al. [22] showed that the breakdown voltage fluctuation has a power

relationship with respect to time, by evaluating the time and avalanche current dependence of such fluctuation, and proposed a model to explain the origination of the positive charge. The model suggested that due to the holes caused by avalanche breakdown, trap levels were generated by the desorption and diffusion of hydrogen atoms terminating at the Si/buried-SiO_2 interfaces at the bottom of the trench, and became positive. This proposed model was similar to the Negative Bias Temperature Instability (NBTI) test results for the p-ch MOSFET. In this way, the physical understanding of the breakdown voltage fluctuation is being gradually deepened by measurement and simulation.

A characteristic feature of the field-plate trench structure is that the feedback capacitance (C_{rss} or C_{gd}) between the gate and the drain is low, because the gate electrode is shielded from the drain by the buried electrode, called a shield gate. Further, the capacitance between the buried electrode and the drain, and the embedded wiring resistance, equivalently form a snubber circuit, meaning that this element itself has the function of suppressing noise and is a suitable structure for high-speed switching. On the other hand, the capacitive coupling between the buried electrode and the gate electrode may cause shoot-through or self-turn-on operation.

In light of this, modeling technology using TCAD and SPICE (simulation program with integrated circuit emphasis) is becoming increasingly important. In [23], analysis of the equivalent circuit in the field-plate trench structure, represented by the parasitic capacitance around each terminal, the gate electrode wiring resistance, and the buried electrode wiring resistance, showed that the potential of the embedded electrode is transiently increased by the displacement current. This result suggested that the field-plate effect was suppressed and that the breakdown voltage of the device was transiently lowered enough to cause a dynamic avalanche, which could lead to shoot-through. In addition, using TCAD mixed-mode simulation and experimentation, Roig et al. proposed a configuration designed to optimize the trade-off characteristics of the shoot-through and ringing, through the use of a built-in snubber [24].

13.2.4 Superjunction MOSFET

In 1982 [25] and 1988 [26], Coe et al. introduced the concept of alternate n- and p-stripes in power devices. A device structure with a RESURF (reduced surface field) device was presented with lateral structures in 1979 [27]. The RESURF junction incorporated in an LDMOSFET enables more efficient depletion layer expansion in the drift region and enhanced doping concentration in the n-drift region, utilizing the interaction of the depletion layers expansion from two p-n junctions. The name "superjunction" was introduced in [28], and a theoretical analysis of this structure was presented in

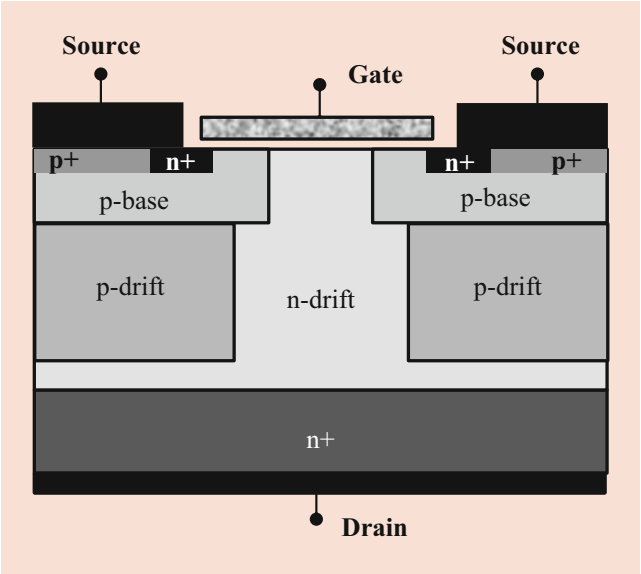

Fig. 13.19 Planar gate SJ-MOSFET structure

[29]. The primary feature is that the high doping drift region comprises several alternating n- and p-type stripes. If these stripe layers are reasonably narrow and the net doping concentration in both stripes is roughly equal, the stripes can be completely depleted at relatively low biases; at which point, the stripe layers act as an intrinsic layer and a uniform electric field distribution is attained, leading to a high breakdown voltage. According to [30], one of the first vertical MOSFET devices to incorporate superjunction physics was introduced in early 1980, and commercial devices were presented as CoolMOS [31] and MDMESH [32], in the late 1990s.

Figure 13.19 shows a cross sectional view of the superjunction MOSFET structure, which is similar to the CoolMOS structure. Two basic approaches to fabricating the superjunction MOSFET have been proposed. The first is based on the utilization of p-type and n-type multiple ion implantations process, followed by n-type epitaxial growth one [33]. The second is based on the application of etching process to make deep trenches into an n-drift region, followed by refilling of the trenches with the p-type epitaxial layer [34]. Numerous other structures of the superjunction MOSFET have also been introduced and demonstrated [30]. After forming the alternating n- and p-type columns vertically, the wafer surface is smoothed by CMP (chemical mechanical polishing), then the planar gate structure is formed. Trench and UMOSFET structure can be formed to minimize the channel resistance. The superjunction structure could, for example, be designed three dimensionally, as stripes in parallel with, or orthogonal to the trench gates.

The charge-coupling concept has enabled augmentation of the breakdown capability in power MOSFETs. In designing the superjunction MOSFET, it is critical to properly spec-

ify the doping density and thickness of the n- and p-type columns. The doping Q_{opt} and width are optimized and given by [6]

$$Q_{opt} = 2qN_D w = \varepsilon_s E_c, \tag{13.33}$$

where q is the electron charge, N_D is the doping concentration in the n- column region, w is half the width of the n- column region, ε_s is the dielectric constant of the semiconductor materials, and E_c is the critical electric field.

The physics of superjunction MOSFET operation in forward blocking is different from that of the VDMOSFET and UMOSFET described above. The theoretical analysis of superjunction devices was presented in [28]. When the positive voltage is applied to the drain, a depletion layer is expanded not only under the planar or trench gate electrode but also the vertical p-n junction of the p and n columns in the drift region. This two-dimensional depletion layer expansion leads to the suitable charge coupling, which makes the electric field distribution rectangular and can utilize the very high doping concentrations in the drift region. The latter results in extremely low on-resistance $R_{ON,\,sp}$, which has been presented [29]. Assuming a principle structure similar to superjunction devices such as JFETs, the on-resistance of vertical devices has been analytically related to the breakdown voltage V_B as follows [30]:

$$R_{ON,sp} = 4w\frac{V_B}{\mu\varepsilon E_C^2}, \tag{13.34}$$

where w, μ, ε, and E_c are the half pitch of columns in the superjunction devices, mobility of electrons, dielectric constant of silicon, and critical electric field, respectively. The remarkable potential of superjunction devices to minimize the on-resistance, in comparison with the trade-off relation in conventional devices as illustrated by

$$R_{ON,sp} = \frac{27}{8} \times \frac{V_B^2}{\mu\varepsilon E_C^3}, \tag{13.35}$$

was theoretically demonstrated in [28].

This is particularly suitable for the realization of high-performance silicon power MOSFET with large blocking voltage in 500–700 V range. To reduce the $R_{ON,sp}$, the lateral pitch must, in principle, be narrowed, in order to maintain a high vertical field even with the increase in the n-column doping concentration. Reflecting this design, $R_{ON,sp}$ improvement with lateral pitch narrowing has been demonstrated [35, 36]; and the $R_{ON,sp}$ has been continuously reduced in 600–650 V class power MOSFET products [30, 37–39]. For example, the latest CoolMOS has successfully lowered the specific on-resistance to 8 mΩ cm^2 for 600 V-rated devices. This extremely low on-resistance has been achieved by extreme shrinkage of the pitch of the underlying superjunction structure. Precise tailoring of the doping profiles is required to yield process windows wide enough for mass production; however, with further improvements in related manufacturing processes, an on-resistance in the range of 5 mΩ cm^2 could be achievable.

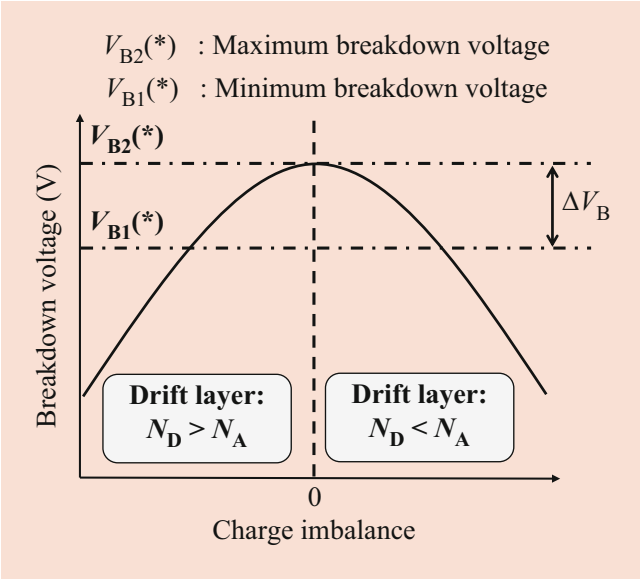

Fig. 13.20 Breakdown voltage degradation due to charge imbalance in superjunction MOSFETs

The breakdown voltage of the superjunction MOSFET degrades through the charge imbalance between the n- and p-columns, because of the intrinsic electric field modulation. Thus, the charge imbalance margin must be designed with an eye to process controllability in mass production. Figure 13.20 is a schematic of such breakdown voltage lowering through charge imbalance. Saito provided an analytical expression for determining the on-resistance limit when taking the influence of charge imbalance in superjunction MOSFETs into account [40]. The breakdown lowering ΔV_B with a flat doping profile in the superjunction is given by

$$\Delta V_B = V_{B2} - V_{B1} = \frac{q\,|N_A - N_D|}{4\varepsilon_s} t_{SJ}^2 = \frac{q\alpha N_{SJ}}{4\varepsilon_s} t_{SJ}^2, \tag{13.36}$$

where q is the electron charge; ε_s is the dielectric constant of the semiconductor materials; N_A is the doping concentration in the p-column; N_D is the doping concentration in the n-column, which is equal to N_{SJ}; and α is the charge imbalance ratio.

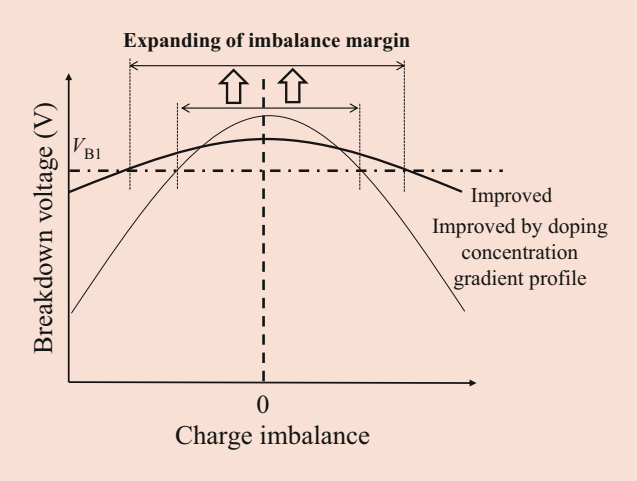

Fig. 13.21 Expanding of charge imbalance margin by doping concentration gradient profile

In order to keep the charge balance margin large, it is necessary to increase the breakdown voltage in the balanced state; but then the on-resistance increases because the pillar is deep and the concentration is reduced. Therefore, it is highly important to improve the trade-off characteristics between the on-resistance and charge imbalance margin. To suppress the decrease in breakdown voltage when the charge balance collapses (Fig. 13.21), it is effective to add a concentration gradient to the pillar. As shown in Fig. 13.22b, the maximum breakdown voltage V_{B2} in the balanced state decreases due to the electric field modulation, but the electric field distribution when the charge balance collapses can be improved, resulting in suppression of the breakdown voltage lowering. Therefore, a graded doping profile expands the charge imbalance margin.

The V_B lowering with a graded doping profile in the superjunction is given by

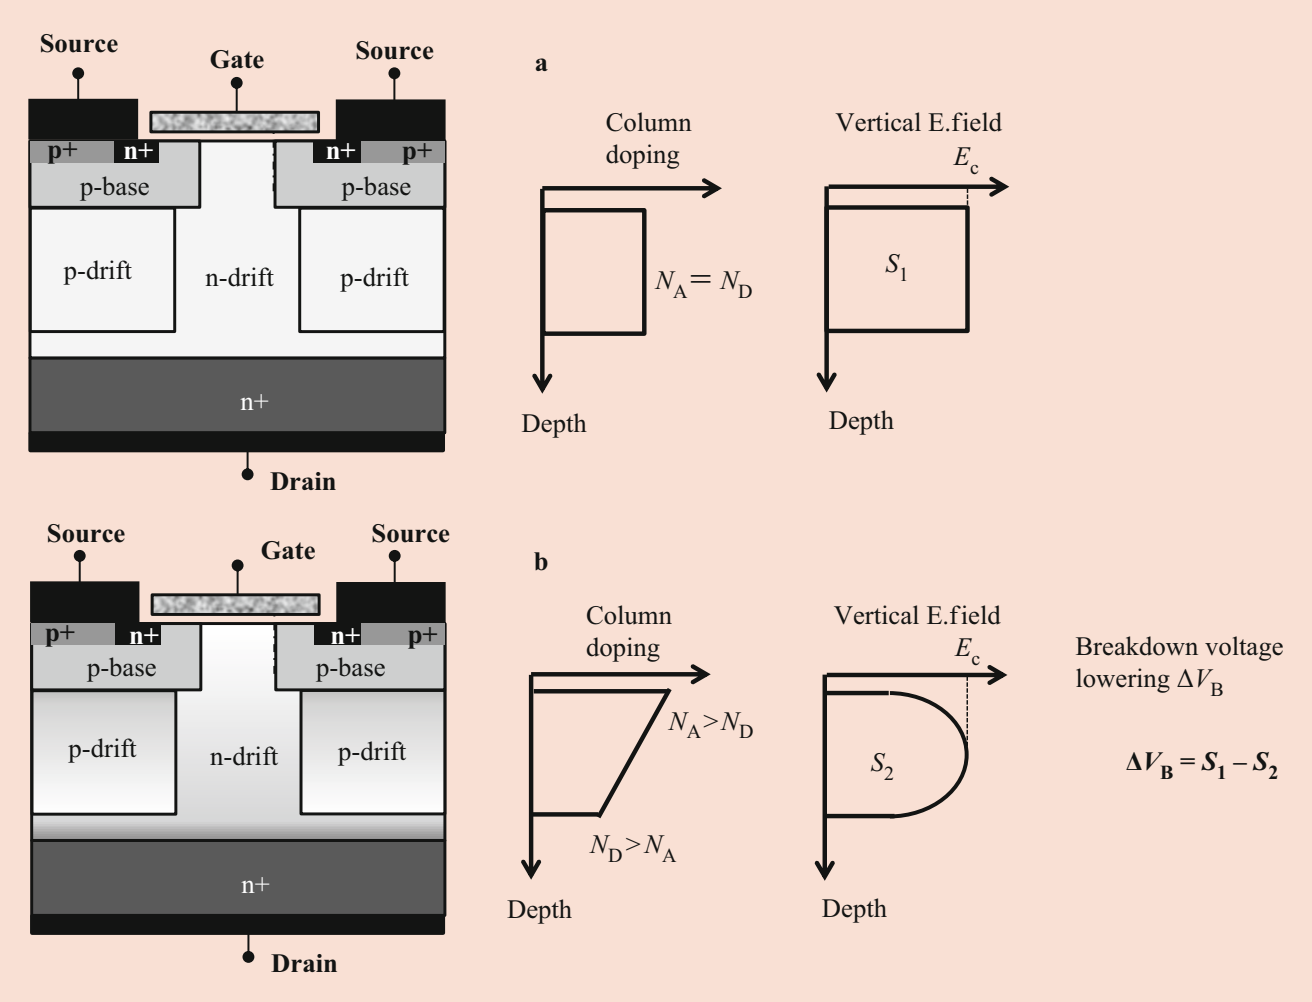

Fig. 13.22 Doping profile and vertical field distribution in columns (**a**) w/o concentration gradient and (**b**) with concentration gradient

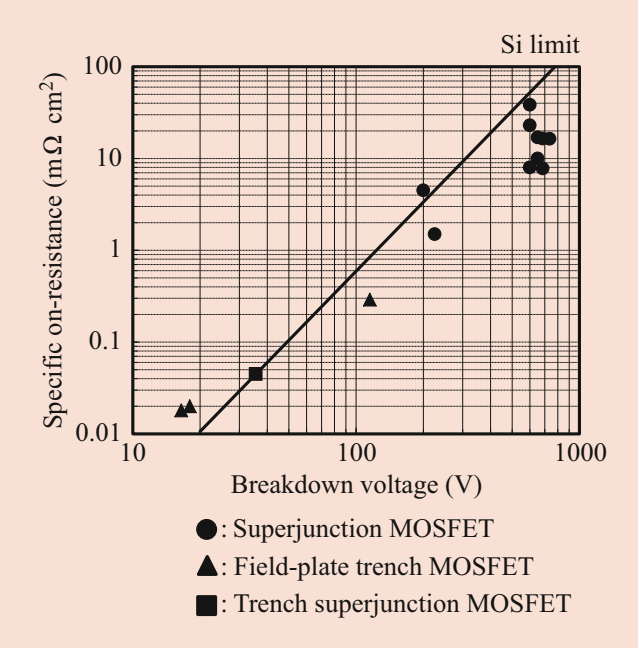

Fig. 13.23 Specific on-resistance versus breakdown voltage of trench and superjunction MOSFETs. This graph was drawn using data in [7] and [30]

$$\Delta V_B = \frac{qN_{SJ}}{24\varepsilon_s} t_{SJ}^2 \left(\gamma + 3\frac{\alpha^2}{\gamma}\right); \tag{13.37}$$

and to minimize ΔV_B, the optimum γ is given by $\gamma = \sqrt{3}\alpha$ from Eq. 13.37, so that ΔV_B is expressed by

$$\Delta V_B = \frac{q\alpha N_{SJ}}{4\sqrt{3}\varepsilon_s} t_{SJ.}^2 \tag{13.38}$$

Graded doping can reduce ΔV_B by $1/\sqrt{3}$ compared to the value with a flat doping profile, as shown in Eq. 13.36; and as a result, the amount of charge in the drift region can be increased and low on-resistance can be achieved. In [40], the theoretical limit of on-resistance in 600 V devices was estimated to be 7 mΩ cm^2 with a charge balance margin of ±3%.

Figure 13.23 shows a recent achievement of $R_{ON,sp}$ versus breakdown voltage of trench (including field-plate trench) and superjunction MOSFETs [7, 30].

13.2.5 MOSFET Body Diode

When applying a negative voltage to the drain electrode of VDMOSFET and UMOSFET structures, the junction of the p-base and n-drift region is in a forward-biased state, and the current starts to flow. This is the pn diode operation, and the current flows when the drain voltage exceeds roughly 0.7 V in the negative direction. This is referred to as the current flow through the MOSFET body diode . A cross section of the UMOSFET structure with the body diode is illustrated in Fig. 13.24, along with the equivalent circuit. The MOSFET body diode can be used as a free-wheeling diode in voltage source converters, so its forward voltage drop and reverse recovery power dissipation must be kept at a low value. When the negative voltage is applied to the drain electrode of MOSFET, the body diode is driven into forward conduction, resulting in the hole injection from the p-base region into the n-drift layer. A large number of holes and electrons flow in the n-drift region, leading to low on-state voltage drop. When the drain voltage of the MOSFET changes from negative to positive, the stored holes and electrons in the n-drift region must be swept out, and then the p-n junction between the p-base and n-drift regions is reverse recovered. The swept-out charge generates a large current flow in the reverse direction, resulting in power loss in the MOSFET. The reverse recovery characteristics of the body diode in power MOSFETs can, however, be controlled by some lifetime control techniques, such as electron irradiation [41, 42].

It has been recognized that power MOSFETs can fail in certain situations involving the body diode operation. Such failure sometimes occurs as the drain voltage rises sharply at the reverse recovery of the p-n junction (p-base and n-drift regions). This sharp increase in drain voltage (i.e., surge voltage) is caused by a rapid decrease in the current (dI/dt) associated with a higher level of recovery current and stray inductance L_{stray} in the circuit ($L_{stray} \times dI/dt$). Therefore, optimal design of the forward voltage drop, reverse recovery loss characteristics, and surge voltage reduction in the body diode is highly important for achieving superior circuit efficiency in the voltage source converter. A suitable method for improving the body diode characteristics involves the integration of a Schottky barrier diode in the power MOSFET device [43]. The reverse leakage current from the integrated Schottky barrier diode can be reduced by using a junction barrier Schottky (JBS) diode [44]. In low-voltage power MOSFETs, such configurations are highly effective; however, in high voltage power MOSFETs (500 V and more), this approach can be ineffective due to the higher on-resistance.

In superjunction MOSFETs, the reverse recovery current flowing through the body diode becomes very strong, resulting in large reverse recovery loss; thus, such devices are not often utilized in voltage source converters with a free-wheeling mode. In order to alleviate this difficulty, a new type of circuit technology, utilizing the synchronous reverse blocking method was proposed [45]; the basic circuit topology is shown in Fig. 13.25. In this configuration, a second low-voltage MOSFET is added in series with the main switch, to block the reverse current in the associated body diode. This second switch must be synchronized with

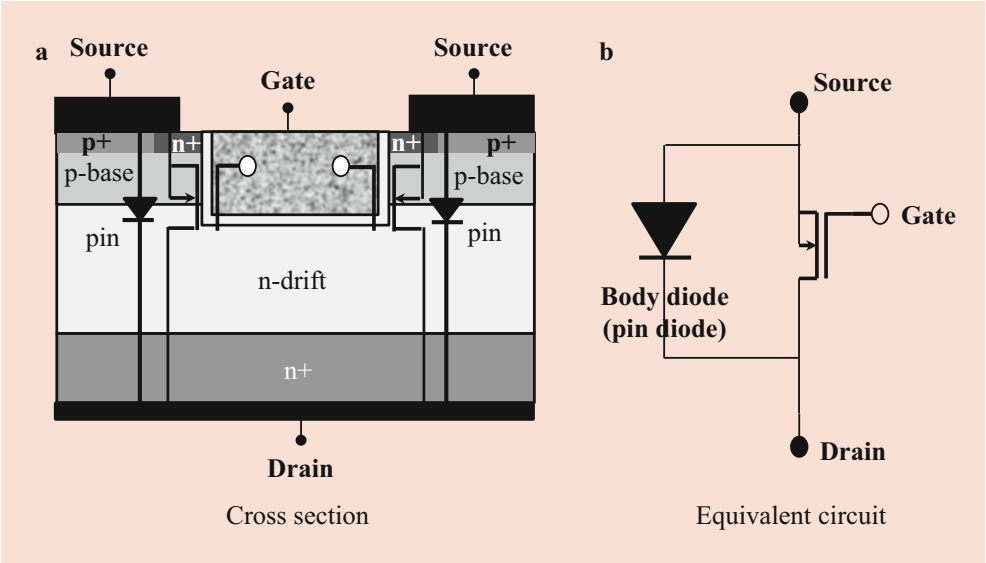

Fig. 13.24 Body diode within the UMOSFET structure. (a) Cross section. (b) Equivalent circuit

the main switch (superjunction MOSFET) so that the reverse current flows through a parallel SiC Schottky diode. In this way, the reverse recovery characteristics of superjunction MOSFET body diodes can be improved.

13.2.6 Edge Terminations for Silicon Power Devices

Figure 13.26a shows a top view of an actual power MOSFET. As can be seen from the figure, on its top surface a power MOSFET has a source electrode and a gate electrode for applying a control signal; and the current flows between the source electrode and a drain electrode on the rear surface, which does not appear in this figure. There is a ring-shaped band around the element, to enclose the gate electrode and the active region (see Fig. 13.26b) where the drain current flows. This band called edge termination region, in which no drain current flows, simply provides a region for supporting high drain voltages (see Fig. 13.26c) and is incorporated not only in power MOSFETs but in IGBTs and diodes.

Figure 13.27 shows a cross section of the end of a power MOSFET with no edge termination regions. Power MOSFETs are fabricated in silicon wafers, and when the wafer process is completed, many square chips are cut out by sawing through the wafer. This process called dicing is performed by diamond-coated blades and results in severe damage to the silicon crystals. In the case of power MOSFETs with no edge terminations (as shown in Fig. 13.27), when the dicing cuts through pn junctions, a large amount of leakage current can be generated and flow in the forward blocking state, because the depletion layer intersects with the crystal damage regions, resulting in degradation of the breakdown voltage and its stability with respect to time. This problem can be addressed, however, by incorporating an edge termination region around the power MOSFET, so that the depletion layer of the pn junction, which must support the high drain voltage, does not intersect with the cutting lines of the dicing saw, where there is severe crystal damage.

A planar junction edge termination has a number of guard rings (or floating rings), and is generally utilized in silicon power MOSFETs, IGBTs, and diodes. Figure 13.28 shows a cross-sectional view of the edge structure. Notably, the guard rings can be fabricated with the pn junction in active regions (or main junction) with no additional process steps at the same time. The breakdown characteristic of the edge termination region depends on the distance of the leftmost guard ring from the main junction (W_{G1}) and the distance of each ring (W_{Gn}). If the distance W_{G1} is too wide, the electric field at the edge of the main junction becomes high ("A" in Fig. 13.28), leading to a breakdown voltage close to a planar junction with no edge termination. If the distance W_{G1} is too narrow, a high electric field is concentrated on the next-outermost ring, resulting in the breakdown voltage worsening. Hence, optimum distance is necessary to show a high breakdown voltage. The breakdown voltage of a planar junction with one single guard ring can be analyzed by calculations [46]; however, at present, to achieve much more reliable characteristic in the edge structure, a number of guard ring structures is utilized in power MOSFET devices. More sophisticated design optimization can be achieved using TCAD simulations of the structure.

Another approach to junction edge termination involves junction termination extension (JTE) structures, which have been shown to dramatically improve the breakdown voltage. As illustrated in Fig. 13.29, these structures contain a p-type

region formed at the peripheral region of the p-n junction [6]. This p-type region, which is very lightly doped, is commonly formed by ion implantation in order to control the dopant charge precisely. If the doping density in the p-type region is too heavy, breakdown at lower voltage takes place at the edge ('C' in Fig. 13.29), because of the smaller radius of p-n junction curvature at this edge. When the doping density in the p-type region is too light, the region is fully depleted at a low reverse voltage, leading to breakdown at the main junction ("B" in Fig. 13.29) at the similar voltage as a structure without termination region.

According to [6], the charge in the p-type region is optimized by

$$Q = \varepsilon_s \times E_c, \tag{13.39}$$

where E_c is a critical electric field for silicon and ε_s is the dielectric constant of silicon. So, the optimum dopant dose in the JTE region (see Fig. 13.29) can be calculated as roughly 1.3×10^{12} cm^{-2} in silicon. A sophisticated optimization of the p-type region can be achieved using TCAD simulations. Although the breakdown voltage of the JTE structure depends on the p-type region, the total dose in this region can be precisely controlled by the ion implantation process, and the breakdown voltage is not likely to vary significantly, even with uneven doping in the p-type regions.

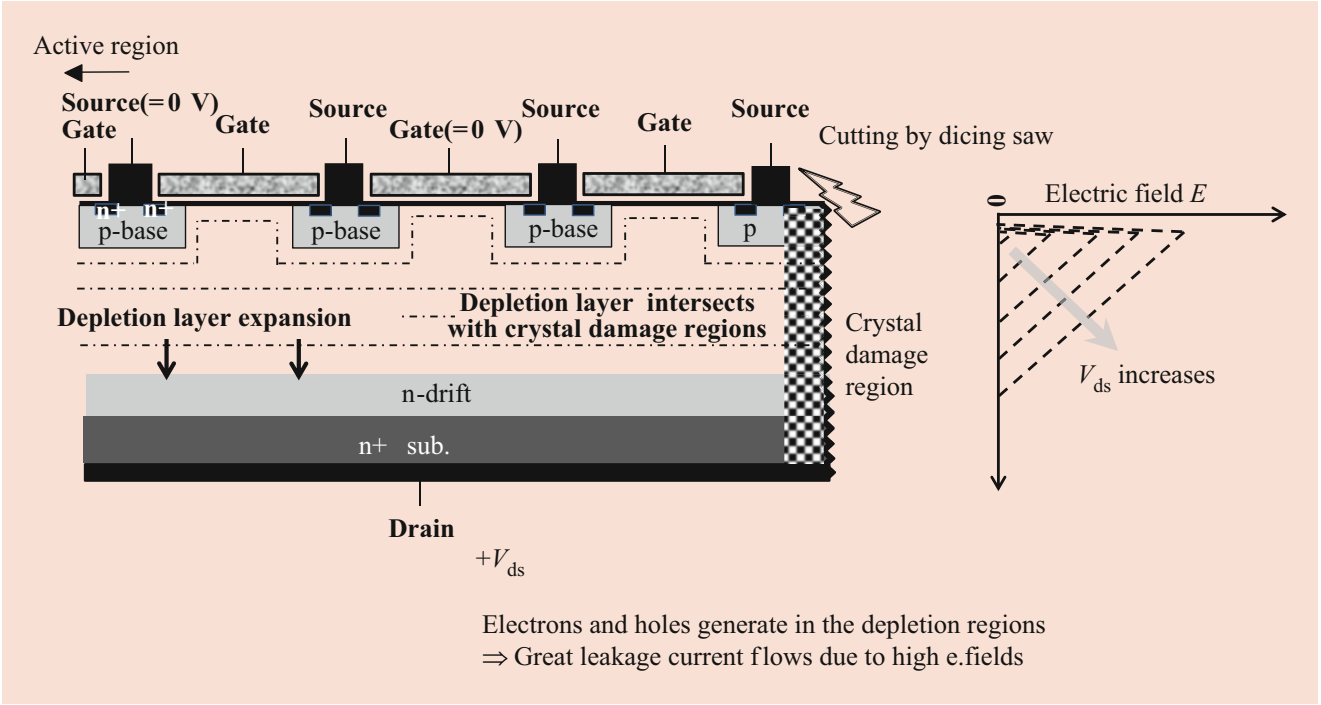

Fig. 13.27 Cross section of power MOSFET end region with no edge termination region. In a forward blocking state, depletion layer expands and intersects with the crystal damage regions

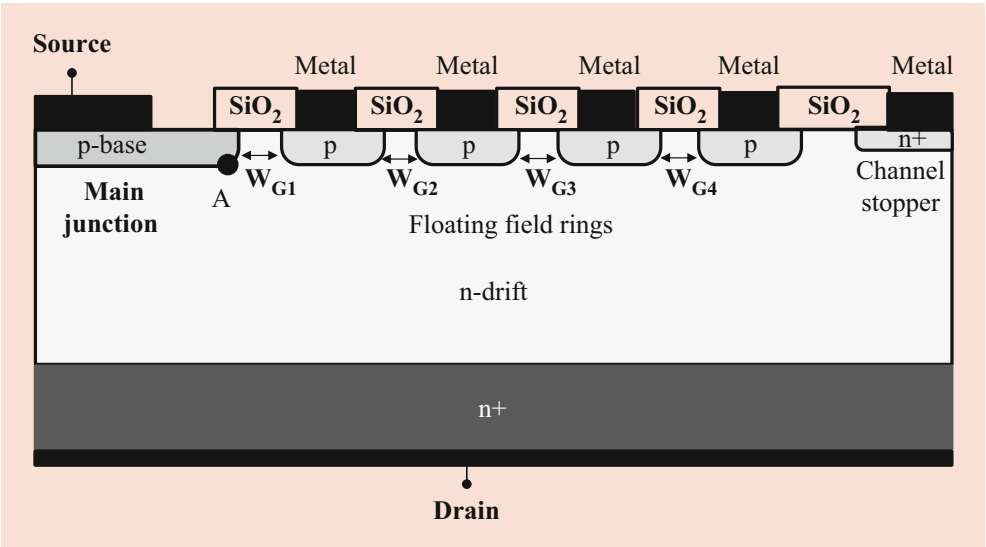

Fig. 13.28 Schematic cross section of multiple floating field ring terminations

Field-plate structures are also popular for use as edge structures. Figure 13.30 shows the effect of the field plate, which expands the depletion region at the edge. In this case, the metal layer is formed on the p+ region and extended over the silicon dioxide layer (SiO_2) at the edge of the power device. Notably, combining the field plate with guard rings means that less rings are needed, thus reducing the area requirement. It is important to minimize the edge termination area as possible to reduce device cost, because this edge termination area cannot be utilized for main current flow in the device. This approach obviates the need for additional photomasks and photolithography processes; however, the edge region can be a weak point for power semiconductor devices, and optimum design and reliable fabrication are highly important for stable and rugged power device development in this case.

13.2.7 Epitaxial Layers and Substrate Wafers

In vertical MOSFETs such as VDMOSFETs, UMOSFETs, and superjunction MOSFETs, when the electrons reach the lower side of n-drift region, they are distributed throughout the n+ substrate, enabling them to flow evenly through the substrate. The resistance in the n+ substrate is obtained by

$$R_{SUB} = \rho_{SUB} \times t_{SUB}, \tag{13.40}$$

where ρ_{SUB} is the resistivity and t_{SUB} is the thickness of the substrate. Therefore, the resistance in the n+ substrate is strongly dependent on its thickness and resistivity, necessitating the use of available technologies for minimizing its thickness and resistivity while keeping manufacturability well. The base silicon wafer has the function of providing mechanical support; therefore, vertical power MOSFETs for low-voltage application especially require substrates heavily doped with arsenic, phosphorus, or antimony, as well as a post-fabrication wafer thinning process, to achieve the low on-resistance. Power MOSFET device fabrication utilizes epitaxial wafers, which are already pre-deposited in specific epitaxial layers on the n+ substrate. VDMOSFETs and UMOSFETs usually utilize epitaxially grown layers on the substrates, with the base wafer enhanced with specially designed epitaxial layers grown to a precise thickness and doping concentration. Since power MOSFETs utilize heavily doped substrates, special attention must also be paid to substrate polishing, in order to prevent stacking faults and Frenkel defects in the epitaxial layers [7].

In recent UMOSFETs, the unit cell width has become very small, so that special wafers, with features such as exceptional smoothness, are strongly required to insure alignment between the trench mask and specific crystallographic planes. The depth of the trench in gate electrode fabrication must not exceed the n-drift layer thickness during the trench etching process; and as a final fabrication stage, UMOSFET wafers are mechanically thinned and a backside metal is deposited. This backside metal consists of multiple layers

such as titanium, nickel, and silver or gold, in order to obtain an ohmic contact; to provide a solderable low-resistance layer to attach to a lead frame; and to prevent diffusion of the deposited metals into the wafer contact interface. In a recently developed three-step process, the first step involves rough-grit grinding to adjust the wafer to a specific thickness; followed by chemical etching to remove the stress and wafer bow, and complete the thinning; and finally roughening the backside of the wafer surface to improve metal adhesion [7].

13.3 Insulated Gate Bipolar Transistors (IGBTs)

Insulated gate bipolar transistors (IGBTs) were developed in the 1980s as a superior substitute for bipolar power transistors. Though the latter had been utilized for many applications, they had a variety of drawbacks as described in Sect. 13.2.1. The IGBT combines the operational physics of MOSFET and bipolar transistor, as shown in Fig. 13.31. The gate drive signal for the IGBT is applied to the power MOSFET structure, providing the advantages of small size, inexpensive gate circuits that enable high input impedance and voltage-controlled operation. In an operation of the IGBT, the power MOSFET structure supplies electrons to the built-in pnp bipolar power transistor as a base current ($-I_B$), which is in conductivity modulation of the n-drift region, thereby enabling a high collector current (I_c) with low on-state voltage drop. Recently, IGBTs have been utilized in a variety of power electronic apparatus, especially medium and high voltage/current range, such as motor drive application for xEVs (electric vehicles, plug-in hybrid cars, etc.), and uninterruptible power supply (UPS). They continue to play the major role in operating power electronics apparatus, with continual advancement in the devices themselves and in the related packaging technologies.

13.3.1 Background of IGBT Development

In the 1970s, there was a strong need for "self-turn-off" devices, which featured fast switching characteristics with high withstand capability, along with the innovation of control technology such as a pulse width modulation (PWM). To satisfy this need, gate turn-off (GTO) thyristors, which can operate high power, and the Darlington bipolar power transistor with planar type structure and multi-diffusion layers, emerged. The devices show low on-state voltage drop and high current capability, with little base-current control. Moreover, because of the wide reverse biased safe operating area (SOA) and high withstand capability in short-circuit state enabled by optimal design, bipolar power transistors can be highly effective in reducing the power dissipation

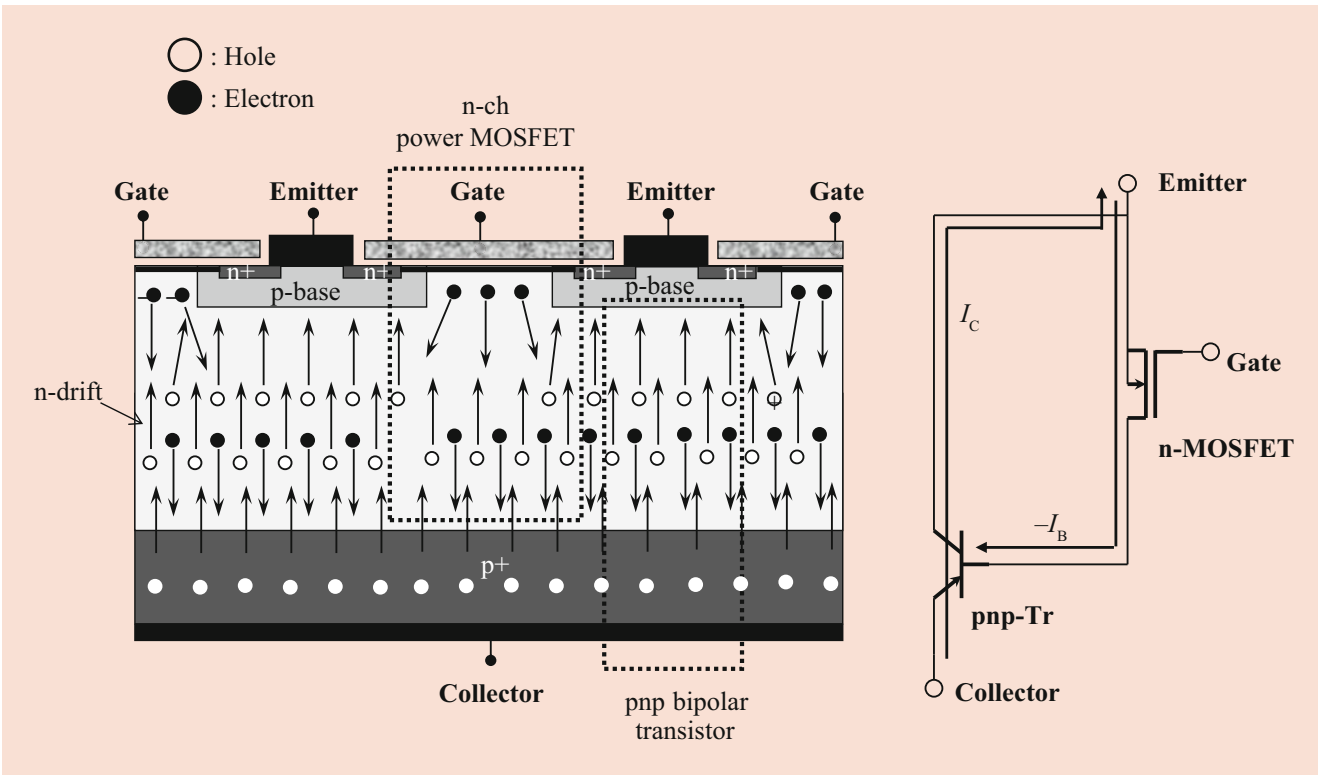

Fig. 13.31 Operational physics of IGBT in the on-state and its equivalent circuit

in voltage source converters, even in high-speed switching operation. Along with these device developments, the package technology advancement, which makes several transistor devices possible to be assembled and connected to each other in a specific circuit configuration, such as three-phase bridge and an H-bridge, in one module, has succeeded in the bipolar transistor power modules development, which have become widely utilized in many power electronics applications.

Power MOSFETs became commercially available in the 1970s, for lower voltage applications such as switching mode power supply, mainly because they require little power for gate control owing to the MOS gate structure, and exhibit very fast switching speeds. In the early 1990s, GTO thyristor and bipolar power transistors still played the major roles for medium- and high-voltage/current applications. However, MOS-gated devices with the fast switching speed were also needed in the case, because carrier frequency in the PWM control increased. Power MOSFETs shows the features of low control power and fast switching, but the on-resistance increases very sharply with the breakdown voltage; as a result, the MOSFET exhibits less power handling capability than bipolar power transistors. For higher power systems, new types of power devices, combining bipolar transistor and MOSFET physics, were presented. Against this background, the IGBT emerged [47, 48]. K. Yamagami et al. presented the principle concept of the IGBT: a wide-base pnp transistor controlled by an n-MOSFET (see Fig. 13.32) [49]; and from the late 1970s to the early 1980s, a number of research groups produced several papers and patents exploring this approach. Scharf and Plummer [50] revealed the first measured results for a lateral type MOS gate thyristor, which operated as a bipolar transistor at relatively low current levels. Baliga showed a MOS gate thyristor in vertical structure, which exhibited high-voltage current saturation at low gate voltage level, with the MOS gate thyristor operating as the wide-base pnp transistor [51]. Plummer developed a MOS gate thyristor with a similar operational mechanism [52]. In 1982, Becke et al. introduced a novel power MOSFET structure with a p anode layer [53]. In the related patent, Becke claimed that the device did not latch up under any operating conditions, meaning that it operated as a pnp transistor at all times. Based upon this patent, in 1983, Russell et al. published measurement results for another novel power MOSFET, the COMFET (conductivity-modulated FET) [54]. In 1982, Baliga et al. presented fabrication and measurement results for an insulated gate rectifier (IGR), as shown in Fig. 13.33 [55]. In this paper, Baliga et al. noted that the parasitic thyristor action should not be activated in normal current range of its operation. Although the device was presented as a rectifier, it was clearly designed as a bipolar transistor with MOS gate. In 1983, GE (General Electric) released the first IGBT product: a power MOS IGBT D94FQ4, R4 with ratings of 400, 500 V, and 18 amperes [56, 57]. However, there was still a problem involved in the practical use of the devices at that time, namely, their poor latch-up withstand capability [58, 59]. Nakagawa et al. [60, 61] overcame this critical obstacle by operating the MOS channel current with a 'non-latch-up' IGBT structure characterized by a surface cell concept of an n+ source and shallow p+ regions with heavy doping (Fig. 13.34); at the same time, solving the SOA problems by means of this structure.

13.3.2 IGBT Structure and Operation

A cross-sectional view of the IGBT structure is illustrated in Fig. 13.35, along with its equivalent circuit. The structure is almost the same with that of the power MOSFET, but with a p+ substrate instead of n+ one; and this structural similarity has enabled quick commercialization of the device, because the IGBT fabrication process is nearly identical to that of the power MOSFET, though the operational physics is absolutely different.

IGBTs have blocking capability both in forward and reverse direction, because the forward voltage can be sustained by the reverse biased p-n junction of the p-base and n-drift regions, and the reverse voltage can be supported by the junction of p+ substrate and n-drift region. However, real commercial devices do not have reverse blocking capability

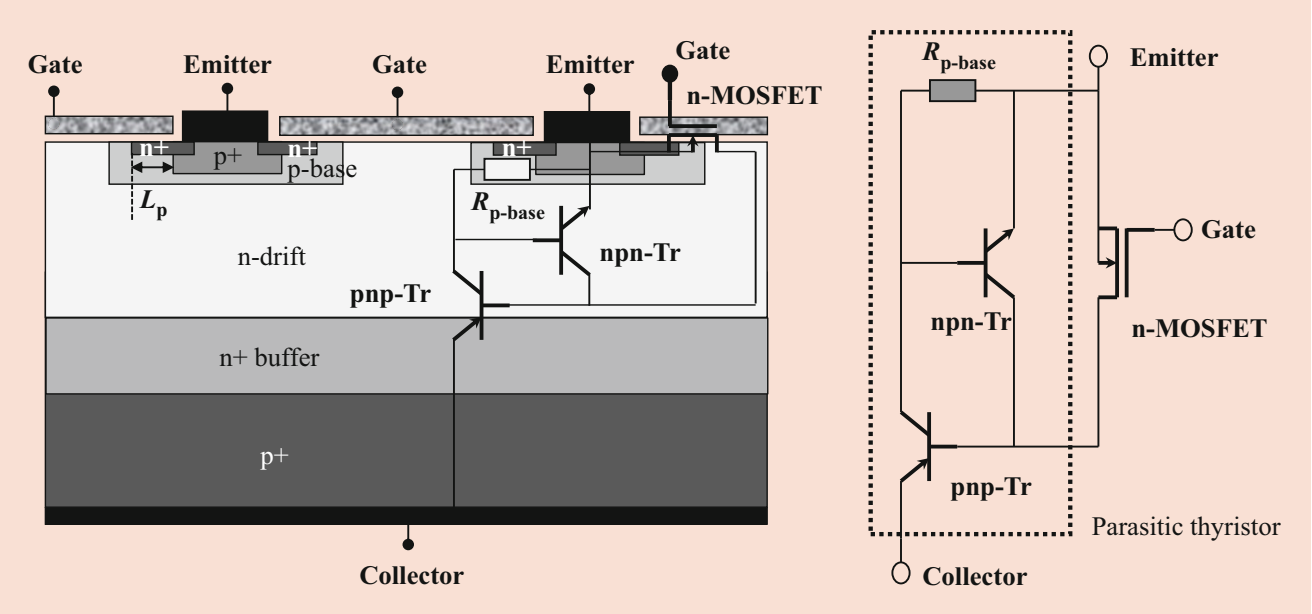

Fig. 13.35 Cross section of the punch-through (PT) type IGBT and its equivalent circuit

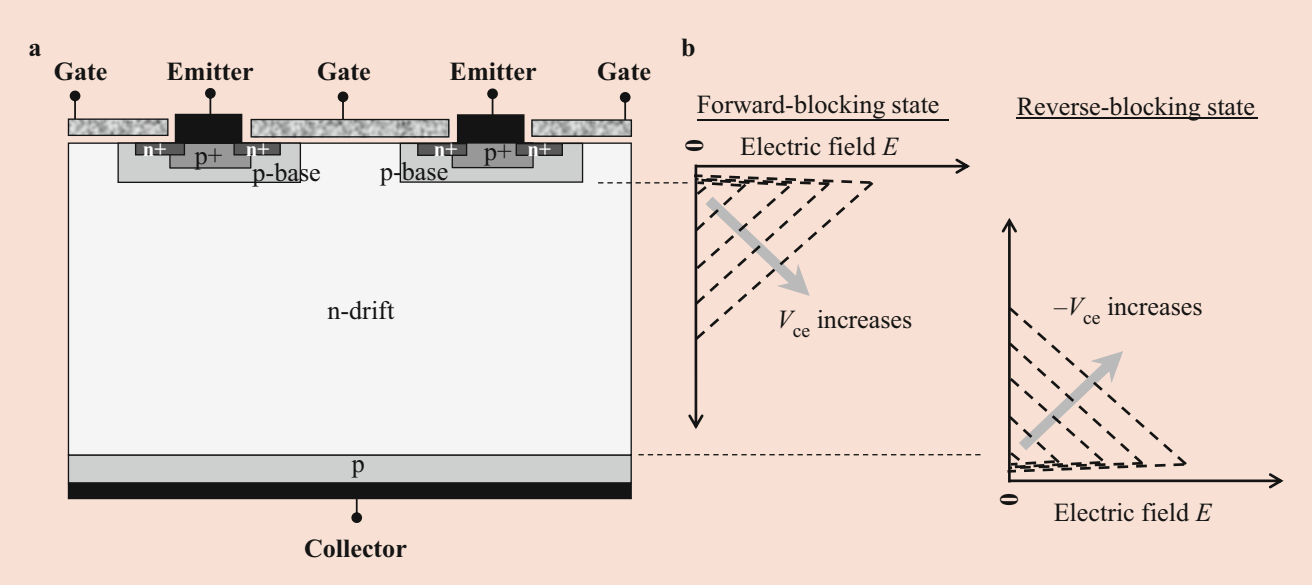

Fig. 13.36 (**a**) Cross section of the non-punch-through (NPT) type IGBT. (**b**) Electric field distribution in forward- and reverse-blocking state in NPT type IGBT

because they have a highly doped n+ buffer layer between the n-drift substrate. This is referred to as a punch-through (PT) structure shown in Fig. 13.35 [62]. In addition, some manufacturers have been developing devices with no n+ buffer layer, named as a non-punch-through (NPT) structure shown in Fig. 13.36 [63].

The current and voltage characteristics of a typical IGBT are shown in Fig. 13.37. With the application of a positive gate voltage over the threshold voltage to form the inversion layer on the surface of p-base region, the device turns on and to its forward conduction state. Electrons can then flow from the n+ emitter region, and after flowing through the inversion layer, the electrons reach the n-drift region. In this state, the backside of the p-n junction is forward biased and holes will be injected from the p+ collector to the n-drift region. Therefore, unlike in a power MOSFET, the collector current starts to increase when the collector voltage exceeds a built-in p-n junction potential of approximately 0.7 V. With the increase of collector forward voltage, the injected hole concentration increases until it exceeds the background

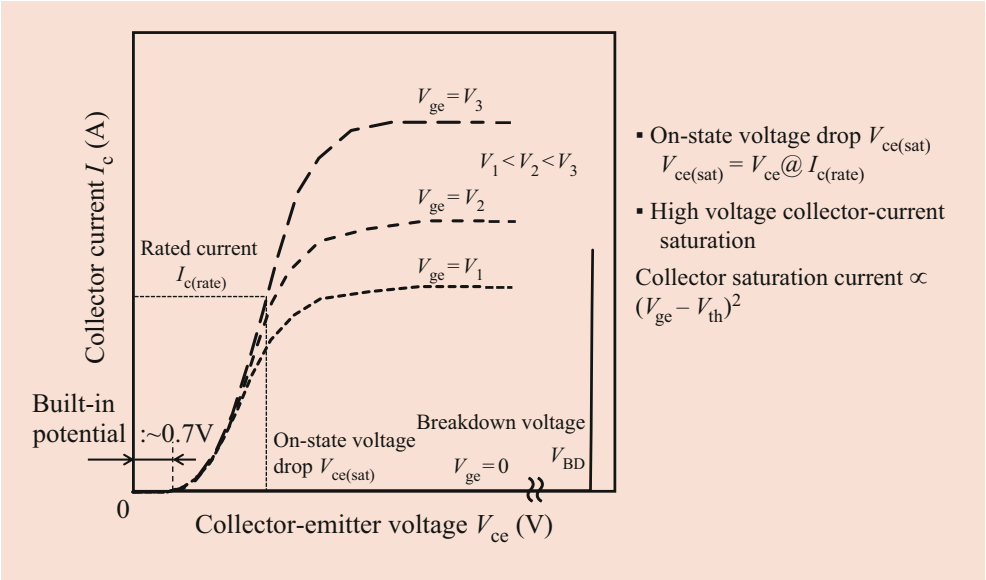

Fig. 13.37 Current and voltage characteristics of typical IGBT

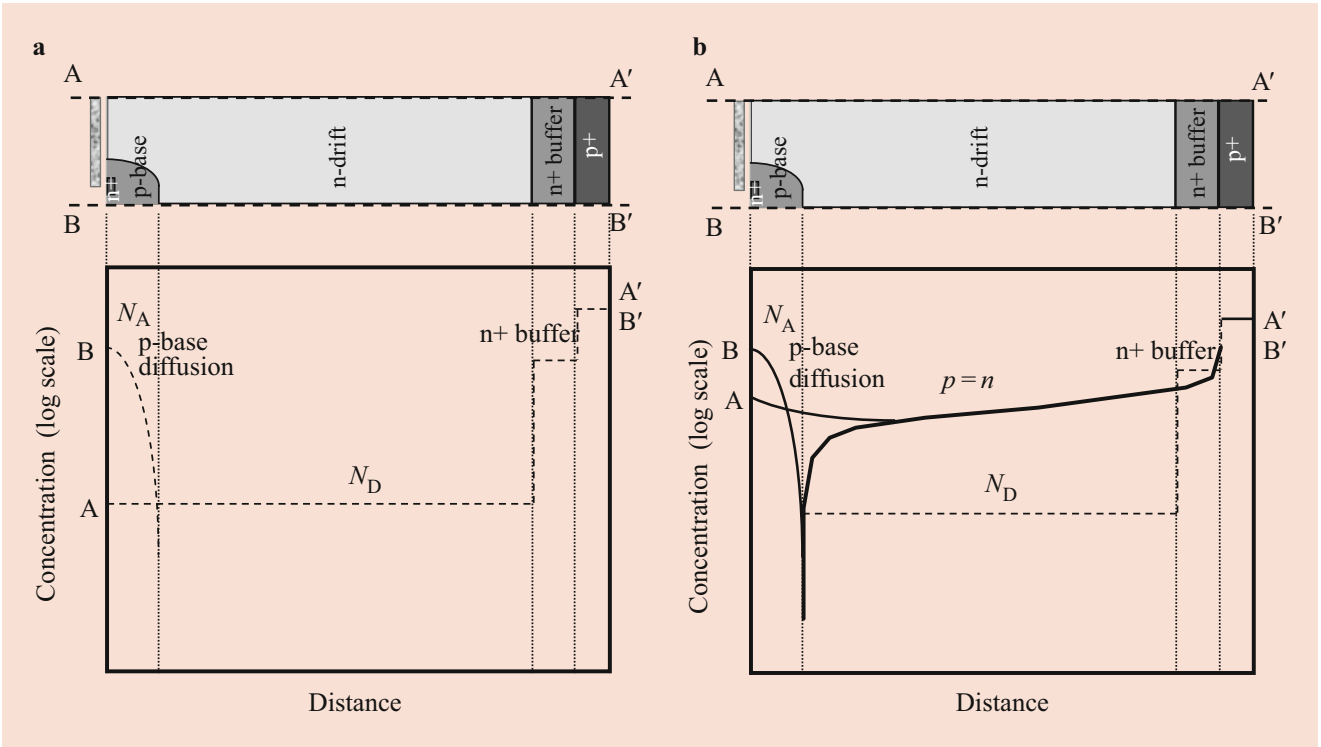

Fig. 13.38 (**a**) Doping profile and (**b**) carrier distribution in the on state within the pnp transistor portion of the PT-IGBT structure

doping level of the n-drift region. The equivalent circuit for the IGBT comprises a wide-base pnp transistor controlled by an n-ch MOSFET in the cascade configuration. In this operational regime, the device behaves like a forward biased wide-base pnp transistor, resulting in high current density operation, with the gate-controlled and high-voltage current saturation characteristics of a power MOSFET. Thus, when the gate voltage is set slightly higher than the threshold voltage, the MOSFET operates in current saturation state, and the IGBT collector current saturates as well (Fig. 13.37).

Figure 13.38 shows the electron and hole plasma distribution in the on-state of PT-IGBT structure, together with the doping profile. As described above, the hole injection from the p+ collector substrate gives rise to great increase in elec-

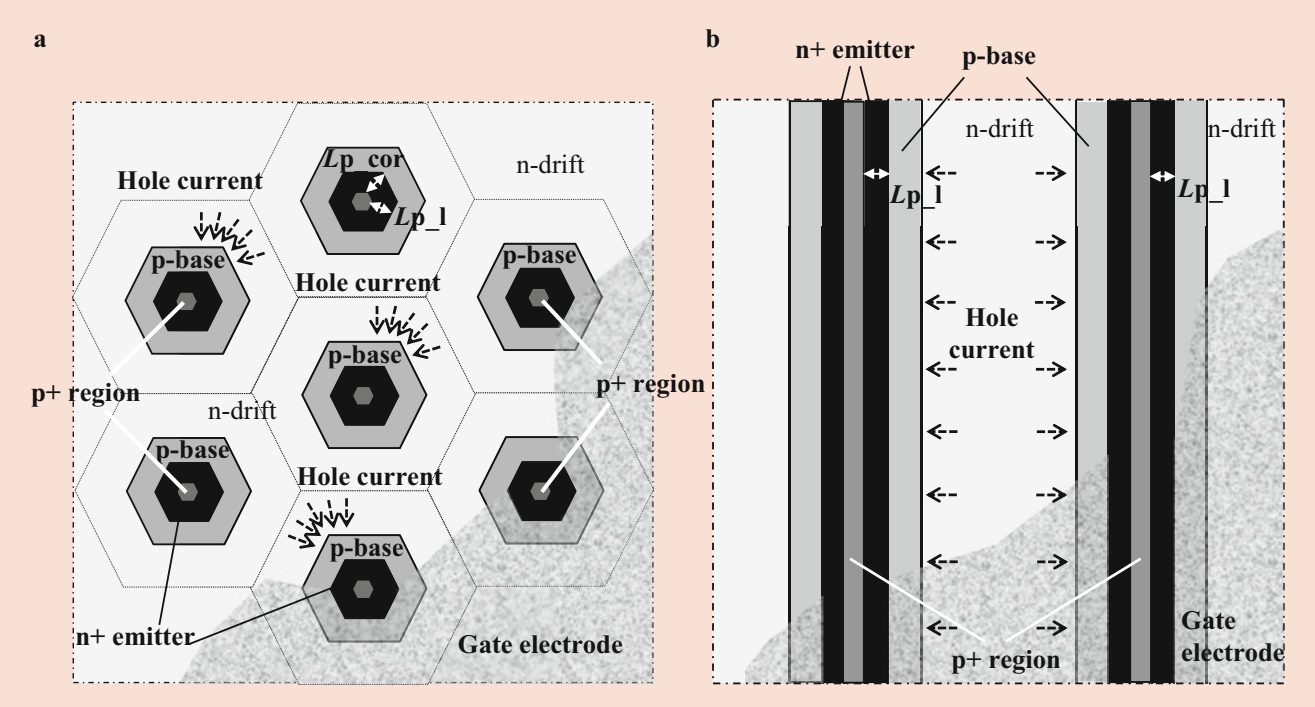

Fig. 13.39 Cell layout and hole current distribution in IGBT structure with (**a**) hexagonal form arranged in hexagonal pattern and (**b**) stripe cell layout

tron and hole concentrations in the n-drift layer, becoming several hundred times higher than the doping density.

In order to switch off the IGBT, it is required to switch the gate voltage off by short-circuiting the gate to the emitter. The operation removes the inversion layer at the surface of the p-base and thus restricts the electron flows to the n-drift layer, initiating the turn-off process. With this, the abundance of electron and hole plasma in the n-drift layer begins to decrease through recombination. The switching behavior is characterized by the rate of this recombination process during turn-off. For low-frequency applications, devices with a relatively long minority carrier lifetime of roughly 10 μs are satisfactory. However, for motor control or high power supply applications, where a turn-off time of less than 0.2–0.3 μs is desired, it is required to minimize the minority carrier lifetime by a lifetime control process like electron irradiation [64]. Unfortunately, IGBTs with a shorter turn-off time exhibit higher on-state voltage drop. Generally, there is a trade-off relation between the on-state voltage drop and the turn-off speed in IGBT structures; however, careful optimization, by controlling the lifetime in the n-drift region and the thickness and doping density of n+ buffer layer in PT-IGBT structures, has resulted in the production of effective commercial devices.

The equivalent circuit shown in Fig. 13.35 has a parasitic thyristor between the collector and emitter electrodes, a structural element characteristic of IGBT structures. Latch-up of this thyristor leads to the loss of gate control and IGBT failure. In the VDMOSFET cell design, square or hexagonal cells arranged in a square or hexagonal pattern have been utilized in order to achieve a larger channel width, resulting in lower on-resistance, as described in Sect. 13.2.2. However, in the IGBT cell design, these VDMOSFET configurations can lead to degradation of the IGBT latch-up capability. The length of the p-base region beneath the n+ emitter (L_p in Fig. 13.35) increases at the corner because the p+ region is formed by a hexagonal window with smaller area, as illustrated in Fig. 13.39 ($L_{p_cor} > L_{p_l}$). In addition, the hole current injected from the backside p+ collector is concentrated at the corner (see Fig. 13.39), so the latch-up current in the hexagonal cells is degraded more than in stripe cells; a characteristic experimentally confirmed in [65]. Therefore, in most IGBT devices, latch-up is suppressed by utilizing a variety of technologies to reduce the resistance $R_{p\text{-}base}$ in the stripe cell structure, as shown in Fig. 13.39. This is aimed at deactivating the npn transistor, so that the IGBT operates as a wide-base pnp transistor controlled by the n-ch MOSFET.

Switching Characteristics

IGBTs are utilized in many power electronics systems, such as motor drive for consumer and industrial applications, to control the power delivered to the inductive load. The typical circuit configuration and switching waveforms of collector current, and collector and gate voltages are illustrated in

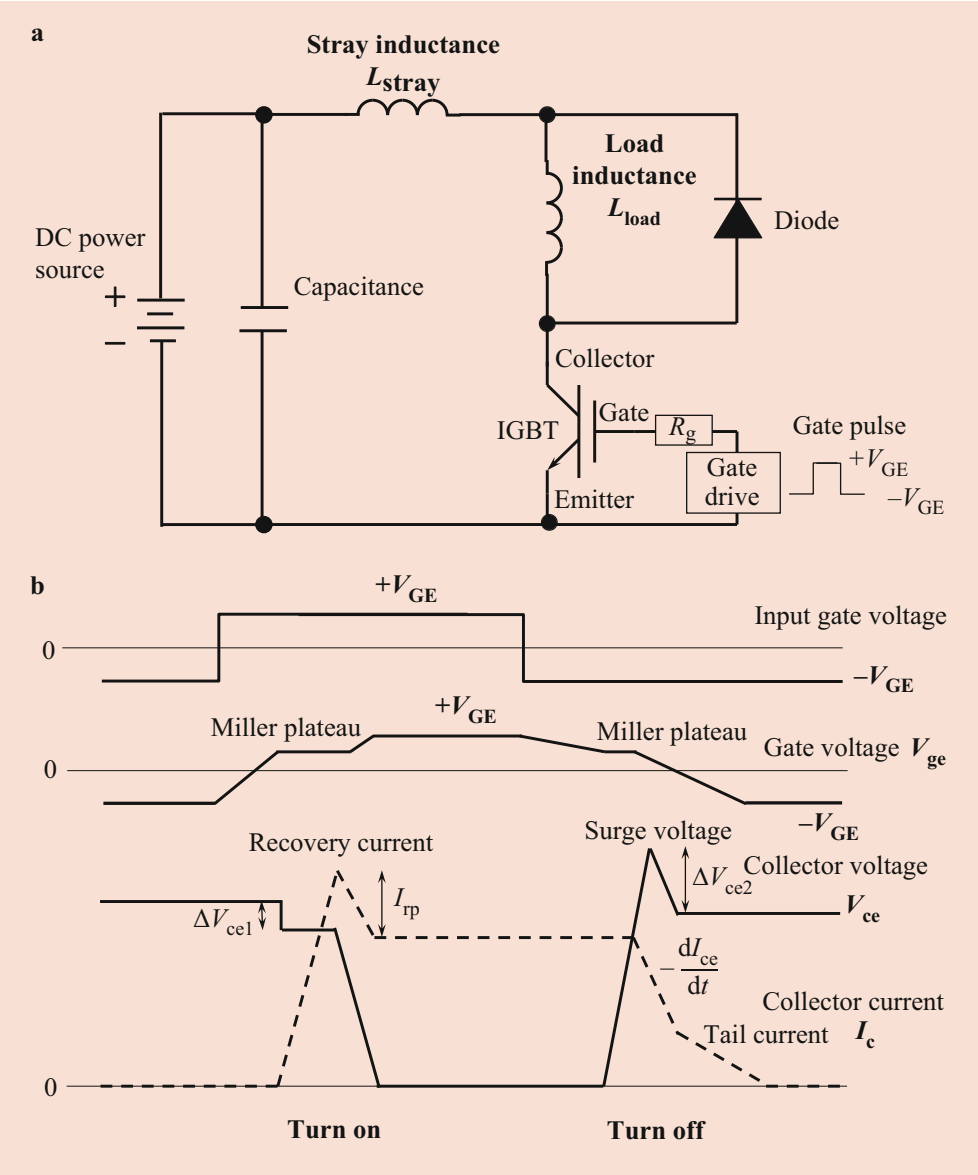

Fig. 13.40 (**a**) Inductive load circuit configuration. (**b**) Schematic of IGBT Inductive load switching waveforms

Fig. 13.40. After turn-on, the IGBT current increases rapidly and gets to an apex point defined by the total amount of the load current and peak reverse recovery current of the diode. After this, the IGBT operates in its forward conduction state, with almost constant collector current flow. When turned off, its collector current decreases by sweeping the stored electron-hole plasma in the n-drift region out and electron-hole recombination. The switching behavior of IGBTs is more complicated than that of power MOSFETs, because of the holes injected from the p+ collector; thus, in this section, the relevant processes will be discussed through investigation of the turn-on and turn-off physics of the IGBT structure.

The turn-on current and voltage waveforms for an inductive load are shown in Fig. 13.41, and details of the stored-carrier dynamics, and electric field and voltage distribution for the turn-on in the PT IGBT with trench gate are shown in Fig. 13.42. These results were derived using two-dimensional TCAD mixed-mode device simulations. The circuit comprises the IGBT and an inductive load, connected in series with the power source by a free-wheeling diode. With IGBT turn-on, the free-wheeling current still flows through the diode. When the gate bias is switched on ("A" in Fig. 13.41), the gate voltage begins to slowly increase due to the capacitance components of the IGBT and the connected gate resistance R_g. The collector current increases while the load is clamped to the source voltage by the conducting free-wheeling diode. When the V_{gs} reaches the threshold voltage V_{th}, the IGBT operates in the active region and the collector current starts to flow. This is a similar mechanism to that of the power MOSFET described in Sect. 13.2.2, but with the addition of backside hole injection from the p+ collector. The collector current flows, due to IGBT operation,

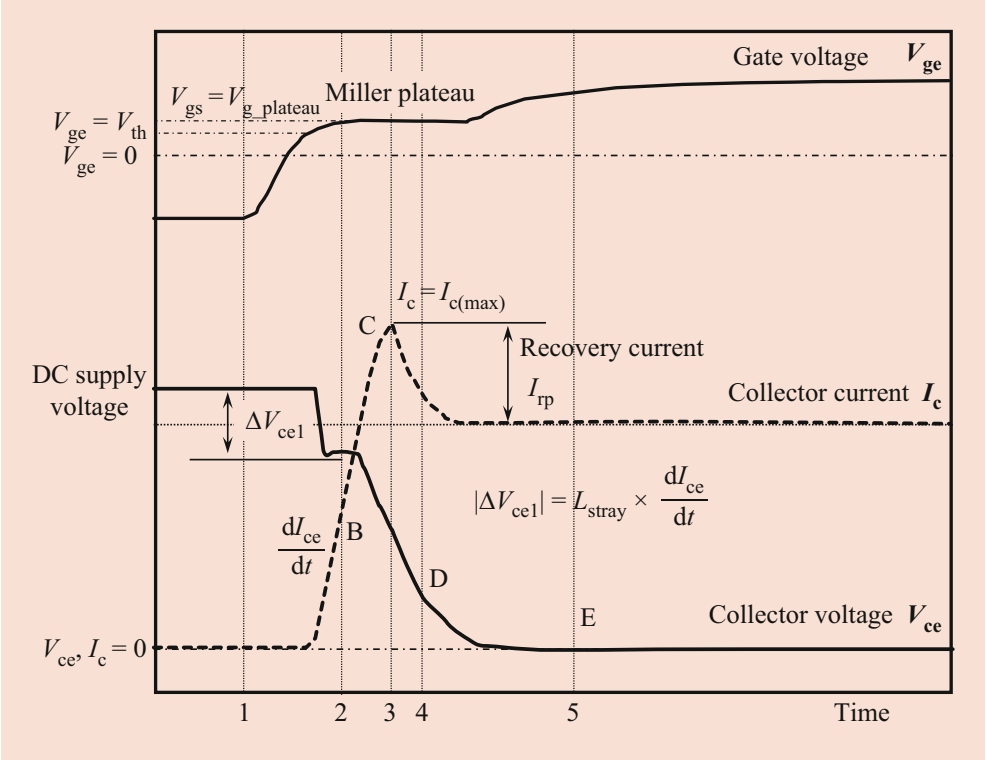

Fig. 13.41 IGBT turn-on waveforms with an inductive load

after the gate voltage increases above the gate threshold voltage. In this regime, the IGBT supports a high collector voltage by expanding the depletion layer in the n- layer ("B" in Fig. 13.41; Time 2 in Fig. 13.42); therefore, there is no conductivity modulation region in the n-drift layer. In Fig. 13.41, the collector voltage drop ΔV_{ce} can be seen in this period. The voltage drop is caused by a constant increase in the IGBT collector current (dI/dt), multiplied with stray inductance L_{stray} in the circuit ($L_{stray} \times dI/dt$). The IGBT current increases and gets to an apex $I_{c(max)}$ defined by the total amount of the load current and the peak reverse recovery current in the free-wheeling diode ("C" in Fig. 13.41; Time 3 in Fig. 13.42), and then the collector current is reduced to a load current. At the same time, the collector voltage V_{ce} starts to fall ("D" in Fig. 13.41; Time 4 in Fig. 13.42), and the voltage continues to fall until it reaches the on-state value ("E" in Fig. 13.41; Time 5 in Fig. 13.32). Finally, the gate voltage starts to increase and continues to do so as long as the gate current I_g flows.

Figure 13.43 shows the inductive load turn-off current and voltage waveforms, and Fig. 13.44 details the stored-carrier dynamics, and electric field and voltage distribution for in the PT IGBT with trench gate. The circuit is comprised of the IGBT and an inductive load, connected in series with the power source, with a clamping diode across the load to transfer the current when the IGBT is turned off. When the gate bias is switched off ("A" in Fig. 13.43, Time 1 in Fig. 13.44), the gate voltage begins to slowly decrease due to the capacitance components of the IGBT and the connected gate resistance R_g. The collector current keeps flowing at its on-state level because of the inductive load ("B" in Fig. 13.43). This collector current is sustained due to pnp bipolar transistor operation, even after the gate voltage drops below the threshold voltage. In this regime, the base current of the pnp transistor is supplied via electron flow due to depletion layer expansion (Time 2 in Fig. 13.44). When the collector voltage reaches the level of the power supply voltage (Time 3 in Fig. 13.44), the current starts to transfer from the IGBT to the diode. Thus, the current initially decreases abruptly ("C" in Fig. 13.43) and then decreases gradually with an exponential shape, through the electron-hole recombination in n-drift layer near the p+ collector side ("D" in Fig. 13.43; Times 4 and 5 in Fig. 13.44). This simultaneous presence of high voltage and current leads to large power dissipation in the IGBT, so it is required to lower the level of the tail current and to shorten the time duration of the turn-off operation.

It should be noted that the sharp increase in the collector or surge voltage ("E" in Fig. 13.43) is caused by a sudden decrease in the IGBT collector current (dI/dt) associated with stray inductance L_{stray} in the circuit ($L_{stray} \times dI/dt$). Therefore, optimal design of the forward voltage drops, turn-off characteristics, and surge voltage reduction in the IGBT are also strongly required in order to achieve superior circuit

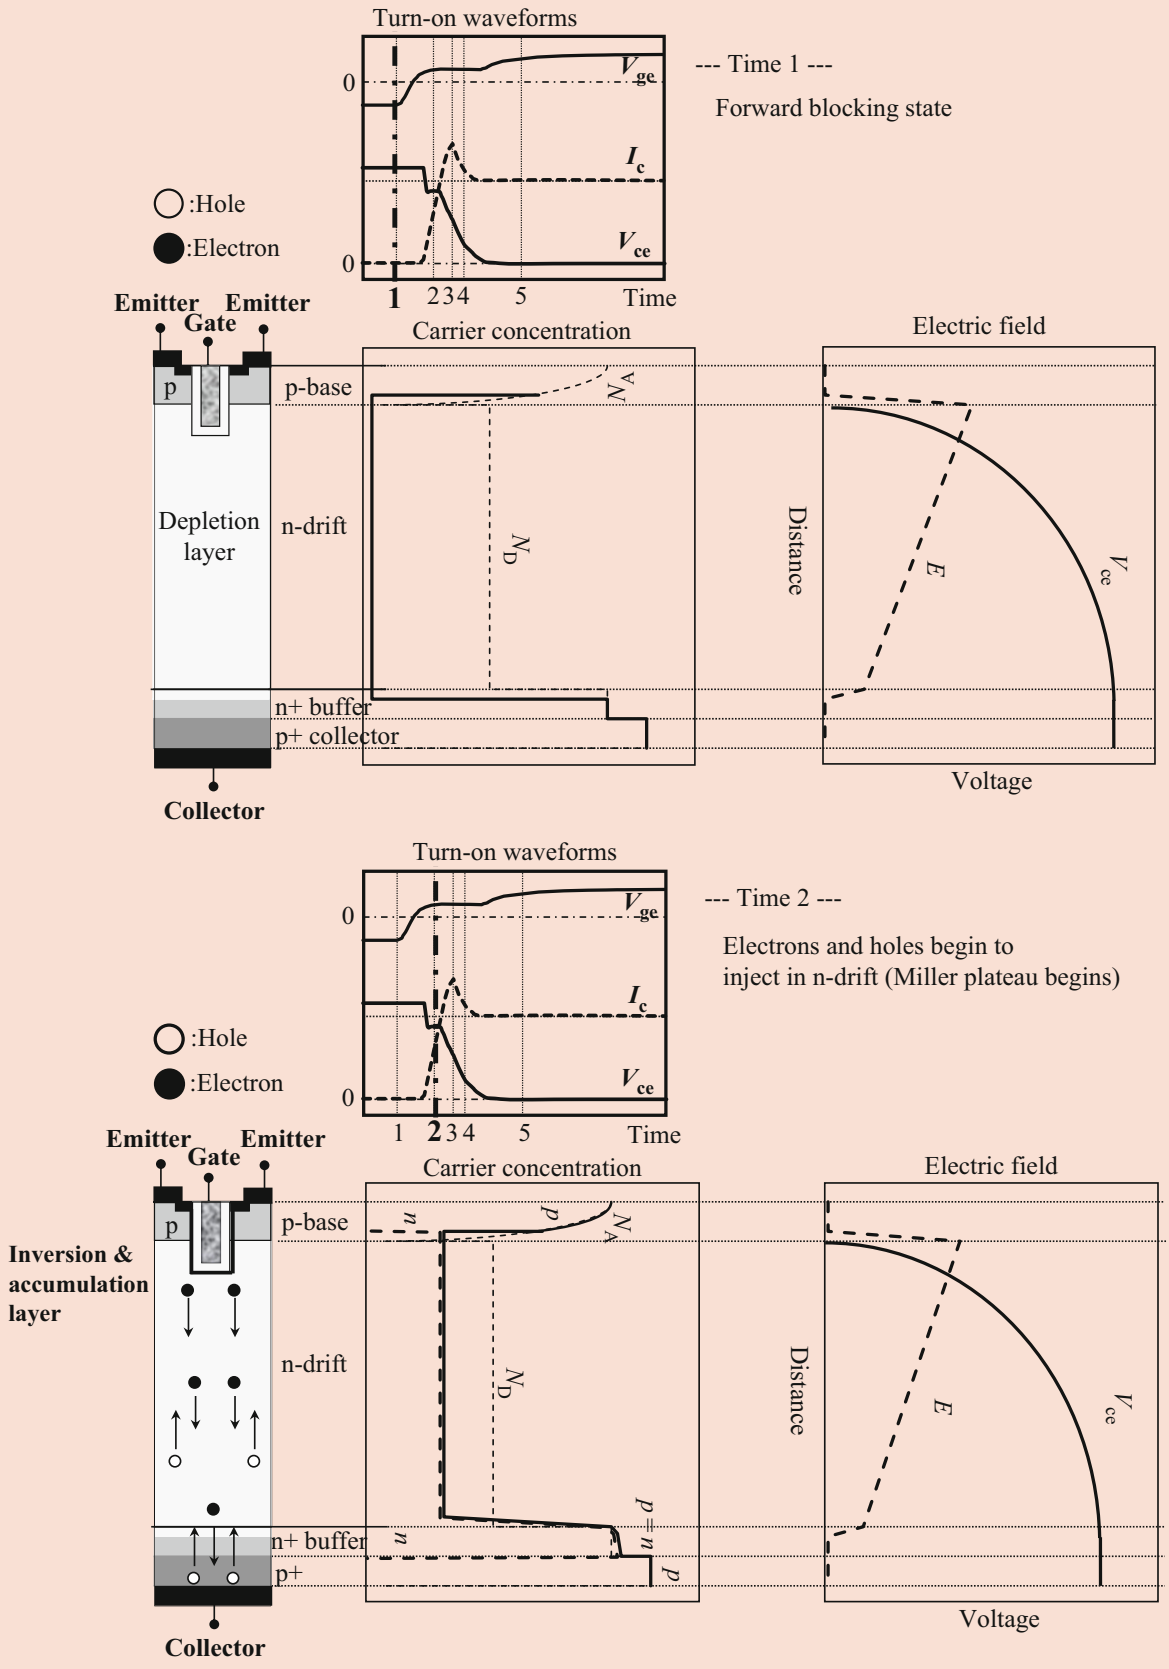

Fig. 13.42 (continued)

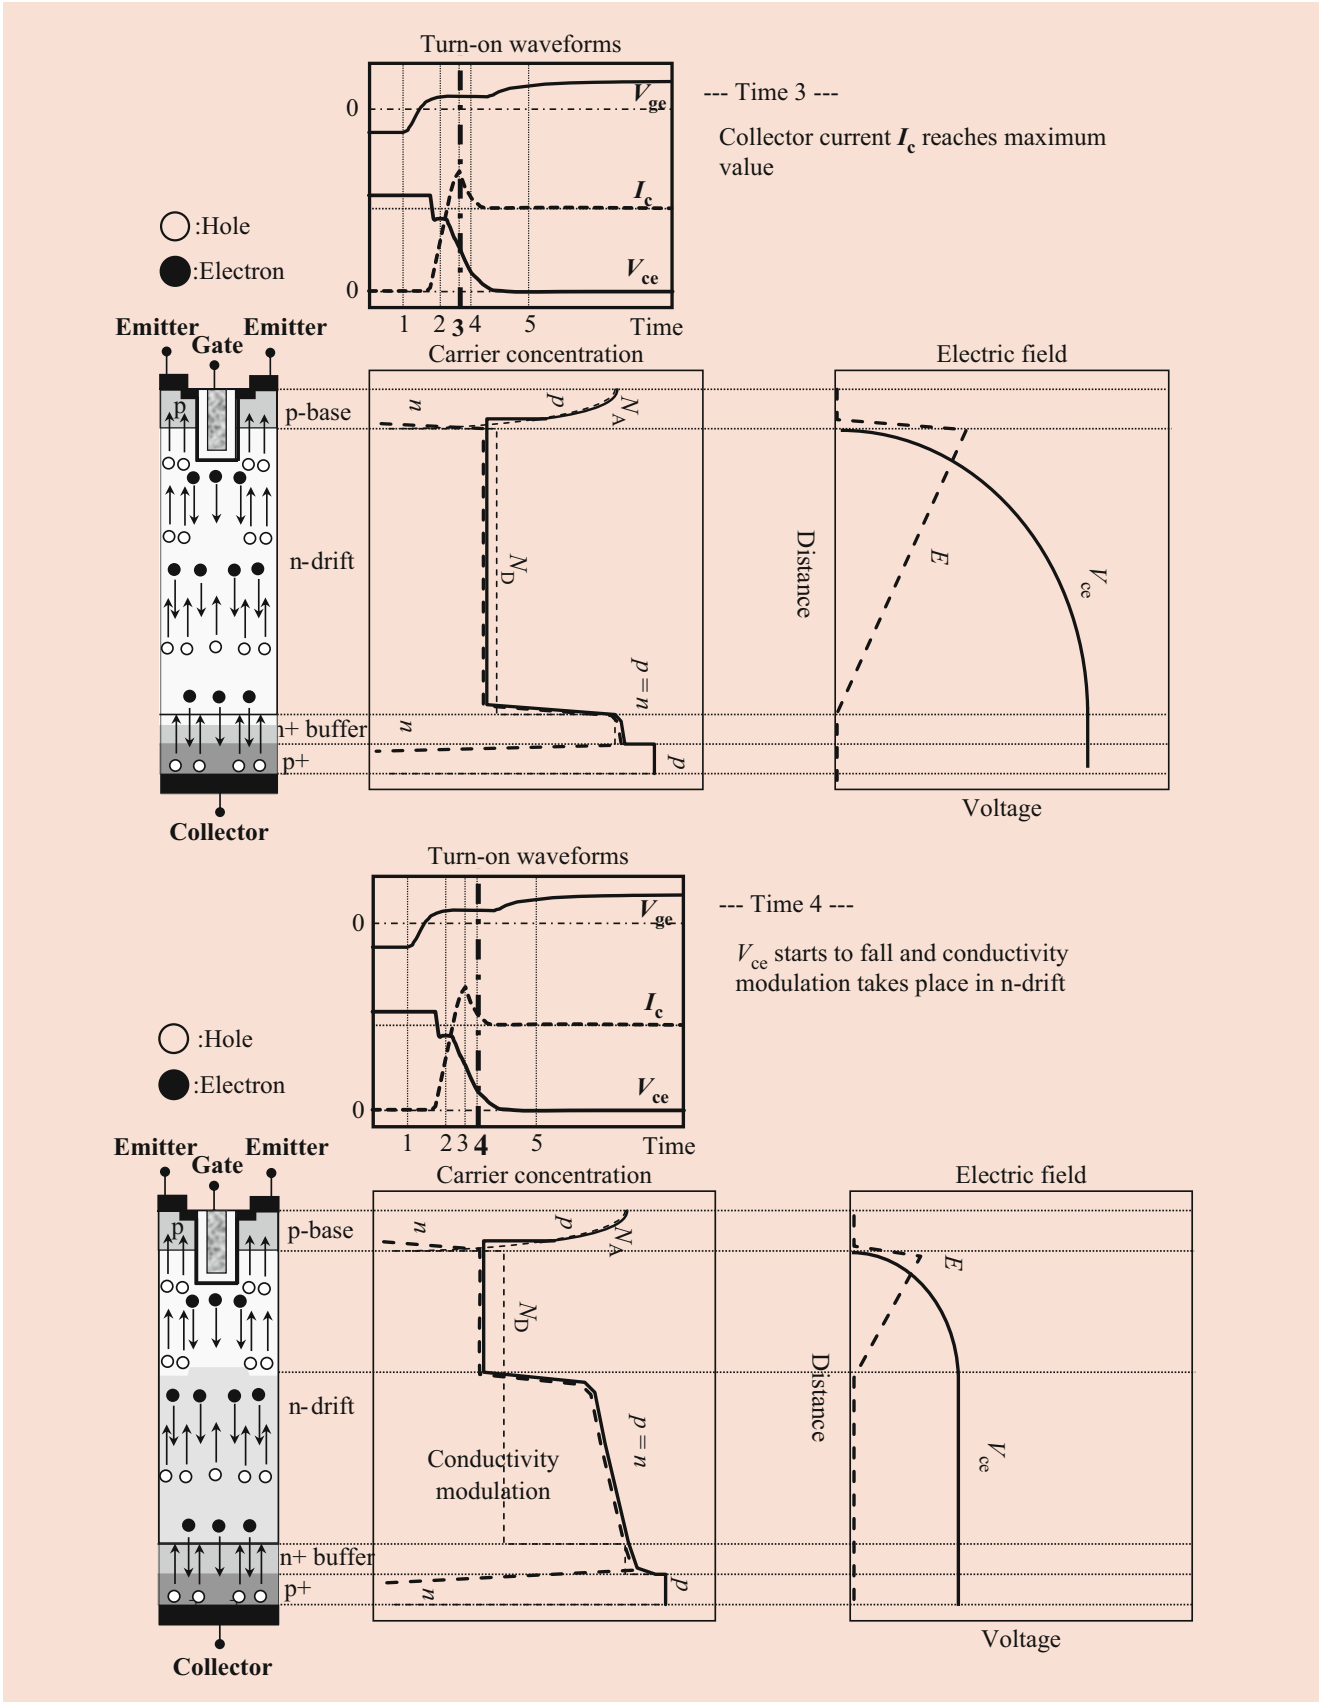

Fig. 13.42 (continued)

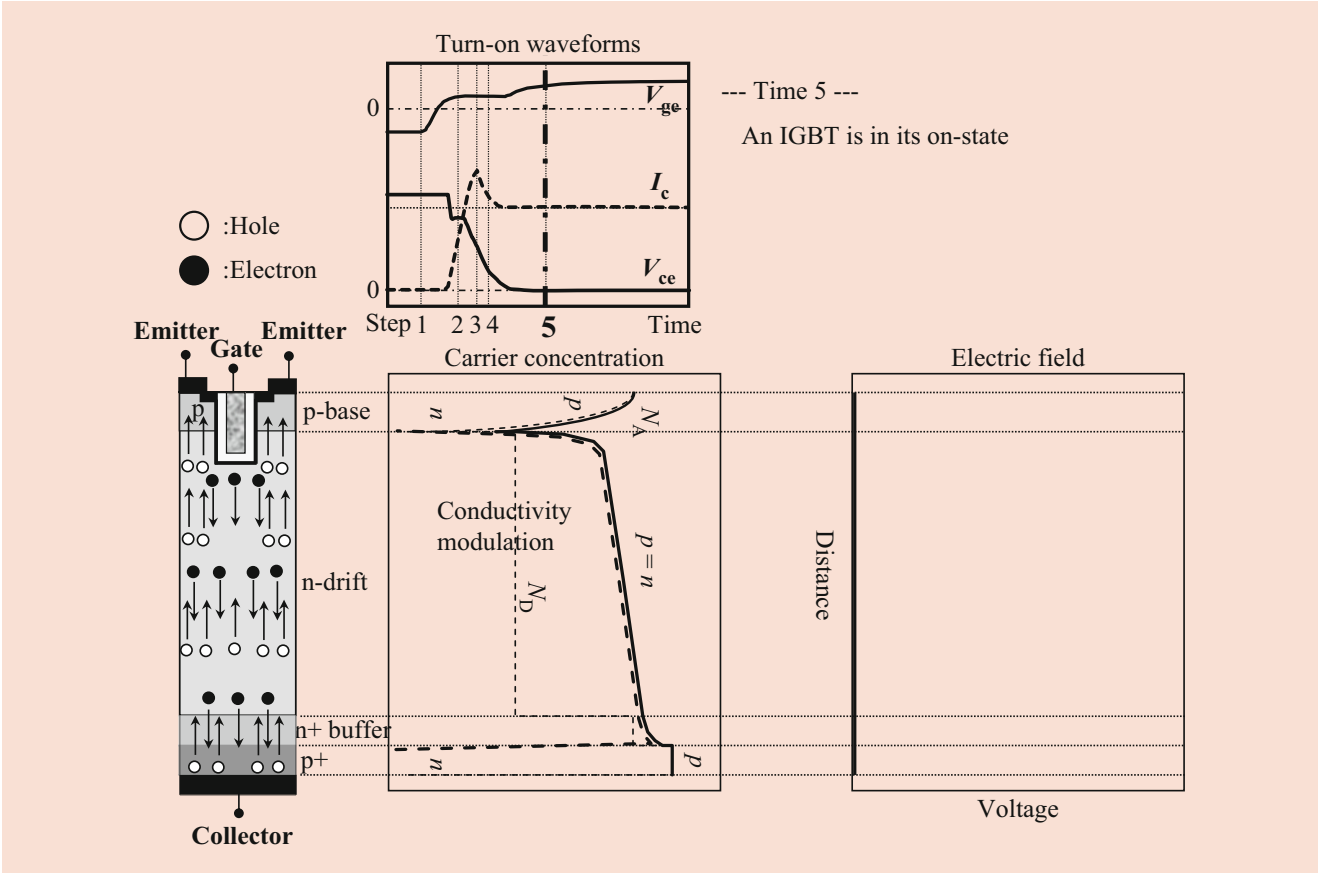

Fig. 13.42 Trench IGBT carrier dynamics, electric field, and voltage distribution during an inductive turn-on operation

efficiency in the voltage source converters. Finally, the collector current falls to zero and the off-state is reached (Time 6 in Fig. 13.44).

13.3.3 IGBT Safe Operating Area

Reverse-Biased SOA

Among the IGBT characteristics, high withstanding capability is extremely important, along with low on-state voltage drop and fast switching speed. With the recent widespread adoption of hybrid and electric vehicles, IGBT destruction during travel represents a serious, even life-threatening danger. As described above, the parasitic thyristor latches up when a large current flows; and avalanche breakdown, which occurs when a large voltage is applied between the collector and emitter, also causes IGBT breakdown. In general-purpose motor drive control applications, for example, there are two operation modes in which the IGBT is most likely to breakdown: IGBT turn-off and load short circuit, in which high voltage and current are applied over the same period.

In an IGBT, the safe operating area (SOA) refers to a voltage/current area that can be safely turned off without breaking. This IGBT turn-off SOA is referred to as a reverse biased SOA (RBSOA). Most of the current IGBTs guarantee that they can be turned off up to twice the rated current within the rated voltage range. The SOA is represented by a rectangle whose horizontal axis is the collector voltage and vertical axis is the collector current (Fig. 13.45). To evaluate an RBSOA, an inductive load circuit, with the assumption of motor load, is generally utilized (Fig. 13.40a). However, the real RBSOA of an actual IGBT is designed to be larger than this rectangle. The maximum turn-off current is determined by the minimum current that will trigger latch-up of the parasitic thyristor, and the maximum applied voltage is determined by the avalanche breakdown voltage at each turn-off current. The minimum current to trigger latch-up of the parasitic thyristor is almost independent of the collector voltage, because it is determined by the parasitic npn transistor structure, as described above. On the other hand, the avalanche breakdown voltage strongly depends on the level of the turn-off collector current. When the turn-off current is zero, the avalanche breakdown voltage is equal to the breakdown voltage between emitter and collector electrodes. However, when the turn-off current starts to increase, mobile holes flow through the depletion layer with the application of high collector voltage (Time 3 in Fig. 13.44); thus, not

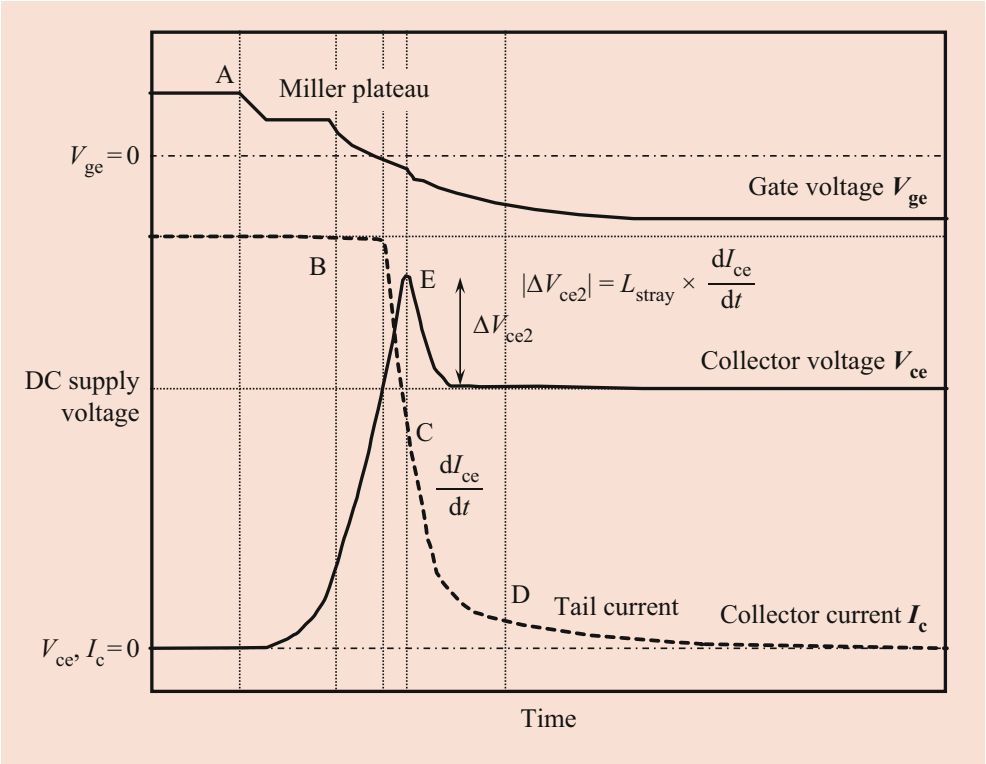

Fig. 13.43 IGBT turn-off waveforms for an inductive load

only the ionized donor density N_D, but also the mobile hole density p, is present in the depletion layer, resulting in increased positive charge there. Therefore, the depletion layer width W_{dep} decreases with the turn-off current, and is expressed as

$$W_{dep} = \sqrt{\frac{2\varepsilon_{Si} V_{ce}}{q\,(N_D + p)}}, \tag{13.41}$$

where N_D is the donor concentration, p is the mobile hole density in the depletion layer, and V_{ce} is the applied collector voltage. We can see that the N_D component in the denominator has changed from that of Eq. 13.7 to $(N_D + p)$; thus, the depletion layer expansion is suppressed by the increased hole concentration at collector current turn-off, resulting in reduction in the avalanche breakdown voltage.

Short-Circuit SOA

If a load connected to an IGBT is shorted for accidental reasons, a high DC voltage is immediately applied directly to the IGBT, and high collector current instantaneously flows because the gate has already been activated. Since an IGBT has high-voltage current saturation characteristics, collector currents are suppressed below a certain specified level. In this situation, the IGBT is subjected to simultaneous high-voltage and high-current duty, and it is necessary to remove the duty as rapidly as possible. The time from the occurrence of the load short circuit to the safe interruption of the current, without destruction of the IGBT, is termed the short circuit SOA (SCSOA), and current IGBTs guarantee roughly 10 μs (at 125 or 150 °C). Figure 13.46 shows a measurement circuit for the SCSOA, as well as typical collector voltage and current waveforms in SCSOA measurement. A number of published studies have analyzed the device failure mechanism, and a detailed analysis has been made in [66]. Here, the IGBT failure mechanism in the short-circuit state is illustrated in Fig. 13.47 and summarized as follows:

(i) The parasitic thyristor latch-up ("A" in Fig. 13.47)
Breakdown due to latch-up of the parasitic thyristor. In the latest IGBTs, the latch-up withstanding capability is sufficiently high, and the device is unlikely to be destroyed by this event.

(ii) Avalanche breakdown ("B" in Fig. 13.47)
Breakdown as a result of an increase in the electric field strength on the p+ collector layer side due to low hole-injection efficiency.

(iii) Dissipated energy destruction ("C" in Fig. 13.47)
Temperature rise in the device due to energy dissipation from high voltage and current flowing at the same time. Finally, destroyed by thermal runaway. A frequently observed cause of failure.

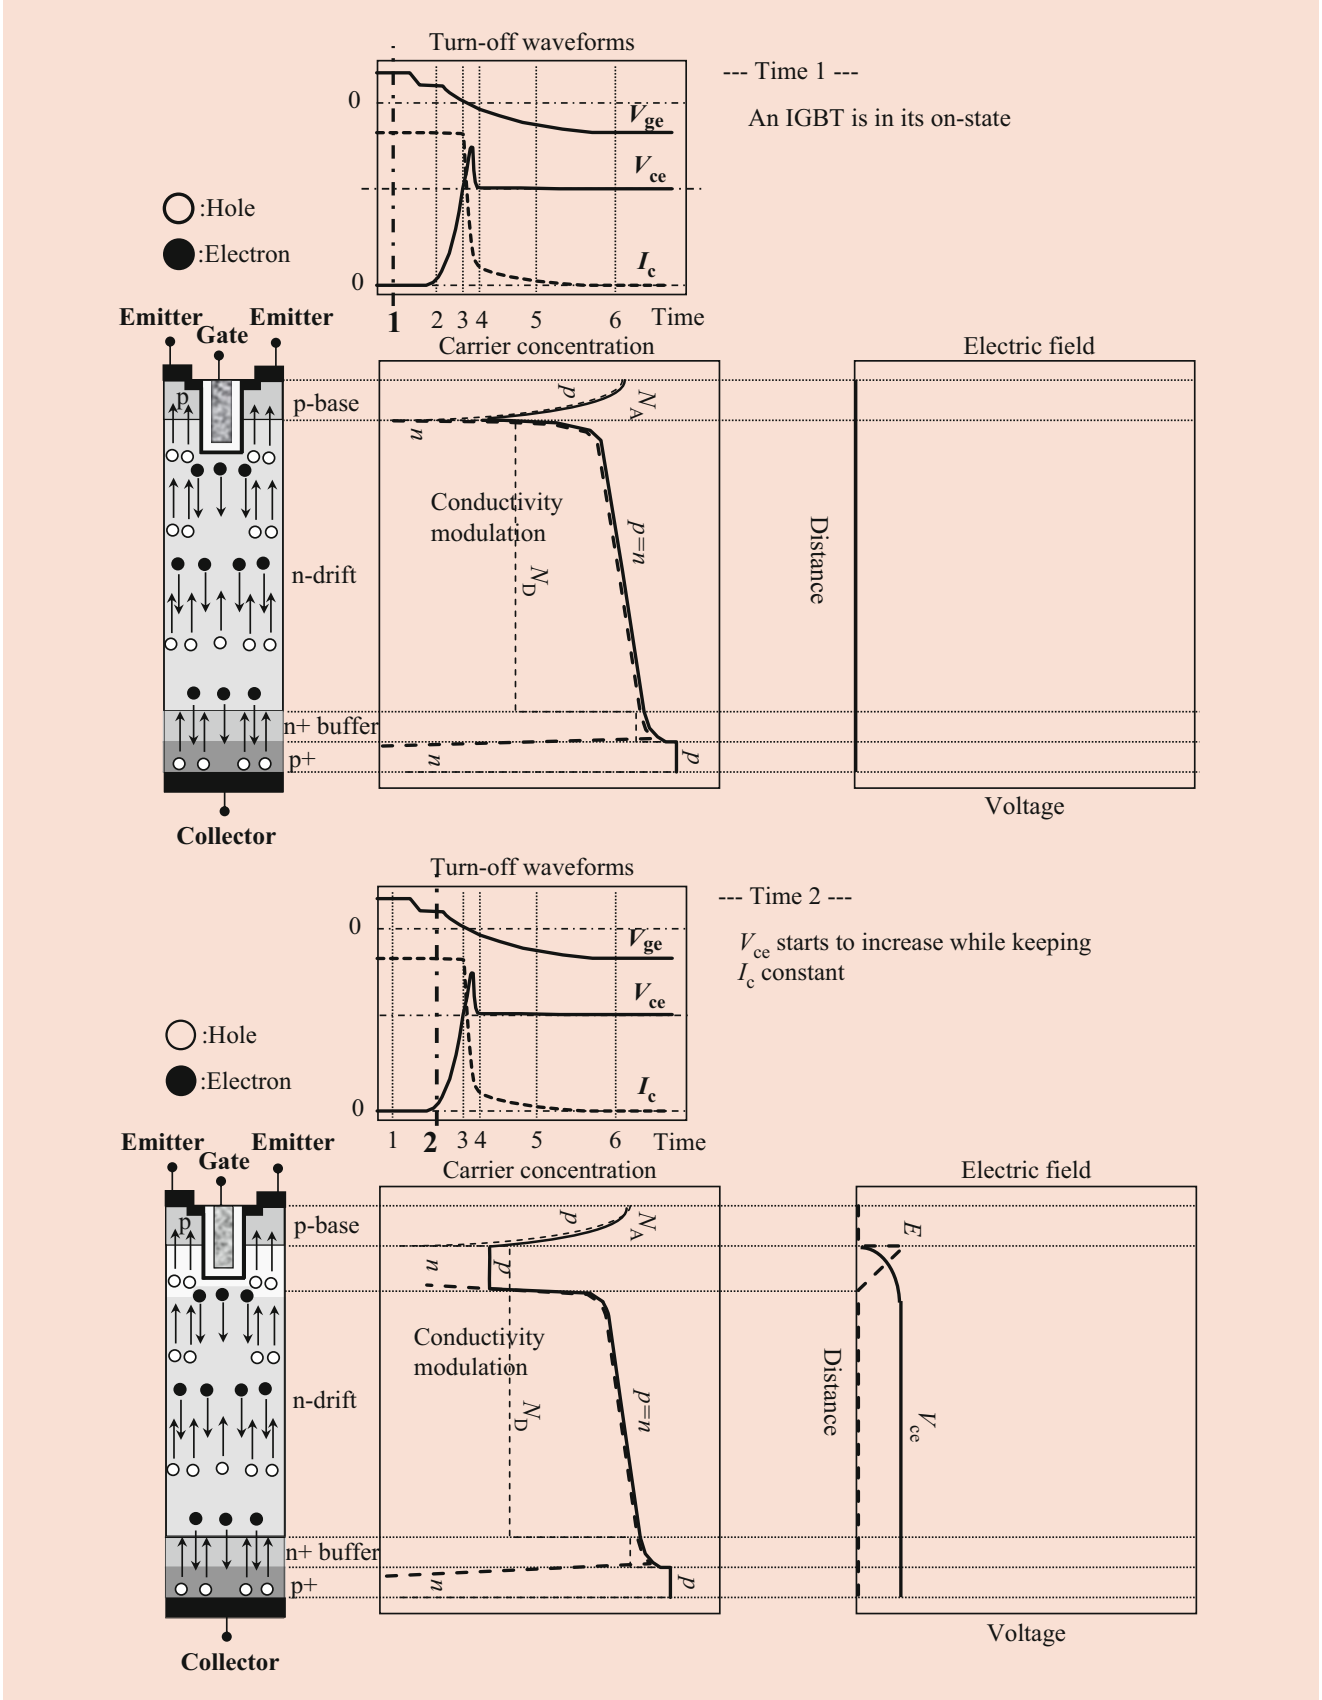

Fig. 13.44 (continued)

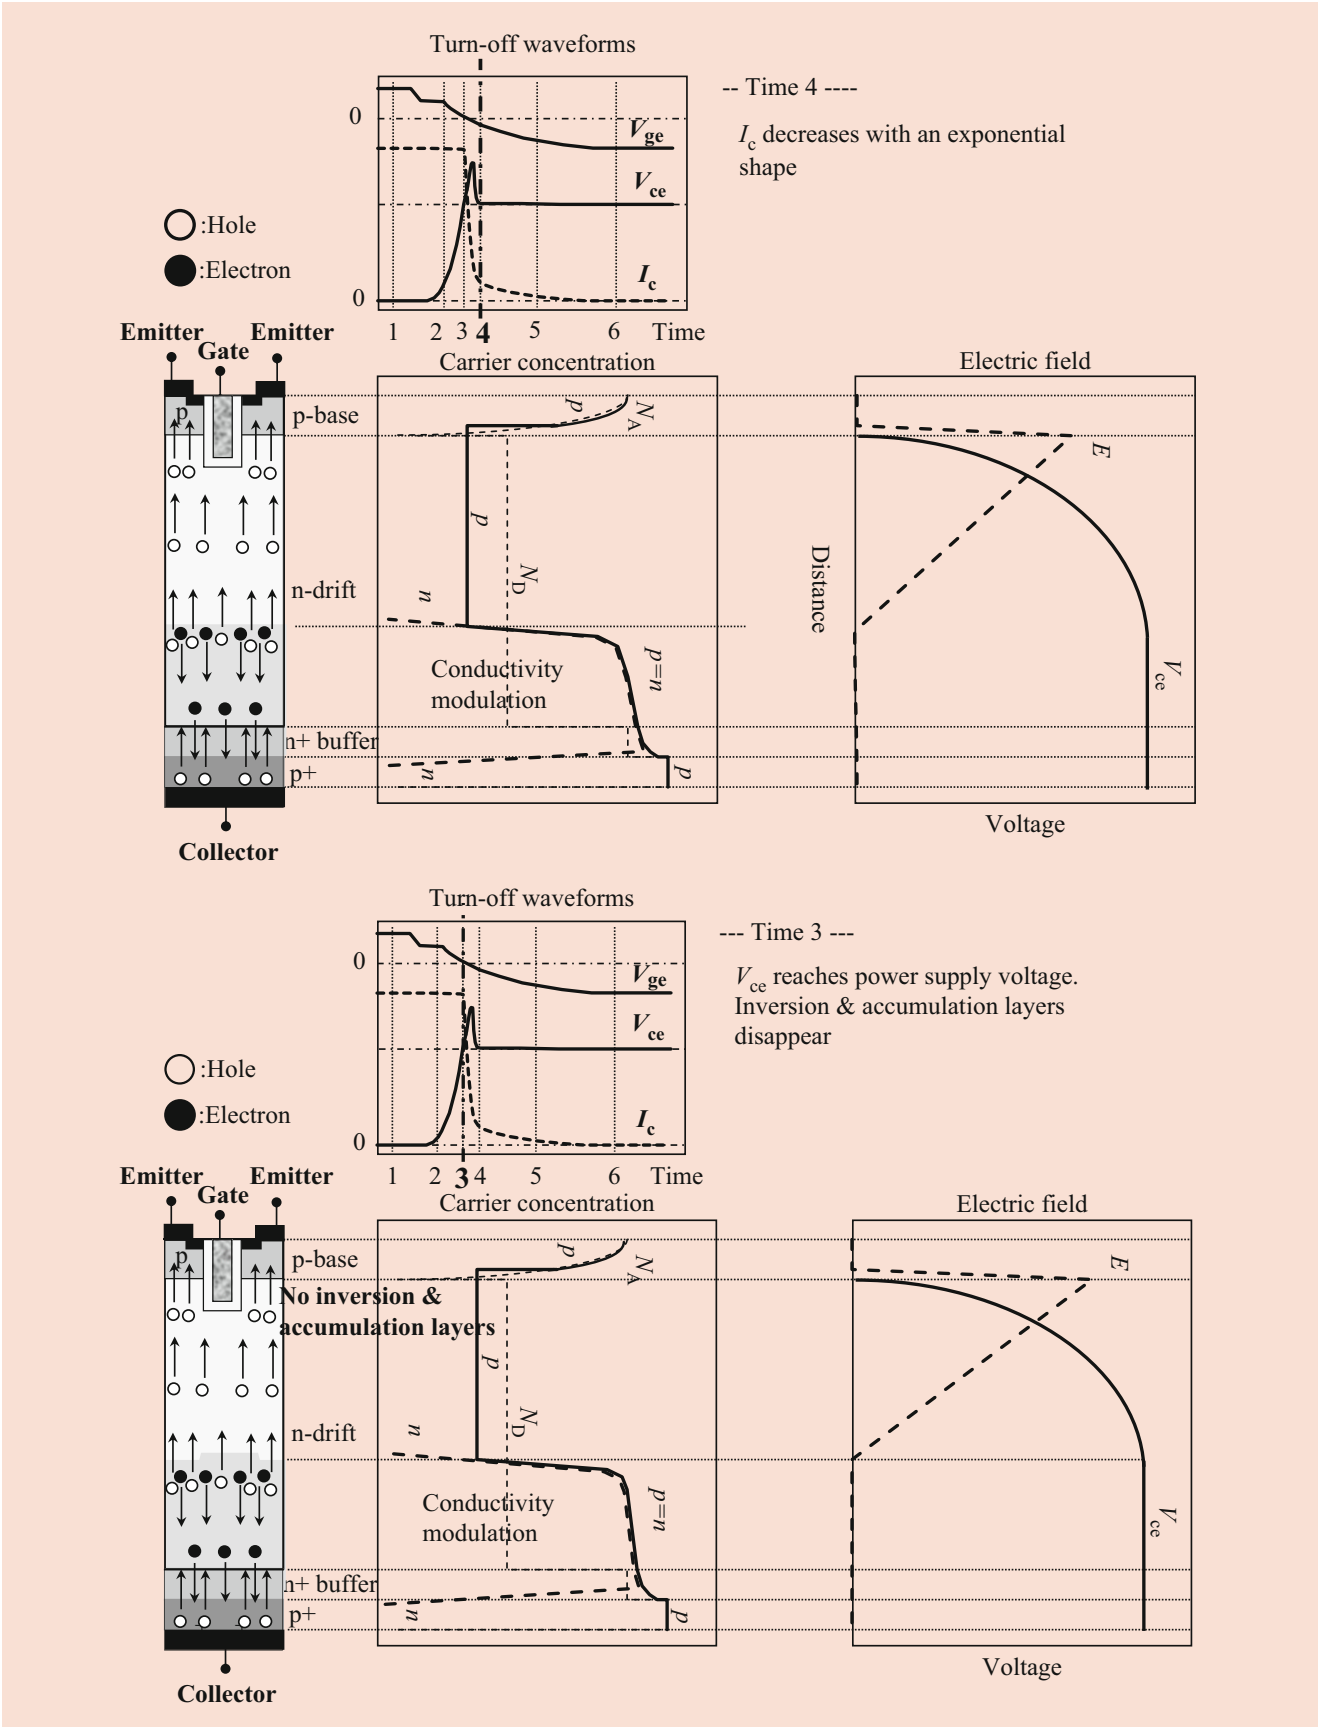

Fig. 13.44 (continued)

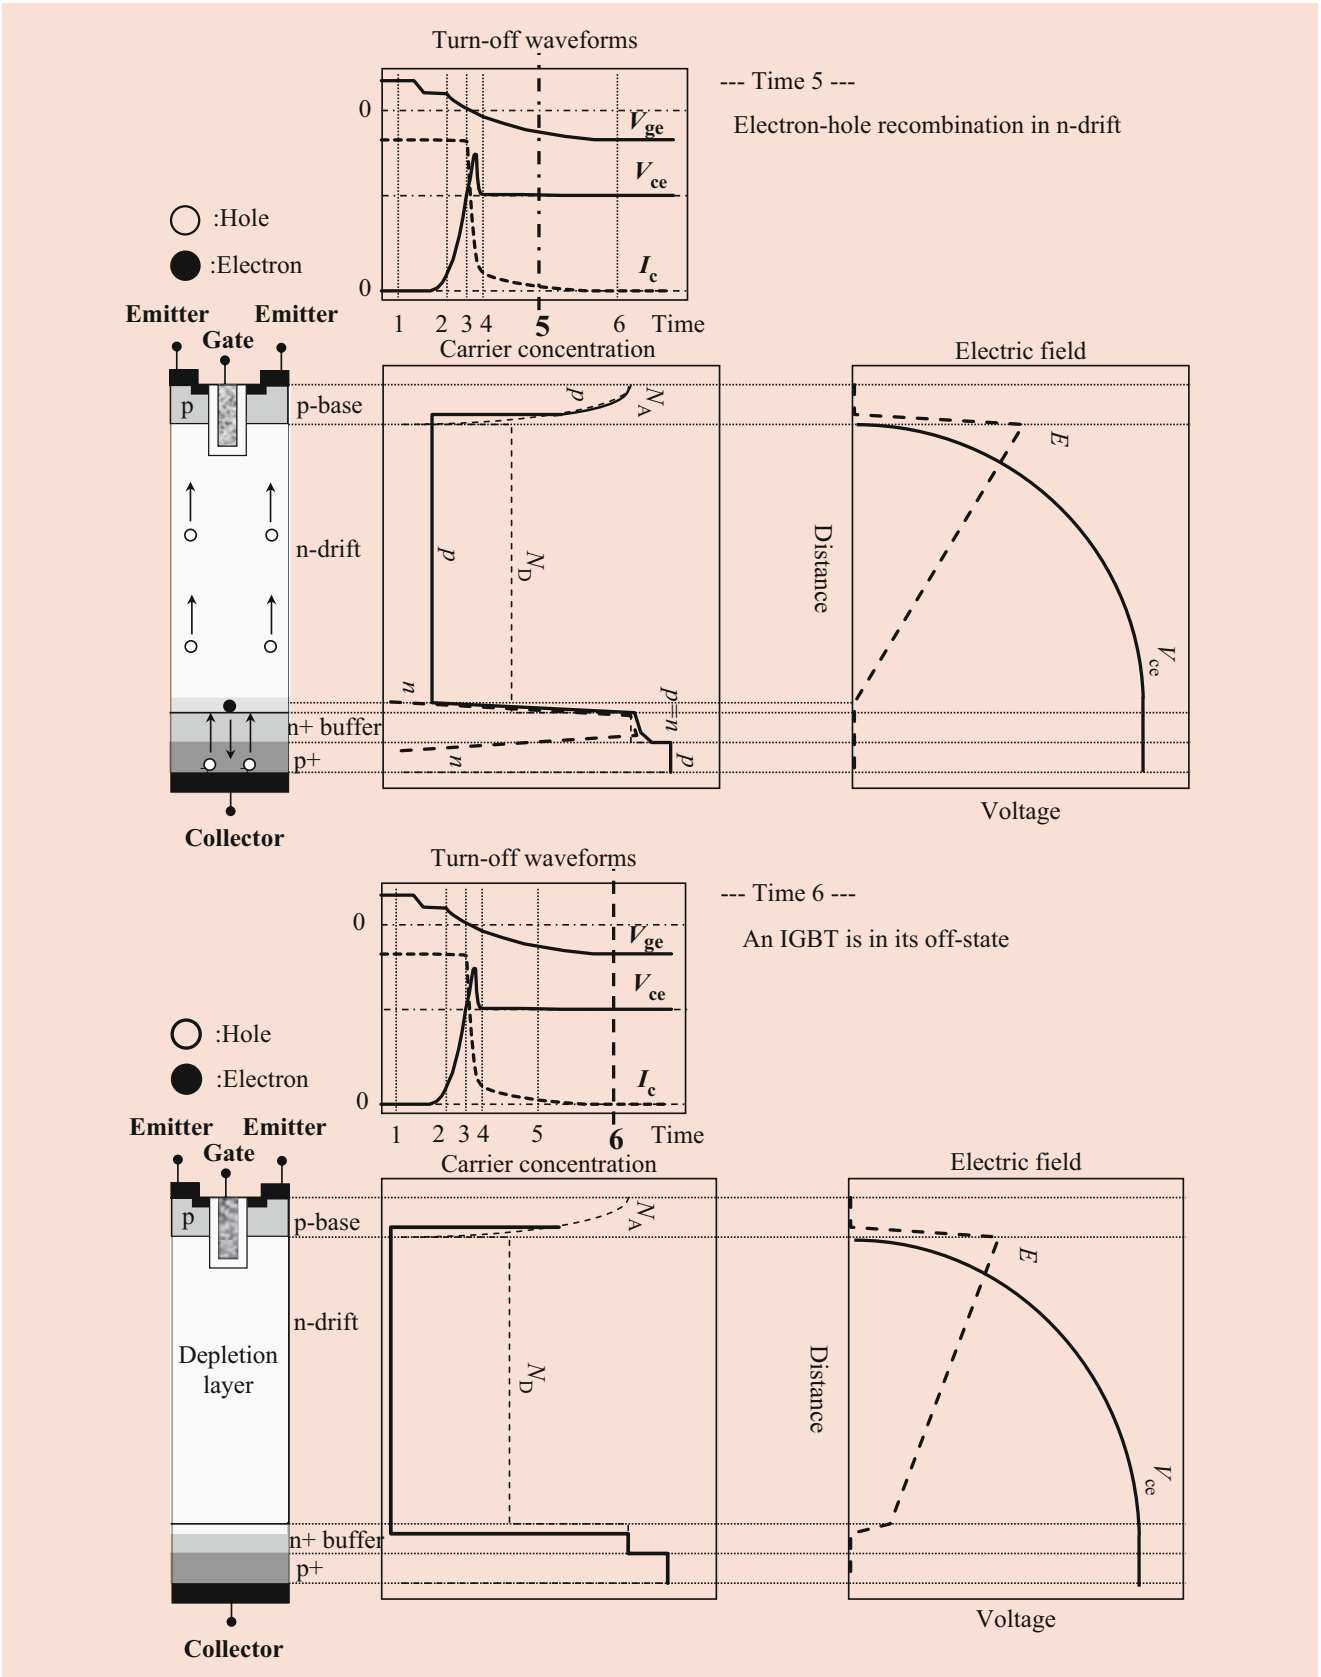

Fig. 13.44 Trench IGBT carrier dynamics, electric field, and voltage distribution during an inductive turn-off operation

(iv) Turn-off breakdown ("D" in Fig. 13.47)
Breakdown by avalanche generation due to collector surge voltage generated by the product of dI_c/dt and the stray inductance (L_{stray}) of the measurement circuit. This can be avoided by increasing the gate resistance to reduce the turn-off dI_c/dt.

(v) Thermal runaway destruction ("E" in Fig. 13.47)
Temperature rise in the device due to energy dissipation, followed by thermal diffusion to the p+ collector layer side after turn-off, resulting in leakage current increase. Finally, destroyed by thermal runaway. This is occasionally found in thin wafer IGBTs.

State-of-the-art IGBTs are rarely broken by (i) latch-up, (ii) avalanche breakdown, or (iv) turn-off breakdown, due to the advanced design technology; instead, (iii) energy dissipation and (v) thermal runaway destruction are the major causes of device failure. These two failure modes are due to the energy dissipated during high voltage and current flows. Therefore, it is required to suppress high current flow in the device, for improving failure tolerance; however, this leads to an increased on-state voltage drop meaning that the IGBT on-state voltage and SCSOA are in a trade-off relation.

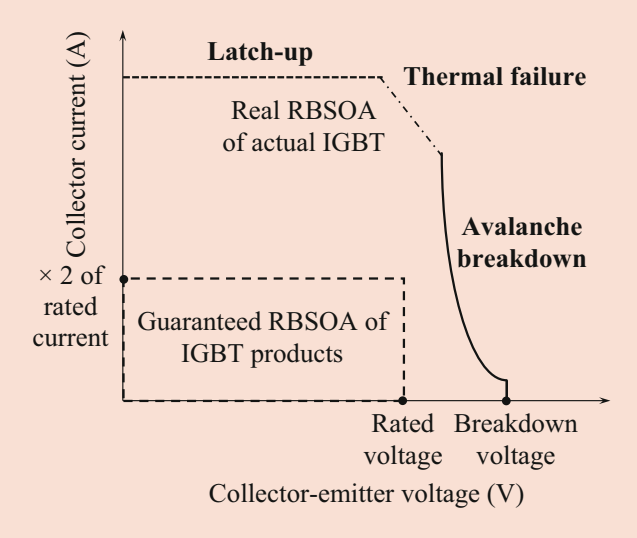

Fig. 13.45 Reverse biased SOA (RBSOA) of IGBT

13.3.4 Evolution of the IGBT Structure and Design Concept

The IGR (insulated gate rectifier) was a serviceable MOS gate bipolar transistor device. However, its turn-off speed was too slow, and its RBSOA [55, 56] and SCSOA were too small, to offer a superior substitute to the power bipolar transistor, though Nakagawa [60, 61] solved the SOA problems with the non-latch-up structure described above. To improve the switching characteristic, Goodman et al. developed a new type of IGBT, with an n^+ buffer layer between the n-drift region and p+ collector [62]. With this modification, the IGBT can achieve fast switching speed by a lifetime control process, with almost no sacrifice of the on-state characteristics. Further innovation is required for the IGBT if a breakthrough is to be achieved in the trade-off relation between low on-state voltage drop, fast switching speed, and high withstand capability. Therefore, as in the case of integrated circuits, a lot of the most sophisticated technological innovations are being utilized to the IGBT structure, with the aim of mitigating, if not overcoming, this trade-off relation. Among them, the technologies for IGBT cell design and fabrication process have been leading to advancement in the device characteristics.

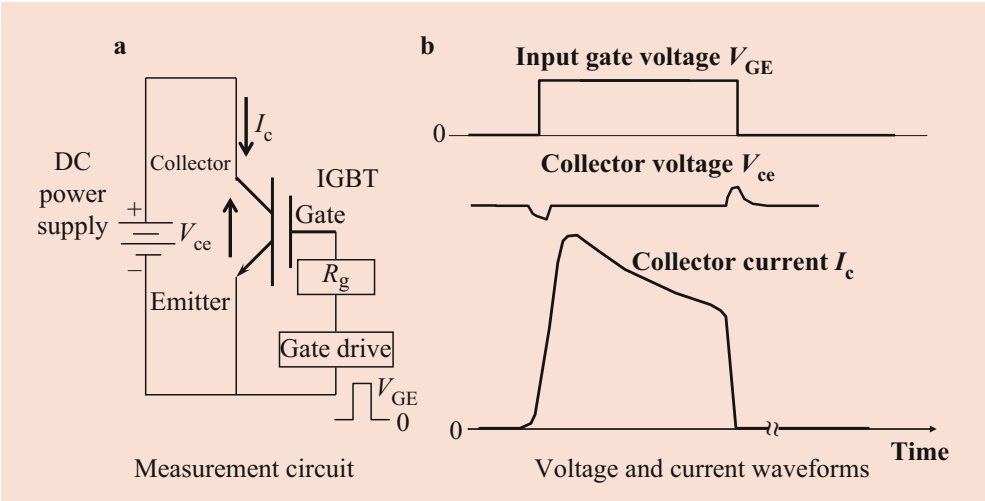

Fig. 13.46 Voltage and current waveforms in IGBT SCSOA measurement. (a) Measurement circuit. (b) Voltage and current waveforms

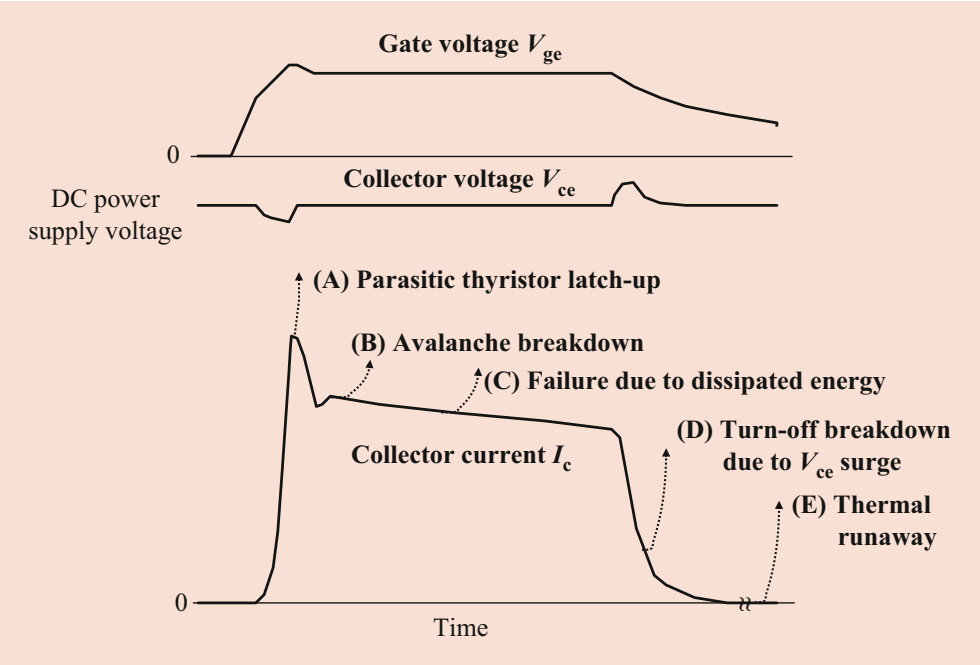

Fig. 13.47 Failure mechanisms in IGBT SCSOA measurement

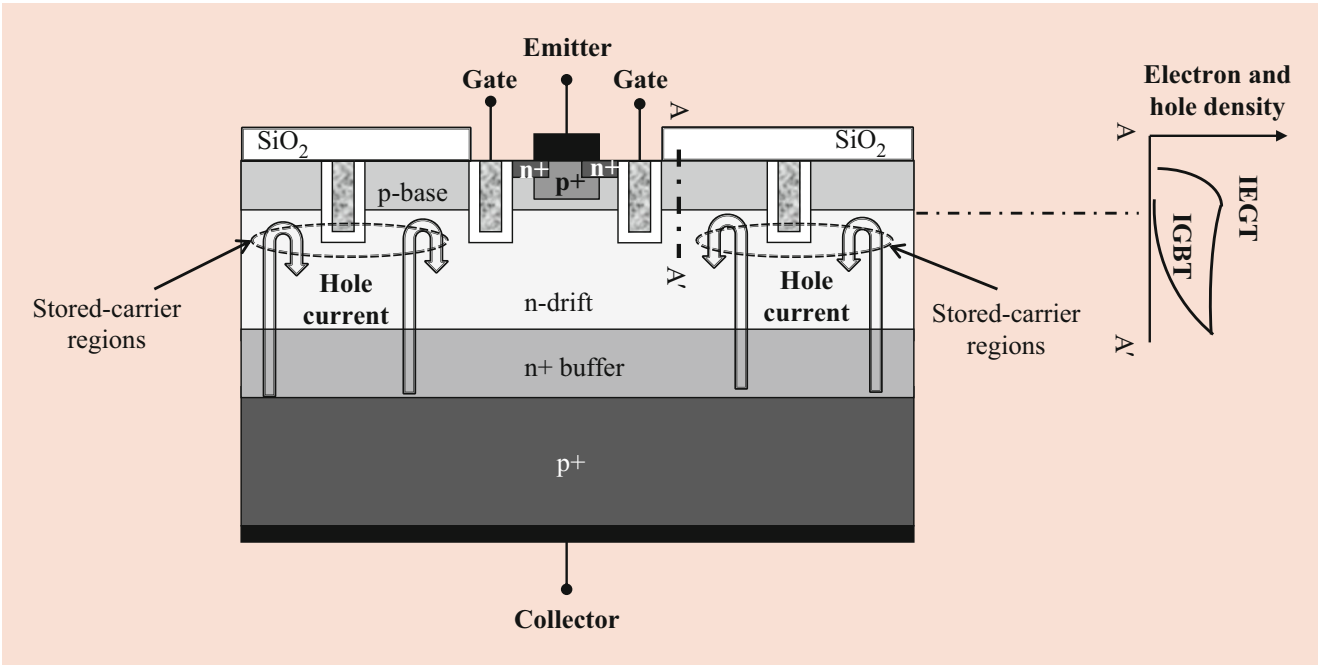

Fig. 13.48 Cross section of IEGT structure and comparison of schematic carrier distribution between IEGT and IGBT

The IGBT has the power MOSFET structure with p^+ collector substrate, so that the design and fabrication process technologies are similar with those of the power MOSFET. Hence, trench-gate technologies have been utilized to improve the on-state voltage drop, and the trench IGBT was ultimately developed by utilizing cutting-edge U-LSI (ultra-large-scale integrated circuit) design and process technologies. After this, several important breakthroughs in design and understanding followed for IGBT improvement. Initially, there had been many works to incorporate trench gate technologies into the IGBT, with a common approach being the creation of a trench structure with a very fine cell pitch [67]. However, in this case, the device has a huge channel width, unable to control short-circuit conditions without the addition

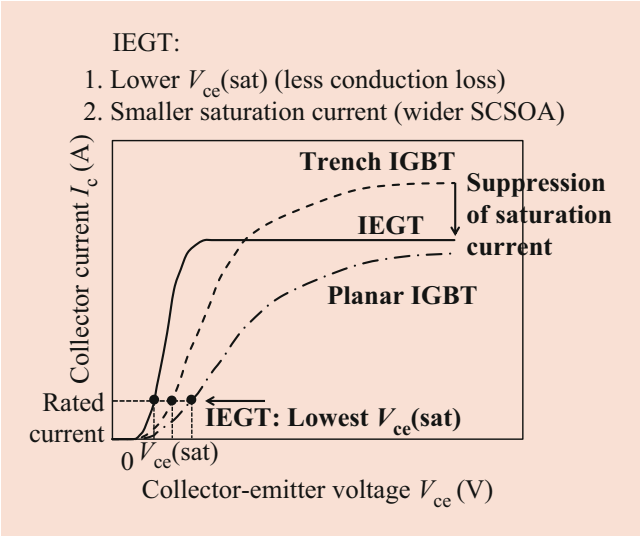

Fig. 13.49 Comparison of I–V characteristics between IEGT, trench IGBT, and planar IGBT

of an internal or external circuit for current limitation, such as was utilized in some IGBTs with planar gate [68]. Moreover, the electron-hole plasma distribution was not suitable for enabling lower on-state voltage drops.

In one important approach to addressing these issues, Kitagawa et al. proposed utilization of the injection enhancement (IE) effect [69] and developed the IEGT (injection enhanced gate transistor) device shown in Fig. 13.48. This configuration achieves an extremely lower forward voltage drop, through an improvement in the gate structure that increases the resistance to hole current flow into the emitter electrode, which results in enhancement of electron-hole plasma around the device surface. The structure became widely used in IGBT development and is still utilized in current IGBT devices.

Figure 13.49 shows another effect of the application of the IEGT structure. By eliminating some of the gate and emitter electrodes from the surface, the total channel width in the IEGT structure is reduced, which in turn reduces the saturated current level in the device. This results in wider SCSOAs, with lower on-state voltage drop; and this means that the device achieves lower on-state voltage drop and higher short-circuit withstanding capability at the same time. Alternative IGBT structures, which included an additional doped n layer underneath the p-base of the trench and/or planar cells, were developed by Takahashi et al. (the CSTBT, or carrier stored trench-gate bipolar transistor) [70] and M. Mori et al. (the HiGT, or high-conductivity IGBT) [71], respectively. Laska et al. developed a 1200 V trench IGBT device which attempted to optimize the cell design in terms of size, distance, and shape for enabling lower on-state voltage drop and wider SCSOA, simultaneously [72].

The IGBT products in early days below 1200 V were fabricated based on a design concept involving an n- epitaxial layer grown on a p^+ substrate. The design concept led to an extremely high hole injection from the p+ collector, requiring strong lifetime control to get fast switching speed and resulting in a relatively poor SCSOA and unsuitability for operating in parallel. Thus, Miller et al. developed a new type of bulk IGBT structure, a non-punch-through (NPT) IGBT [63], with the following characteristics:

(i) Utilizable with inexpensive floating zone (FZ) bulk wafer
(ii) Thinner wafer thickness needed
(iii) Low hole injection from the p collector
(iv) Non-requirement of lifetime control

With its low hole injection and non-requirement of lifetime control, the NPT IGBT attains an almost flat electron-hole plasma distribution, enabling both on-state voltage drop and faster switching speed, and offers the further advantage of a positive temperature coefficient in the forward current. This makes the NPT IGBT suitable for operating in parallel, resulting in easy use in high power applications. Notably, it also exhibits wider RBSOA and SCSOA owing to the thicker n-drift region, leading to minimization of electric field in the device. Consequently, the NPT IGBT development has accelerated the change from conventional power bipolar transistors to IGBTs.

An obvious means of improving the NPT structure lies in utilizing a configuration that involves a field distribution with trapezoidal shape in forward blocking states, as is typical of the PT IGBT. This is enabled by incorporating a relatively low-doped n-type field-stop layer enough to avoid affecting the low-doping p-collector in the NPT IGBT, but high enough to restrict the electrical field in forward blocking state. In this way, it enables to thin the drift-layer in the NPT structure. In a 1200 V device, an IGBT with the field-stop layer can be produced with a drift-layer thickness of roughly 120 μm instead of 180 μm, for example. Figure 13.50 and Table 13.2 compare the unit cell cross sections and design concepts of the NPT IGBT and field-stop IGBT. The field-stop (FS) IGBT was introduced by Matsudai et al. [73, 74] and then by Laska et al. [75]. It was optimized by the NPT IGBT design concept described above. The FS IGBT does not require as thick an n-drift layer as the NPT IGBT, because the former incorporates a field-stop layer to restrict the expansion of depletion layer. Commonly, the field-stop layer has a relatively low doping concentration (roughly below 1.0×10^{16} cm^{-3}), far less than the n+ buffer regions in the PT IGBTs shown in Fig. 13.35. Consequently, almost the flat distribution of electron-hole plasma can be obtained in its forward conduction state, and its on-state voltage drop is lowered. In addition, the FS IGBT can exhibit smaller switching power dissipation,

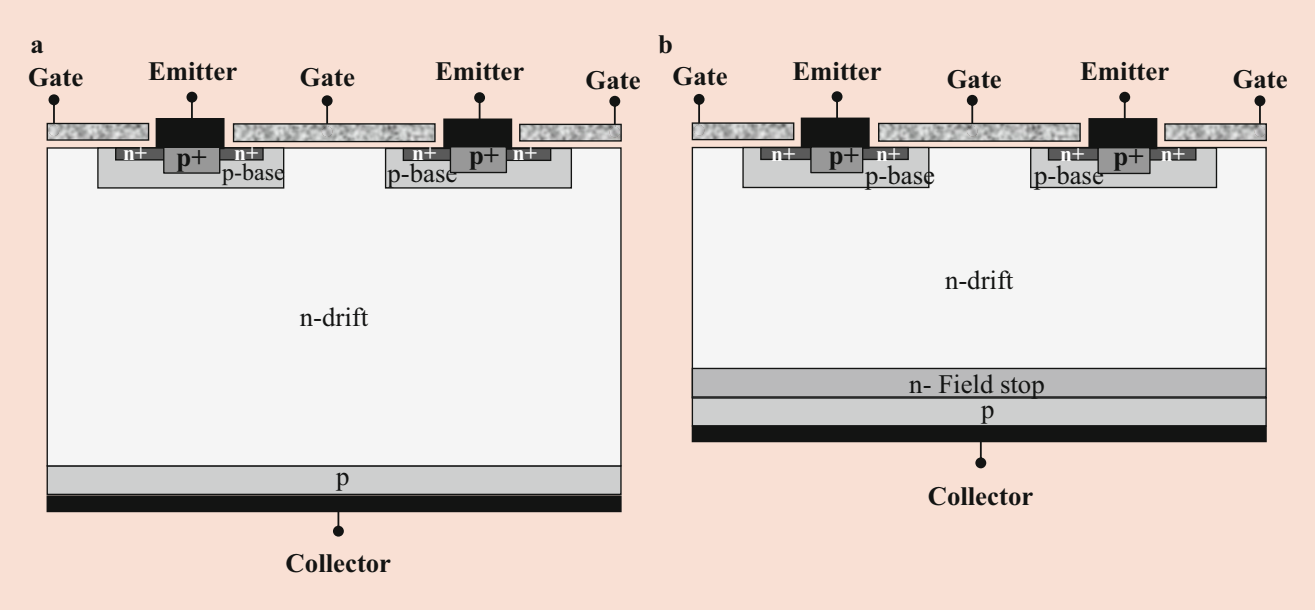

Fig. 13.50 Structural change of IGBT cell design. (**a**) NPT-IGBT; (**b**) FS-IGBT

due to the lesser number of excess carriers as a result of the thinner drift layer. Figure 13.51 shows a comparison of the schematic electron-hole plasma distribution in the FS-IGBT and early PT IGBT, in the on-state. Based on the drift-diffusion theory, the hole current density J_p and electron current density J_n in the IGBT can be expressed, respectively, as follows:

$$J_p = -qD_p\nabla p - q\mu_p p\nabla\varphi \tag{13.42}$$

$$J_n = qD_n\nabla n - q\mu_n n\nabla\varphi, \tag{13.43}$$

where q is the electron charge ($q = 1.6 \times 10^{-19}$ C); D_p and D_n are the hole and electron diffusion constants, respectively; μ_p and μ_n are the hole and electron mobility; p and n are the hole and electron concentrations; and φ is the electrostatic potential. It is clear from these equations that each current density consists of diffusion- and drift-current components.

From Fig. 13.51, it should be noted that in the PT structure the hole drift and diffusion currents are added, while the corresponding electron currents cancel each other, and this makes the hole current predominate over the total current flow in the IGBT on-state. In the FS IGBT, on the other hand, due to the almost flat carrier distribution, the hole and electron diffusion currents are both reduced dramatically, and as a result, the electron current predominates. Therefore, since electron mobility is much greater than hole mobility in silicon material, a higher current with lesser amounts of carriers is achieved, with both lower on-state voltage drop and higher switching speed. By incorporating a trench-gate structure, the increased channel density is achieved and the on-state voltage drop can be significantly lowered. Thus, the FS IGBT with trench gate is the most sophisticated IGBT structure.

Figure 13.52 shows the improvement of IGBT wafer thickness for the 600 V, 1200 V, and 1700 V voltage class [76]. Thin wafer technology is especially critical in the case of the IGBT, not only for the usual benefits of wafer thinness, but also for impurity implantation and diffusion, and for evaporation of the metal electrode on the wafer backside with absolutely no wafer breakage. Thus, the thin wafer technology for FS-IGBT is recognized as one of the most advanced technology in the entire semiconductor field, though advancement in thin wafer technology began to slow down around 2003, and the thickness of recent IGBT dies is roughly comparable to, or only slightly thinner than, those in 2003, mainly due to silicon material limitations. However, 50-μm wafers for 600 V devices, and 90-μm wafers for 1200 V devices, seem feasible in the near future; though with thinner IGBT dies, the soft switching characteristic, cosmic ray robustness, and thermal SCSOA will become more critical. In any case, the thin wafer design based on field-stop vertical cell optimization has contributed vastly to expansion of the IGBT rating limit, especially with respect to blocking voltage, which has attained 6.5 kV at present.

13.3.5 IGBT Module Technologies

The goal of the IGBT technological innovation discussed above was advancement not only in power dissipation but

Table 13.2 Comparison of the different IGBT design concept

	PT-IGBT	NPT-IGBT	FS-IGBT (or SPT-IGBT)
Injection efficiency from p collector	High	Low	
n buffer layer	High dose Functions (a) To stop an electric field	N.A	Moderately low dose Functions (a) To stop an electric field
	(b) To reduce the very high injection efficiency	(b) To optimize injection efficiency	
n-drift layer	Thin	Medium	Thin
Lifetime control	High (lifetime killing)	No lifetime killing	
Wafer	Epi layer on CZ wafer	Bulk wafer (FZ or MCZ)

also in cost reduction through improvement in device characteristics that results in shrinkage in die size, as shown in Fig. 13.53. IGBT modules comprise multiple IGBT devices assembled on a substrate with ceramic isolation, which is itself set up on a thick-copper (Cu) base plate. FWDs are also assembled in the module, for simple system assembly and to enable to minimize both inside and outside stray inductances of the module. Several technological innovations related to the FWD are discussed in Sect. 13.5.

In a structure of the IGBT module on a cooling fin shown in Fig. 13.54, the direct copper bond (DCB) substrate is connected through a solder layer to a heat-dissipating thick Cu base, and a cooling fin is attached to the Cu base. In order to minimize the module size, shrinking a die size of the IGBT and FWD chip is required. However, such die-size shrinking results in increased power density, leading to reduced reliability due to increased device temperature. Nonetheless, the advanced IGBT module has been achieved side by side with IGBT and FWD device characteristics. State-of-the-art module packages give higher reliability and improved electrical characteristics, exploiting the new DCB substrate holding both high thermal conductivity and me-

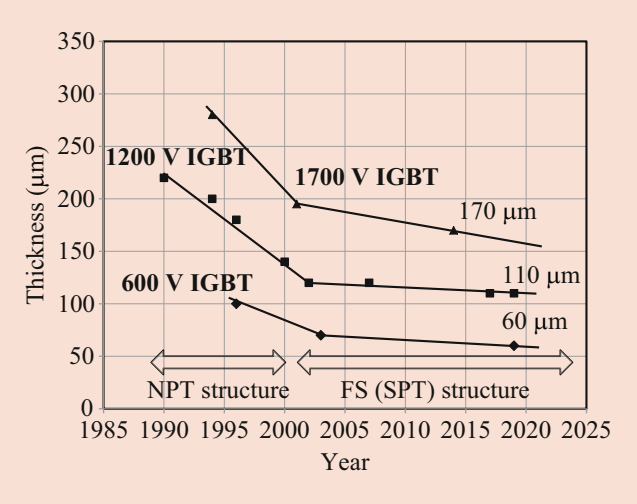

Fig. 13.52 Chronology of the IGBT wafer thickness improvement for 600, 1200, and 1700 V devices

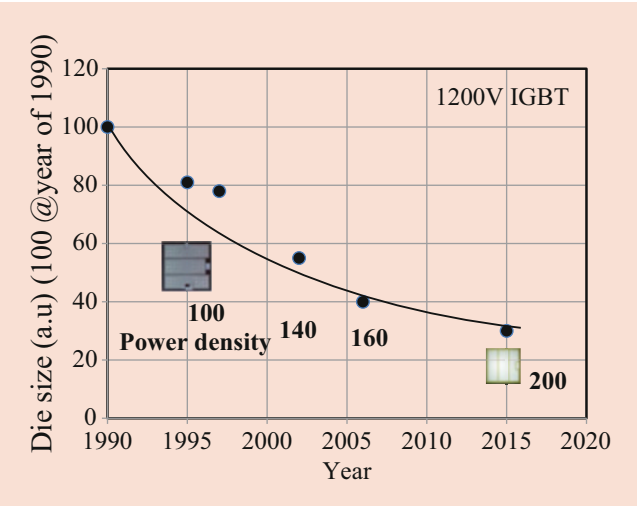

Fig. 13.53 Chronology of 1200 V IGBT chip size shrinkage and its power density

chanical strength, to enhance the operable power density of the module while achieving minimized size with low cost [77]. Thus, improvement in the module technology and shrinkage in the die size have both led to footprint reduction in the IGBT module and thereby to greater IGBT module applicability to smaller-sized power electronics devices. In a whole system of power electronics, higher energy efficiency and smaller-sized output power are of great importance, and IGBT modules are thus in wide use. With this in mind, in 1984, a new design incorporating dedicated drive and protection circuits into IGBTs, to surmount the inherent parasitic limitations of IGBT and enhance its performance as possible, was introduced. This is an intelligent power module, IPM for short [78]. A key feature of the IPM is that the printed circuit board (PCB) containing the gate drive and control circuit is assembled directly above the IGBTs and diodes. Extremely effective over-current sensing and short-circuit protection were achieved by using the advanced current sensing IGBT cells that enabled non-stop monitoring of the IGBT current; and system reliability was enhanced more by the incorporated over-temperature sensing and protection in the IPM. Hence, the IPM has shown improvements in a whole system performance and reliability over conventional IGBT modules and, consequently, has been widely used in a variety of power electronics apparatus, along with uninterrupted improvement in IGBT and diode devices, and packaging and control circuit technologies.

13.3.6 P-ch IGBT Devices

In the 1980s, p-ch IGBT structures were developed as complementary inverters in high-power range. In high-power inverter circuits, complementary topologies of common source types [12, 79] can minimize the dead time as possible between the upper and lower arm in one leg, alleviating the problems caused by dead time, such as harmonics generation as described in Sect. 13.2.2. A leg consisting of complementarily set up n-ch and p-ch devices can reduce the dead time and enable increased switching frequency with no shoot-through of a DC voltage. Traditionally, there has been considerable need for high-power p-ch applications, but no p-ch power devices acceptable for these applications. For example, the area of a p-ch MOSFET requires roughly 2.5 to 3 times larger than that of the corresponding n-ch MOSFET, in order to exhibit the same on-resistance. However, this dramatic size disadvantage is not observed in the case of the IGBT structure, because of the conductivity modulation in the drift region, and this advantage helped launch p-ch IGBT development. Chang et al. reported that the trade-off characteristics between on-state voltage drop and turn-off power dissipation in a p-ch IGBT were marginally worse than in an n-ch counterpart, because of the higher channel resistance in the p-ch IGBT [80]. However, a severe issue for the p-ch IGBT was poor RBSOA and SCSOAs, and this issue is theoretically unsolvable [81, 82]. It has been demonstrated numerically and experimentally that p-ch IGBT structures are easily destroyed, not by latch-up of the parasitic thyristor, but by avalanche multiplication, because the electrons, which have a much higher avalanche ionization rate than holes in silicon material [83], flow across the p-n junction of n-base and p-drift region in the p-ch IGBT structure, where there is a high electric field under turn-off and short-circuit conditions. Carriers flowing through a high electric field gain sufficient energy to excite electron-hole pairs. The carrier generation rate G is expressed as

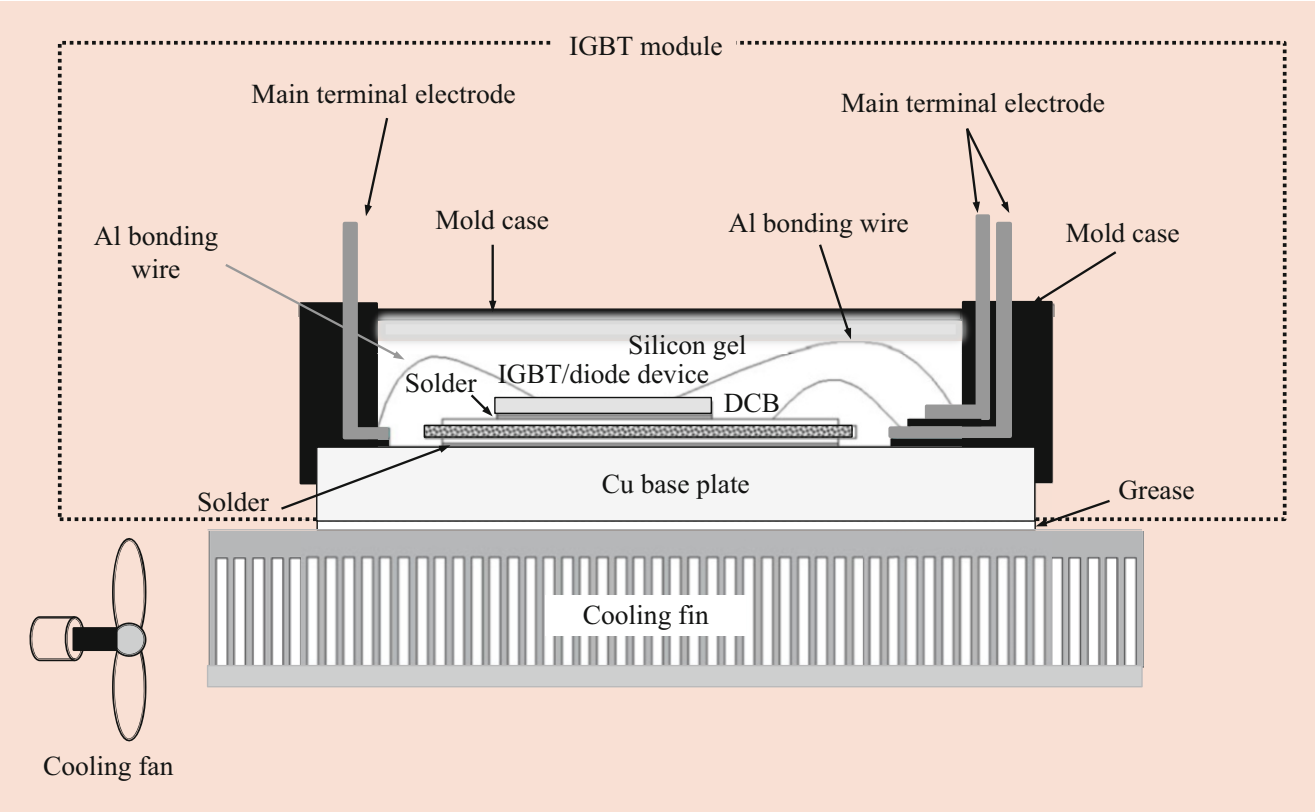

Fig. 13.54 Cross section of IGBT module on a cooling fin

$$G = \frac{1}{q}\left(\alpha_{\mathrm{p}}\left|J_{\mathrm{p}}\right| + \alpha_{\mathrm{n}}\left|J_{\mathrm{n}}\right|\right), \tag{13.44}$$

where q is the electron charge ($q = 1.6 \times 10^{-19}$ C), α_{p} and α_{n} are the hole and electron impact ionization rate respectively, and J_{p} and J_{n} are the hole and electron current density.

As a result, avalanche generation takes place near the junction, so that many generated holes flow toward the n+ collector region as additional base current in the wide-base npn transistor, resulting in huge current flows when the positive feedback between the avalanche generation and electron injection from the n+ collector takes place. Finally, this huge current flows through the p-ch IGBT, causing destructive failure of the device.

Figure 13.55 compares the SCSOA of p-ch and n-ch IGBTs. The n-ch IGBT exhibits poor latch-up capability in this figure; however, this characteristics can be improved through utilization of the non-latch-up structure mentioned in Sect. 13.3.3. However, the poor p-ch IGBT avalanche capability cannot be similarly improved through the application of device design technologies. For this reason, most IGBTs have been developed by n-ch structures, and consequently, there are hardly high-power complementary inverter circuits incorporating both n-ch and p-ch IGBTs.

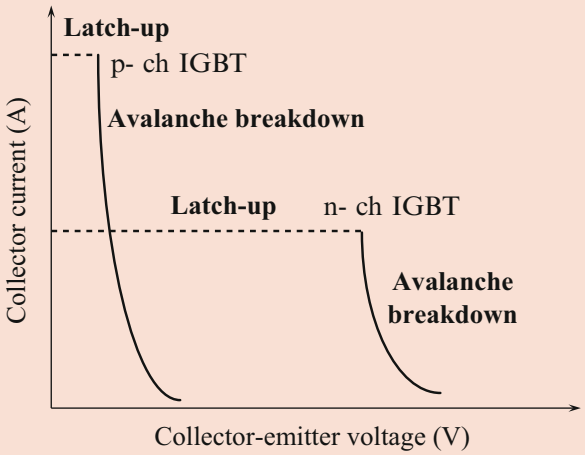

Fig. 13.55 Comparison of the short-circuit SOAs between p-ch and n-ch IGBT

13.3.7 State-of-the-Art IGBTs

The most critical components of an IGBT are its wide-base pnp transistor design in the upper region of the device, and the vertical cell structure comprising an n-drift layer, a field-stop layer, and back-side p+ collector, as shown in Fig. 13.50b.

Design Concepts for the IGBT Transistor Cell and Vertical Structure

Trench cell technology has been widely introduced and incorporated over the entire voltage class range, from 400 V to 6.5 kV cell designs; from the trench cell-based IEGT [84] with its wide distances between the cells [72], to structures with narrower or otherwise different gate and/or source trenches; and in designs that do or do not include an additional doped n layer underneath the p body [67, 70]. However, all the designs share the basic principle of enhancing the amounts of electrons and holes in the upper part of the device during the on state, through hole confinement or the injection enhancement effect [69]. Consequently, the on-state voltage drop in such trench cell-based IGBTs with increased carriers is greatly lowered compared to earlier, planar cell-based IGBTs.

The latest efforts to further enhance the carrier concentration on the upper part tend to focus on reducing the cell size and pitch to the micro or even sub-micron level [85–87], as shown in Fig. 13.56. However, if the increase in electron and hole plasma in the upper part is overemphasized, the result can be excessive turn-off power dissipation as the excess plasma is not swept out rapidly enough. Thus, carrier engineering with respect to the electrons and holes in the surface side of the IGBT must be carefully balanced, to enable low on-state voltage drop and fast turn-off characteristics at the same time.

An equally critical IGBT design element is the vertical structure. The current vertical design is a punch-through configuration with a low-doped field-stop layer interposed between the n-drift region and the back-side p collector with low hole injection, without lifetime control process (see Fig. 13.50b), which is often referred to as a field-stop [73, 75] or soft punch-through structure [88]. This self-evident development from the earlier NPT [63] and PT [89] design concept seeks to optimize both the cost and performance of industrial IGBTs. It has traditionally been utilized in 1200 V voltage class devices, and then stepwise up to 6.5 kV devices, but has also been incorporated in lower voltage classes, from 600 V to even less than 400 V, and in devices ranging in thickness from roughly 45 μm (400 V) to roughly 700 μm (6.5 kV).

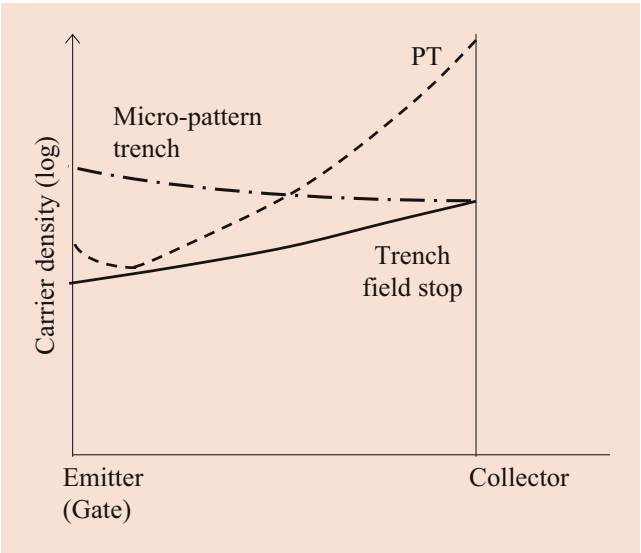

Fig. 13.56 Schematic electron-hole plasma distribution in the on state among the different cell concept of IGBT (PT, trench FS, and micro-pattern trench)

Reverse Blocking IGBT and Reverse Conducting IGBT

Among the recent developments in current-art IGBT technology is integrating additional functions in the device. One example is the reverse blocking IGBT (RB IGBT) [90], which offers advantages for particular applications such as matrix converters for AC to AC direct conversion, but drawbacks for process difficulty and vertical optimization restrictions compared to field-stop IGBTs (see Fig. 13.57). The main feature of RB IGBT is the reverse blocking capability. The RB IGBT structure is a type of NPT configuration and has been improved by the addition of a junction isolation region (Fig. 13.57), which is absent in conventional IGBTs. A lateral or dicing face is generated during the manufacturing of a cut-out from the wafer, and crystal deformations and high-density crystal defects typically occur. At this lateral face, carriers continuously generated from these crystal defects are transported by the electric field of the applied negative voltage, leading to large leakage current. Thus, without the junction isolation region, conventional IGBTs do not have enough reverse blocking capability, because there is leakage current flow through the IGBT device when reverse voltage is applied between the collector and emitter electrodes. In the RB IGBT, on the other hand, the junction isolation region prevents leakage current from flowing through the RB IGBT and enhances the reverse blocking capability. An example of the measured forward and reverse blocking characteristics of a 1.2 kV RB IGBT is provided in Figs. 13.58 and 13.59. The reverse breakdown voltage of about 1270 V is similar to the forward breakdown voltage. In spite of their distinct differences, RB IGBTs and NPT IGBTs are similarly structured in the active regions, and their turn-off characteristics are therefore similar. In terms of the trade-off characteristics between forward voltage drop and turn-off loss in the RB IGBT and NPT IGBT with diode in series, a clear benefit is shown in Fig. 13.59. The turn-off of the RB IGBT is similar to that of an IGBT with a diode; however, the former has a much lower forward voltage drop than the latter, due to the absence of an additional diode. This improvement contributes to a reduction of power dissipation when utilizing an RB IGBT as a bi-directional switch.

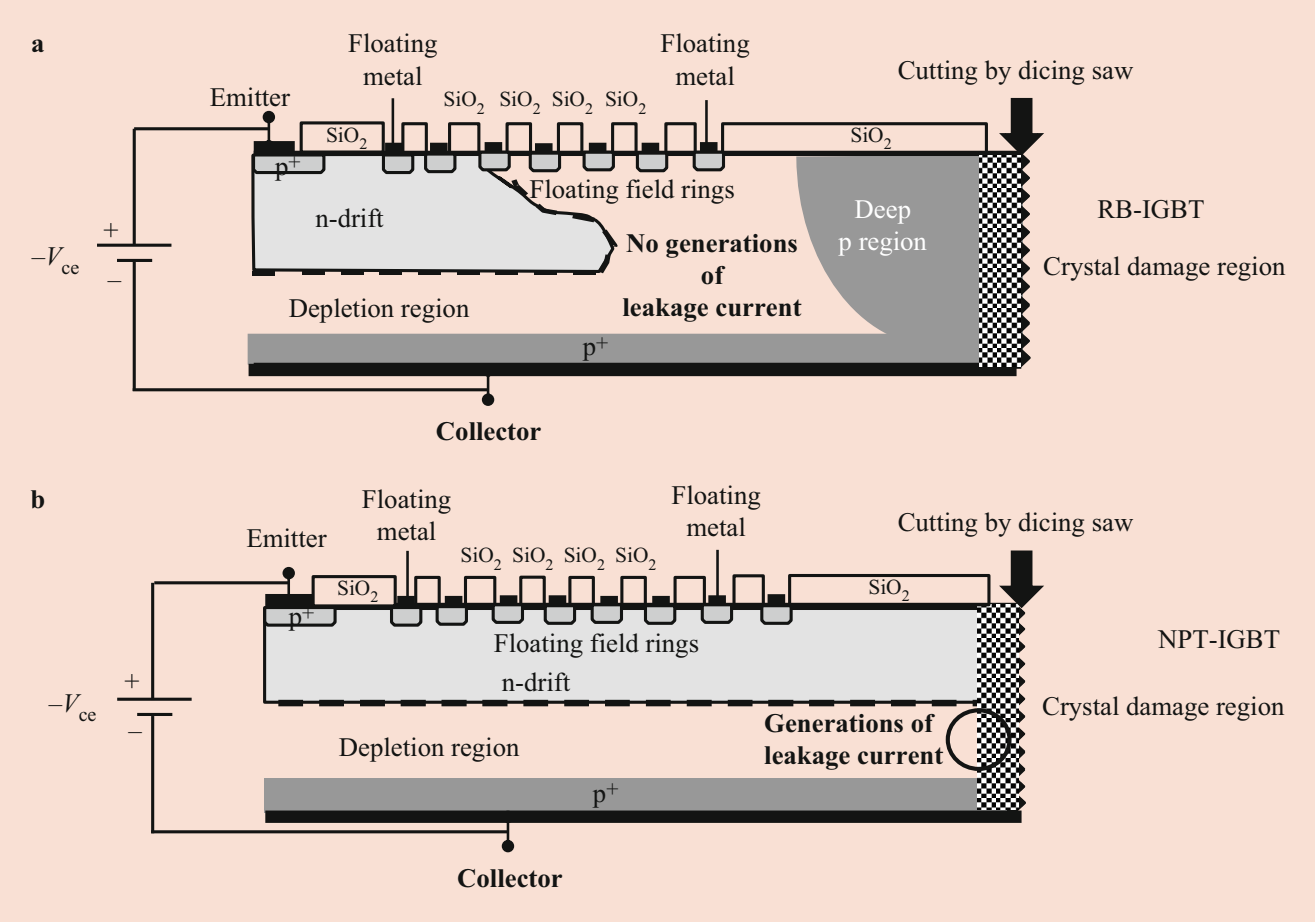

Fig. 13.57 Comparison of cross section between RB-IGBT and NPT-IGBT. Depletion expansions by a reverse bias are drawn in these figures

Another promising focus for integration is the incorporation of free-wheeling diode functionality in the IGBT, resulting in a so-called reverse conducting or RC IGBT (Fig. 13.60). In these devices, the IGBT and free-wheeling diode (FWD) are integrated into a single device, resulting in significant reduction in the RC-IGBT module size. The RC IGBT structure was proposed as part of the p-ch IGBT

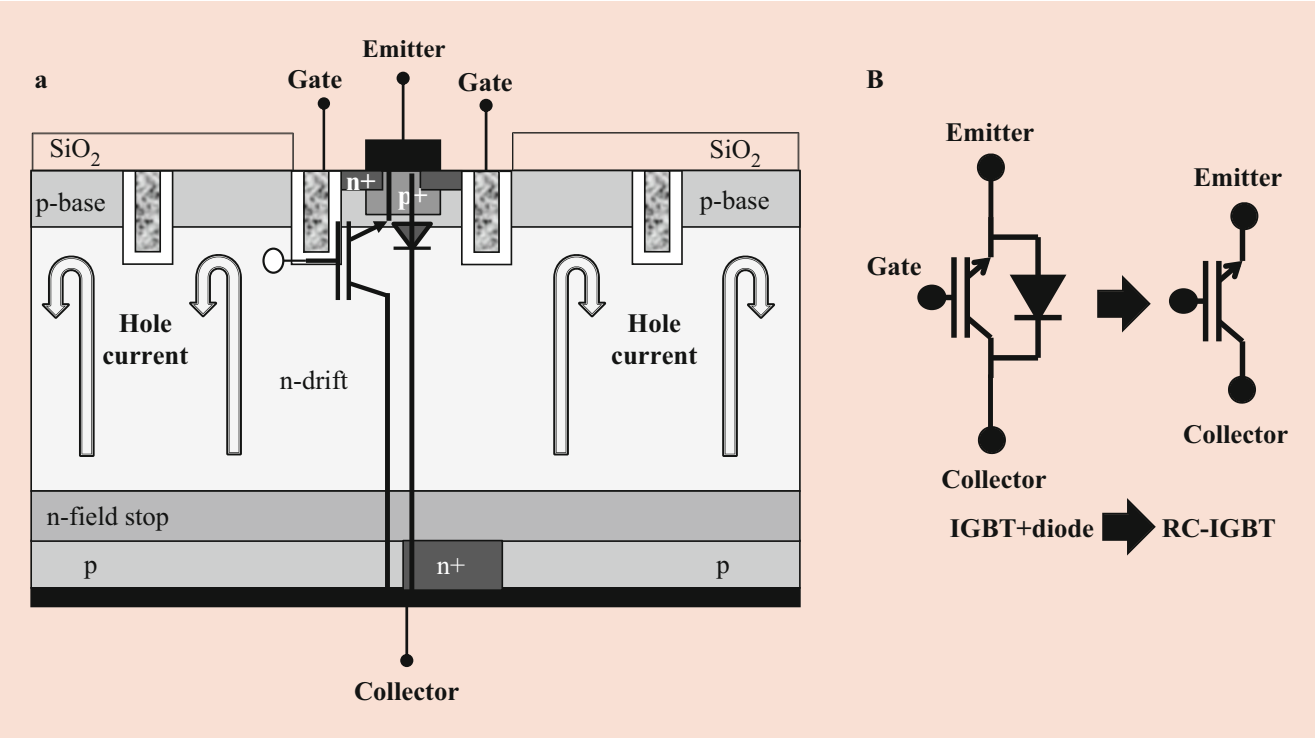

Fig. 13.60 RC IGBT as an integration of IGBT and FWD within one die. (a) Cross section. (b) Equivalent circuit

with collector short [91], based on the design concept in [92]; and in 2004, the structure was presented in the context of NPT technology [93]. FS-IGBT technology was initially applied and well-suited only to particular applications such as induction heating [94]; however, it could also be optimally designed, in terms of the integrated diode function, for typical applications for industry and consumer electronics in the 600 V and 1200 V voltage ranges, with its requirement for hard diode commutation [95, 96]. The particular challenge here is to integrate highly disparate optimized features, such as low lifetime in diode and highly doped p-base in IGBT cell, in a single die. A current RC-IGBT module was recently developed for automotive and industrial applications, and trench FS-IGBT technology with finer cell pitch and thinner wafers has been developed. Consequently, the forward voltage drop in IGBT plus diode operation has been reduced in comparison with previous-generation devices [97]. In addition, IGBT and FWD components are alternately located on the RC-IGBT die, resulting in better thermal resistance than in conventional IGBTs, because the dissipation from individual components is radiated from the entire die surface. This is especially useful in so-called rotor locks, step-up converters, and active short-circuit systems. In the case of rotor locks, the RC IGBT can dramatically suppress temperature increase, because of the large heat radiation area; and even traction applications in the high voltage region of 3.3 kV have been discussed [98, 99]. The structure is generally highly useful for high voltage applications, because the IGBT and FWD share edge termination regions, leading to a significant reduction in the silicon wafer area.

The future of this competition between the standard combination of independent IGBTs and diodes, and integrated solutions such as RB IGBTs and RC IGBTs, is unclear, but may at least partly depend on development in inverter topologies and applications for cooling and gate drive design.

Increase of the Maximum Junction Temperature and Power Density

The evolution from the earliest IGBTs to the current state-of-the-art structure can also be considered in terms of the maximum junction temperatures (T_j) of the dies in the package. From 125 to 150 °C appears to be the standard maximum junction temperature for IGBTs in conventional modules. Further, state-of-the-art IGBT modules are also specified for a T_j of 175 °C, both as a continuous condition [100, 101] and for overload cases [102, 103]. Improvements to support these enhanced junction temperatures come from both the semiconductor device side (reduced leakage current at high temperature, high intrinsic over-current and short-circuit robustness) and the module side, as well as from interconnected die technologies in the package.

Increased junction temperature enables dramatic shrinkage in die size for a given nominal current, with shrinkage correlated to the increased in T_j. This enhanced current rating per device die size can be utilized either for minimizing the module footprint for a given power level or enhancing the output power for a given module footprint. Both designs lead to higher power density and enable the module users to either reduce the size and weight of the given inverter or significantly increase its power. The increase in nominal current and output power in a standard industrial IGBT module over several generations, enabled by shrinkage of device die size, is shown in Fig. 13.53. Thus, power density enhancement has been a crucial trend in, and remains the primary driver behind, IGBT innovation and has been enabled not only by improvements in transistor cell and vertical technology but also by successful approaches to increasing the junction temperature.

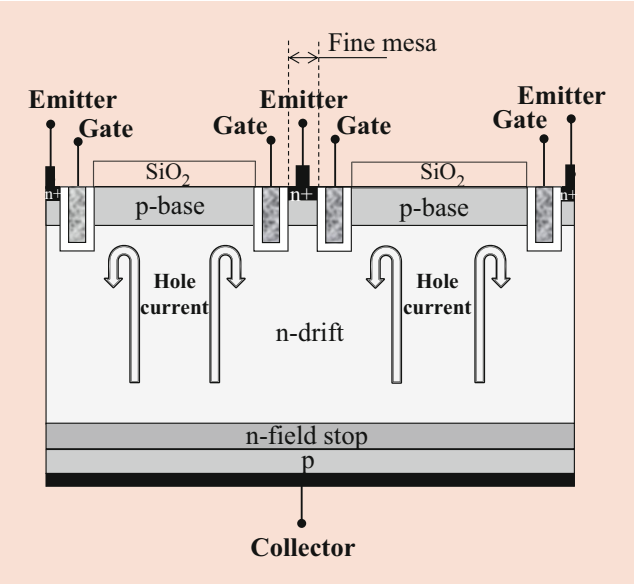

Fig. 13.61 An example of IGBT structure with fine mesa

13.3.8 Future Prospects of IGBT Devices

There are numerous questions concerning the nature and significance of further development in IGBT technology, especially given the new wide bandgap power devices that mainly utilize silicon carbide (SiC) (≥1200 V) or gallium nitride (GaN) (<1200 V). As silicon IGBTs approach their theoretical limits, it becomes even more important to determine which properties are critically necessary from an application point of view.

Typical examples include voltage slope (dV/dt) limitation at turning on and turning off of IGBT and short-circuit withstanding capability. These properties define the direction of silicon IGBT development and must be reconceptualized in the context of wide bandgap power devices. For example, the advantages provided by the latter devices, due to their very low switching losses, are only in effect when they are allowed to switch very quickly; and this may not suit the requirements of many power current electronics users seeking a dV/dt value of less than 10 kV/μs, owing to concerns about electromagnetic interference (EMI) and a desire to minimize motor deterioration. Allowing higher dV/dt would enable switching loss reduction than for silicon IGBTs. However, the actual correlation between dV/dt values and the EMI spectrum in current applications is often unclear.

Reducing the usual short-circuit requirements from 10 μs to 5 μs, or even less, would raise the possibility of increasing of ratio of channel width W to length L (W/L), enabling on-state loss reductions in both SiC MOSFETs and silicon IGBTs [104]. Even if the current requirements for dV/dt and short-circuit withstanding are adopted, there are ways to further improve silicon IGBT technology; however, the more these requirements are eased, the more likely it will be that improvements will take place. In order to envisage possible future developments, it will be useful to briefly reconsider single-cell and vertical-structure IGBT devices.

Next-Generation Transistor Cell and Vertical Structures

In light of the theoretical limits of IGBT on-state characteristic [105], much current research is focusing on sub-micron (down to 0.5-μm) mesas between adjacent deep trenches [84, 106, 107], as shown, for example, in Fig. 13.61. In addition, there are indications that the on-state voltage drop can be lowered nearly 1 V devices rated for a 1200 V blocking; however, excessively high turn-off switching losses due to excessive amounts of electron-hole plasma, as well as problems related to short-circuit robustness, remain to be addressed. If such difficulties are overcome, next-generation IGBTs may benefit from significant loss reduction in the on-state and device shrinkage by incorporating mesa structures in the deep submicron region or even below.

There is also room for improvement in IGBT vertical structure design. As is the case in every vertical bipolar power device, the thinner the n-drift layer, the greater the opportunity for reduction in both forward conduction and switching power dissipations. Recently, 1200 V IGBTs with a device thickness of roughly 110-μm, and 600 V IGBTs of roughly 70-μm thickness, have become common. Based on the theoretical limits for blocking capability, 1200 V devices of roughly 90-μm thickness, and 600 V devices of roughly 50-μm thickness, seem feasible, with recent ultrathin wafer technology seemingly able to satisfy these requirements [108]. However, the thinner the IGBT device, the more critical will be the softness in switching waveforms, cosmic ray robustness, and SCSOA determined by thermal reasons. About the softness in switching waveforms, module and

inverter systems with low stray inductance will play an important role, along with optimized engineering of field-stop and refinement in the specification of injection efficiency in p collector. The last, in particular, must be considered, especially given the recent elucidation of the three-dimensional trade-off between on-state and switching losses and overvoltage at turn-off [86]. It is becoming clear that unfavorable high injection efficiency in the back-side collector could be in the best compromise about overall losses and overvoltage, at least as long as high stray inductances take place. To maintain the robustness for cosmic ray at a sufficiently high level, the doping concentration in the n-drift region can be increased; and a sufficiently high level of thermal SCSOA can be achieved, even with reduced device thickness, by incorporating a thick metal layer on the device surface.

Intelligent Gate Drive Control

As one means to address the trade-off between short-circuit withstand capability and forward voltage drop, IGBT devices have been designed with increased ratio of channel width W to length L (W/L), over-current sensing, and reduced gate-voltage capability. This is because, in the case of short circuiting, the current still flows at a manageable level within the first few micro seconds. As this approach is common in intelligent power modules (IPMs) [109], in the future it may also be utilized in standard IGBT modules, as it ensures at least one significant improvement in IGBT performance compared to standard short-circuit rated IGBTs [110].

Another important improvement, based on sophisticated gate drive operation, is available for RC IGBTs. By also utilizing trench cells for the diode function in the IGBT, a dedicated gate drive operation can be achieved, to vary the electron and hole carrier distribution from a higher concentration level during free-wheeling mode to a lower concentration level shortly before commutation [110]. Using this operational scheme, a reverse conducting diode controlled IGBT (RCDC IGBT) can increase its potential to high-voltage, such as 3.3 and 6.5 kV, traction and HVDC applications. A similar approach is evident in the design of the BIGT (bimode insulated gate transistor) [111], which illustrates a means of power density enhancement for 3.3, 4.5, and 6.5 kV power modules. If these more sophisticated gate drive technologies also become standard in the medium voltage range (600–1700 V), the RCDC IGBT design can enhance power density compared to the conventional approach involving independent optimized IGBT and diode devices [112]. And in the future, the electron-hole plasma concentration at a high level during on-state, and then varying it to a lower level before the switching, may become more popular also in IGBTs .

Advanced Thermal Management

The trend of improving the maximum junction temperature (T_j) will likely continue, up to at least 200 °C. It has already been demonstrated that silicon IGBTs can operate at high temperature levels up to 200 °C, making overload operations of RBSOA and SCSOA at 200 °C seem feasible [113, 114]. The peripheral region around the power device, such as the package with its plastic components, and the terminals and peripheral components outside the package, must have capability to withstand such high temperature levels. More specifically, the mold compound in discrete IGBTs, and the silicone gel in standard IGBT modules, presents challenges at increased temperatures, but there already exist solutions for gels up to 200 °C [115].

Two other important issues in this context are the increased temperature swings that result in baseplates and lead frame connections stressing power devices, and inadequate wire bonding on the surface of the IGBT, resulting in fewer power and temperature cycles until failure. For these innovations, sophisticated solutions already in place may also be feasible even up to 200 °C, whether in the form of sintering interconnection technology on the back and surface side of the semiconductor device [116–118], or alternatively, through surface side copper wire bonding [100]. Using the recently developed technique involving thick copper metallization on the surface side, to facilitate the copper bonding process, also improves the thermal SCSOA, which can enable reduction in die size and device thickness [119].

It is strongly expected that the such combined solution of semiconductor device and module will encourage the use of higher T_j up to 200 °C in the future, and that these will lead to innovations in not only single cell and vertical structures but also gate driving with higher-power density.

13.4 MOS Gate Thyristors

In a range of high blocking voltage, the IGBT shows much lower forward conduction loss than the power MOSFET, and it is commonly known that thyristor structures show lower conduction loss than bipolar transistors. The thyristor family consists of several structures from the simple silicon-controlled rectifier (SCR) [120] to the complex triac [121]. A basic thyristor structure comprises four semiconductor layers (p_1, n_1, p_2, n_2) and three pn junctions (J_1, J_2, and J_3) in series, as shown in Fig. 13.62. Thyristor operation can be understood in terms of a two-transistor model, with transistor T_1 being an npn bipolar junction transistor (BJT) comprised of n_1-p_1-n_2, and transistor T_2 being a pnp BJT comprised of p_2-n_2-p_1. A positive voltage is applied between the anode and cathode electrodes, and current conduction does not take place because the central pn junction J_2 is reverse-biased. When a gate current I_g is supplied as the base current, the collector current of the npn BJT T_1 begins to flow, providing the base current drive for the pnp BJT T_2. Thus, a regenerative

situation will occur when the sum of the current gain in the two BJTs exceeds unity ($\alpha_1 + \alpha_2 > 1$).

There has been much greater interest in developing thyristor devices with MOS control capability, for achieving a much lower forward conduction loss. Although the turn-on of a vertical thyristor structure through MOS gate has been demonstrated [51], the turn-off of the thyristor current using the MOS gate is very hard because of the regenerative activity occurring in the thyristor. Some promising ideas to achieve this capability have been introduced and presented experimentally; and several promising structures have been developed. In this section, the some promising MOS gate thyristor structures and their operation are introduced.

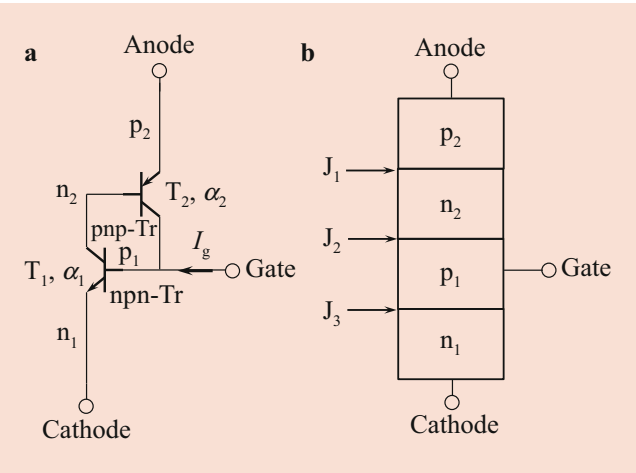

Fig. 13.62 Thyristor: (**a**) npn-pnp transistor model; (**b**) basic structure. α_1: current gain of npn bipolar transistor; α_2: current gain of pnp bipolar transistor

13.4.1 The MOS-Controlled Thyristor (MCT)

Figure 13.63 shows a cross section and an equivalent circuit of the MCT structure [122]. The thyristor structure is formed by coupled n+/p-base/n-drift (npn-Tr as shown in Fig. 13.63) and p+/n-drift/p-base (pnp-Tr as shown in Fig. 13.63) transistors, and the on-state current flows through the thyristor. When the positive anode voltage is applied, the device can be switched on by a positive gate voltage to form the inversion layer at the surface of the p-base region in the n-ch MOSFET (n-MOSFET). Electrons from the cathode begin to flow through the inversion layer into the n-drift region, and these electrons act as the base current for the pnp transistor (pnp-Tr) in the thyristor structure. Holes are injected from the p+ anode into the n-drift region and collected by the p-base region. Eventually, the hole current flow triggers the activation of npn transistor (npn-Tr) and latch-up of the thyristor, at which point, the positive gate voltage can be removed, and the on-state current keeps flowing in the thyristor region while showing a low on-state voltage drop. The MCT can be turned on by using the n-ch MOSFET and has an extremely low on-state voltage drop of roughly 1.0 V and more. The thyristor operation can be halted by turning on the p-ch MOSFET (p-MOSFET) incorporated into the p-base region. Also, it has been made clear that the MCT must be operated with a snubber circuit because of the limited RBSOA [123, 124]. As the MCT does not possess high-voltage current saturation characteristics, it has no short circuit SOA. Another drawback of the MCT is that its triple-diffusion junction structure makes its manufacture more difficult. Despite these problems, however, MCT devices have become commercially available.

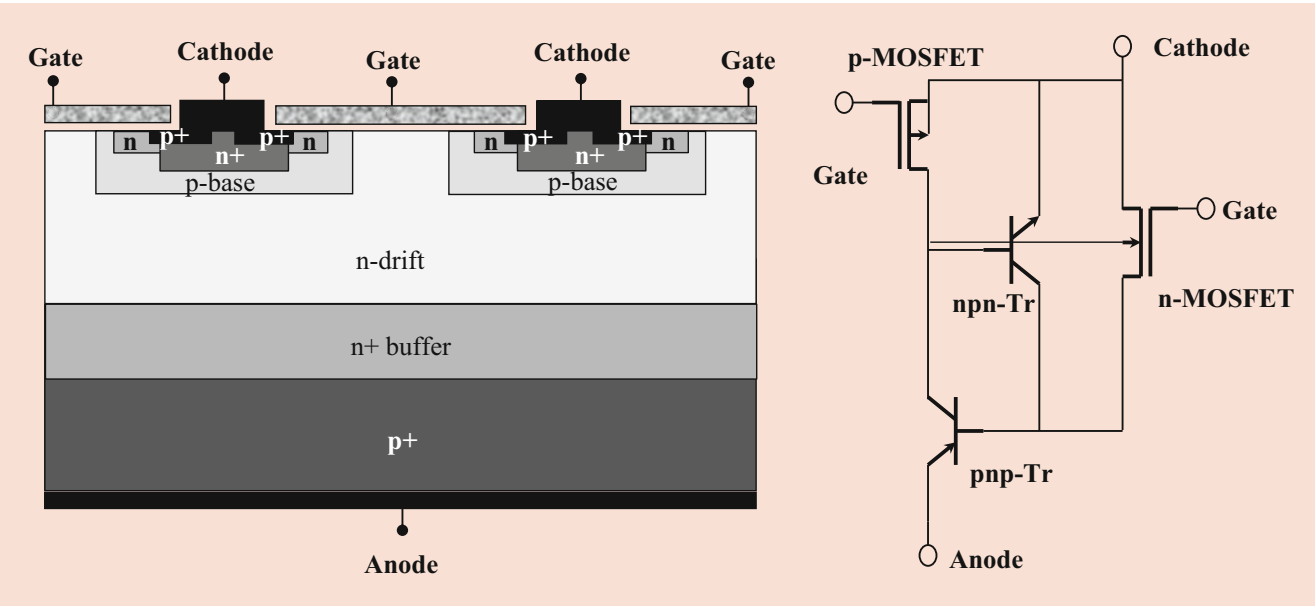

Fig. 13.63 Cross section of the MOS-controlled thyristor (MCT) and its equivalent circuit

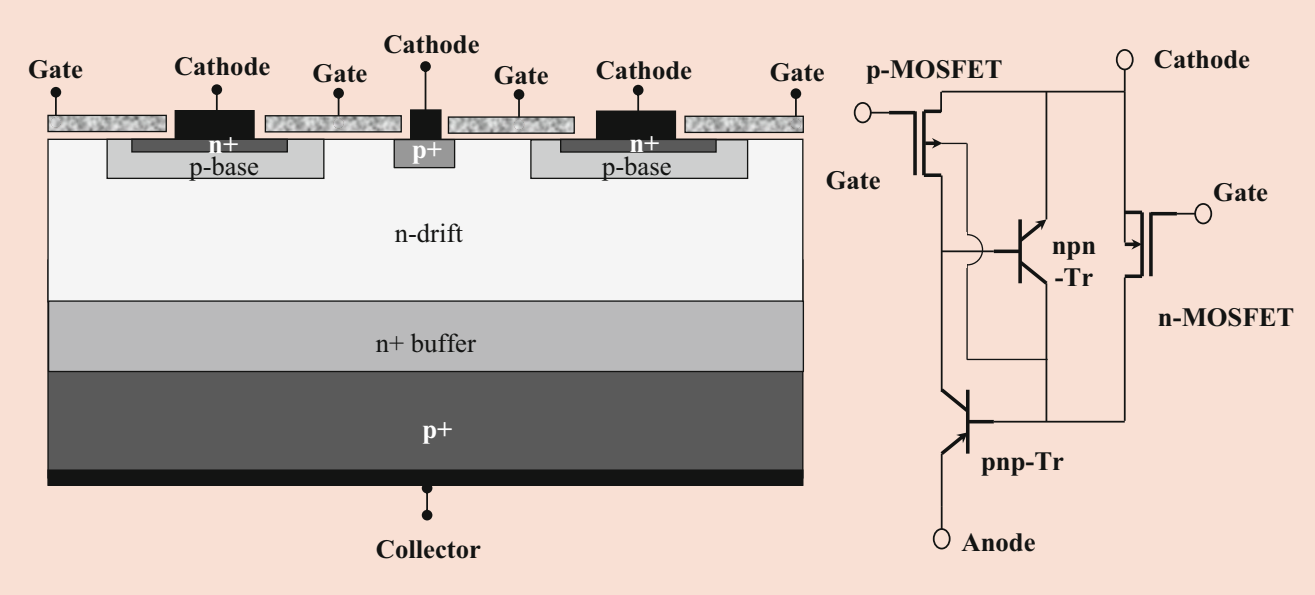

Fig. 13.64 Cross section of the base resistance-controlled thyristor (BRT) and its equivalent circuit

13.4.2 The Base Resistance-Controlled Thyristor (BRT)

A cross section of the BRT device is shown in Fig. 13.64, along with its equivalent circuit [125]. This device has a thyristor region with adjacent n-ch and p-ch MOSFETs. Notably, the p-ch MOSFET is fabricated in the n-drift region in the device. The thyristor region can be activated by a positive gate voltage, creating an inversion layer through which electrons flow into the n-drift region in the IGBT operation. Holes are injected from a p+ substrate in the anode side into the drift region and collected by the p-base, where they flow laterally underneath the n+ cathode region to the p+ region. The device shows IGBT mode operation at low current levels, and the hole current flow in the p-base generates a voltage drop that forward biases the n+ cathode/p-base junction. This forward-biased potential is sufficient to inject electrons from the n+ cathode, leading to latch-up of the thyristor. Once this thyristor is latched up, the current keeps flowing in the thyristor region with an extremely low on-state voltage drop. When a negative gate bias is applied, the BRT can be turned off to form a p-ch MOSFET at the surface of the n-drift region. Through the action of the p-ch lateral MOSFET, the thyristor's regenerative activity can be halted by diverting the hole current flowing into the p-base region to the cathode electrode. This device has exhibited excellent on-state characteristics, with a forward voltage drop of roughly 1.0 V and more and high current turn-off capability owing to diverting the hole current into the p-base. In addition, the process for BRT fabrication is compatible with that for the IGBT fabrication. However, the device does not possess high voltage current saturation characteristics and thus has the same drawbacks as the MCT without any short-circuit SOA.

13.4.3 The Emitter-Switched Thyristor (EST)

The EST structure (dual channel EST) is shown in Fig. 13.65, along with its equivalent circuit [126]. It differs from the EST structure originally reported [127]. The lateral n-ch MOSFET is formed using a standard DMOS process. This leads to the formation of a dual-channel MOSFET connecting n+ floating in thyristor region with the cathode electrode. Applying a positive anode voltage, the device can be switched on by a positive gate voltage to form an inversion layer at the surface of the p-base region. Electrons from the cathode flow through the inversion layer then enter the n-drift region. These electrons act as the base current for the pnp transistor in the main thyristor; then, holes are injected from the p+ anode into the n-drift region, and collected by the p-base region. Before latch-up of the main thyristor, these holes flow laterally in the p-base beneath the n+ floating region to the emitter short formed along the cathode finger orthogonal to the cross section. In this operation mode, the device works as an IGBT. As the current increases, the n+ floating and p-base junction in the npn transistor is forward biased and the main thyristor latches up. The device is turned off by lowering the gate voltage below the threshold voltage of the n-ch MOSFET, which leads to the elimination of inversion layer for electron flow, so that the n+ floating emitter is disconnected from the cathode, halting the thyristor action. In the EST, MOS-gated control makes the thyristor current flow through inversion layer in the MOSFET channel, which not only shows capability of MOS gated turn-off but also enables high voltage current saturation. These are features unique to the EST. The physics of the high-voltage current saturation derives from pinch-off of the n-ch MOSFET. When a high anode voltage is applied with low gate bias, the n+ floating

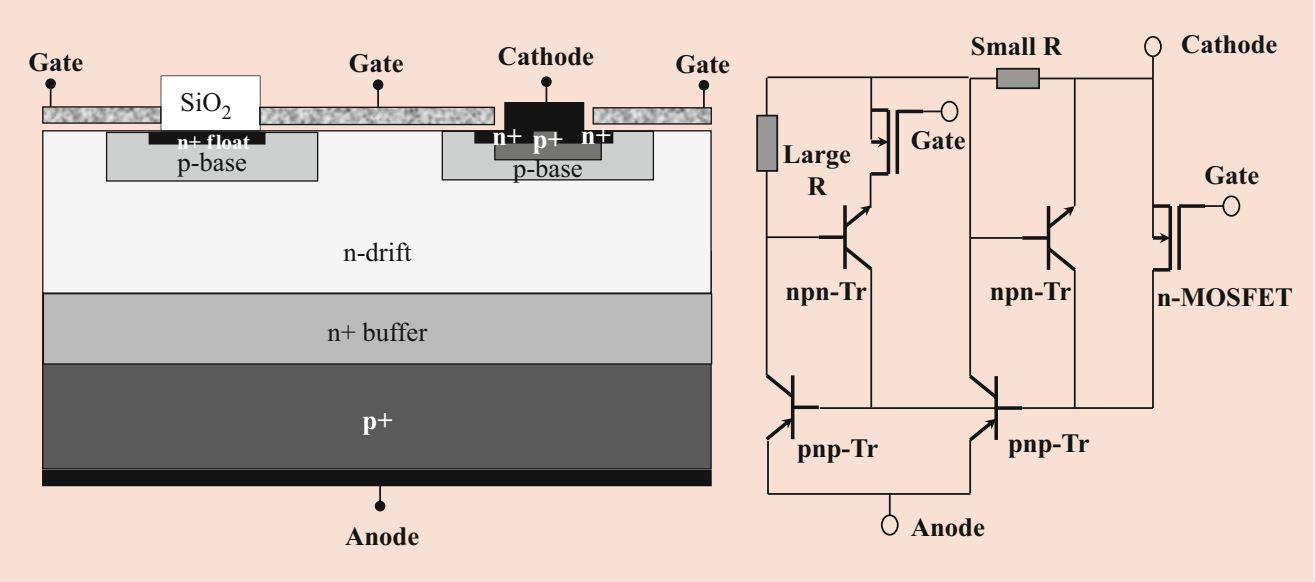

Fig. 13.65 Cross section of the dual channel emitter switched thyristor (EST) and its equivalent circuit

region is in isolation state by the channel pinch-off between the p-base diffusion regions, and as a result, the injection of electrons from the n+ floating region ceases. Consequently, the EST operates as an IGBT, with high voltage current saturation capability [128]. However, the device has a somewhat higher forward voltage drop across the MOSFET, and this adds to the voltage drop across the thyristor, as shown in Fig. 13.66.

The MOS-controlled cascode thyristor (MCCT) structure and operation are very similar to the dual channel EST, with the main structural feature being the absence of electrode connection to the deep n+ emitter and p-base region in the main thyristor [129]; and like the EST devices, the MCCT possesses the twin capabilities of MOS gate controlled turn-off and high voltage current saturation.

13.4.4 MOS Gate Thyristors and IGBT Competition

The IGBT is distinguished by its simple gate drive and high-voltage current saturation, and numerous works have investigated its suitability for high power applications. At the same time, MOS gate thyristors such as MCTs and BRTs have been similarly studied, as potentially superior alternatives, because of their equally simple gate characteristics and lower forward voltage drops. However, since the latter do not have high voltage current saturation, resulting in much more limited short-circuit SOAs, the market has not accepted them as feasible alternatives to the IGBT. The dual channel EST and MCCT are the only reported MOS gate thyristors with gate controlled current saturation capability, which makes them suitable for applications requiring short-circuit protection, because they can limit the anode current to a specific value even in the short-circuit state, by reducing the gate voltage using an integrated protection circuit. However, since the EST and MCCT have dual channel MOSFETs connecting the n^+ floating region and cathode electrode in series, they exhibit higher on-state voltage drop than other thyristors. Therefore, with the advent of recent sophisticated IGBT designs such as the IEGT [69] and CSTBT [70], which show extremely lower on-state voltage drop through electron-hole plasma enhancement around the surface of the device (see Sect. 13.3.4), the improvement in forward voltage drop provided by the dual channel EST and MCCT is not significant enough to make them superior alternatives to IGBTs. Finally, MOS gate thyristor research and development has been gradually declining, resulting in very few such devices being in the market at this time .

13.5 Power Rectifiers

13.5.1 Unipolar Devices

A Schottky barrier diode (SBD) with rectification capability can be simply fabricated by forming a metal layer on the silicon surface. SBD products are commonly designed for relatively low breakdown (<200 V). The features of SBDs over pin diodes is the very fast reverse recovery due to the absence of minority carriers; and silicon SBDs are now utilized in a variety of high frequency applications. When reverse voltage is applied to an SBD, a very small leakage current flows; and when forward voltage is applied, a large forward current flows and its on-resistance is low. It is well known that the on-state voltage drop in the

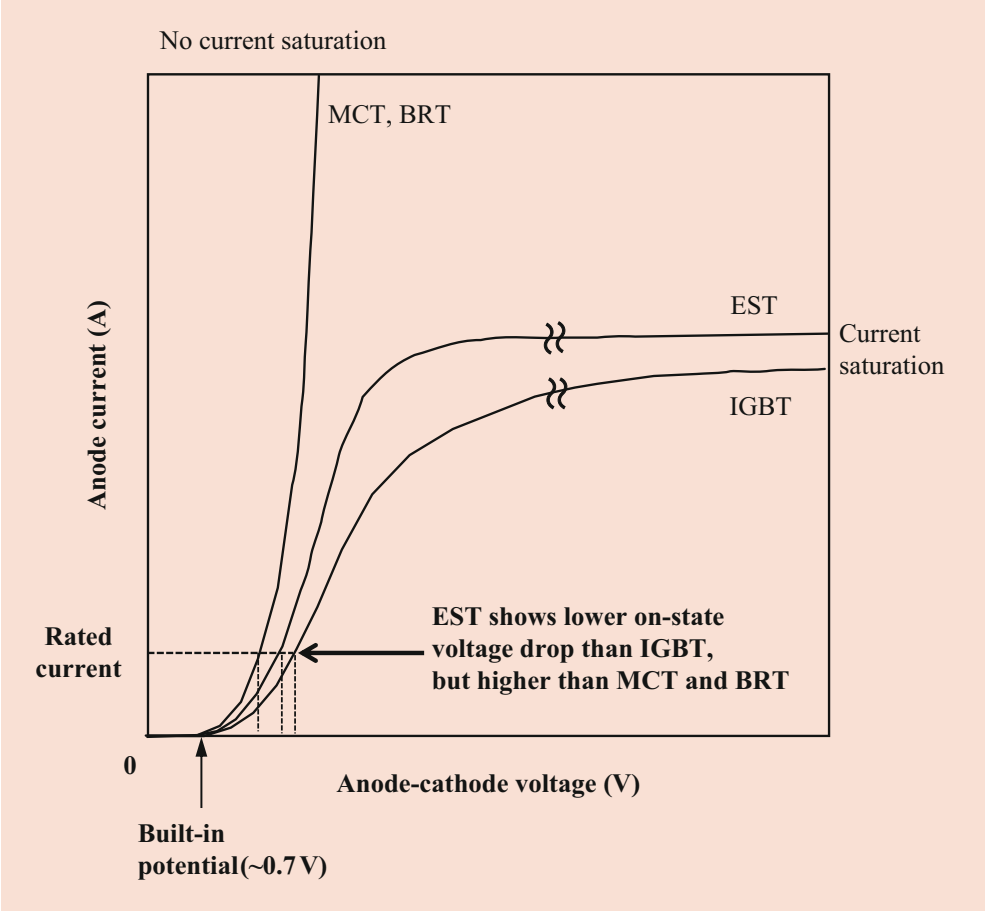

Fig. 13.66 Comparison of current-voltage curves of MCT, BRT, EST, and IGBT

forward current mode and the leakage current in the reverse blocking state are in a trade-off relation. For this reason, the metal formation should be optimized carefully to meet the specific target and application for which the SBD is designed.

Figure 13.67 shows cross sections of a junction barrier controlled Schottky (JBS) diode, along with a Schottky barrier and pin diodes. The JBS diode was presented first in [44] and has a Schottky contacts with p-n junctions consisting of a p+ region and n-drift layer incorporated into the n-drift region. The Schottky contacts are formed with the n-drift region and the ohmic contacts are with the p+ regions, so the JBS diode comprises SBDs and pin diodes connected in parallel. The JBS diodes show low-power dissipations in reverse recovery, and thus the important point to design the JBS diodes is to reduce the on-state voltage drop for the target breakdown voltage. The total on-state voltage drops are mainly the sum of the voltage drops over the Schottky junction and the n-drift layer. The important design parameters are Schottky barrier height and current ideality factor as the Schottky properties, and the dimensions (depth and width) of p+ region, and the doping concentration and thickness of the n-drift layer. The n-drift layer immediately beneath the Schottky contact is placed between p+ regions, to deplete the layer in the Schottky interface region in order to limit the leakage current, with the level of restraint correlated to the thickness of the depletion layer. When reverse voltage is applied, the depletion layers expand into the channel between the p+ regions and pinch off the Schottky barrier. With this, a potential barrier is formed, which restricts the high electric field at the Schottky interface while a further increase in reverse voltage is supported by the n-drift region. The distance between the p+ regions must be so designed that the pinch-off is completed before a high electric field at the Schottky interface exceeds the point where inordinate leakage current takes place.

When a forward voltage is applied, the unipolar current flows through the channels. The channel regions should be placed with a sufficient distance that their depletion regions do not contact each other in a forward voltage or even zero voltage application; thus, a conductive current path is kept enough through the n-drift region between Schottky interface and the n+ substrate. Since forward voltage drop results in on-state power dissipation, the thickness and doping

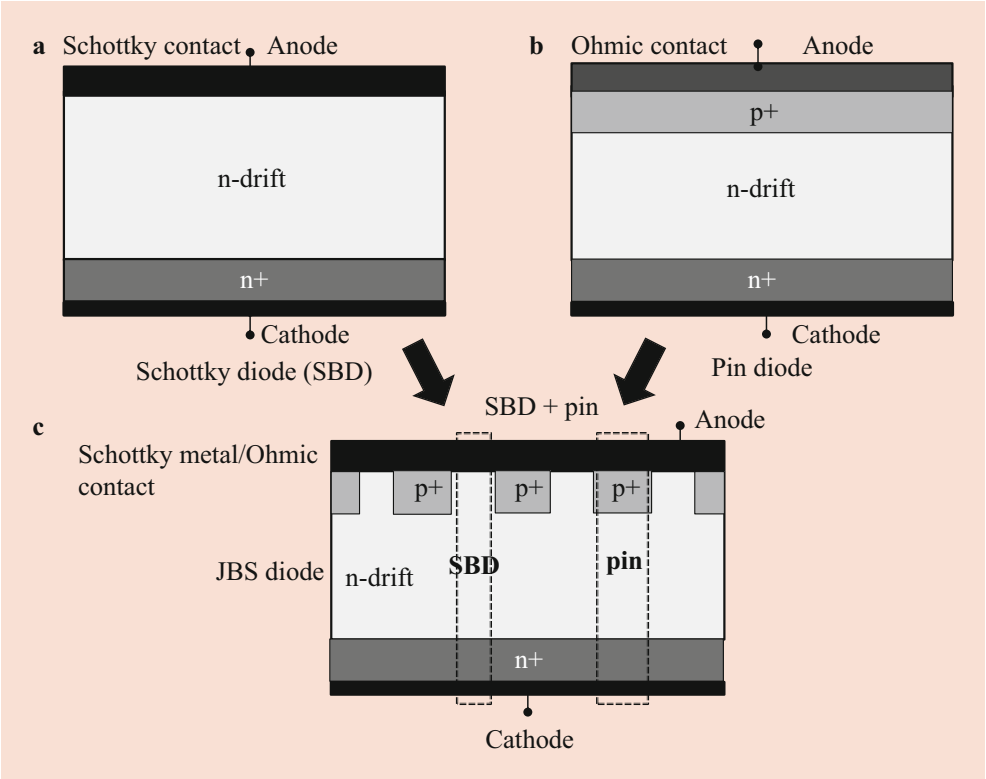

Fig. 13.67 Schematic cross section of the (a) Schottky, (b) Pin, and (c) JBS diodes

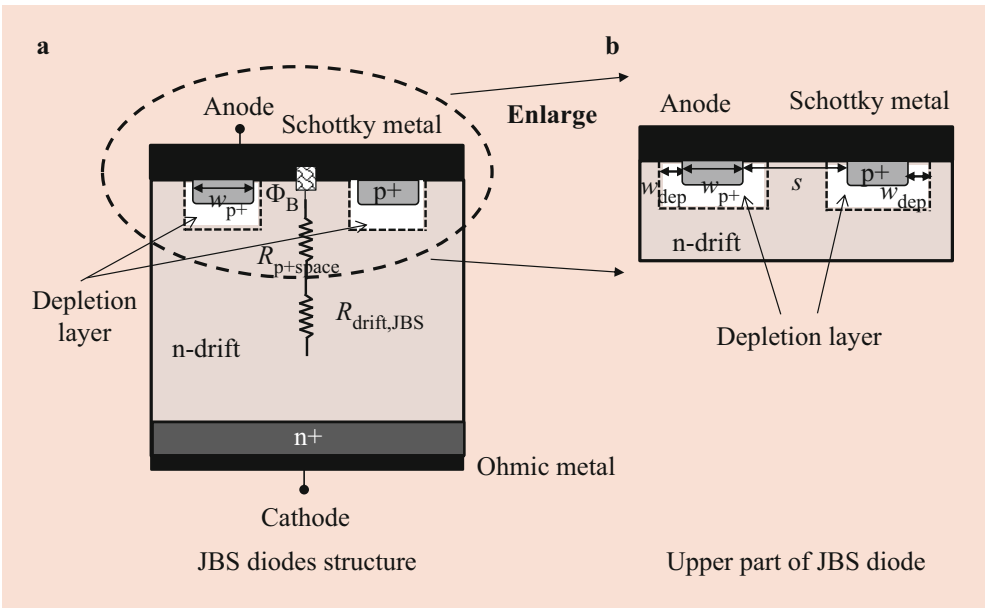

Fig. 13.68 Unit cell of JBS rectifier with geometrical parameters defined. (a) Cross section of JBS rectifier. (b) Upper part of JBS diode

concentration of the n-drift layer should be optimized in the diodes, to simultaneously attain lower on-resistance and higher blocking voltage. Figure 13.68 shows a unit cell and an enlarged view of a JBS diode. According to [130], the current density through the Schottky barrier for a stripe p+ region is given by

$$J_{\mathrm{F,JBS}} = \frac{s + w_{\mathrm{p+}}}{s - 2w_{\mathrm{dep}}} J_{\mathrm{F}}, \tag{13.45}$$

where s is the spacing in between the p+ regions, $w_{\mathrm{p+}}$ is the width of the p+ regions, and w_{dep} is the junction depletion width from the p+ regions. Based on the thermionic emission model, the total forward voltage drop of a JBS diode at a given current density is expressed by

$$V_{\mathrm{F,JBS}} = \frac{kT}{q} \ln\left(\frac{J_{\mathrm{F,JBS}}}{A^{**}T^2}\right) + \Phi_{\mathrm{B}} + R_{\mathrm{p+space}} \times J_{\mathrm{F}} + R_{\mathrm{drift,JBS}} \times J_{\mathrm{F}}, \tag{13.46}$$

where k is Boltzmann's constant, q is the charge on electron, T is the absolute temperature, J_{F} is the forward current density at $V_{\mathrm{F,JBS}}$, A^{**} is Richardson's constant, $R_{\mathrm{drift,\,JBS}}$ is the resistance of n-drift region, and $R_{\mathrm{p+\,space}}$ is the total amount of the resistance from the p+ regions and current flowing and distributing below the region. According to this equation, it is found that the main parameters to optimize are Schottky barrier height, the dimension of the p+ region (width and depth), and the resistance in n-drift region, thereby controlling the trade-off between on-state voltage drop and reverse leakage current. So, the improvement of the reverse leakage characteristics without an increase in on-resistance is achieved when the spacing and width/depth of the p+ region are optimally designed.

13.5.2 Bipolar Devices

In medium- and high-voltage applications (600–3300 V), it has become highly important to design the power bipolar rectifier, typically a pin diode with a low on-state voltage drop and good switching performances. Since IGBT modules comprise several IGBT devices and free-wheeling diodes (FWDs) mounted on an isolated substrate in the module for ease of system assembly, the superior characteristics of IGBT modules strongly depend on improvement not only in IGBT but also FWD technology. The crucial characteristics for FWDs are (i) low forward voltage drop, (ii) short reverse recovery time, (iii) small peak reverse recovery current, and (iv) soft reverse recovery characteristic. As described above (Sect. 13.3.2), IGBT modules are utilized in many power electronics applications, to control the power transmitted to the inductive load (see Fig. 13.40). After IGBT turn-on, the IGBT current increases rapidly and gets to an apex defined by the total amount of the load current and the peak reverse recovery current in the diode. In this operation, the diode current decreases at a constant rate until the diode can support voltage; and as a result, a large reverse-recovery current flows because of the stored charge. As in the case of IGBTs, pin diode reverse recovery is discussed through analysis of the reverse recovery physics of the pin diode structure. Figure 13.69 shows the current and voltage waveforms of pin diode reverse recovery for an inductive load, and Fig. 13.70

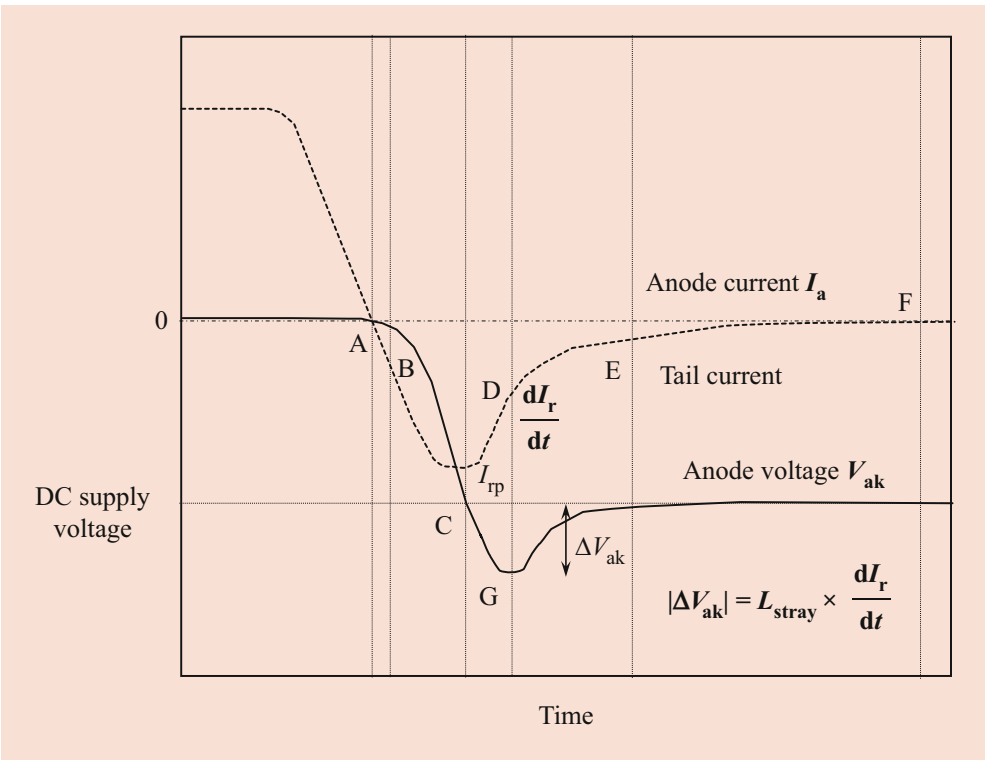

Fig. 13.69 Pin diode reverse recovery waveforms for an inductive load

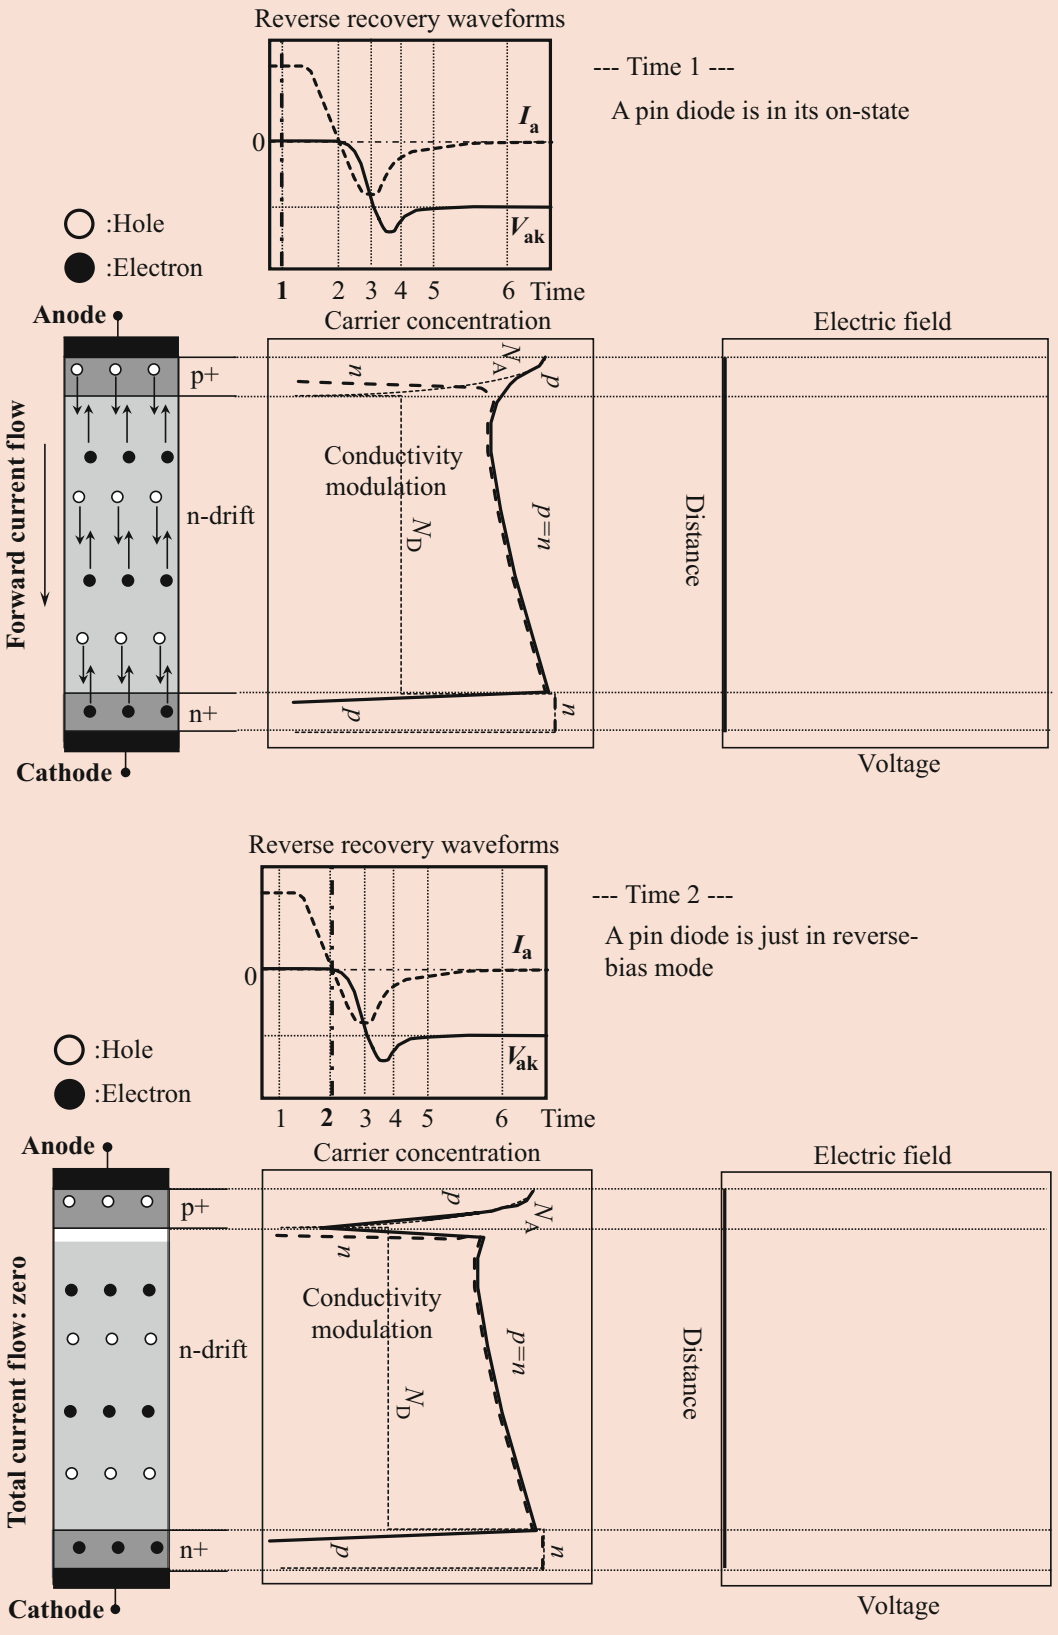

Fig. 13.70 (continued)

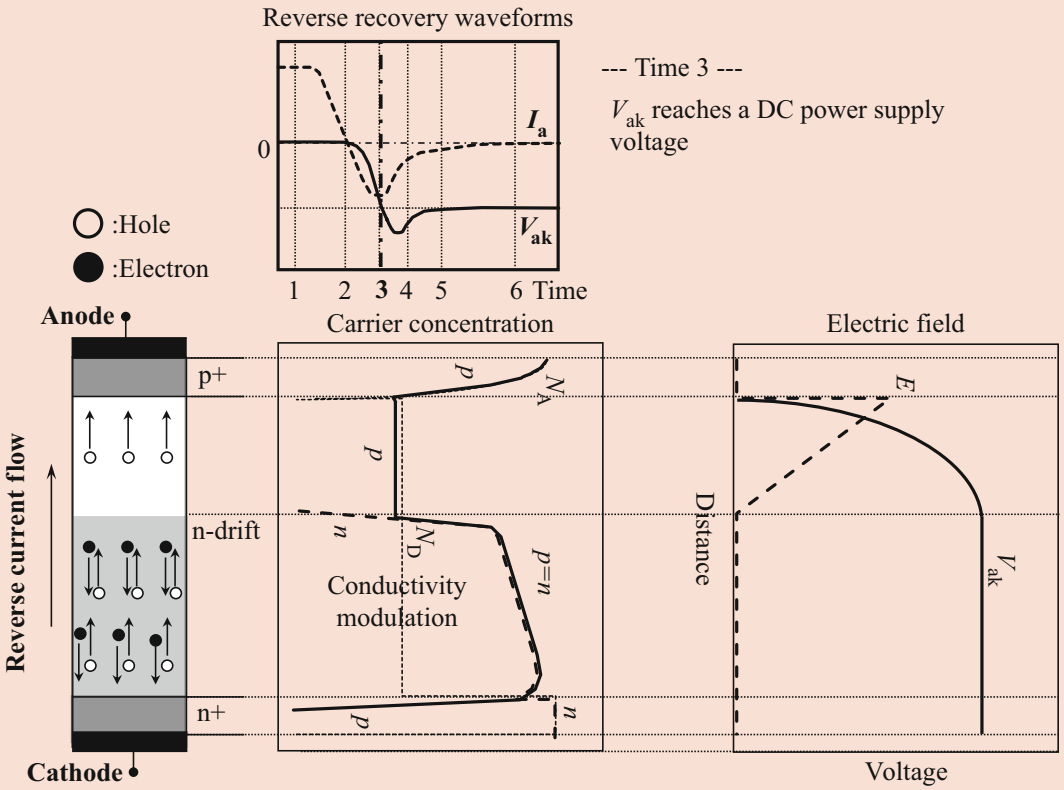

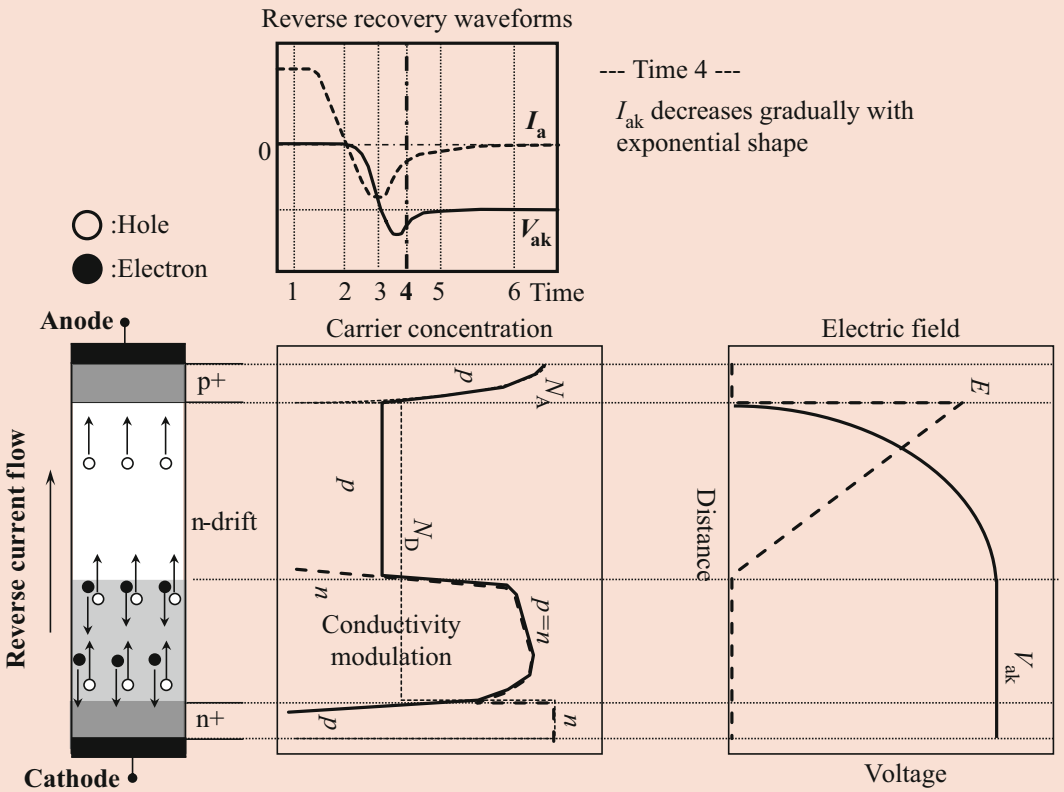

Fig. 13.70 (continued)

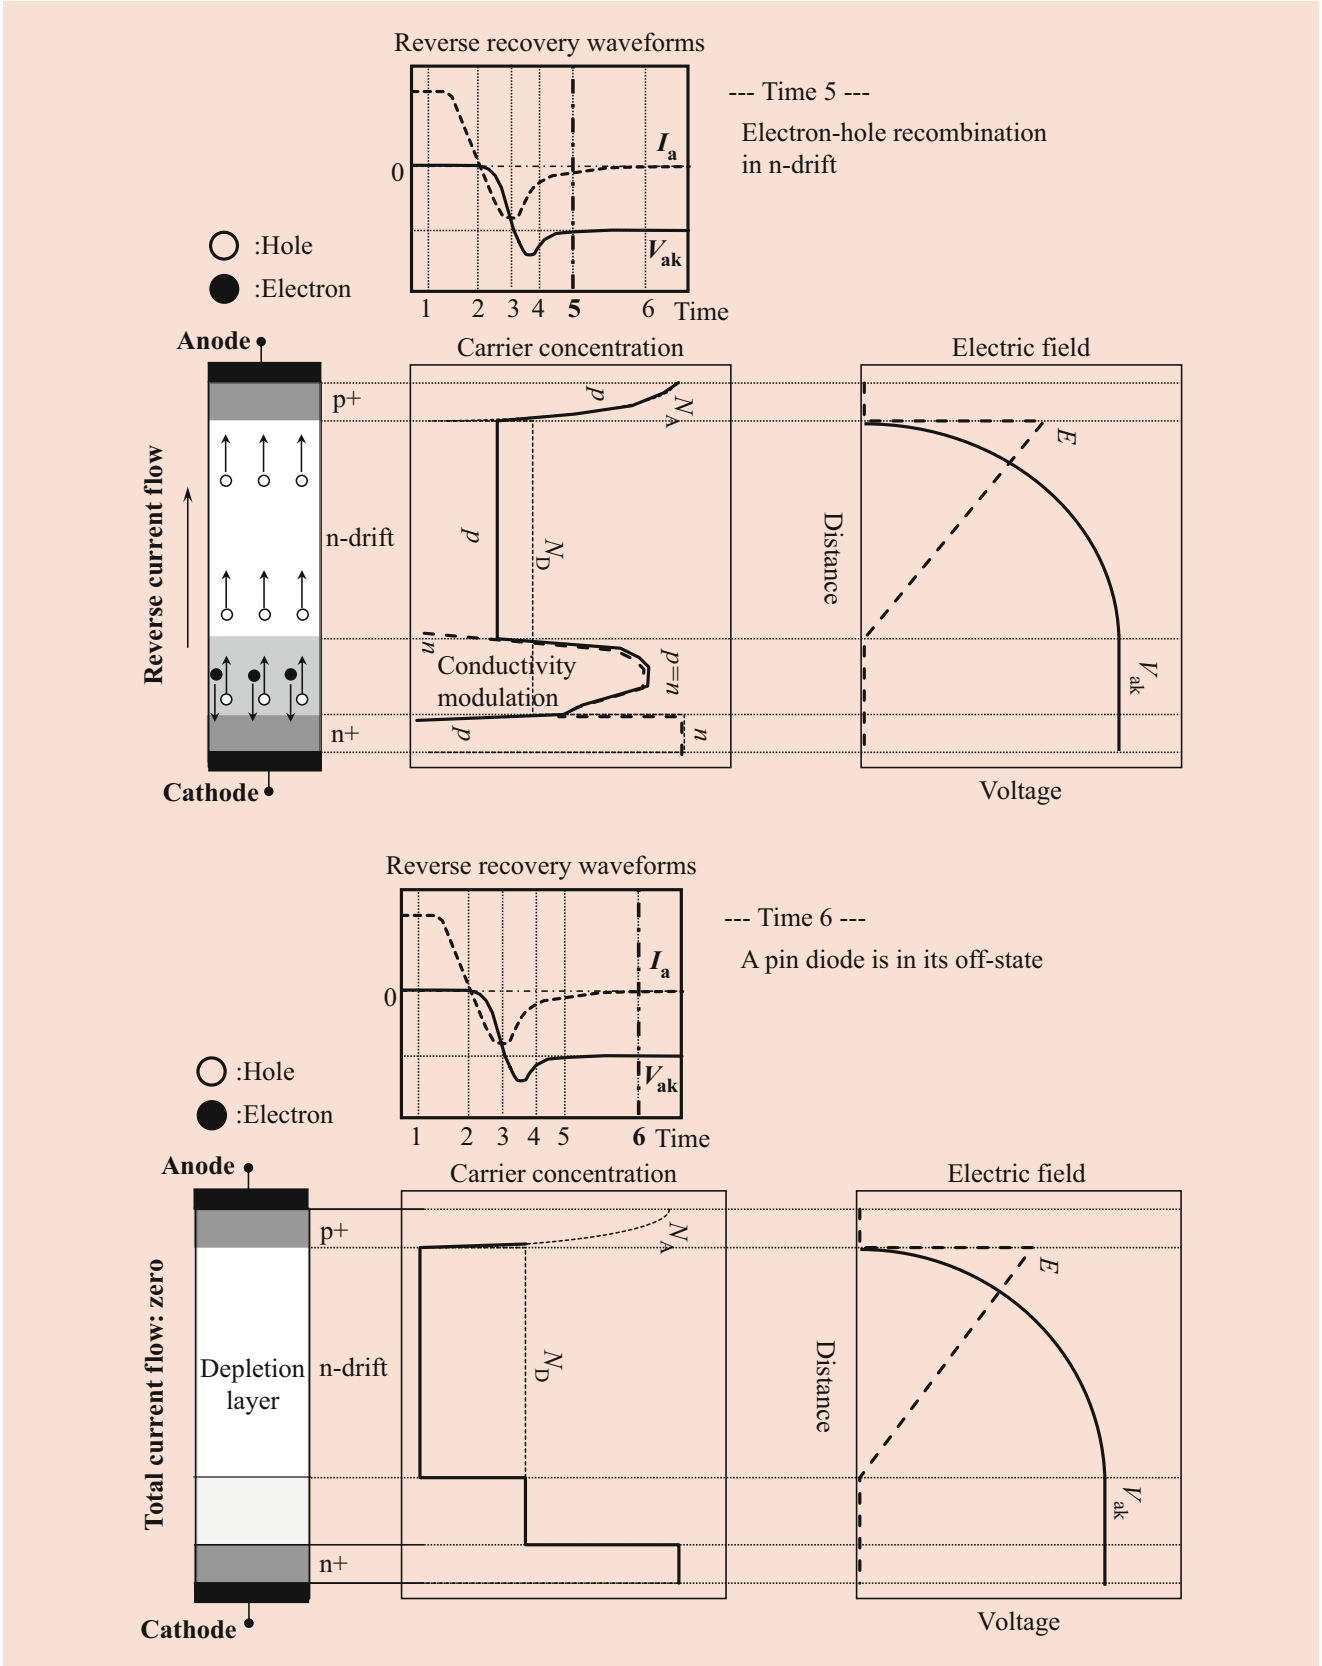

Fig. 13.70 A pin diode carrier dynamics, electric field, and voltage distribution during reverse recovery process

details the stored-carrier dynamics and electric field and voltage distribution in the reverse recovery.

When a forward current flows through pin diodes, the n-drift layer is strongly conductivity-modulated, and electron and hole concentrations become much larger than the donor density in the n-drift layer, resulting in low forward voltage drop of the diode (Time 1 in Fig. 13.70). First, the anode current in the diode decreases at a constant rate and remains in its forward-biased mode until Point A in Fig. 13.69. After the direction of current flow is changed from forward to reverse, the voltage across the diode starts to increase in the module, with the diode in reverse-bias mode, until it reaches the power source voltage ("B" in Fig. 13.69; Time 2 in Fig. 13.70). In this regime, the stored electrons and holes are swept away by depletion layer expansion. When the reverse voltage equals the voltage in the DC power source, the current flowing through the diode in reverse direction reaches its peak level, I_{rp} ("C" in Fig. 13.69; Time 3 in Fig. 13.70). Then, the current starts to transfer from the diode to the IGBT; thus, the current initially decreases relatively sharply ("D" in Fig. 13.69), and then more gradually with an exponential shape, due to the recombination of large amounts of stored electrons and holes in the n-drift layer near the n+ cathode side ("E" in Fig. 13.69; Times 4 and 5 in Fig. 13.70). As in the case of IGBT turn-off waveforms, the simultaneous presence of high voltage and current leads to large power dissipation in the pin diode, so it is necessary to lower the level of the tail current and shorten the time duration of the turn-off operation.

It should be noted that the sharp increase in the anode or surge voltage ("G" in Fig. 13.69) is caused by a sudden decrease in the diode anode current ($\mathrm{d}I/\mathrm{d}t$) associated with stray inductance L_{stray} in the circuit ($L_{stray} \times \mathrm{d}I/\mathrm{d}t$). This is referred to as a "hard recovery characteristic" and could cause noise emission and device failure. Therefore, optimal design of the forward voltage drop, reverse-recovery characteristics, and surge voltage reduction in the pin diode are also strongly required in order to achieve superior circuit efficiency in voltage source converters. Finally, the anode current falls to zero and the off state is reached ("F" in Fig. 13.69; Time 6 in Fig. 13.70).

As in the IGBT switching operation, the high voltage and current present at the same time, resulting in large power loss in the diode. Since the peak reverse recovery current flows through the IGBT, which controls this switching operation, it is highly important to minimize the peak level of the reverse recovery current and reverse recovery time of the diode (i.e., the duration of the reverse recovery operation).

It should be noted that the sharp increase in the anode voltage in reverse direction (i.e., the surge voltage) is caused by a sudden decrease in the diode current ($\mathrm{d}I/\mathrm{d}t$) associated with stray inductance L_{stray} in the circuit ($L_{stray} \times \mathrm{d}I/\mathrm{d}t$). Therefore, optimal design for forward voltage drop, reverse recovery, and surge voltage reduction in the diode is also strongly required in order to achieve superior circuit efficiency in the voltage source converter. The requirement for soft reverse recovery behavior derives from the high-voltage spikes that can occur if the reverse recovery $\mathrm{d}I/\mathrm{d}t$ is large. The pin diode technological innovation presented a breakthrough in removal of the surge and spike voltage and current and voltage oscillation under any severe conditions as well as in power dissipation and cost reduction. The tendency for oscillation enhances during reverse recovery of the lower current, especially around one-tenth of the nominal current, so the softness characteristic can be improved by an enhanced holes and electrons injection in the device; however, this results in higher recovery power dissipations at the pin diode. The device was designed and developed to show the maximized softness with a minimum of injected holes and electrons; consequently, the latest pin diodes must exhibit both softness characteristic and the minimized recovery loss with a very smooth switching waveform in high output power applications. A variety of high-voltage diodes have been proposed and investigated in the attempt to achieve these goals [131–133]. Figure 13.71 shows the structures of the static shielding diode (SSD) and merged pin and Schottky (MPS) diode. In these diodes, the goal is to minimize the amount of stored charge within the n-drift region during a forward conduction operation, by reducing the hole injection of the p+/n- surface junction.

SSD and MPS Diodes

In the SSD (Fig. 13.71a), a shallow lightly doped p-layer and a part of the n-layer are surrounded by a heavily doped p+ region. The width of the p-n junction surrounded by the p+ region is defined as the channel width W_{ch} . The p-layer is thin and has a low doping concentration. In the SSD, the main forward current path is the p-n-n+ diode region. It has been shown that the on-state voltage drops and reverse recovery time in a p-n-n + diode decreases with decreasing doping concentration in the p-layer [44], and this provides the SSD with low-loss, high-speed capability. The channel region is narrowed such that the electrical field near the p-n junction is lowered in the reverse blocking mode, resulting in higher blocking voltage. And as the p-n junction is shielded by applying a reverse voltage, the diode is designated as a static shielding diode or SSD.

The MPS diode design concept is based on the integration of a Schottky contact region and p-n junction of p+ region and n-drift region grid structure, as shown in Fig. 13.71b. In terms of reverse blocking capability, pure Schottky rectifiers fabricated for high breakdown voltage have been shown to often exhibit extremely soft breakdown waveforms, which has been associated with the Schottky barrier lowering effect. However, the barrier lowering effect can be reduced in the MPS diode, through the use of p-n junctions surrounding

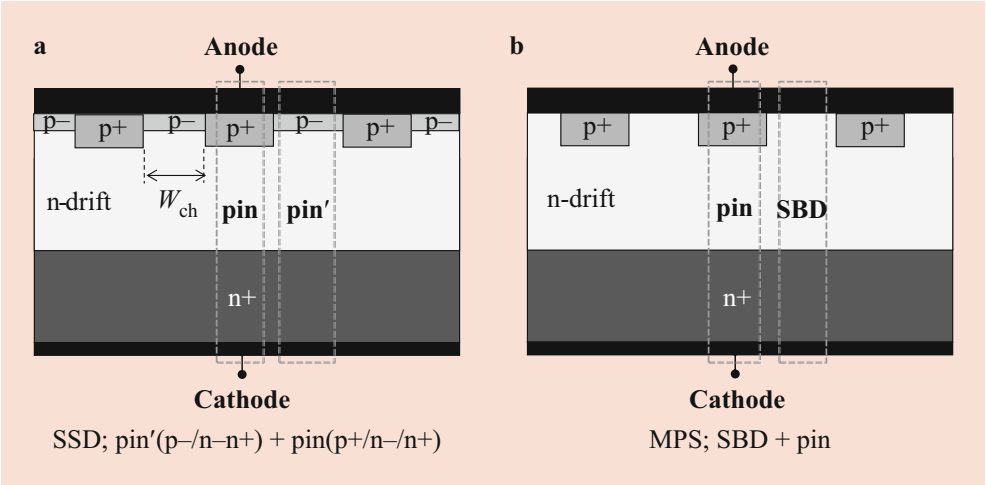

Fig. 13.71 Cross section of the power rectifier structure. (**a**) SSD; (**b**) MPS

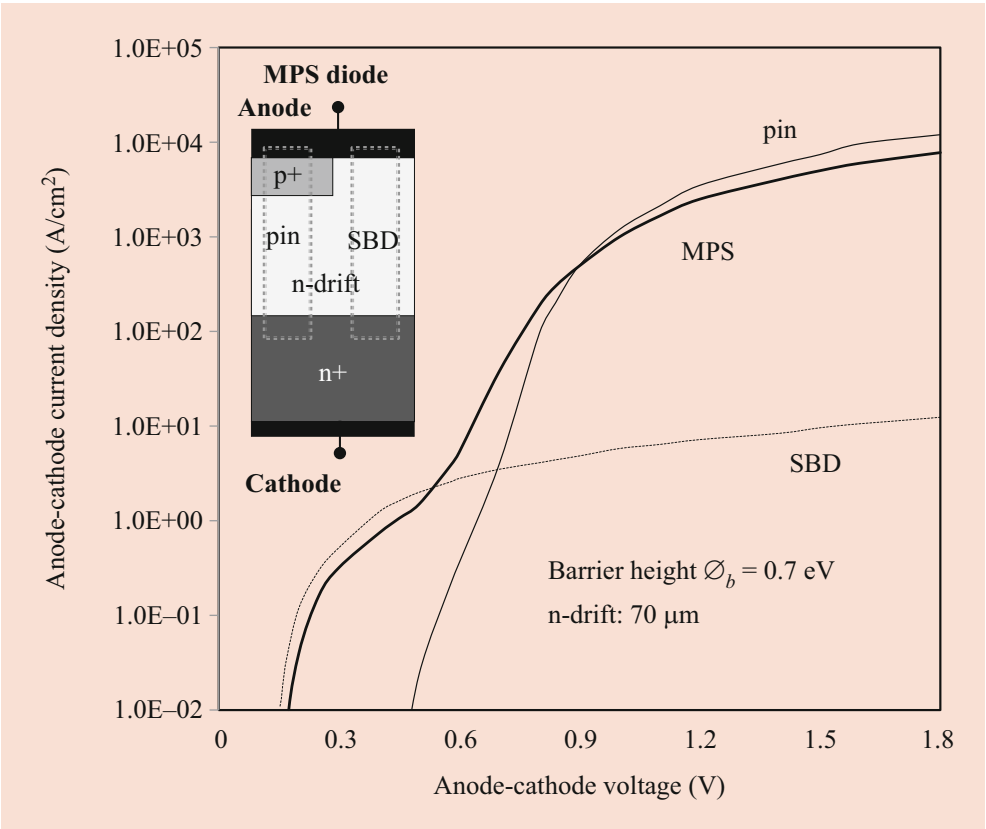

Fig. 13.72 An example of calculated forward characteristics of an MPS diode with 50% Schottky area (breakdown voltage = 700 V)

the Schottky interface. The depletion layers related to these junctions produce a potential barrier below the Schottky interface, preventing the electric field from increasing at the interface. In this way, the MPS diode can be designed to show a breakdown voltage equal to that of the pin diode. Figure 13.72 shows examples of calculated forward characteristics. The MPS diode operates at current densities intermediate to the Schottky and pin diodes at forward voltage drops of less than roughly 0.6 V. However, at higher forward voltage drops, the diode operates at a higher current density than these diodes. In terms of reverse recovery, the MPS diode exhibits a lower peak recovery current, shorter recovery time, and smaller dI/dt. This improvement in performance is because of the decrease in stored electrons and holes in the n-drift region. Consequently, an MPS diode trade-off curve between forward voltage drop and stored electrons and holes

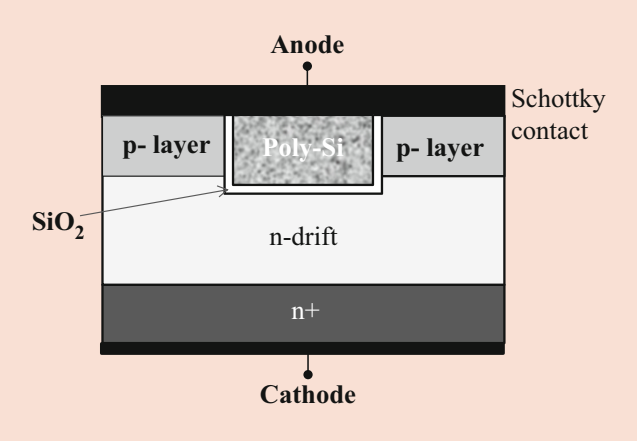

Fig. 13.73 Cross section of the trench MOS barrier Schottky diode structure

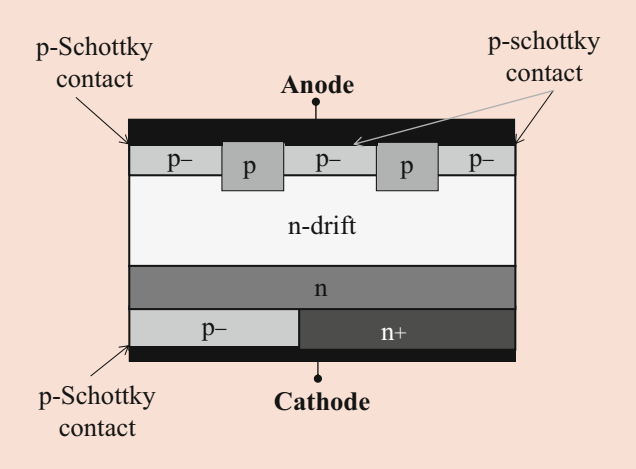

Fig. 13.74 Cross section of the Schottky controlled injection diode structure

has been obtained by changing the areal percentage of the Schottky region while maintaining a constant lifetime [134]. The results clearly indicate that a much superior trade-off is achieved by optimizing the width and depth of each region in the device in the MPS diode. Notably, this method of MPS diode optimization has the advantage that it can be performed during device layout and design, without the additional processing costs associated with the lifetime control processes used in pin diode design.

State-of-the-Art Diode Structure

Diode improvement is steadily undergoing structural optimization of the anode and cathode regions, including advancements in lifetime distribution design. Given the comparative simplicity of the basic diode structure, there remains room for further improvement in characteristics such as forward voltage drop and recovery loss, through optimization of the anode structure and lifetime control is still available at this time [134–137]. Hsu et al., for example, reported improvement in the on-resistance of 300 V and 600 V diodes, with the use of so-called trench MOS barrier Schottky (TMBS) (Fig. 13.73) or tandem PiN Schottky (TPS) structures [135, 136], in which the anode layer is composed of a combination of a thin p-layer and a Schottky barrier junction. Since the Schottky characteristics can be maintained, the forward voltage drop can be dramatically reduced; and since the minority carriers in the n-drift region can be minimized in the on-state, the trade-off characteristic between the forward voltage drop and reverse recovery loss is dramatically improved. Kameyama et al. [137] reported that by controlling the hole and electron trap density, it is possible to fabricate diodes with low loss dissipation and spike voltage suppression in reverse recovery transient. In their study, the energy level and hole and electron trap concentration were adjusted by varying the helium irradiation and annealing process parameters. Matsudai et al. proposed the so-called Schottky controlled injection diode structure [138] (Fig. 13.74), in which a flat and linear carrier profile is achieved during the on-state by controlling the electron flow in the p-Schottky region, low hole injection from the p-anode region, and electron injection from the cathode and by ensuring a high lifetime effect in the drift region; with the result that low forward voltage drop, short reverse recovery time, and small leakage current can be simultaneously attained even at high temperatures.

Abstract

Power and energy in all sectors of the economy are controlled using power semiconductor devices. Power electronics has relied up on silicon power devices for over half a century. Improvement in performance by replacing silicon devices with silicon carbide devices was recognized in the early 1980s. Subsequent progress with the growth of high-quality large diameters SiC wafers and innovations in SiC device structures have enabled their commercialization since 2005. This chapter discusses the physics and design of SiC unipolar devices, as well as their applications.

14.1 Introduction

The efficient generation, distribution, and management of power is essential in modern society to mitigate environmental impact and global warming. This was accomplished using bipolar silicon power devices in the 1950s. Silicon bipolar transistor and thyristor ratings were enlarged rapidly to serve

more applications. The cumbersome control and protection circuitry for these devices led to high cost and unwieldy solutions. The advent of MOS technology for digital circuits created a new class of devices in the 1970s for power switching applications. Silicon power MOSFETs are now extensively used in high-frequency applications with relatively low operating voltages (under 100 V). Another class of silicon devices evolved in the 1980s with the merger of MOS and bipolar physics. The Insulated Gate Bipolar Transistor (IGBT) [1] has been the most successful innovation among these types of devices. It has become the technology of choice for all medium- and high-power applications due to high power density, simple interface, and ruggedness.

The concept of two-dimensional charge coupling was created in the 1990s to significantly reduce the on-state resistance of silicon power devices [2, 3]. An electrode embedded inside a deep vertical trench formed the basis for the first approach. A new generation of silicon power MOSFETs and diodes has been commercialized with voltage ratings of 30–200 V with this method. A second approach relies up on alternating vertical columns of P and N type silicon regions. Power MOSFETs with blocking voltages around 600 V have been commercialized using this method. All wide bandgap semiconductor power devices must compete with these advanced silicon power devices that are now available in the market.

Applications for power devices range over a broad spectrum of power levels and frequencies as shown in Fig. 14.1. On one extreme, HVDC power distribution and electric trains require control of megawatts of power at low frequencies. On the other extreme, very high frequency applications require only 100 watts of power. Device power ratings decrease when the operating frequency increases. These applications are primarily utilize silicon devices today.

The current and voltage requirements for some applications are shown in Fig. 14.2. In telecommunications and display drives, multiple high-voltage devices are required. Silicon devices can be integrated on a single monolithic chip when the current falls below 1 ampere for these applications. Discrete power MOSFETs are needed for automotive

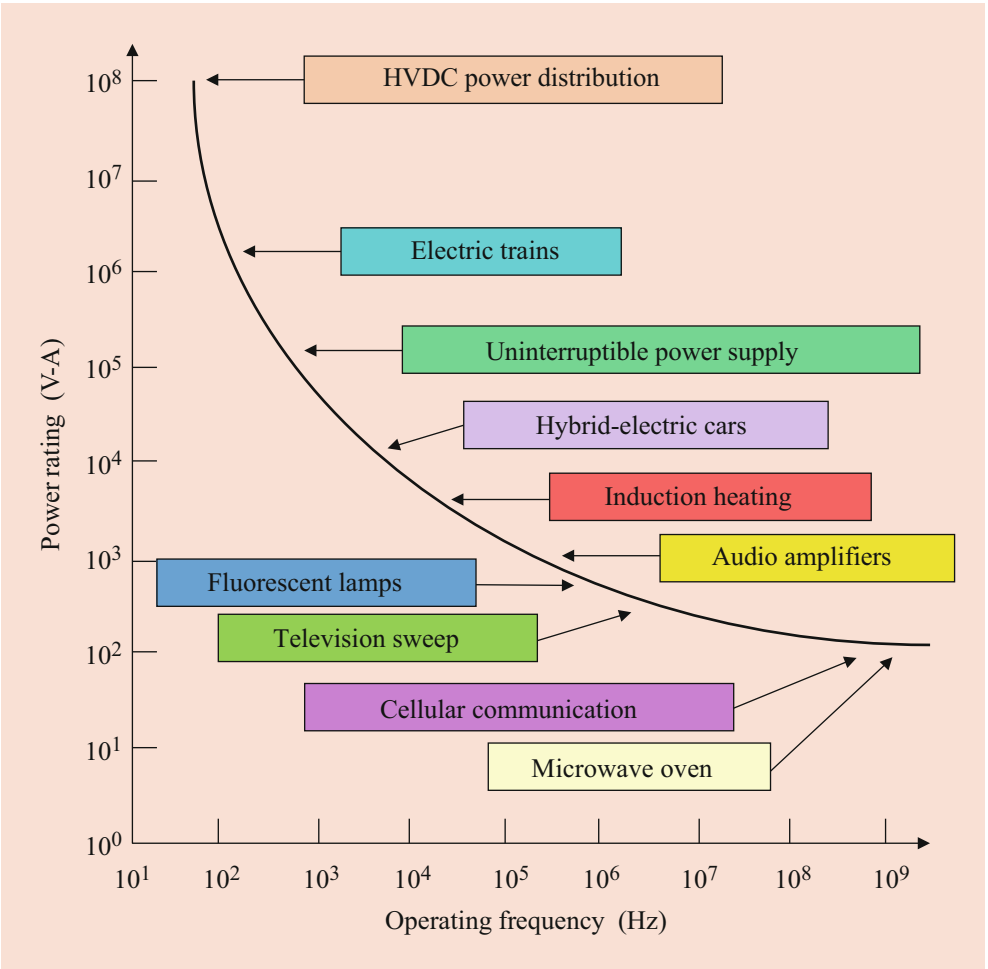

Fig. 14.1 Power semiconductor device applications

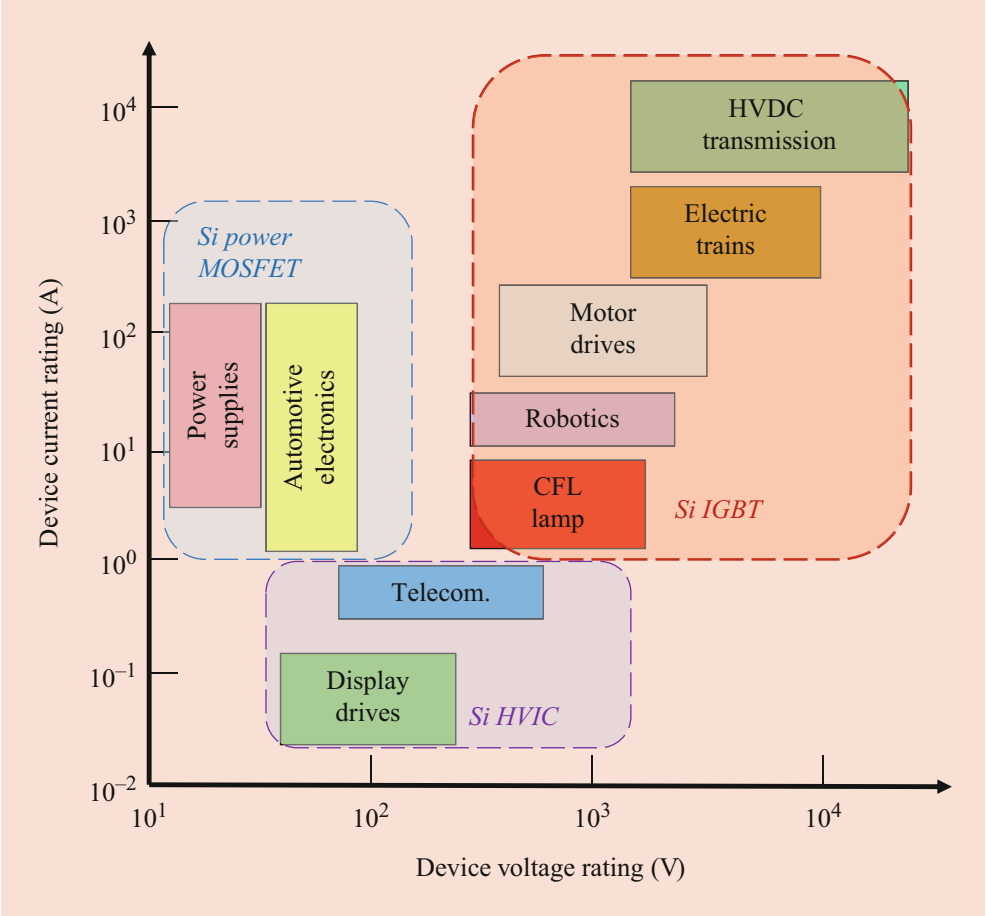

Fig. 14.2 Silicon power device ratings for various applications

electronics and switch mode power supplies where high currents must be delivered. Silicon IGBT modules have been developed during the last decade with blocking voltages of 6500 V and current handling capability of 1000 A. They have enabled voltage source converters for HVDC power distribution. For applications with operating voltages over 300 V and high current handling capability, the IGBT has been proven to be the best technology. All sectors of the economy, including consumer, industrial, transportation, lighting, medical, defense, and renewable energy generation, rely up on this device today [1].

Despite huge strides in improving the performance of silicon power MOSFETs and IGBTs during the past 25 years, it has become apparent that the performance of power electronic applications can be enhanced in terms of efficiency, size, and weight by replacement of silicon devices with devices made from wide band gap semiconductors. This has motived the development of power devices from silicon carbide material due to its large band gap of 3.3 eV compared with 1.1 eV for silicon. This chapter discusses the merits of silicon carbide and the performance of power rectifiers and MOSFETs that can be made using this material.

14.2 Ideal Specific on-Resistance for Silicon Carbide

The performance of vertical unipolar power devices is constrained by the ideal specific on-resistance for the drift region given by [4]

$$R_{\text{on-ideal}} = \frac{4\ \text{BV}^2}{\varepsilon_S\ \mu_n\ E_C^3} \tag{14.1}$$

where BV is the device breakdown voltage, ε_S is the semiconductor dielectric constant, μ_n is the electron mobility, and E_C is the critical electric field for breakdown. The denominator is now commonly referred to as Baliga's Figure-of-Merit (BFOM) [5, 6] for semiconductors:

$$\text{BFOM} = \varepsilon_S\ \mu_n\ E_C^3 = \frac{4\ \text{BV}^2}{R_{\text{on-ideal}}} \tag{14.2}$$

It allows assessment of the maximum power handling capability (W/cm^2) of unipolar power devices made from var-

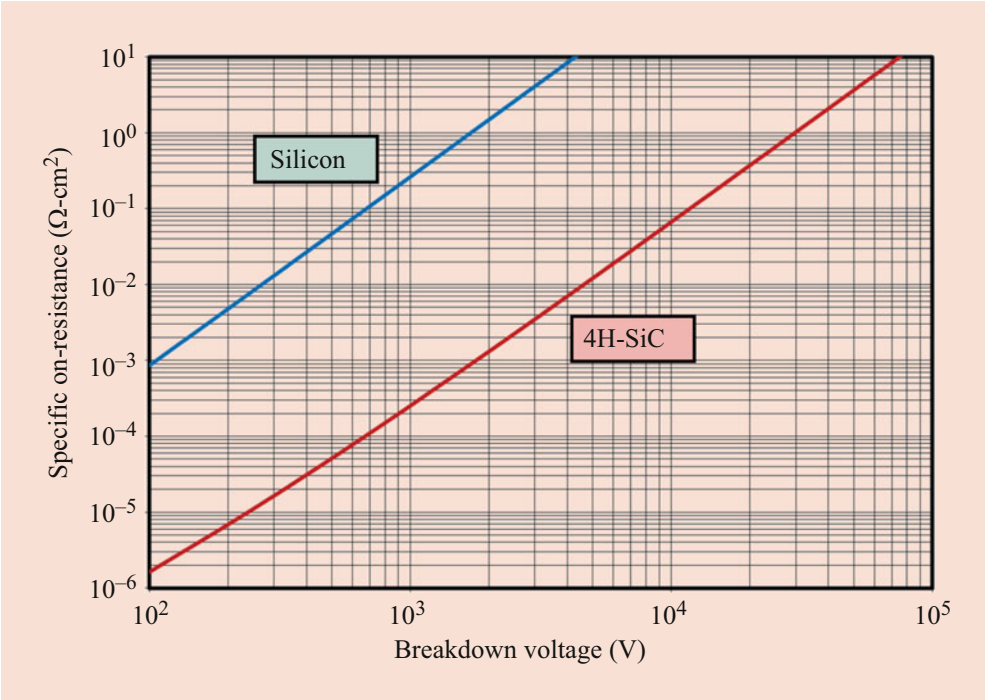

Fig. 14.3 Ideal specific on-resistance for silicon carbide power devices

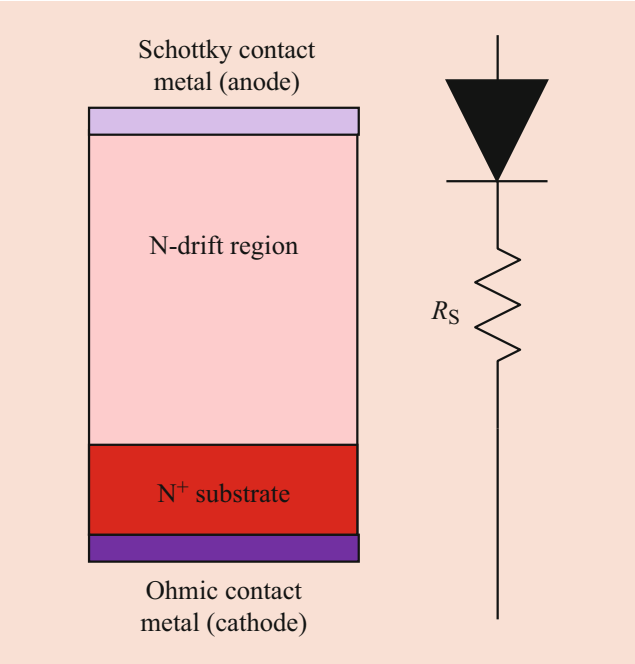

Fig. 14.4 Basic power Schottky rectifier structure

ious materials. The BFOM for silicon carbide is 1000 times superior to that for silicon mainly due to the approximately tenfold increase in the critical electric field for breakdown. Silicon carbide unipolar high-voltage power devices with low on-state voltage drop can be created due to the large BFOM for this material.

The 4H-SiC ideal specific on-resistance is shown in Fig. 14.3 for devices with breakdown voltages ranging from 100 to 100,000 V. The values for the ideal specific on-resistance of silicon devices are shown in the figure for comparison. The ratio of the specific on-resistance for these materials increases from about 500 at 100 V to 1300 at 40,000 V. Unipolar SiC power devices such as Schottky rectifiers and power MOSFETs have been created with low on-state voltage drop and excellent switching speed. They have begun to replace silicon bipolar power devices such as P-i-N rectifiers and IGBTs.

14.3 Silicon Carbide Power Rectifiers

Power P-i-N diodes made from silicon rely up on the injection of minority carriers during on-state current flow [4] to achieve low on-state power losses. The reverse recovery process produces a large reverse current during turn-off for removal of these minority carriers. Significant power losses occur in the diode and the power switches in circuits due to the reverse recovery current. The unipolar Schottky rectifier operates without minority carrier injection eliminating the reverse recovery current. The power Schottky rectifier structure is illustrated in Fig. 14.4. It has an n-drift region designed to support the reverse blocking voltage. The drift region resistance increases drastically with increasing blocking voltage. Commercially available silicon Schottky rectifiers are limited to blocking voltage rating up to 150 V because the

on-state voltage drop becomes unacceptably large. Silicon P-i-N rectifiers are required circuits with larger operating voltages in spite of their high switching losses.

The low drift region resistance of silicon carbide Schottky rectifiers, as shown in Fig. 14.3, allows creating low on-state voltage drop devices with very high blocking voltage capability. The on-state characteristics of SiC Schottky rectifiers with various voltage ratings are shown in Fig. 14.5 for the case of a typical metal-semiconductor barrier height of 1.1 eV. The current flow is limited by the Schottky barrier at low on-state current levels. The series resistance of the drift region begins to contribute to the on-state voltage drop when the current density exceeds 100 A/cm^2. This contribution is small for devices with blocking voltages of up to 3000 V. The on-state voltage drop has an acceptable value even for devices with a blocking voltage of 5000 V. SiC Schottky rectifiers can therefore be expected to replace silicon P-i-N rectifiers with blocking voltages as high as 5000 V.

A large increase in the reverse leakage current with increasing reverse bias voltage is observed in SiC Schottky rectifiers. The reverse leakage current goes up by five orders of magnitude due to the Schottky barrier lowering and tunneling phenomena as demonstrated in Fig. 14.6. The resulting larger power loss during the blocking mode of operation becomes a serious thermal runaway problem for these rectifiers.

The Junction-Barrier controlled Schottky (JBS) structure [7, 8], shown in Fig. 14.7, was proposed to prevent the rapid increase in leakage current for Schottky rectifiers with increasing reverse bias voltage. In this structure, P^+ regions are selectively introduced below the Schottky contacts. The depletion region developed at the junction forms a potential barrier under the Schottky contact suppressing the electric field at the Schottky contact. The Schottky barrier lowering and tunneling phenomena are mitigated by the lower electric field at the Schottky contact [2].

The reduction in leakage current achievable with the JBS structure is demonstrated in Fig. 14.8. Here, the width of the P^+ region was kept fixed at 1 μm while changing the cell pitch. The increase in leakage current is only 10 times for a cell pitch of 2 μm (i.e. a Schottky contact width in the cell of 1 μm) compared with 100,000 times for the Schottky diode.

The P^+ region reduces the area of the Schottky contact and increases the drift region resistance by constriction of current flow between the junctions. The on-state voltage drop increases when compared with the Schottky rectifier as shown in Fig. 14.9. The increase in on-state voltage drop is small (~100 mV) if the cell pitch of 2 μm is used. This cell pitch is adequate to suppress the increase in leakage current as shown in Fig. 14.8.

All commercially available SiC power rectifiers utilize the JBS structure. Devices with voltage ratings of 1.2 kV have been used as anti-parallel diodes for silicon IGBTs since 2005. Devices with voltage ratings of 1.7 kV have recently been commercialized. Eventually, SiC JBS rectifiers are expected to become commercially available with voltage ratings extending from 600 V to 5 kV.

14.4 Silicon Power MOSFETs

Silicon power MOSFET with blocking voltages below 150 V is available from many companies. Their structures are shown in Fig. 14.10. The P-base and N$^+$ source regions are self-aligned to the edge of the polysilicon gate electrode in the D-MOSFET structure. This is achieved by ion-implantation of boron flowed by its drive-in cycle to create the P-base region and then ion-implantation of phosphorus with its drive-in cycles to create the N$^+$ source regions. The difference in the lateral diffusion of the impurities under the gate electrode defines the channel length. A positive drain bias is supported across the P-base/N-drift region junction. The doping concentration and thickness of the drift region decides the voltage blocking capability. A rapid increase in the drift region resistance with increasing blocking voltage limits silicon power MOSFETs to below 150 V [4].

The gate electrode is embedded within a trench etched into the silicon surface for the silicon U-MOSFET structure shown in Fig. 14.10. The vertical extension of the P-base and N$^+$ source regions, as determined by the ion-implant energies and drive times for the dopants, determine the channel length. The channel is formed on the side-wall of the trench at the surface of the P-base region. The on-state resistance of the silicon U-MOSFET structure is less than that of the D-MOSFET structure because of elimination of the JFET region [2].

An important advancement in silicon power MOSFET technology was achieved by the introduction of the charge coupling concept. It allowed supporting high drain voltages with large drift region doping concentrations [3]. The silicon charge coupled graded-doped GD-MOSFET structure is illustrated in Fig. 14.11a [9, 10]. A deep trench region with a source connected electrode is added to the drift

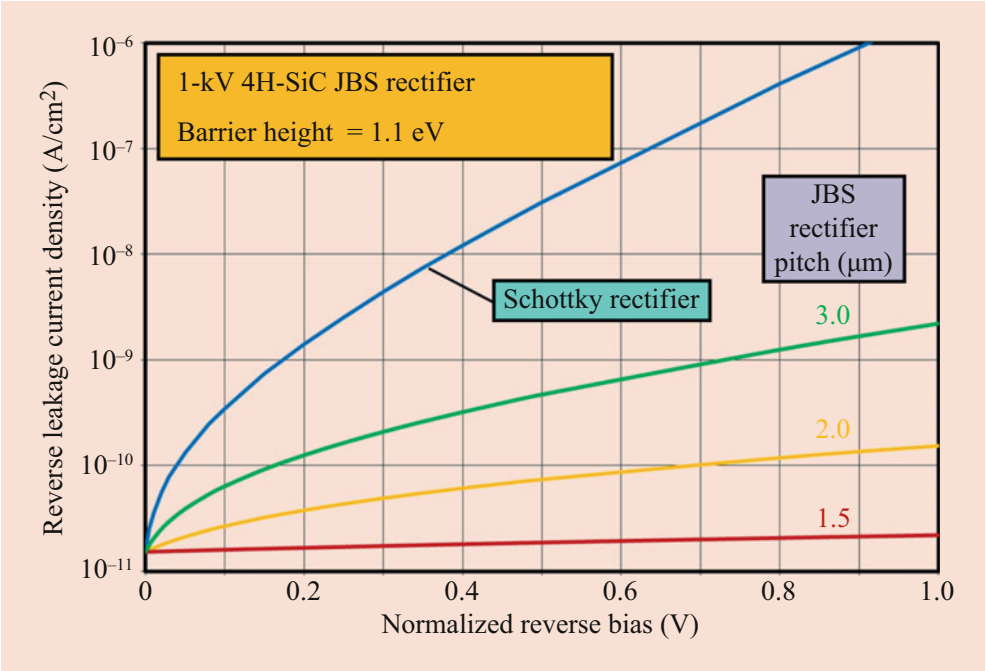

Fig. 14.8 Reduction of leakage current with the JBS structure

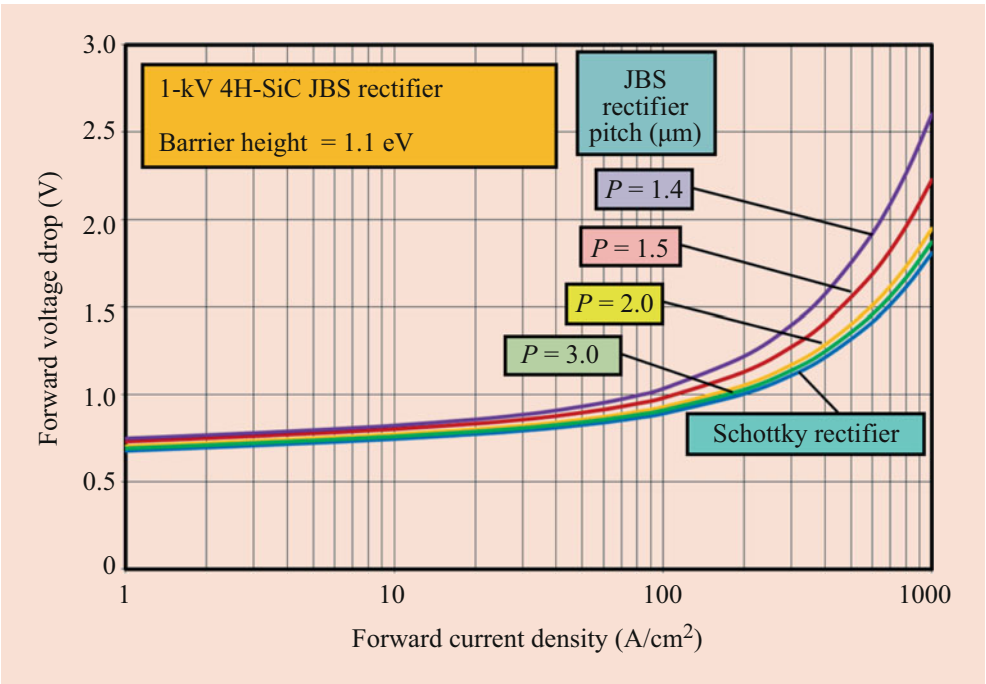

Fig. 14.9 Increase in on-state voltage drop for the JBS rectifier structure

region. A graded doping profile in the drift region with high doping concentrations [11] can be used to achieve blocking voltages greater than the parallel-plane breakdown voltage. The specific on-resistance of these devices is much (5–25 times) smaller than that of conventional silicon devices with blocking voltages ranging from 50 to 1000 V [3]. These devices have also been called split-gate devices.

A charge-coupled silicon power MOSFET with the superjunction structure is shown in Fig. 14.11b. The vertical P-N junction formed between columns of P and N drift regions [12] produces the charge coupling effect. This device has been optimized for blocking voltages between 600 and 900 V [3]. It has 3–10 times lower specific on-resistance compared with the conventional silicon power MOSFETs for

a breakdown voltage of 600 V. The specific on-resistance of 600 V rated superjunction devices is about 10 mΩ-cm^2.

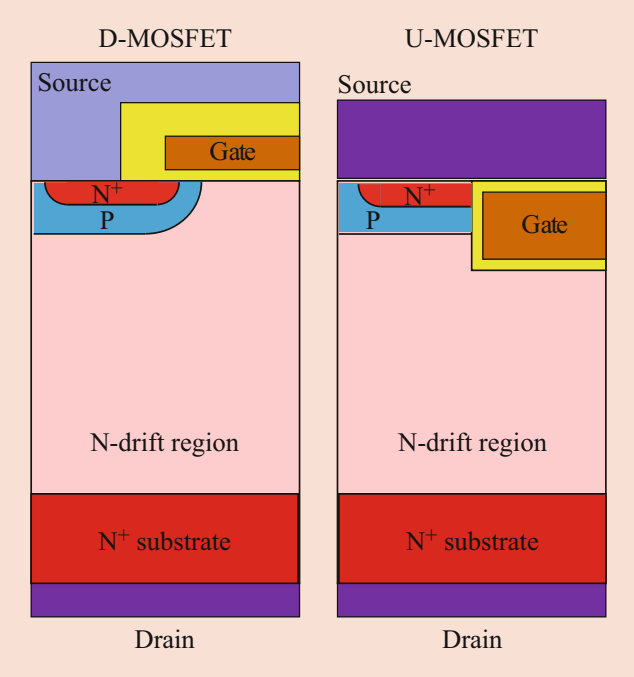

Fig. 14.10 Silicon power MOSFET structures

Products have been released by many companies using the above approaches. SiC power switches must compete with these new charge coupled silicon power MOSFET products. The charge coupled silicon devices require a more expensive fabrication process. This reduces the cost differential with SiC power MOSFETs.

14.5 SiC Power DI-MOSFET Structure

Due to the low diffusion coefficients for dopants in silicon carbide, it was proposed [13] that photoresist masks be used to stagger the P-base and N^+ source ion implantations as illustrated in Fig. 14.12. High-voltage power MOSFETs, called DI-MOSFETs because of the Double-Implant process, were subsequently made using the approach [14].

14.5.1 Blocking Characteristics

The voltage is supported by a depletion region formed on both sides of the P-base/N-drift junction in the forward blocking mode of the SiC planar power MOSFET structure. The maximum blocking voltage occurs when the electric field at the junction becoming equal to the critical electric field for breakdown. The parasitic N^+/P/N bipolar transistor is suppressed by short-circuiting the N^+ source and P-base

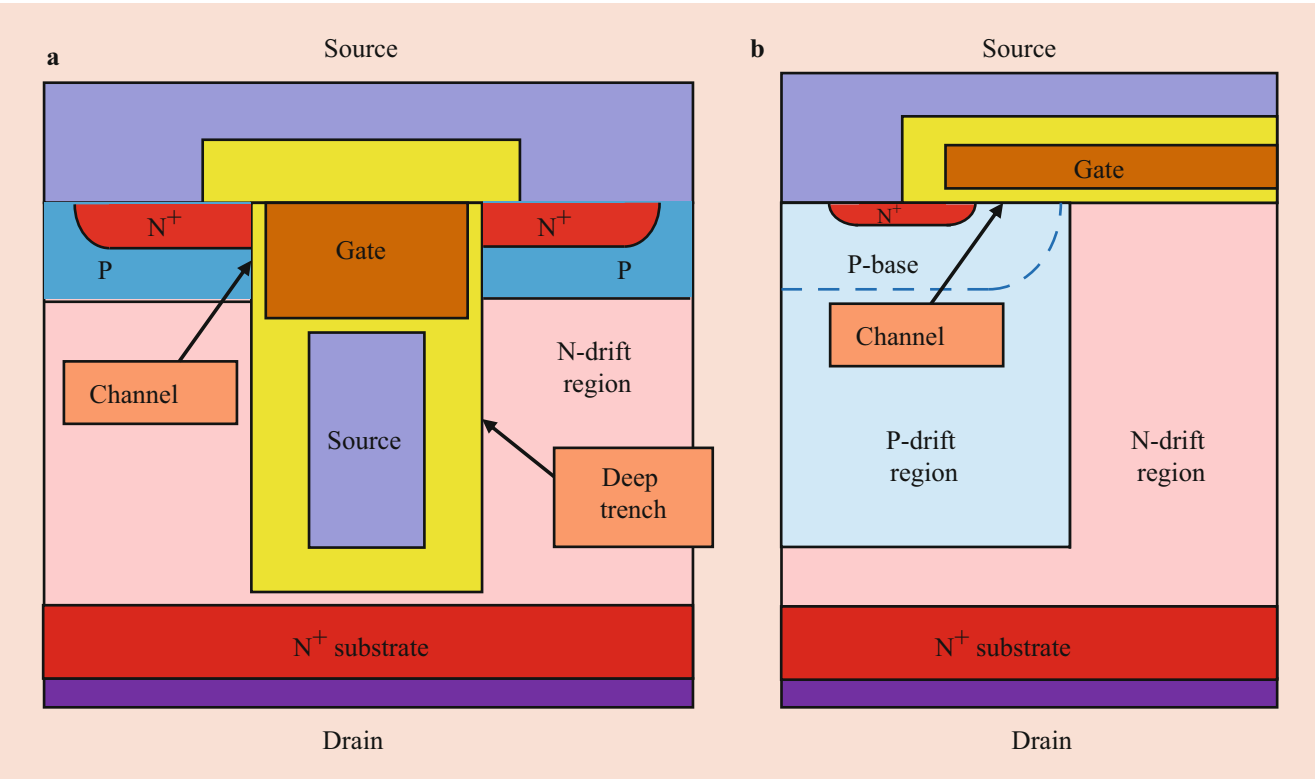

Fig. 14.11 Charge-coupled silicon power MOSFET structures. (**a**) GD-MOSFET structure. (**b**) Superjunction MOSFET structure

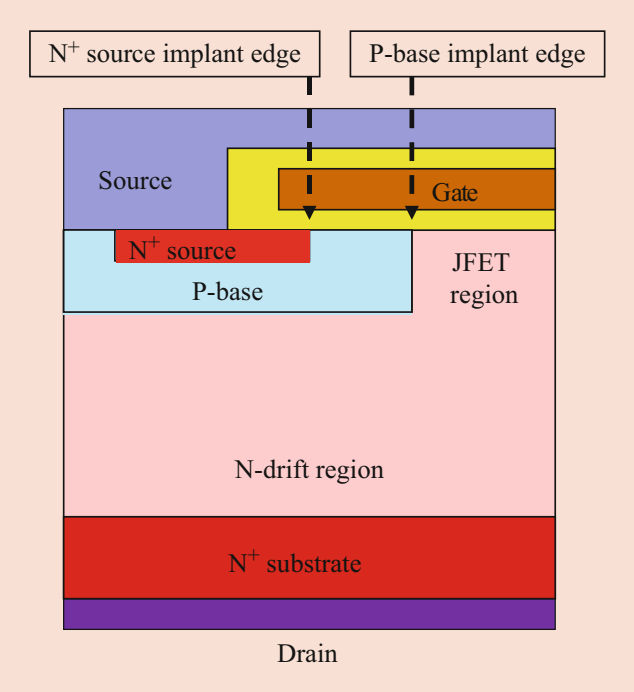

Fig. 14.12 The SiC planar power DI-MOSFET structure

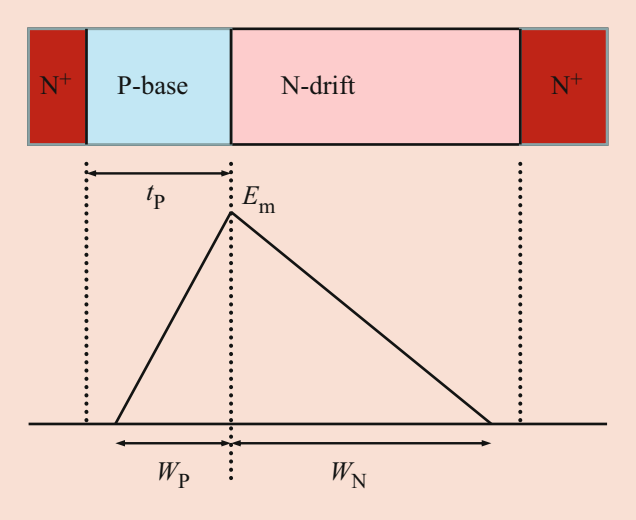

Fig. 14.13 Reach-through problem in a SiC power MOSFET structure

regions using the source metal as shown in Fig. 14.12. In spite of this, the blocking voltage can be compromised by reach-through of the depletion region in the P-base region. The doping concentration and thickness of the P-base region must be sufficient to prevent this problem.

The reach-through problem is worse for SiC devices when compared with silicon devices due to the high doping concentration of their N-type drift region and the higher electric field at the P-N junction [4]. A triangular electric field distribution is shown in Fig. 14.13 for the case of uniform doping on both sides of the junction with the maximum electric field at the P-base/N-drift junction. The depletion width in the P-base is given by

$$W_P = \frac{\varepsilon_S E_m}{qN_A} \tag{14.3}$$

where N_A is the doping concentration of the P-base region. The minimum P-base thickness required to prevent reach-though limited breakdown is obtained when the P-base region is completely depleted with the critical electric field for breakdown at the junction:

$$t_P = \frac{\varepsilon_S E_C}{qN_A} \tag{14.4}$$

where E_C is the critical electric field for breakdown.

The minimum P-base thickness for 4H-SiC power MOSFETs can be compared with that for silicon devices in Fig. 14.14. The thickness for 4H-SiC devices is about six times larger than for silicon for the same P-base doping concentration [4]. This limits the minimum channel length for silicon carbide devices to much larger values than for silicon devices making the channel resistance high. The 10 times lower channel inversion layer mobility observed for silicon carbide makes this problem worse.

A threshold voltage between 1 and 5 V can be achieved in silicon power MOSFETs with typical P-base doping concentration of 1×10^{17} cm^{-3} and gate oxide thickness of 500–1000 angstroms. This allows reducing the channel length to 0.5 μm without reach-through. The P-base doping concentration must be increased to above 4×10^{17} cm^{-3} for 4H-SiC to prevent reach-through with a 0.5 μm P-base thickness resulting in a threshold voltage above 10 V.

In the silicon carbide power MOSFET structure, a very high electric field also develops in the gate oxide under forward blocking conditions. Gausses Law determines the electric field developed in the oxide based up on the electric field at the semiconductor interface:

$$E_{Oxide} = \left(\frac{\varepsilon_{Semi}}{\varepsilon_{Oxide}}\right) \cdot E_{Semi} \tag{14.5}$$

where ε_{Semi} and ε_{Oxide} are the dielectric constants of the semiconductor and oxide and E_{Semi} is the electric field at the semiconductor interface. The electric field in the oxide ($\varepsilon_{Oxide} = 3.85$) is approximately 3-times larger than in the semiconductor for both silicon ($\varepsilon_{Semi} = 11.7$) and silicon carbide ($\varepsilon_{Semi} = 9.7$). The electric field in the oxide does not exceed the reliability limit of about 4×10^6 V/cm because the maximum electric field in the silicon cannot exceed 3×10^5 V/cm due to avalanche breakdown. In contrast, the electric field in the oxide approaches 9×10^6 V/cm when

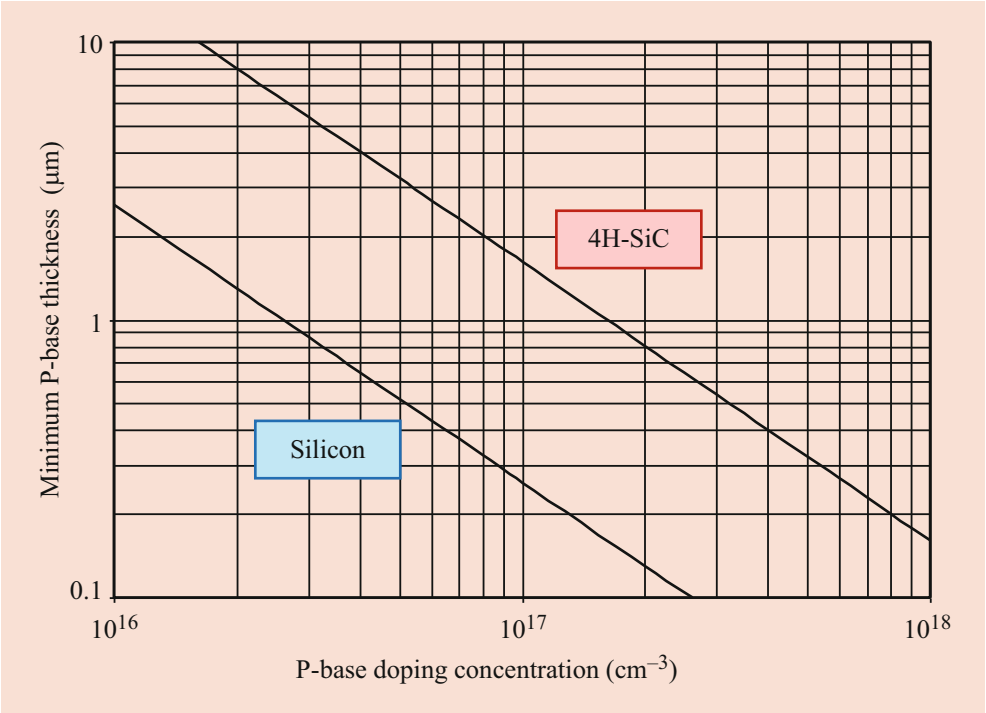

Fig. 14.14 Minimum P-base thickness required to prevent reach-through breakdown in 4H-SiC and Silicon devices

the electric field in 4H-SiC reaches its breakdown strength of 3×10^6 V/cm. This exceeds not only the reliability limit but produces rupture of the oxide leading to catastrophic failure. The electric field in the gate oxide must be carefully examined during the design of silicon carbide MOSFET structures. Innovative SiC power MOSFET structures were proposed [15] that shield the gate oxide from high electric field in the drift region to address this problem.

14.5.2 On-Resistance

On-state current flow occurs in the power MOSFET by forming an inversion layer channel at the surface of the P-base region due to a positive gate bias above the threshold voltage. The shaded area current path in Fig. 14.15 indicates the path for current flow [4]. The current flows from the channel into the JFET region. An accumulation layer above the JFET region distributes electrons into the JFET region. The current then flows uniformly through the JFET region. From the JFET region, the current spreads at a 45 degree angle into the N-drift region. It becomes uniform after a certain depth which depends on the width of the P-base region (s in the figure). The total on-resistance for the planar power MOSFET structure can be calculated by adding all the resistances shown in the figure:

$$R_{on,sp} = R_{CH} + R_A + R_{JFET} + R_D + R_{subs} \qquad (14.6)$$

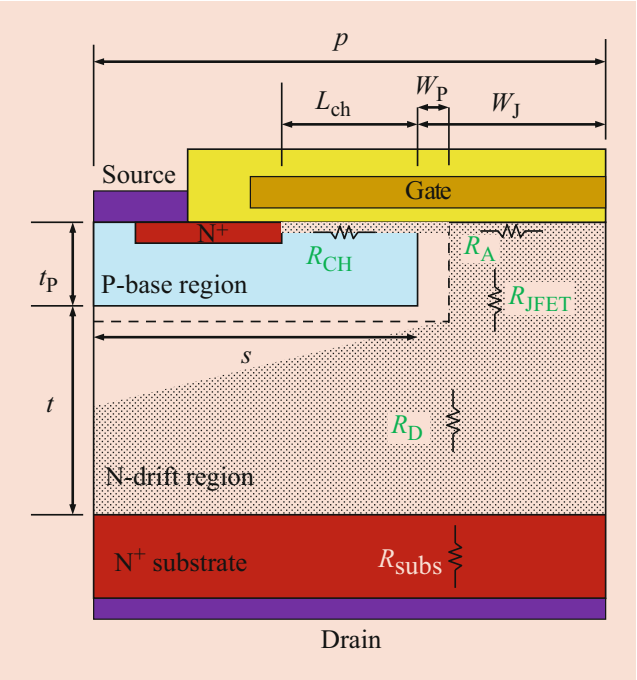

Fig. 14.15 Internal resistances for the planar 4H-SiC power MOSFET

where R_{CH} is the channel resistance, R_A is the accumulation region resistance, R_{JFET} is the resistance of the JFET region, R_D is the resistance of the drift region, and R_{subs} is the resistance of the N^+ substrate. These resistances can be analytically calculated:

(a) The specific channel resistance

$$R_{CH} = \frac{(L_{CH}.p)}{\mu_{inv} C_{ox} (V_G - V_T)} \tag{14.7}$$

where L_{CH} is the channel length as defined in Fig. 14.15, μ_{inv} is the electron inversion layer mobility, C_{ox} is the specific capacitance of the gate oxide, V_G is the applied gate bias, and V_T is the threshold voltage. The specific capacitance is given by

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{14.8}$$

where ε_{ox} is the dielectric constant for the gate oxide and t_{ox} is its thickness.

(b) The specific accumulation layer resistance

$$R_A = \frac{K (W_J - W_P) p}{\mu_a C_{ox} (V_G - V_{TA})} \tag{14.9}$$

where W_P is the P-base/N-JFET junction zero-bias depletion width, μ_a is the electron accumulation layer mobility and V_{TA} is the accumulation threshold voltage. The factor K is 0.1–0.3 for SiC power devices because of the low accumulation layer mobility and the low JFET region resistance. The JFET region doping concentration ($N_{D,JFET}$) is increased above the drift region doping concentration. The depletion width is

$$W_P = \sqrt{\frac{2\varepsilon_S V_{biP}}{qN_{D,JFET}}} \tag{14.10}$$

where V_{biP} is the built-in potential (typically 3.3 V) for 4H-SiC.

(c) The specific JFET region resistance

$$R_{JFET} = \rho_D \cdot t_P \left(\frac{p}{W_J - W_P} \right) \tag{14.11}$$

where t_p is the depth of the P-base region.

(d) The drift region spreading resistance

$$R_D = \rho_D \cdot p \cdot \ln \left(\frac{p}{W_J - W_P} \right) + \rho_D \cdot (t - s - W_P) \tag{14.12}$$

where t is the thickness of the drift region below the P-base region and s is the width of the P-base region.

(e) The N^+ substrate resistance

$$R_{subs} = \rho_{subs} \cdot t_{subs} \tag{14.13}$$

where ρ_{subs} and t_{subs} are the resistivity and thickness of the substrate. A typical value for the N^+ substrate resistivity for 4H-SiC is 0.020 Ω-cm and its thickness if typically 350 μm leading to a contribution of 7×10^{-4} Ω-cm^2.

The various components of the specific on-resistances for a 1.2 kV rated 4H-SiC planar MOSFET with a drift region doping concentration of 1×10^{16} cm^{-3} and thickness of 10 μm were modeled using the above equations with a gate oxide thickness of 0.1 μm. An accumulation channel mobility of twice the inversion layer mobility was assumed. The P-base had a depth of 1 μm. The gate drive voltage (V_G) was assumed to be 20 V above the threshold voltage.

The on-resistance components are shown in Fig. 14.16 for the case of a channel mobility of 100 cm^2/V-s. An inversion layer mobility above 100 cm^2/V-s was first experimentally observed [16] in 1998. The drift region resistance is dominant for this large channel mobility even for a channel length of 2 μm. A total specific on-resistance of 2.7 mΩ-cm^2 is obtained for a channel length of 1 μm. This value is ten times the ideal specific on-resistance. A channel mobility of 15–20 cm^2/Vs has been reported for modern commercially available 4H-SiC planar power MOSFETs. They have a specific on-resistance of 3.5–4.0 mΩ-cm^2 by reducing the channel length to 0.5 μm and using a gate oxide thickness of 500 angstroms.

The JFET width in SiC planar power MOSFETs must be optimized to achieve a low specific on-resistance while reducing the electric field in the gate oxide. The optimization of the JFET width is illustrated in Fig. 14.17. The specific on-resistance is very large when the JFET width is below 0.8 μm because the zero bias depletion width is 0.6 μm. When the JFET width is increased, its resistance decreases rapidly while the increase in cell pitch produces an increase in the channel specific resistance. The minimum specific on-resistance is observed at a JFET width of 1 μm. The electric field in the gate oxide under forward blocking mode must be monitored when optimizing the JFET width [3]. The electric field in the gate oxide is sufficiently low at the JFET width of 1 μm for reliable operation of the devices.

The channel mobility has a large impact on the specific on-resistance of lower breakdown voltage SiC planar MOSFETs. This is demonstrated in Fig. 14.18 by modelling devices with a JFET doping concentration of 1×10^{16} cm^{-3}. The other cell parameters are P-base depth of 1 μm, gate oxide thickness of 0.05 μm, accumulation layer mobility of 200 cm^2/V-s, and channel length of 1 μm. A gate bias voltage of 10 V above the threshold voltage was assumed here. For the case of a channel mobility of 100 cm^2/Vs, the specific on-resistance becomes nearly equal to the ideal value when the breakdown voltage exceeds 5000 V. However, the channel

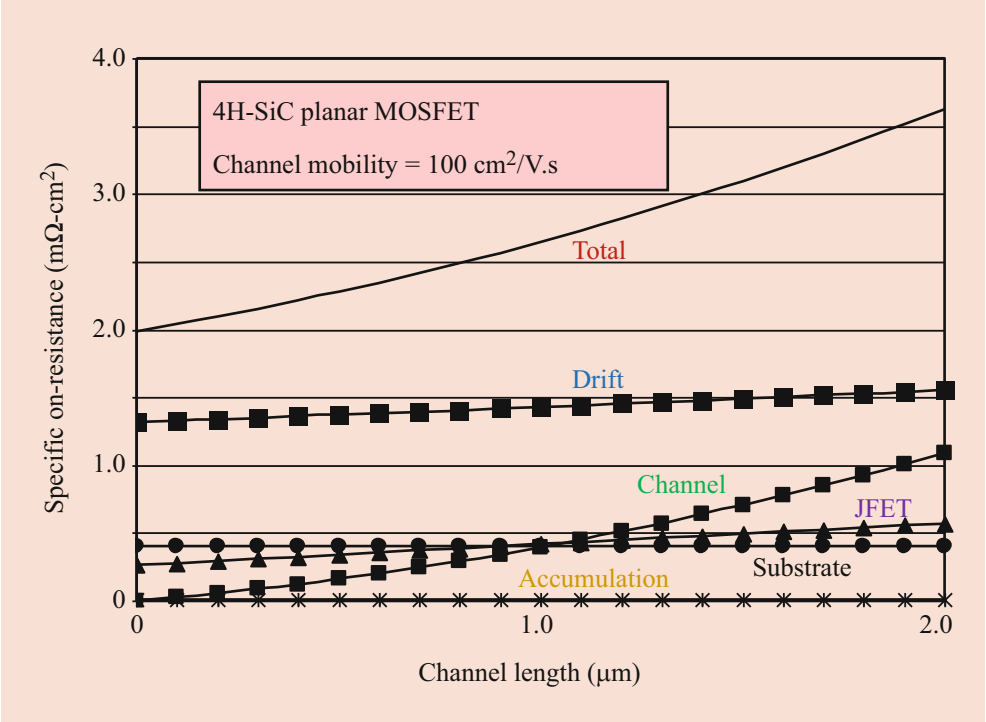

Fig. 14.16 Components of On-Resistance for 1.2 kV rated 4H-SiC Planar MOSFETs inversion layer mobility = 100 cm^2/v-s

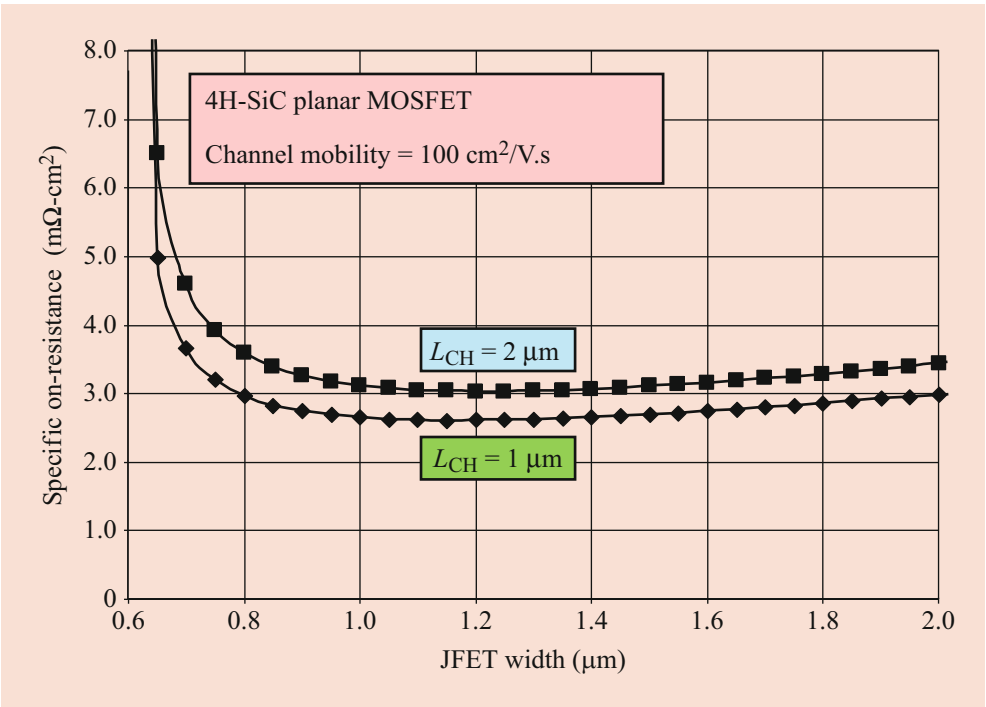

Fig. 14.17 Specific on-resistance for 1.2 kV 4H-SiC planar MOSFET as a function of JFET width: inversion layer mobility = 100 cm^2/v-s

resistance limits the performance of SiC planar MOSFETs when the breakdown voltage is less than 1000 V. The performance is degraded even at large breakdown voltages if the channel mobility is reduced to 10 cm^2/V-s. 4H-SiC planar MOSFETs can surpass the performance of silicon devices by several orders of magnitude at breakdown voltages above 1000 V if a channel mobility of at least 10 cm^2/V-s is achieved.

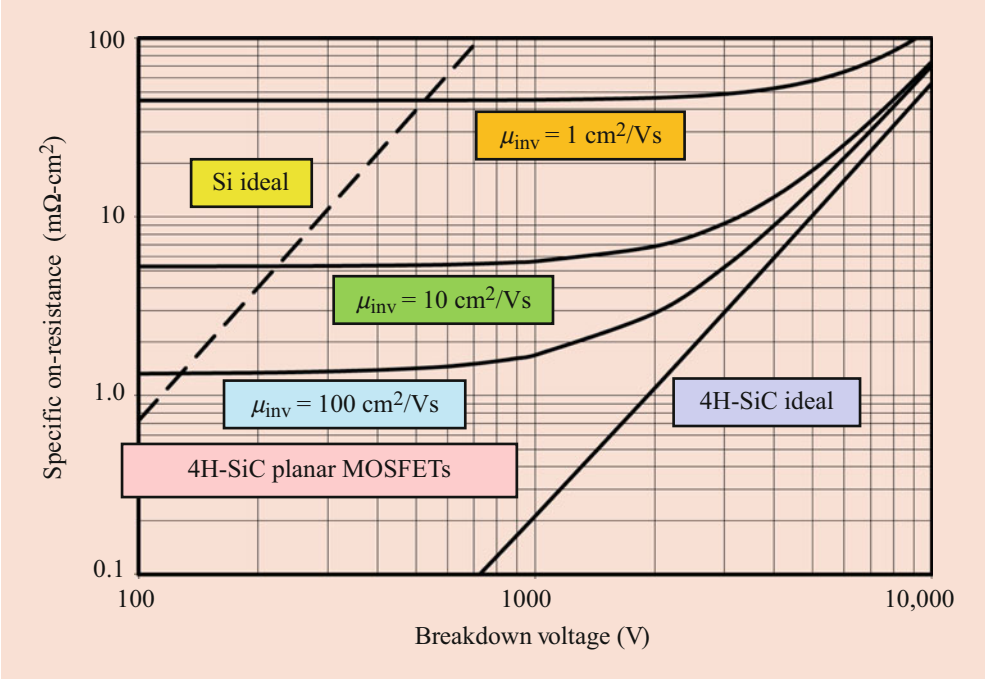

Fig. 14.18 Specific on-resistance for 4H-SiC planar MOSFETs with three cases of channel mobility

14.5.3 Threshold Voltage

A minimum threshold voltage above 1 V is required for power MOSFETs for most applications to prevent inadvertent turn-on during voltage spikes in the circuit. However, a high threshold voltage increases the channel resistance. Most high voltage power electronic circuits use a gate drive voltage of 15 V. The threshold voltage should therefore be kept at 2–3 V. The threshold voltage is defined as the gate bias for the on-set of *strong inversion* [17]:

$$V_{TH} = \frac{\sqrt{4\varepsilon_S kTN_A \ln(N_A/n_i)}}{C_{ox}} + \frac{2kT}{q}\ln\left(\frac{N_A}{n_i}\right) \quad (14.14)$$

where N_A is the doping concentration of the P-base region, k is Boltzmann's constant, and T is the absolute temperature. Positive fixed oxide charge shifts the threshold voltage in the negative direction:

$$\Delta V_{TH} = \frac{Q_F}{C_{ox}} \quad (14.15)$$

Heavily doped N-type polysilicon gate electrode produces a negative shift of the threshold voltage by 1 V [3].

The threshold voltage for 4H-SiC planar MOSFETs calculated using Eq. (14.15) is provided in Fig. 14.19 for a gate oxide thickness of 0.1 μm. The values for a silicon device with the same gate oxide thickness are shown in this figure for comparison. A threshold voltage of 3 V is obtained for a P-base doping concentration of 1×10^{17} cm^{-3} for silicon devices. Silicon power MOSFETs with channel lengths of 0.5 μm operate without reach-through problems. However, a P-base doping concentration of 3×10^{17} cm^{-3} must be used for 4H-SiC (see Fig. 14.14) to prevent reach-through breakdown. The threshold voltage for the 4H-SiC MOSFET approaches 20 V for this doping concentration. The conventional power MOSFET structure shown in Fig. 14.12 cannot be used silicon carbide power MOSFETs.

14.5.4 Reliability

Power MOSFETs are prone to shift in the threshold voltage due to the injection of electrons into the gate oxide if they gain sufficient energy to overcome the potential barrier between the semiconductor and the oxide. The energy band offsets with silicon dioxide for the case of silicon and SiC are shown in Fig. 14.20. The band offset between the conduction band edges is much smaller for SiC than for silicon.

The band diagram in the on-state for the 4H-SiC MOS structure with polysilicon gate is shown in Fig. 14.21 for a positive bias applied to the gate. A narrow barrier is formed at the SiC-SiO_2 interface allowing the tunneling of electrons from SiC into the oxide. Current flow due to Fowler-Nordheim tunneling injects electrons into the oxide. This has been in measurements reported on 6H-SiC [18] and 4H-SiC [19] MOS-capacitors. The trapping of electrons in the gate oxide causes threshold voltage shifts violating reliability requirements [20]. Based up on time-dependent

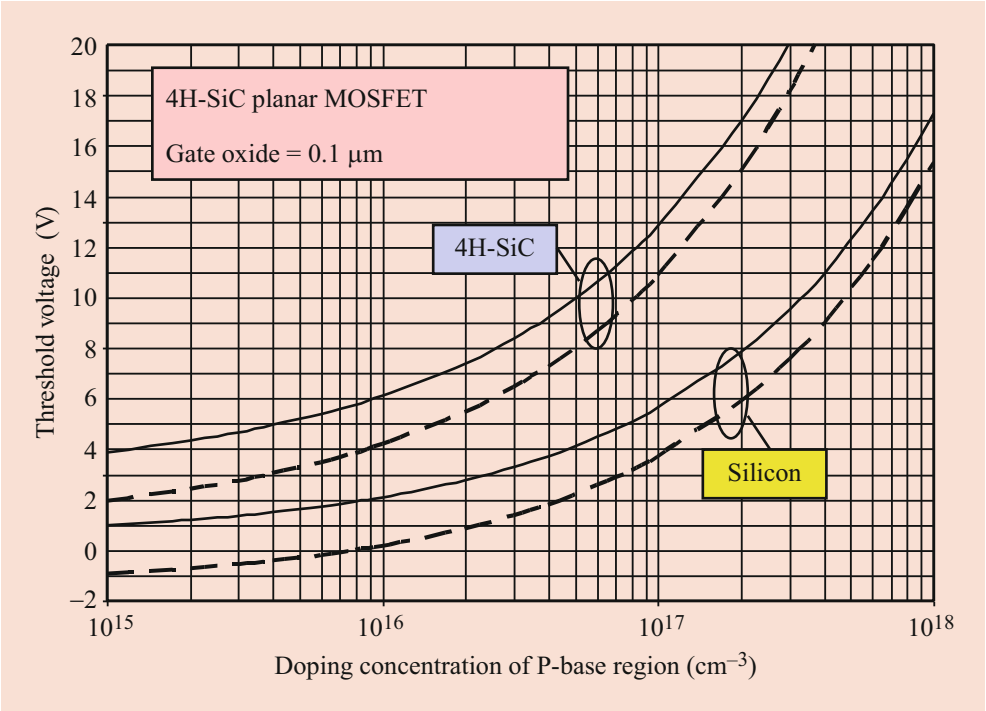

Fig. 14.19 Threshold voltages for 4H-SiC planar MOSFETs (solid lines). Contribution of N^+ polysilicon gate and 2×10^{11} cm^{-2} oxide fixed charge is shown by dashed lines

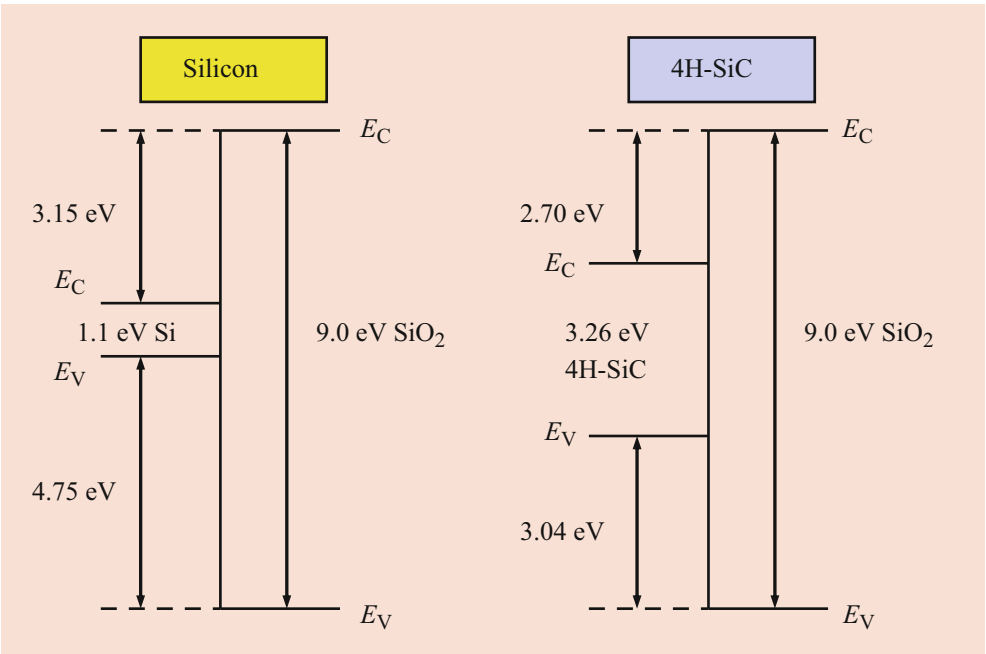

Fig. 14.20 Band offsets for Si and SiC with SiO_2

dielectric breakdown studies [21], a 100-year mean-time-to-failure (MTTF) was projected at 175 °C assuming a gate oxide electric field of below 3 MV/cm. Low gate oxide electric field under blocking conditions can be achieved by using the shielded planar power MOSFET structure discussed in the next section.

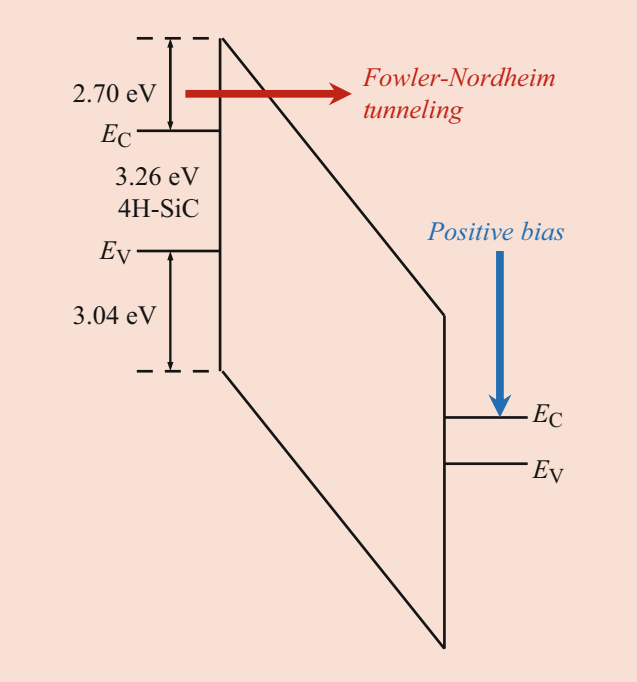

Fig. 14.21 Polysilicon/oxide/4H-SiC band diagram under on-state gate bias

14.6 Shielded SiC Planar Power MOSFET Structure

The conventional silicon planar power DMOSFET structure cannot be used to make SiC devices because of (a) a reach-through problem, (b) a high threshold voltage, (c) a high gate oxide electric field, and (d) a low channel mobility. These problems were solved with the shielded planar-gate structure proposed [15] at NCSU in 1995.

14.6.1 Device Structures

The shielded SiC planar-gate power MOSFET structure with inversion and accumulation channels are shown in Fig. 14.22. The P^+ shielding region extends under both the N^+ source region and the base region. The JFET region formed between the P^+ shielding regions is optimized to minimize the specific on-resistance. The electric field in the gate oxide is reduced by the potential barrier formed in the JFET region by the P^+ shielding regions. The reduced electric field near the surface also prevents lateral reach-through of the base region. This allows reducing the base doping levels to achieve a good threshold voltage of 2–3 V.

Enhancement-mode operation is achieved in the accumulation mode structure by choosing the doping and thickness of the N-base region so that it is completely depleted by the built-in potential of the P+/N junction at zero gate bias [22]. This is fundamentally different than in buried channel MOS devices [23] where an un-depleted N-type channel region allows current flow at zero gate bias resulting in a depletion-mode device which is unacceptable for power electronics applications. On-state state current flow occurs in both structures when a positive bias is applied to the gate with either an inversion or accumulation layer channel. The accumulation-mode structure has a smaller specific on-resistance because of a larger accumulation layer electron mobility.

14.6.2 Gate Oxide Screening

The width of the JFET region determines the highest electric field developed in the gate oxide for both of the shielded structures. The results of numerical simulations [22] to extract the electric field in SiC below the gate oxide are shown in Fig. 14.23 for a drift region doping concentration of 1×10^{16} cm^{-3}. A JFET width of 1.5 μm reduces the SiC electric field to 1.5 MV/cm which keeps the oxide electric field within reliability requirements. A JFET width of 1.5 μm leads to a low specific on-resistance because the zero-bias depletion width is 0.6 μm.

14.6.3 Threshold Voltage

A model for the threshold voltage of accumulation-mode MOSFETs can be developed [24] using the electric field profile shown in Fig. 14.24. The electric field in the SiC and oxide are.

$$E_1 = \frac{V_{bi}}{W_N} - \frac{qN_D W_N}{2\varepsilon_S} \tag{14.16}$$

$$E_2 = \frac{V_{bi}}{W_N} + \frac{qN_D W_N}{2\varepsilon_S} \tag{14.17}$$

$$E_{ox} = \frac{\varepsilon_S}{\varepsilon_{ox}} E_1 \tag{14.18}$$

The threshold voltage is obtained by calculating the area under the electric field profile:

$$V_{TH} = \varphi_{MS} + \left(\frac{\varepsilon_S V_{bi}}{\varepsilon_{ox} W_N} - \frac{qN_D W_N}{2\varepsilon_{ox}} \right) \cdot t_{ox} \tag{14.19}$$

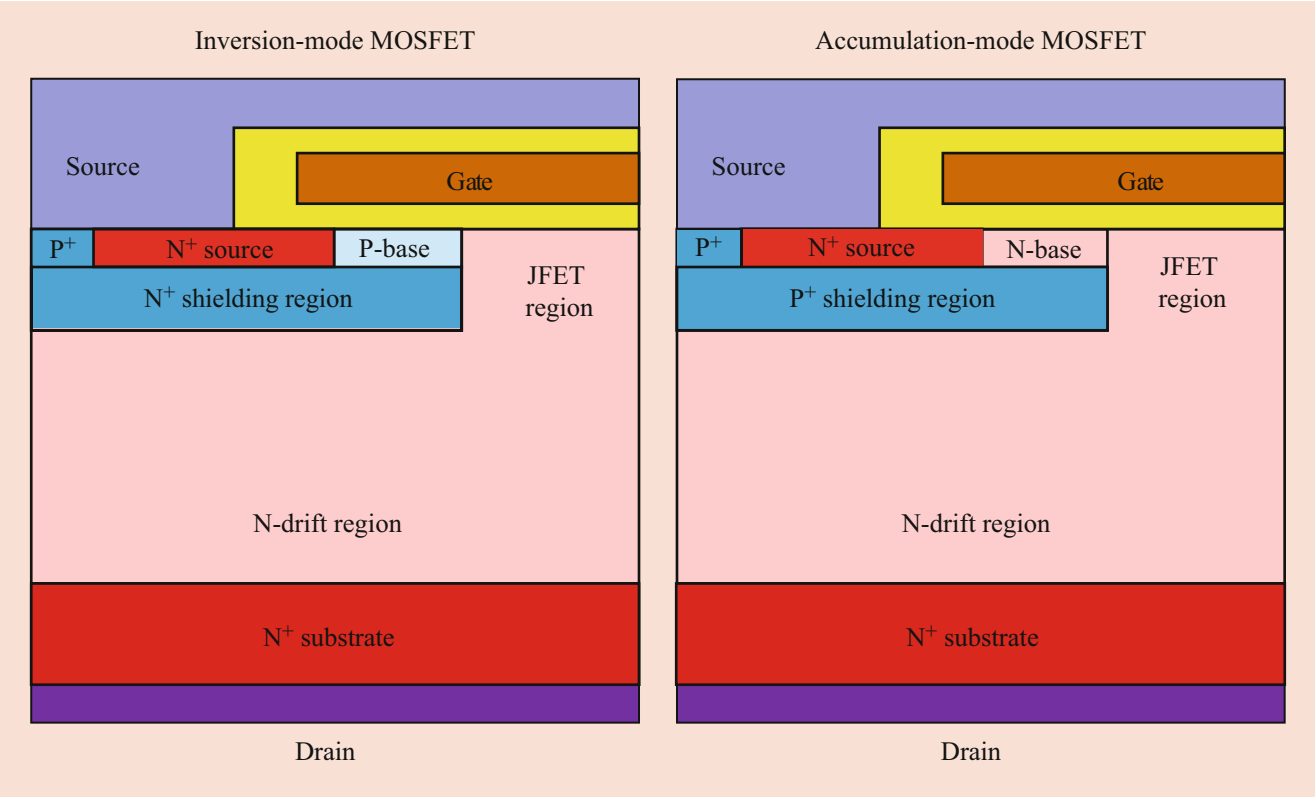

Fig. 14.22 SiC power MOSFET structures with shielding regions

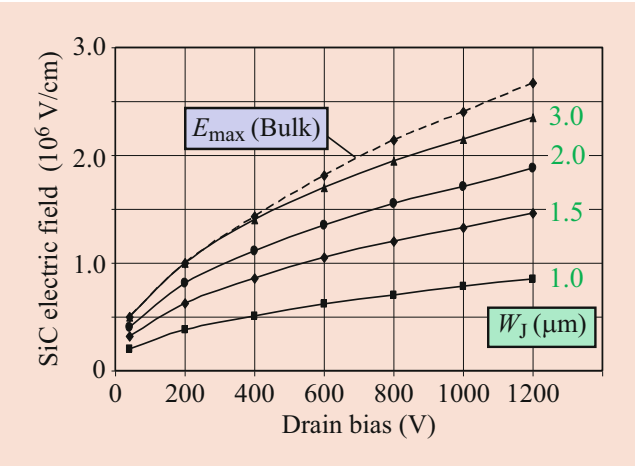

Fig. 14.23 Electric field in the SiC at the gate oxide interface for the planar 4H-SiC shielded accumulation-mode MOSFET structure

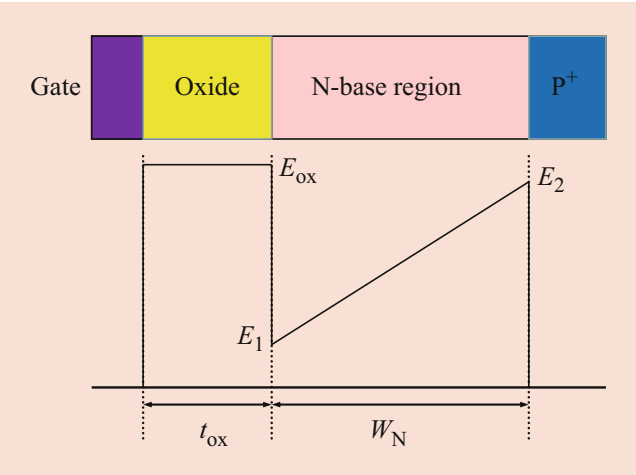

Fig. 14.24 Accumulation-mode MOSFET structure electric field distribution in the gate region

and taking into account the work function difference between the gate material and the lightly doped N-Base region.

The threshold voltages calculated for 4H-SiC accumulation-channel MOSFETs are shown in Fig. 14.25 for a gate oxide thickness of 0.05 μm, N-base thickness of 0.2 μm, and a gate-semiconductor work-function difference of 1 V [22]. The threshold voltages for the conventional inversion-channel 4H-SiC MOSFET are included in the figure for comparison. The threshold voltage for the accumulation-channel case decreases with increasing N-base doping concentration. Lower threshold voltages can be achieved with the accumulation channel than in the inversion-channel structures. A threshold voltage of 2.8 V is obtained for the accumulation-channel device with a N-base doping

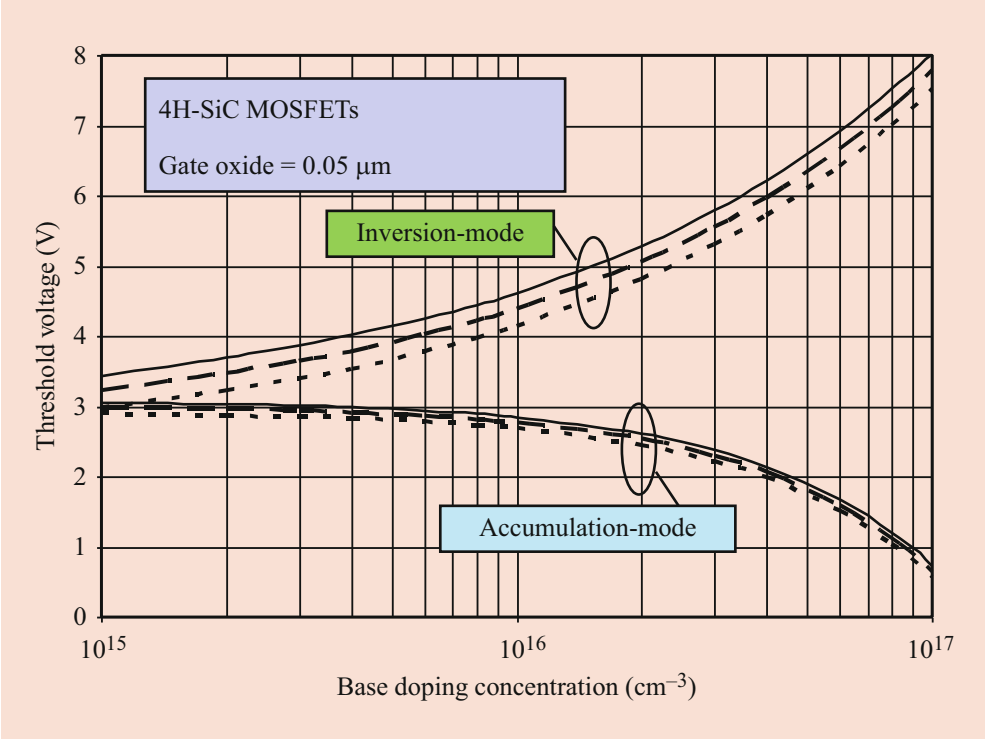

Fig. 14.25 4H-SiC accumulation-mode MOSFETs threshold voltage (Solid line: 300°K; Dash line: 400°K; Dotted line: 500°K)

concentration of 1×10^{16} cm^{-3}. The threshold voltage will be reduced to 2 V due to typical fixed oxide charge of 10^{11} cm^{-2}. This model has been verified by numerical simulations [25].

14.6.4 Channel Mobility

Obtaining a high channel mobility in SiC power MOSFETs was identified as an important goal during the development of these devices [26]. The interface quality was significantly improved for 6H-SiC by anneal thermally grown oxide in a NO ambient [27] producing a peak inversion layer mobility of 70 cm^2/Vs. In contrast, the inversion layer mobility for 4H-SiC was found [28, 29] to be less than 1 cm^2/Vs due to trapping of electrons [30]. In 1998, NCSU reported [31] record high inversion layer mobility of 165 cm^2/Vs using deposited oxides on 4H-SiC. The key process step required for obtaining a high inversion layer mobility was found to be a wet oxide anneal [32]. The first evidence of phonon scattering limited inversion layer mobility was obtained in this work. The results were reproduced by the NCSU sponsors [33] and other research groups [34]. It has been reported that the channel mobility is inversely proportional to the interface state density. A significant reduction in the interface state density has been accomplished by performing annealing at 1175 °C in a nitric oxide (NO) ambient for 2 h [24, 35–37].

4H-SiC power MOSFETs are manufactured with ion-implanted P-base regions. Damage caused by the ion implantation could reduce the channel mobility. N-channel lateral MOSFETs have been fabricated on aluminum implanted layers in 4H-SiC [38] with a doping concentration of 1×10^{17} cm^{-3}. A peak inversion layer mobility of 100 cm^2/V-s was observed.

In 1998, a high accumulation layer mobility of 120 cm^2/Vs was observed by NCSU [39] for 4H-SiC using deposited oxides. A peak accumulation mobility of 140 cm^2/V-s was reported in 2001 with thermally grown oxide on nitrogen implanted regions [40]. The accumulation layer mobility was measured in 2001 using the Hall bar structure [41] to eliminate the impact of charge trapping. The accumulation mobility decreased from 350 cm^2/V-s in weak accumulation to 200 cm^2/V-s in strong accumulation compared with an effective mobility of only 3–5 cm^2/V-s due to trapping of electrons.

14.6.5 On-Resistance

The current path in the on-state for the shielded accumulation-channel planar SiC power MOSFET is similar to that shown in Fig. 14.15. The resistance components for the shielded planar MOSFET structures can be calculated by using the equations in Sect. 14.5.2.

The specific channel resistance for the shielded inversion-channel structure is

$$R_{CH} = \frac{(L_{CH} \cdot p)}{\mu_{inv} C_{ox} (V_G - V_T)} \tag{14.20}$$

where p is the cell pitch, L_{CH} is the channel length, μ_{inv} is the inversion layer mobility for electrons, C_{ox} is the specific capacitance of the gate oxide, V_G is the gate bias, and V_T is the threshold voltage. The specific channel resistance for the shielded accumulation-channel structure is.

$$R_{CH} = \frac{(L_{CH} \cdot p)}{\mu_a C_{ox} (V_G - V_T)} \tag{14.21}$$

where μ_a is the accumulation layer mobility for electrons. Larger accumulation layer mobility than inversion layer mobility has been experimentally observed in silicon carbide. The threshold voltage for creating an accumulation layer is smaller than for creating an inversion layer. These factors reduce the channel resistance contribution in the accumulation channel device.

A comparison between the inversion and accumulation channel devices can be made while keeping all other parameters the same. The specific on-resistance for the shielded planar 4H-SiC MOSFETs with various breakdown voltages is shown in Fig. 14.26 based up on (a) gate oxide thickness of 0.05 μm; (b) "a" value of 1 μm; (c) P^+ region depth of 1 μm; (d) gate drive voltage (V_G – V_T) of 10 V; (e) channel length of 1 μm; (f) JFET width (W_J) of 1 μm; (g) cell pitch of 3 μm; and (h) N^+ substrate resistance of 0.04 mΩ-cm^2. It can be seen in Fig. 14.26 that device specific on-resistance approaches the ideal value when the breakdown voltage exceeds 5000 V for both structures because the drift region resistance becomes dominant. The channel contribution becomes dominant when the breakdown voltage falls below 1000 V. The accumulation-channel device has a specific on-resistance of 1.5 mΩ-cm^2 compared with 4 mΩ-cm^2 for the inversion channel device at a breakdown voltage of 1000-V. These values can be reduced by decreasing the channel length to 0.5 μm.

14.6.6 Experimental Results

Experimental results for 4H-SiC inversion-channel DI-MOSFETs were reported [42] in 2001 using 25 μm thick epitaxial layers with doping concentration of 3×10^{15} cm^{-3}. The 2000 V devices had a large-specific on-resistance (55 mΩ-cm^2) due to an inversion layer mobility of only 14 cm^2/Vs. 10 kV inversion-channel DI-MOSFET devices with specific on-resistance of 236 mΩ-cm^2 were reported [43] in 2003. Significantly better 10-kV 4H-SiC planar inversion-channel power MOSFETs with a specific on-resistance of 123 mΩ-cm^2 were then reported in 2004 by using a drift region with doping concentration of 8×10^{14} cm^{-3} and thickness of 85 μm [44].

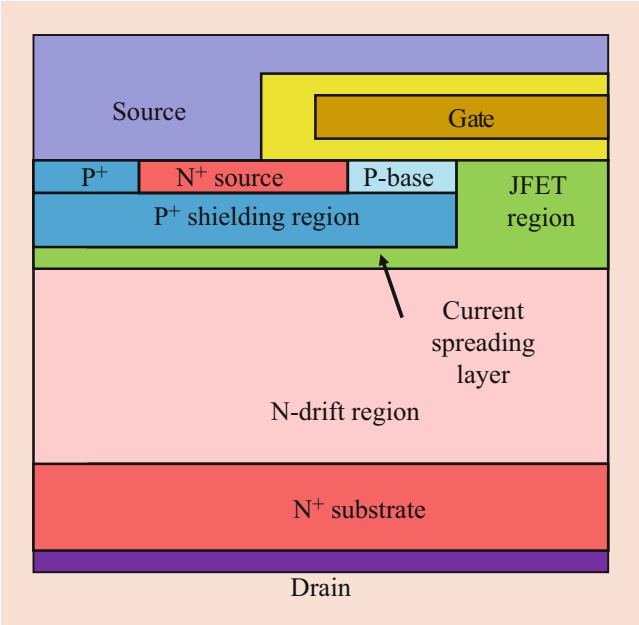

Fig. 14.27 4H-SiC MOSFET with current spreading layer

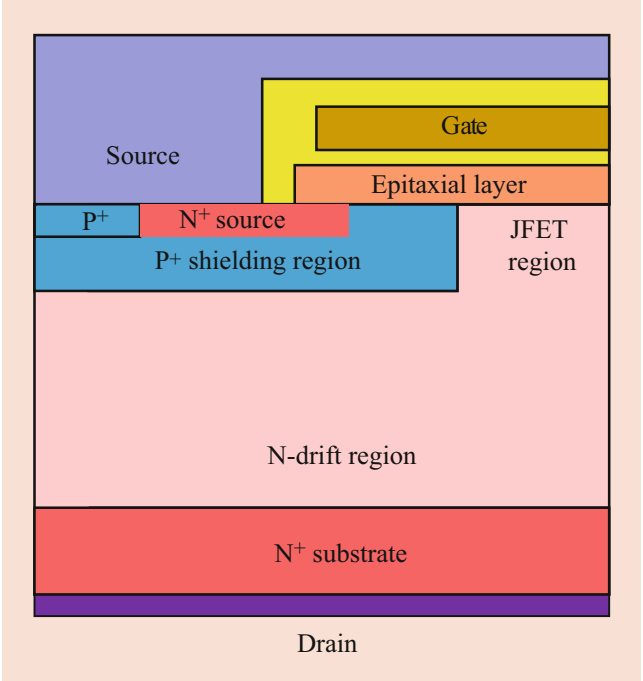

Fig. 14.28 4H-SiC planar-gate ACCUFET structure using an epitaxial N-base region

A self-aligned implant process for planar 4H-SiC MOSFETs was demonstrated in 2004 [45, 46]. A sidewall spacer that serves as an implant mask was formed by the oxidation of a sacrificial polysilicon layer to achieve a channel length of less than 0.5 μm. 2 kV planar 4H-SiC inversion-mode MOSFETs were reported with a specific on-resistance of 27 mΩ-cm^2.

A 1-kV inversion-channel DI-MOSFET structure with current spreading layer (CSL) as shown in Fig. 14.27 was reported in 2007 [47]. The CSL with optimum doping concentration of 1×10^{17} cm^{-3} can be epitaxially grown on top of the n-type drift layer. A catastrophic drop in breakdown voltage occurs when the CSL doping concentration exceeds 2×10^{17} cm^{-3}. Devices with specific on-resistance of 6.95 mΩ-cm^2 were achieved using a self-aligned process to reduce the channel length to 0.3 μm.

Large-area (0.45 cm × 0.45 cm chips with 0.15 cm^2 active area) planar SiC inversion-channel power MOSFETs could be fabricated in 2010 on 3 inch diameter wafers with blocking voltage of 1200 V [48]. The devices can handle 40 A in the on-state with a specific on-resistance of 7.1 mΩ-cm^2. Their performance is limited by the channel resistance.

1.5 kV 4H-SiC planar inversion-channel power MOSFETs were reported [49] in 2011 with a specific on-resistance of 3.7 mΩ-cm^2. A self-aligned implant process was used to achieve a channel length of 0.5 μm. Improved high-current devices with blocking voltage of 1600 V had a specific on-resistance of 7 mΩ-cm^2. 1.6 kV devices with a chip area of 0.56 cm^2 (active area of 0.40 cm^2) were reported [50] in 2013 to allow handling a drain current of 150 A. Much smaller high temperature switching losses were confirmed when compared with silicon IGBTs. In 2014, 1.7 kV 4H-SiC planar inversion-channel power MOSFETs were reported [51] with specific on-resistance of 5.5 mΩ-cm^2.

The first planar shielded accumulation-mode MOSFET structure were fabricated [52] at PSRC in 1997 using 6H-SiC using a drift region with 1×10^{16} cm^{-3} doping concentration and 10 μm thickness. The un-terminated devices had a breakdown voltage of 350 V although the epi-layer was designed to support 1500 V. A specific on-resistance of 18 mΩ-cm^2 was measured at a gate bias of only 5 V for a structure with cell width of 21 μm, channel length of 2.5 μm, and JFET width of 4 μm. The design of the 6H-SiC ACCUFET was analyzed [53] in 1999. The optimization of the JFET width to minimize the specific on-resistance while reducing the gate oxide electric field was explained in this work.

A 4H-SiC ACCUFET structure, shown in Fig. 14.28, was reported [54] in 2006 with the N-base region created by an N-type epitaxially layer. The threshold voltage was near zero volts. A specific on-resistance of 5 mΩ-cm^2 was reported at a gate bias of 20 V.

A 10 kV 4H-SiC ACCUFETs was reported in 2008 with drift layer doping concentration of 5×10^{14} cm^{-3} and 100 μm thickness and the N-base region formed with a 0.1 μm thick epitaxial layer [55, 56]. The 10 kV breakdown voltage was achieved with a three-zone, 750 μm wide, JTE edge termination. The measured specific on-resistance (170 mΩ-cm^2) was within 3-times the ideal case.

The 1 kV, 40 A 4H-SiC ACCUFET devices with the structure shown in Fig. 14.28 were reported in 2010 [57]. A specific on-resistance of 3.5 mΩ-cm^2 was achieved. The devices were evaluated at 30 kHz for induction cook-top applications. Their switching loss was only 5 W compared with 19 W for the silicon IGBT.

14.7 Silicon Carbide Power MOSFETs with Improved High-Frequency Performance

In order to maximize the benefits of replacing silicon IGBTs with SiC power MOSFETs, it is necessary to increase the circuit operating frequency to reduce the size and cost of passive elements. SiC power MOSFETs must be optimized to reduce their switching losses to obtain good higher frequency performance. This can be achieved by reducing the reverse transfer capacitance (C_{GD}) with innovations in the gate structure. Several device structures that produce a significantly improved (smaller) high-frequency figures-of-merit (HFFOM), defined by [R_{on}*C_{GD}] and [R_{on}*Q_{GD}], are discussed in this section.

A P^+ diverter region connected to the source electrode was incorporated in the 4H-SiC planar power MOSFET structure (called the Central Implant or CI-MOSFET), as shown in Fig. 14.29, in 2015 [58]. Additional process steps are required to add the P^+ diverter region. The P^+ diverter increases the specific on-resistance due to a JFET formed between it and the P-base region. Its impact can be mitigated by increasing the doping concentration in the JFET region. The gate-drain capacitance and reverse transfer gate charge were reduced by a factor of 3 times with this approach.

Two alternate SiC planar-gate power MOSFET structures with improved high-frequency performance are shown in Fig. 14.30. The polysilicon gate has an opening in the middle of the gate electrode in the Split-Gate (SG) MOSFET structure. The fabrication process for this structure is identical to conventional SiC planar-gate power MOSFET. Its measured HFFOM [R_{on}*C_{GD}] was experimentally verified to be 1.3-times smaller, while its HFFOM [R_{on}*Q_{GD}] was 2.4-times smaller than for the conventional MOSFET structure [59].

The P^+ shielding region is extended beyond the edge of the gate electrode in the Buffered-Gate (BG) MOSFET structure, as illustrated in Fig. 14.30. A second JFET region (JFET2) with higher doping concentration must be included to prevent complete depletion of the N-type region above the P^+ shielding region. The experimentally measured HFFOM [R_{on}*C_{GD}] for the 1.2 kV rated BG-MOSFET was 3.6-times smaller, and its HFFOM [R_{on}*Q_{GD}] was 4.0-times smaller than the conventional MOSFET structure [60].

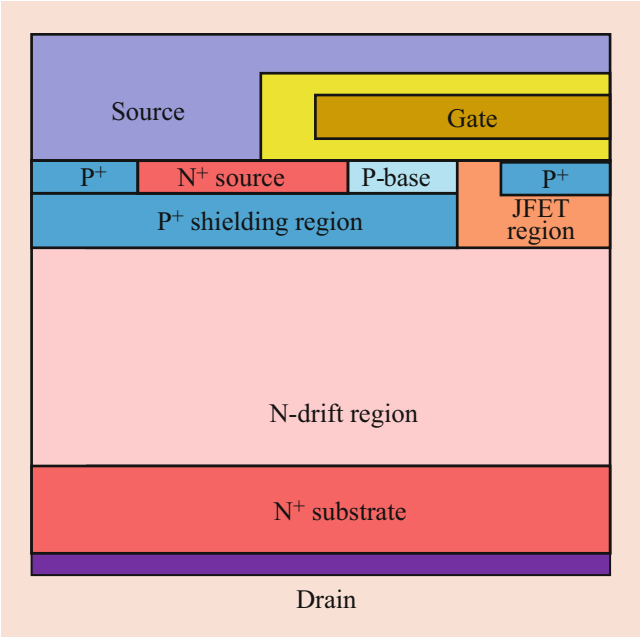

Fig. 14.29 4H-SiC planar-gate MOSFET structure with P^+ diverter region

14.8 SiC Power MOSFET Body-Diode

The body diode in the power MOSFET structure can be used as an anti-parallel diode in power circuits [4]. The body diode is a P-i-N rectifier operating under high-level injection in the on-state. The on-state voltage drop increased [61] after the body diode was turned-on for 1 h for the 10-kV SiC power MOSFET devices. The generation of stacking faults at basal-plane-dislocations (BPDs) due to the release of recombination energy of electrons and holes in the epitaxial layer was discovered as the reason. The on-resistance of the MOSFET was also observed to increase due to mobility degradation by the additional scattering at the stacking faults.

This body diode stability problem is reduced for lower breakdown voltage devices. This has been demonstrated [62] by performing tests on 1200-V 4H-SiC power MOSFETs. An increase by 0.8% for the body diode on-state voltage drop and a 5.4% increase in the on-resistance were observed for 1.2 kV devices after the conduction of the body diode for 1000 hours.

Although stable operation of the body diode in the SiC power MOSFETs may be possible with improved epitaxial layer quality, it has a large on-state voltage drop of 4–5 V. In addition, the injection of minority carriers during current conduction through the body diode generates a stored charge in the drift layer. This stored charge produces a reverse recovery current during operation in typical hard switched inverter circuits used for motor drives or solar PV converters. It has been found that a significant (~50%) increase in turn-on losses is observed in the companion power MOSFETs in

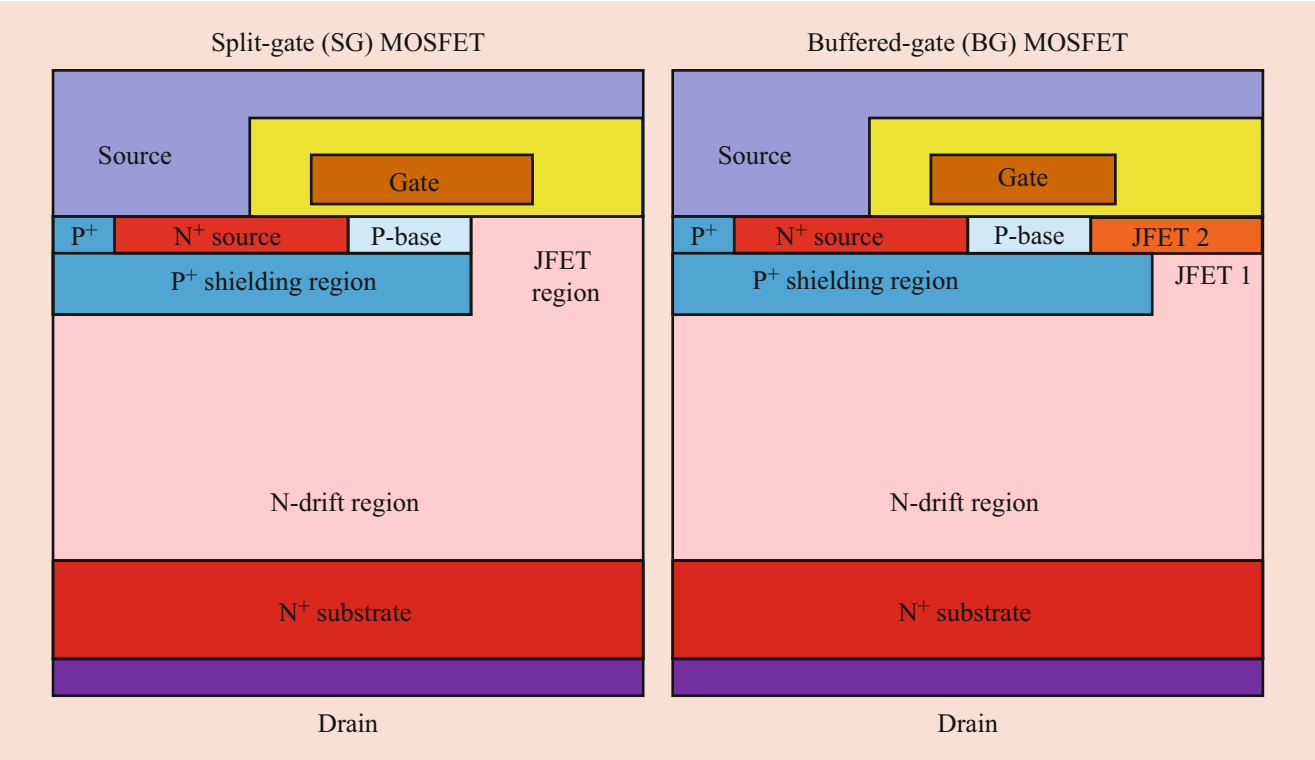

Fig. 14.30 SiC power MOSFETs with improved high frequency operation

the H-bridge inverter at elevated (150 °C) temperatures due to the reverse recovery current in the body diode [63]. The turn-on switching losses can be reduced by using the JBSFET structure discussed in the next section.

14.9 Silicon Carbide Power JBSFETs

Power transistors used in applications, such as the motor drive H-bridge circuit, must allow current flow in the first and third quadrant. The third-quadrant current flow can be conveniently achieved by using the body diode in the power MOSFET structure. The on-state voltage drop of the body diode in SiC power MOSFETs exceeds 4 V resulting in large conduction losses. The removal of the stored charge in the drift region produces a large reverse recovery current which increases the turn-on switching losses in the MOSFETs. This problem becomes worse at elevated junction temperatures.

The SiC JBSFET structure, with a JBS diode integrated into the power MOSFET structure [64, 65] as illustrated in Fig. 14.31, was developed to solve the above problems. The JBS diode can be fabricated using a single metal (Nickel) to simultaneously make a Schottky contact to the N-drift region and ohmic contacts to the N^+ source and P-base regions. The JBS diode has a low on-state voltage drop of 2 V preventing current flow via the body diode.

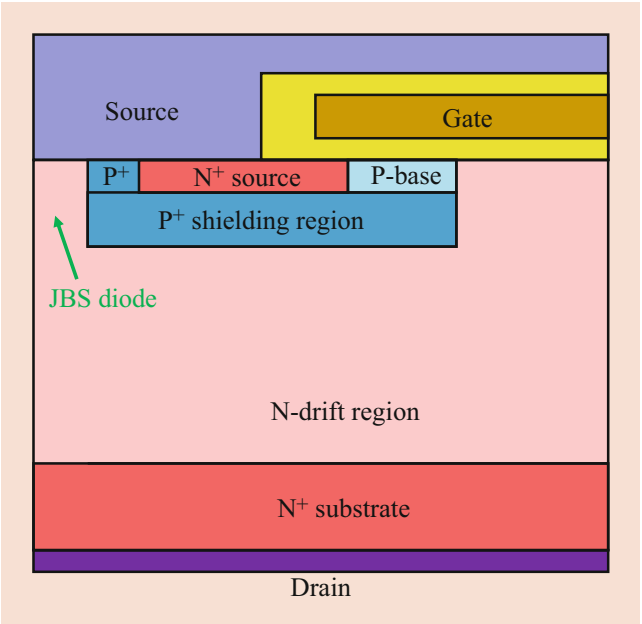

Fig. 14.31 The SiC JBSFET structure with JBS diode integrated into the power MOSFET structure

Measurements performed using 1.2 kV SiC JBSFETs in a typical hard-switched H-bridge inverter circuit have demonstrated that the peak reverse recovery current at elevated

temperature (150 °C) is reduced by 20% when compared with a 1.2 kV SiC power MOSFET's body diode [62]. The turn-on losses were found to be 50% smaller when using the JBSFET when compared with the SiC power MOSFET .

14.10 Unclamped Inductive Switching Stress

Power MOSFETs must be capable of absorbing high stress in circuits with unclamped inductive loads (UIL). The energy stored in the inductor must be absorbed by the device under high current avalanche breakdown. 1.2-kV 4H-SiC power MOSFETs has been studied under UIL stress [66]. A large (∼1000×) increase in leakage current was reported with 4% reduction in on-resistance. The greatest impact ionization was observed in the JFET region adjacent to the channel in numerical simulations. Hot holes are believed to be injected into the gate oxide producing the observed instability. The structure shown in Fig. 14.32 with a thick gate oxide over the JFET region was proposed to alleviate the problem. The thick gate oxide produced a reduction in the impact ionization rate due to smaller electric field near the channel.

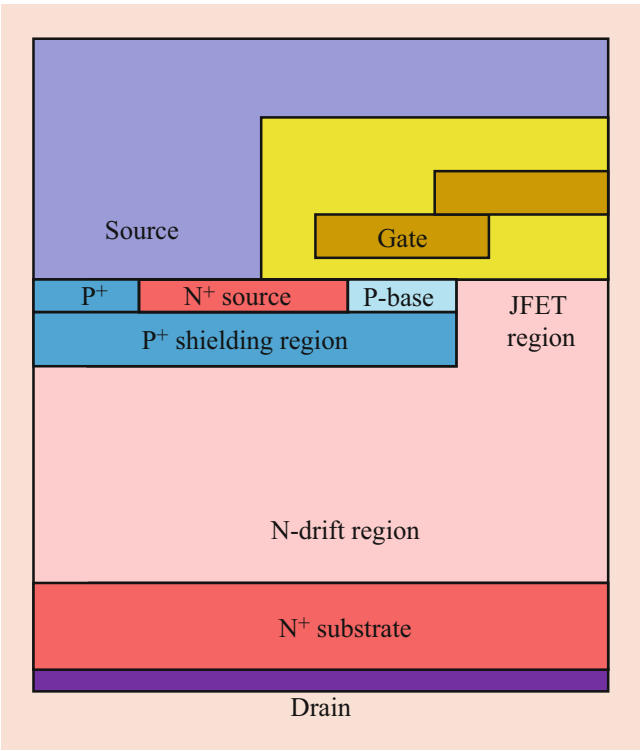

Fig. 14.32 Thick gate oxide planar 4H-SiC MOSFET structure with improved UIS capability

14.11 Short-Circuit Capability

Silicon IGBTs have excellent short-circuit withstand capability that is now commonly utilized in power electronic applications [1]. A similar capability is required for 4H-SiC power MOSFETs. Short-circuit tests on 1.2 kV 4H-SiC power MOSFETs tested with a DC bus voltage of 400 V [67] demonstrated 50 μs short-circuit time at a gate bias of 15 V. Planar-shielded 4H-SiC power MOSFET structures were reported [68] with improved performance due to shielding of the gate oxide. The devices were not evaluated at the typical circuit operating conditions of 800 V drain bias and 20 V gate bias.

1.2 kV Si IGBTs are available with the capability to survive a short circuit event in typical motor-drive applications for a duration of 15 μs with a collector bias of 800 V and on-state gate bias of 15 V. In contrast, typical 1.2 kV SiC power MOSFETs can survive a short circuit duration of only 4 μs with a collector bias of 800 V and on-state gate bias of 20 V [69]. An increase in short-circuit time can be achieved by reducing the saturated drain current at the on-state gate bias by increasing the channel length, reducing the channel width, or increasing the gate oxide thickness. All of these approaches produce an increase in the on-state resistance. Consequently, the short circuit capability must be traded-off against the specific on-resistance.

A recent study has demonstrated that the 1.2 kV SiC JBSFET structure provides a superior trade-off between specific on-resistance and short-circuit withstand capability (time) [70]. The JBSFET has a larger cell width compared with the MOSFET because of integration of the JBS diode. This reduces the channel density leading to a smaller saturation current for the same gate drive voltage. The 1.2 kV JBSFET were found to have a short-circuit time of 7 μs for a gate bias of 20 V and 11 μs for a gate bias of 15 V. As discussed in the previous section, the power SiC MOSFET must be paired with a JBS anti-parallel diode to reduce reverse recovery losses. The specific on-resistance for the JBSFET was found to be 24% smaller than that for a MOSFET with antiparallel diode when the area of the JBS diode is taken into account.

14.12 Shielded Trench-Gate Power MOSFET Structure

The silicon UMOSFET structure shown in Fig. 14.10 cannot be replicated in SiC because a high electric field develops across the oxide at the bottom of the trench leading to destructive failure. This problem occurs because the trench penetrates the P-base region exposing the gate oxide at the bottom of the trench to the high electric field in the silicon carbide drift region. The electric field in the gate oxide

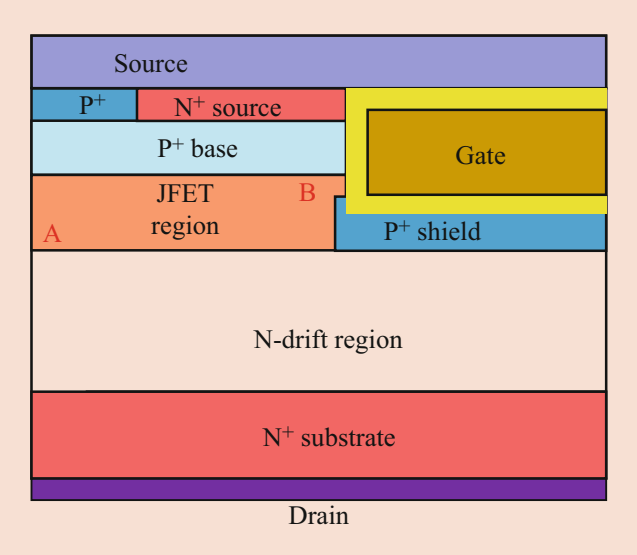

Fig. 14.33 Trench-gate SiC power MOSFET structure with P+ shielding region at trench bottom

reaches its rupture strength well before the electric field in the semiconductor approaches its breakdown field strength [22]. Consequently, in order to operate at any given blocking voltage, the drift region doping concentration has to be reduced and its thickness increased until the specific on-resistance becomes 25 times larger than that for the ideal drift region. This problem inhibited the performance of the first trench-gate 4H-SiC power MOSFETs. The trench-gate SiC power MOSFET structure with a P^+ shielding region at the trench bottom was proposed [71] to solve the problem.

14.12.1 Device Structure

The shielded trench-gate SiC power MOSFET structure is shown in Fig. 14.33. A P^+ region, connected to the source electrode at a location orthogonal to the device cross section, is placed at the bottom of the trench. The P^+ shielding region can be formed by ion implantation after etching the trenches.

The shielded trench-gate power MOSFET blocks current flow at low drain bias voltages with the voltage supported by the P-base/N-drift junction. A positive potential occurs at location "A" in Fig. 14.33 reverse biasing the junction between the P^+ shielding region and the N-drift region. The JFET formed by the P^+ shielding region produces a potential barrier at location "A" shielding the P-base region. This suppresses reach-through in the P-base region allowing shortening the channel length to reduce the on-resistance. It also reduces the electric field at location "B" which prevents high gate oxide electric fields.

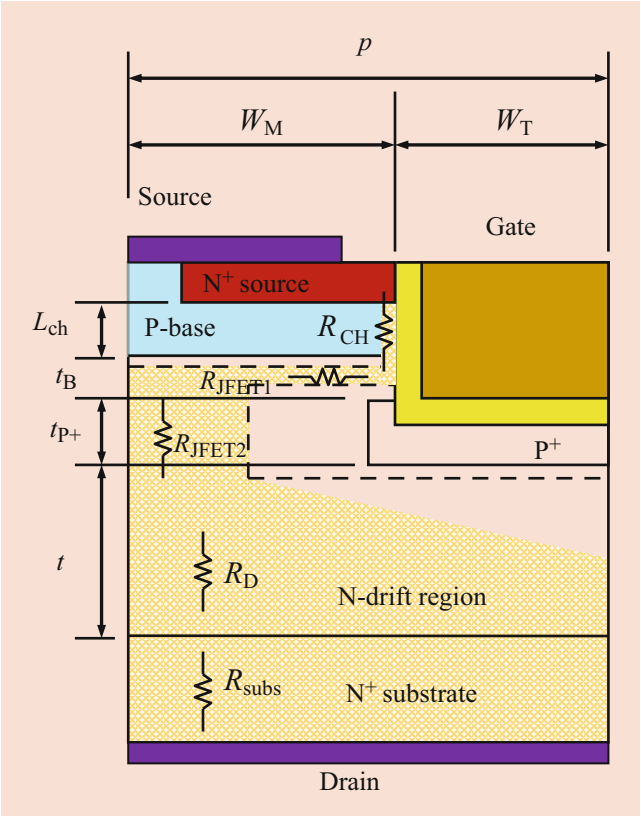

Fig. 14.34 Resistances in the shielded trench-gate SiC power MOSFET

14.12.2 On-Resistance

Current flow between the drain and source occurs in the shielded trench-gate MOSFET structure by creating an inversion layer channel at the trench sidewalls on the surface of the P-base region. Current flows from the source region into the drift region through the channel. The current flow at point "B" in Fig. 14.33 occurs via the first JFET (JFET1) region. It is then constricted by a second JFET (JFET2) region at point A before spreading into the N-drift region at a 45 degree angle. The current flow path is shown by the shaded regions in Fig. 14.34.

The spacing t_B in the figure must be sufficient to prevent it from becoming completely depleted. A smaller spacing can be used by increasing the doping concentration in the JFET1 region. The resistance of the second JFET region (R_{JFET2} in the figure) can also be reduced with this enhanced doping.

The specific on-resistance for the shielded trench-gate power MOSFET structure is

$$R_{on,sp} = R_{CH} + R_{JFET1} + R_{JFET2} + R_D + R_{subs} \quad (14.22)$$

where R_{CH} is the channel resistance, R_{JFET1} and R_{JFET2} are the resistances of the two JFET regions, R_D is the resistance of

the drift region, and R_{subs} is the resistance of the N^+ substrate. The specific channel resistance is.

$$R_{CH} = \frac{(L_{CH} \cdot p)}{\mu_{inv} C_{ox} (V_G - V_T)} \tag{14.23}$$

where L_{CH} is the channel length, μ_{inv} is the inversion layer mobility, C_{ox} is the specific gate oxide capacitance, V_G is the applied gate bias, and V_T is the threshold voltage. The specific gate oxide capacitance is

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{14.24}$$

where ε_{ox} is the dielectric constant for the gate oxide and t_{ox} is its thickness.

The specific resistance of the first JFET region is

$$R_{JFET1} = \rho_{JFET} \cdot p \cdot \left(\frac{x_{P+} + W_P}{t_B - 2W_P} \right) \tag{14.25}$$

where ρ_{JFET} is the resistivity of the JFET region, x_{P+} is the junction depth of the P^+ shielding region, and W_P is the zero-bias JFET region depletion width. The specific resistance of the second JFET region is

$$R_{JFET2} = \rho_{JFET} \cdot p \cdot \left(\frac{t_{P+} + 2W_P}{W_M - x_{P+} - W_P} \right) \tag{14.26}$$

The drift region spreading resistance is

$$R_D = \rho_D \cdot p \cdot \ln \left(\frac{p}{W_M - x_{P+} - W_P} \right) + \rho_D \cdot (t - W_T - x_{P+} - W_P) \tag{14.27}$$

where t is the thickness of the drift region below the P^+ shielding region and W_T, W_M are the widths of the trench and mesa regions, respectively, as shown in the figure. The N^+ substrate resistance is

$$R_{subs} = \rho_{subs} \cdot t_{subs} \tag{14.28}$$

where ρ_{subs} and t_{subs} are the resistivity and thickness of the substrate, respectively. The typical value is 4×10^{-4} Ω-cm^2.

The specific on-resistances obtained by using the above analytical models are shown in Fig. 14.35 for the 1.2 kV rated 4H-SiC shielded trench MOSFETs modeled using the above analytical expressions. Device parameters were (a) drift region thickness (t) of 12 μm; (b) drift doping concentration of 1×10^{16} cm^{-3}; (c) gate oxide thickness of 0.05 μm; (d) mesa width (W_M) of 1.0 μm; (e) trench width (W_T) of 0.25 μm; (f) P^+ shielding region junction depth of 0.2 μm; (g) space between P^+ shielding region and the P-base region (t_B) of 0.8 μm; and (h) JFET region doping concentration of 5×10^{16} cm^{-3}. A gate bias voltage (V_G) of 15 V was assumed with threshold voltage (V_T) of 5 V.

The on-resistance components are plotted in Fig. 14.35 for the case of channel inversion layer mobility of 25 cm^2/Vs. The channel resistance increases with increasing channel length as expected with no change in the other components. The drift region resistance is dominant for channel lengths below 1 μm. A total specific on-resistance of 1.8 mΩ-cm^2 can be achieved with a channel length of 0.4 μm, This is only five times the ideal specific on-resistance of the drift region.

14.12.3 Experimental Results

The trench-gate 4H-SiC power MOSFETs with a P^+ shielding region were experimentally demonstrated [72] in 2002 using a 50 μm thick N-type drift region with doping concentration of 8.5×10^{14} cm^{-3}. The doping concentration in the JFET region was increased by growth of an N-type layer with doping concentration of 2×10^{17} cm^{-3}. The 1 μm thick P-type base region was epitaxially grown with doping concentration of 2×10^{17} cm^{-3}. The N^+ source region with doping concentration of 1×10^{19} cm^{-}3 was also epitaxially grown. After etching the trench regions, the 0.8 μm deep P^+ shielding regions were created by aluminum ion implantation using a dose of 4×10^{13} cm^{-2}. A 0.275 μm thick gate oxide was formed by oxidation of polysilicon deposited into the trench resulting in a high threshold voltage of 40 V. A breakdown voltage of 3000 V was achieved by using a JTE edge termination. The low inversion layer channel mobility of 2 cm^2/V-s resulted in a high-specific on-resistance of 120 mΩ-cm^2 at a gate bias of 100 V. 5 kV devices were subsequently reported using 115 μm thick N-type drift regions with doping concentration of 7.5×10^{14} cm^{-3} [73]. A specific on-resistance of 228 mΩ-cm^2 was observed at a gate bias of 40 V.

An accumulation-channel trench-gate MOSFET structure, shown in Fig. 14.36, was reported with an epitaxially grown N-base region on the trench sidewalls [74] to achieve an accumulation channel mobility of 9–30 cm^2/V-s. A breakdown voltage of 1400 V was obtained by using a 10 μm thick N-type drift region with doping concentration of 2.5×10^{15} cm^{-3}. The 0.13 μm thick gate oxide was created by thermal oxidation of polysilicon deposited into the trenches. 16 mΩ-cm^2 specific on-resistance of was reported at a gate bias of 40 V.

The specific on-resistance of the shielded trench-gate 4H-SiC power MOSFET was improved by using two JFET layers [75] as shown in Fig. 14.37. A JFET layer 1 with doping concentration of 0.5–1 $\times 10^{17}$ cm^{-3} with a thickness of 0.5 μm was used to reduce R_{JFET1} and a JFET layer 2 with doping concentration of 1–2 $\times 10^{16}$ cm^{-3} with a thickness of 3 μm was used to reduce R_{JFET2}. A drift layer doping

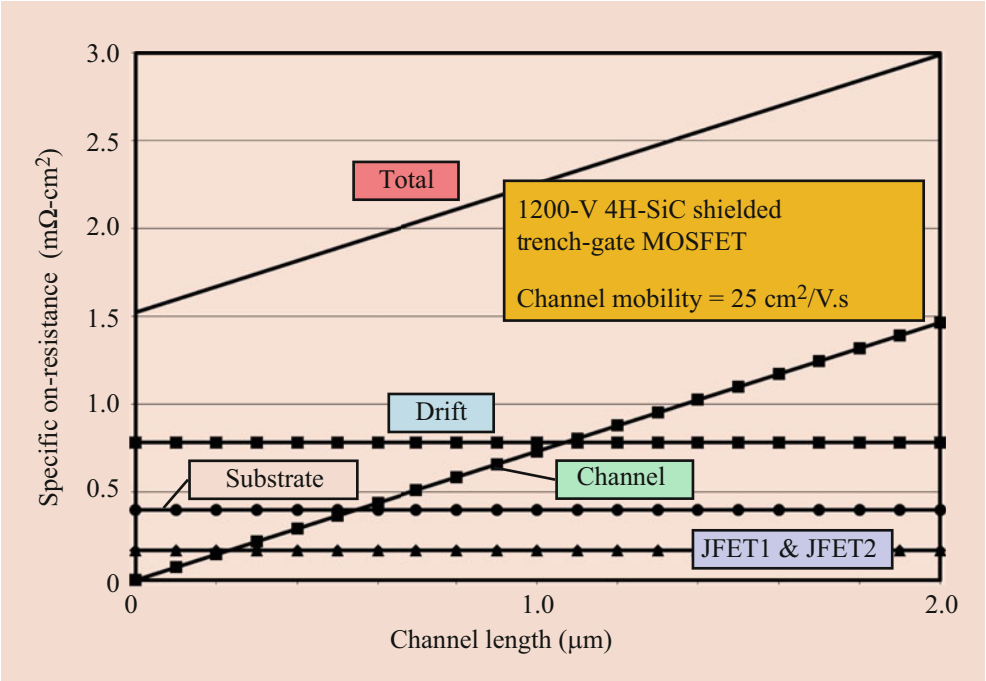

Fig. 14.35 On-resistances within 1.2 kV 4H-SiC shielded trench-gate MOSFET

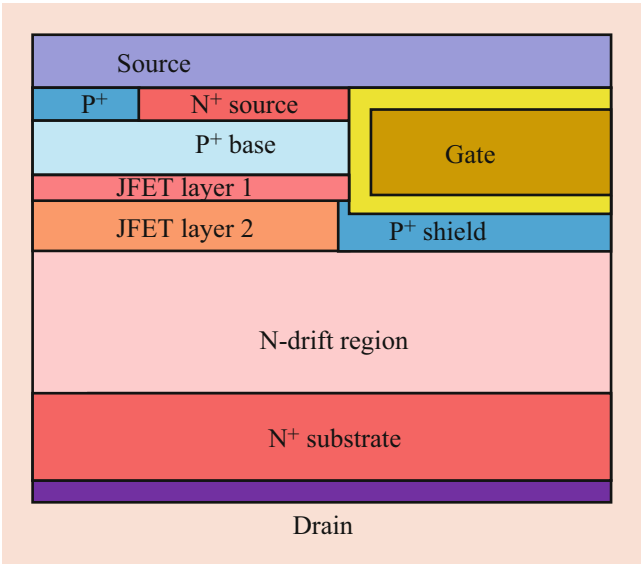

Fig. 14.37 Shielded trench-gate power MOSFET structure containing two JFET layers

concentration of 3–5 × 10^{15} cm^{-3} and thickness of 25 μm produced a blocking voltage of 1600 V. In spite of using a high gate bias of 60 V due to the large gate oxide thickness of 0.16 μm, a high specific on-resistance of 50 mΩ-cm^2 was observed. Various layout designs for connecting the P^+ shielding region to the source electrode have been explored [76]. At least one ground for every 9 cells was found to be necessary to get good short-circuit capability.

14.13 SiC Trench-Gate MOSFET with Thick Trench Bottom Oxide

The 4H-SiC trench-gate power MOSFET with thick trench bottom oxide is illustrated in Fig. 14.38. The electric field in the oxide at the bottom of the trench is reduced due to the larger thickness [77]. The electric field in the thick bottom

oxide was reduced to 5.0 MV/cm compared with 7.8 MV/cm for case with thin bottom oxide at a drain voltage of 1400 V for a drift region doping concentration of 6×10^{15} cm^{-3} and thickness of 13 μm. A specific on-resistance of 4.6 mΩ-cm^2 was reported for a gate bias of 20-V with 0.075 μm thick gate oxide.

Numerical simulations comparing the electrical performance of 1.2 kV rated SiC trench-gate power MOSFETs have been reported [78]. A summary of the findings are shown in Table 14.1. The trench bottom oxide thickness is the same as the gate oxide thickness in the basic structure. The trench-gate structure with thick bottom oxide (0.7 μm) has the lowest specific on-resistance. Its high-frequency-figure-of-merit (HF-FOM = [$R_{ON,SP}$*$C_{GD,SP}$]) is better than the basic trench-gate MOSFET structure. The trench-gate structure with P$^+$ shielding region at the trench bottom (see Fig. 14.33) has a higher specific on-resistance but similar HFFOM. The commercially available trench-gate MOSFETs from Rohm and Infineon have larger specific on-resistance. The Rohm and Infineon devices are discussed in the next section.

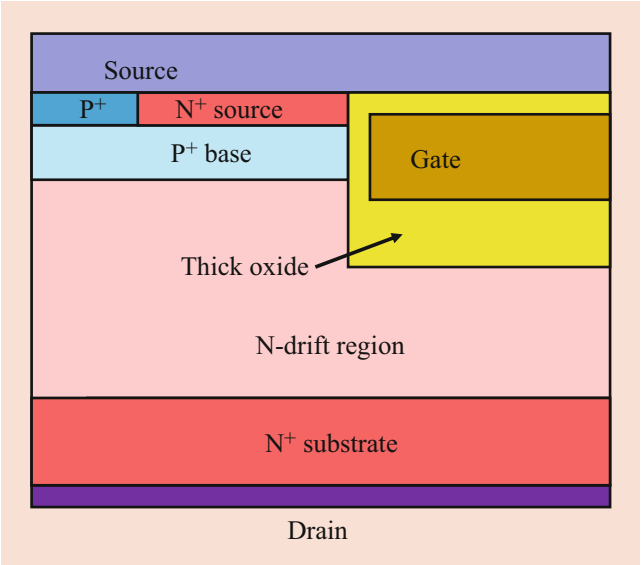

Fig. 14.38 Trench-gate power MOSFET structure with thick trench bottom oxide

14.14 SiC Trench-Gate MOSFET with Deep P+ Trench Regions

An approach taken by Rohm for shielding the gate oxide from high electric fields generated in the silicon carbide drift region is incorporation of a P$^+$ region in the mesa region by etching a second deep trench [79] as illustrated in Fig. 14.39. The deep P$^+$ regions shield the oxide at the bottom of the gate trenches. The electric field in the oxide was found to be less than 3 MV/cm if the P$^+$ region is 1.2 μm deeper than the bottom of the gate trench. 600 V devices were reported [80] with specific on-resistance of 0.79 mΩ-cm^2. Subsequently, 1200 V devices were reported [81] with specific on-resistance of 4 mΩ-cm^2 at a gate bias of 18 V.

The trench-gate SiC power MOSFET structure, shown in Fig. 14.40, with two deep P$^+$ regions has been reported by Infineon [82]. Both P$^+$ regions are used to form the JFET that reduces the electric field in the gate oxide. It is worth pointing out that the channel in this structure is formed along only one sidewall of the trench. This reduces the channel density resulting in the highest specific on-resistance among the trench-gate devices as shown in Table 14.1. However, it has a very low gate-drain capacitance resulting in excellent HFFOM.

14.15 SiC V-Groove Trench-Gate MOSFET

V-groove formation by thermochemical etching in a chlorine ambient [83] was used to make the trench 4H-SiC power MOSFET structure shown in Fig. 14.41. An inversion layer mobility of 80 cm^2/V-s was reported [84] along the sloping trench sidewalls. After growth of the N-type drift layer with doping concentration of 4.5×10^{15} cm^{-3} with a thickness of 12 μm, buried P$^+$ regions were formed by Aluminum ion implantation. A second epitaxial layer was then grown with doping concentration of 7×10^{15} cm^{-3} and thickness of

Table 14.1 Simulation results for trench-gate SiC MOSFET structures

3 μm. A channel length of 0.6 μm is achieved on the sloping trench sidewalls by controlling the P-base and N^+ source region depths. The buried P^+ regions shield the gate oxide. Devices with breakdown voltage of 1700-V had a specific on-resistance of 3.6 mΩ-cm^2 at a gate bias of 18 V. A hexagonal cell topology was optimized [85] demonstrating that the P^+ regions should occupy 30% of the active area to produce the best trade-off between low specific on-resistance and high breakdown voltage.

14.16 Silicon Carbide Bi-Directional Field Effect Transistor

Power devices that can block high voltage in the first and third quadrants and carry gate controlled current in both quadrants are required to create matrix converters [86]. Bidirectional switches have been proposed using either silicon IGBTs or SiC power MOSFETs with multiple independently packaged devices. These approaches are expensive, consume space, and exhibit high on-state voltage drop. The SiC-based Bi-directional Field Effect Transistor (BiDFET) solves these issues [87, 88]. In the BiDFET, two SiC JBSFETs are connected in series as shown in Fig. 14.42 with a common drain. The JBSFETs can be monolithically integrated on the same SiC wafer to create a four-terminal device. High AC voltages can be applied to terminal T2 of the BiDFET with Terminal T1 as the reference terminal. Gates G1 and G2 can be biased to control current flow in the first and third quadrant.

With zero bias applied to gate G1 with respect to terminal T1, a high positive voltage applied to terminal T2 can be supported across power JBSFET-1 and its edge termination, while the JBS diode in JBSFET 2 is forward biased. With zero bias applied to gate G2 with respect to terminal T2, a high negative voltage applied to terminal T2 can be supported across power JBSFET-2, and its edge termination while the JBS diode in JBSFET 1 is forward biased. This provides the BiDFET with symmetric high blocking voltage capability in both quadrants.

Application of a positive gate drive voltage to both gates G1 and G2 with reference to the corresponding terminals T1 and T2 allows current conduction in the first and third quadrants via the channel for both SiC power JBSFETs. The

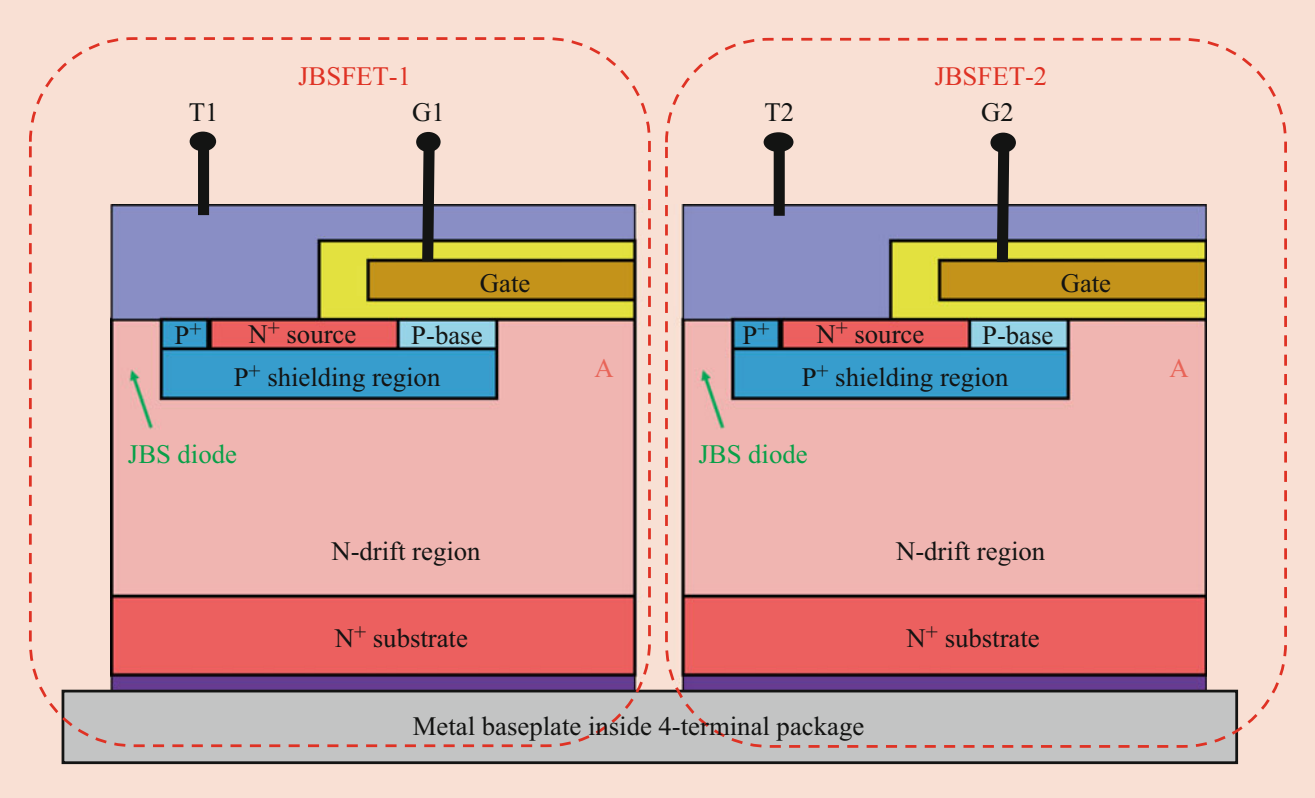

Fig. 14.42 The SiC Bi-Directional Field Effect Transistor (BiDFET) structure

on-resistance of the BiDFET is the sum of the on-resistance of JBSFET 1 and 2.

Excellent output characteristics with gate voltage controlled current saturation are achieved in the BiDFET due to the internal SiC power JBSFETs. Fast switching capability is also ensured in the BiDFET due to the internal SiC power JBSFETs. These features allow matrix converters with BiDFETs to operate at high frequencies to achieve high-power density.

BiDFET were first experimentally demonstrated by using 1.2 kV rated JBSFETs [88]. The devices exhibited gate voltage controlled output characteristics with blocking voltages of up to 1650 V in the first and third quadrant. The on-resistance of the BiDFET in both quadrants was found to be the sum of the resistance of each of the JBSFETs as expected. A low on-state voltage drop can be achieved by increasing the active area of both JBSFETs. A 1.2 kV rated SiC BiDFET with on-resistance of 50 mΩ was achieved by packaging two commercially available SiC power MOSFET dies in a 4-terminal module [89]. In addition, a monolithic 1.2 kV SiC BiDFET was successfully manufactured in a 6-inch foundry and the single die packaged in a 4-terminal module [90]. In comparison with previous bi-directional switches that required 4–6 separately packaged devices, the BiDFET requires only a single four-terminal package.

14.17 Commercial Devices

The commercialization of silicon carbide power devices became feasible with the ability to grow 4H-SiC wafers with diameters of 100 mm. Wafers with diameters of 150 mm are now available from multiple sources. In addition, the ability to grow thick epitaxial layers with doping concentration approaching 1×10^{14} cm^{-3} have made the manufacturing of the very high voltage (>10-kV) silicon carbide products a possibility. However, companies have targeted the 1200-V and 1700-V markets for their initial products. At this voltage range, the 4H-SiC unipolar devices offer much better switching characteristics than silicon IGBTs while providing a lower on-state voltage drop as well.

The first 4H-SiC products were JBS rectifiers. Two kinds of silicon carbide switches have been developed as products: JFETs and MOSFETs. The JFETs were introduced earlier because of problems with poor channel mobility in MOSFETs. Recent progress with improving MOS-channels – with advanced gate oxide and interface preparation, and by utilizing the accumulation-mode concept – has made high performance 4H-SiC power MOSFET products feasible. The momentum for power switch product commercialization has now shifted from JFETs to MOSFETs.

14.18 Silicon Carbide Power Device Applications

Silicon carbide power MOSFETs are excellent candidates to replace silicon IGBTs in all applications because of their low on-resistance and reduced switching losses. However, the cost of the SiC power MOSFETs is substantially larger than that of silicon IGBTs. As a consequence, SiC power MOSFETs have been successfully used only in selected applications as shown in Fig. 14.43. One of these applications is inverters for solar power generation. The replacement of silicon IGBTs with SiC power MOSFETs has been shown to increase the efficiency by 1–2%. This modest gain in energy generation offsets the larger initial cost of the SiC devices.

Another promising application for SiC power MOSFETs is in inverters for electric and hybrid-electric vehicles. The improved inverter efficiency allows extending the range of the vehicles. In addition, the SiC inverters can be operated at higher frequencies than those based on silicon IGBTs. This allows reduction of passive component size and weight, an important benefit for electric vehicles.

As the cost of SiC power MOSFET is reduced in the future, it is anticipated that their applications will expand as indicated by the arrows in Fig. 14.43. The penetration of SiC power MOSFETs into applications served by the Si IGBT will be accelerated by making products with superior HF-FOMs, such as the SG-MOSFET and BG-MOSFET.

Due to the low switching losses for silicon carbide power MOSFETs, they are good competitors to silicon IGBTs in circuits operating at higher frequencies. One example is a 1 MVA solid-state power substation (SSPS) designed using 10-kV SiC modules [91] soft-switching at 20 kHz. Twenty-four MOSFETs and twelve Schottky diodes were used per module to achieve a current handling capability of 120 A per switch. Low voltage silicon Schottky diodes were placed in series with the SiC power MOSFETs to prevent conduction of the body diode. This can be avoided in the future by using the SiC JBSFET structure. The SSPS converted 13.8-kV to 300-V with 97% efficiency resulting in 75% reduction in weight and 50% reduction in size over the conventional 60-Hz transformer.

4H-SiC power MOSFETs have also been used to create a solid-state transformer (SST) to convert the 3.6-kV distribution grid voltage to 400-V DC and 240/120-V AC voltage [92]. By using 13-kV SiC power MOSFETs on the primary side, the topology of the SST is simplified to a single H-bridge AC/DC rectifier, an isolated dual half-bridge (DHB) DC/DC converter, and a DC/AC inverter. The DC link operates at 6-kV inside the SST. The DHB is

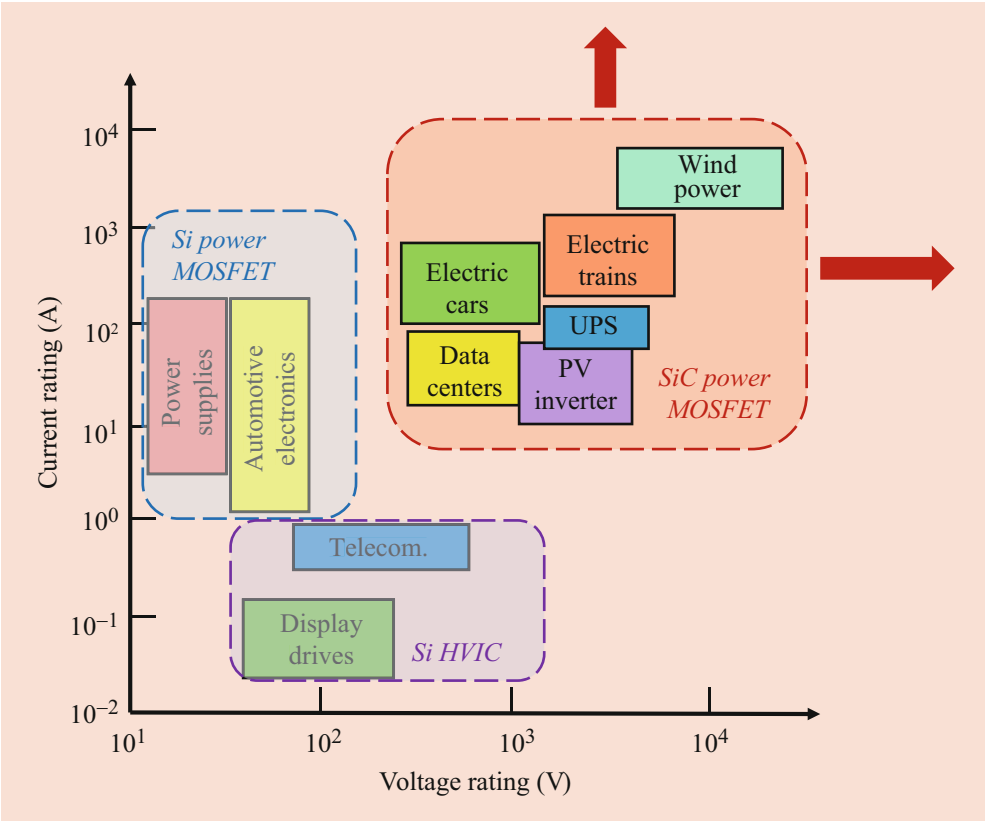

Fig. 14.43 SiC power device application opportunities

operated at 15 kHz to reduce the size and weight of the high-frequency transformer. The switching losses in the SiC power MOSFETs are reduced by soft-switching. 1.2 kV SiC power MOSFETs are used on the secondary side to produce the 400-V DC and 220/120 V AC outputs. The rectifier stage and the DHB were found to have an efficiency of over 98%, while the peak efficiency for the inverter stage was 97%.

14.19 Conclusions

In this chapter, the inclusion of a P-N junction to shield the Schottky contact was shown to be essential to create SiC JBS rectifiers that became successful products. These devices are now commercially available for use as anti-parallel diodes with IGBTs in inverter circuits.

In the case of SiC planar-gate power MOSFETs, the incorporation of a sub-surface P^+ shielding region was found to be essential to prevent P-base reach-through limited breakdown and for preventing high electric fields from developing across the gate oxide during the blocking mode. Since relatively low inversion layer mobility has been reported for 4H-SiC MOSFETs, an accumulation-mode structure was proposed with an N-base region that is completely depleted by the built-in potential of the underlying P^+/N junction. This structure takes advantage of the much larger accumulation mobility observed in semiconductors.

The operating principle of the planar shielded MOSFET structures has been reviewed in the chapter providing guidelines for the design of the structures. It has been demonstrated that the JFET width is a critical parameter that controls the electric field at the gate oxide interface as well as the specific on-resistance. Its optimization is important for obtaining high performance devices. In the case of the accumulation-mode structure, the appropriate combination of the doping concentration and thickness of the N-base region must be chosen to ensure that it is completely depleted by the built-in potential of the underlying P^+/N junction. With adequate shielding of the base region, it is found that short channel devices will support high blocking voltages limited only by the properties of the drift region. These devices have excellent safe-operating-area and fast switching speed. This technology has potential for use in systems operating at and perhaps above 10,000 V.

The specific on-resistance for SiC power MOSFETs calculated using two values for the channel resistance are shown in Fig. 14.44 as a function of the blocking voltage. The ideal specific on-resistance for silicon and silicon carbide is included in the figure. It is apparent that the planar-gate devices can approach the ideal limit of performance for blocking voltages above 5 kV. However, devices with blocking voltages below 2 kV become limited by the channel resistance. State-of-the-art devices planar-gate devices have performance consistent with this analysis as shown by the triangular points [93].

In conclusion, silicon carbide power MOSFETs have reached a sufficient degree of maturity to find applications at higher frequencies. They can replace silicon IGBTs in

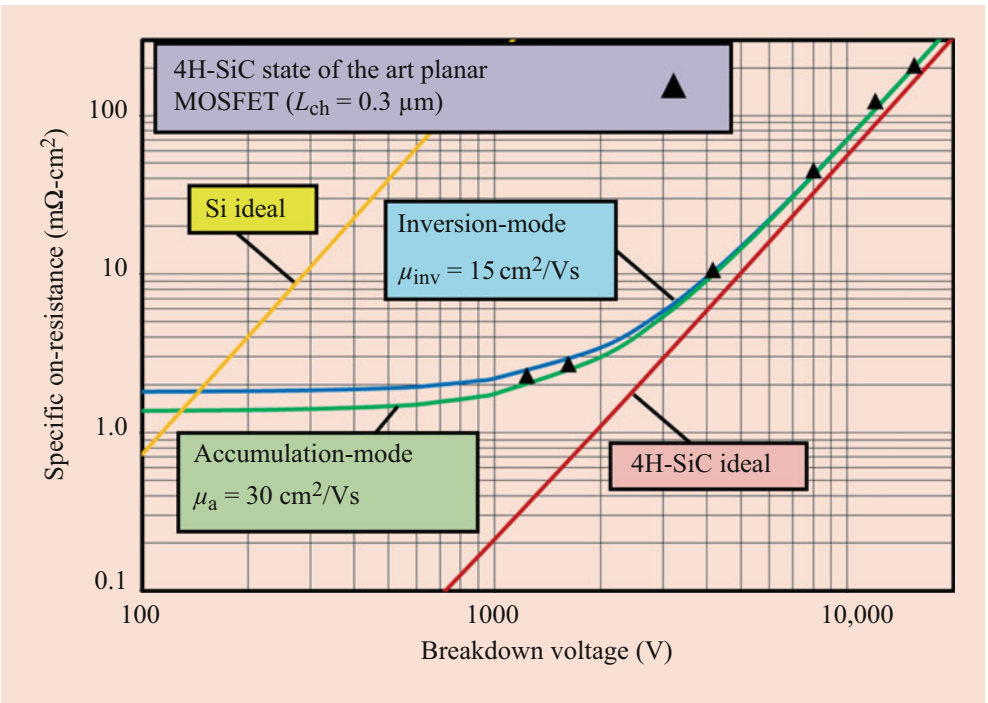

Fig. 14.44 Specific on-resistance for SiC power MOSFETs of various blocking voltages

applications where the switching losses are dominant to achieve significant reduction of size and weight due to improved efficiency. The development of silicon carbide power devices has been motivated by the opportunity to create unipolar devices with high blocking voltage capability. Silicon carbide JBS rectifiers and power MOSFETs with excellent on-state voltage drop have been demonstrated with blocking voltages up to 5000 V. These devices offer low switching losses when compared with the silicon P-i-N rectifiers and IGBTs enabling increasing the circuit operating frequency which reduces the size of passive components and filters in applications. The applications of the SiC devices is constrained by their higher cost when compared with silicon devices. The lower switching losses of these devices can to utilized to increase the circuit operating frequency leading to smaller, less expensive passive elements to offset the higher device cost.

Abstract

In the last decade, GaN has emerged as an excellent material for application in power electronics. The wide energy gap of gallium nitride (3.4 eV) enables high-temperature operation, while the large breakdown field (3.3 MV/cm, 11 times higher than silicon) allows to reach kV-range operation while maintaining a low on-resistance. Thanks to the high mobility of the two-dimensional electron gas at the AlGaN/GaN interface, lateral GaN transistors have a very low on-resistance; commercial products are already on the market, and new technologies are being developed, targeting the 650 V/900 V ranges. Recently, the attention toward vertical GaN transistors has constantly increased: a vertical layout allows to substantially increase current density while taking advantage of the wide bandgap and high breakdown field of GaN. Vertical transistors based on GaN are expected to find application in converters with medium high power levels (>5 to 10 kW), once the technology reaches maturity.

This chapter reviews the main properties of GaN-based materials and devices. The first part focuses on the main challenges related to the growth of high-quality GaN epitaxial stacks. The second and the third parts focus on GaN lateral and vertical devices, respectively. Finally, the fourth section describes the trapping and degradation
