outperform organic semiconductors. Recent works from Rogers' group have shown that both ZnO and a-IGZO are water soluble [28, 49]. Moreover, Ga and In are approved as alloys by the US Food and Drug Administration, and ZnO at concentration <100 μg/ml is biocompatible. Nickel oxide (NiO) is another candidate as semiconductor material [50]. Chemical studies show that NiO is water soluble: $NiO + H_2O \rightarrow Ni(OH)_2$. According to US dietary intake regulation, the tolerable upper limit of dietary nickel is 1000 μg/day, while estimated average ingestion is 69–162 μg/day [51]. Preliminary works have shown that sputtered NiO has a p-type behavior, and it can be used for the fabrication of p-n diodes [52]. Such results, however, were obtained on nonbiodegradable substrates.

Organic Semiconductors Organic materials represent a straightforward and most natural choice for the construction of degradable electronic devices because of their inherent biocompatibility [53]. Various π-conjugated molecules have been used as semiconductors including β-carotene and parylene. Among organic semiconductors for biodegradable electronics, Indigo deserves a special place. It is the most mass-produced dyestuff worldwide primarily for the coloring of the blue jeans. Indigo and its derivatives are thermally and photo-chemically stable and have been used by Bauer's group to realize field effect transistors with mobility in the order of 0.4 cm^2/Vs [54].

28.1.5 Dielectrics

Other water-soluble dielectrics include MgO and Si_3N_4 [55]. As in the case of SiO_2, such materials can be deposited on a large area and good quality and, hence, be used as insulators in thin film transistors [13]. Most of the polymers discussed in the paragraph 1.2 are dielectrics and can be used for the realization of electronics device [53]. One relevant example is PVA that can be deposited in thin film by spin coating [24]. Table 28.3 reports the dissolution rates of the most common degradable dielectrics.

28.2 Devices, Circuits, and Systems

While a lot of work has been done on the study of the dissolution dynamics of the materials, much less has been done on the fabrication of device and circuits. Most of the examples come from medicine and pharmacology. In 2003, Langer group demonstrated a PLGA-based device for multiple drugs delivery (pharmacy in a chip) [59]. A selective and controlled release of different drugs was achieved, thanks to 36 reservoirs and membranes with different molecular masses. Microneedles formed by PLA and carboxymethylcellulose have been also reported for transdermal drug delivery [5]. The dissolution of the needles, once injected into the skin, is responsible of the release. Dissolvable medical devices also include stents for angioplasty and magnesium scaffolds for tissue regeneration [60]. All these examples exhibit poor functionalities which usually consist of mechanical support and/or encapsulation. The development of transient electronics could instill "intelligence" to these systems and meanwhile keep the advantages of eliminating a second surgery for device retrieval. Biodegradable electronics would have great potential in scenarios where devices are only temporarily needed, as long as biocompatibility is not scarified for degradation. Biocompatibility therefore remains an essential consideration for building biodegradable electronics. To achieve ideal biocompatibility and functionality, both biologically benign dissolution products and mechanical/geometric properties have to be taken into account. Strategies ensuring biocompatible end products, reasonable release rates, and minimal and safe disintegrated fragments resulting from degradation would play an important role to maximize the benefits of transient electronics. Moreover,

Table 28.3 Dielectrics. Dissolution rates of degradable inorganic dielectrics in various solutions and conditions

various materials and device strategies have been proposed to realize soft, flexible, or stretchable electronic systems with mechanical properties close to biological systems and desirable device/tissue interfaces [61–65], which has already been involved in designing transient electronics.

28.2.1 Transistors and Circuits

The concept of "transient" or "biodegradable" electronics is very recent. In 2009, Rogers' group, at UIUC, demonstrated, for the first time, silicon transistors on silk substrate which dissolve in water [47]. One year later at Stanford University, Bao's group reported an organic biodegradable transistor on a poly(L-lactide-co-glycolide), PLGA, substrate [24]. The thin film transistors (TFTs) exhibit poor electron mobility which is about 0.253 cm^2/Vs, on/off current ratios (I_{on}/I_{off}) up to 9.4×10^3 and a threshold voltage of about −15 V. The same year, Bauer's group, at Johannes Kepler University, used natural materials like glucose, guanine, adenine, and indigo as semiconductors. The reported devices show a mobility of about 0.015 cm^2/V and an operating voltage as low as 5 V [66]. Another remarkable advancement arrived in 2012 when Rogers' group showed fully dissolvable, high-performance and scalable silicon-based components which dissolve in water at 37 °C. Here, the integration of crystalline silicon nanomembranes (NMs) on silk substrate enables operational characteristics comparable to standard consumer electronics. The resulting electrical properties for an n-channel device include mobility of 560 cm^2/Vs, on/off ratios of about 10^5, subthreshold slopes of 160 mV/dec, and width-normalized current outputs of 0.34 mA/mm.

In digital applications the main figures of merit are the threshold voltage (V_{th}), the ratio between the on and off current (I_{on}/I_{off}), and the subthreshold swing (SS). An ideal digital switch must have the V_{th} and SS as small as possible and the I_{on}/I_{off} ratio as large as possible. Analog designers are mostly interested at the transconductance (g_m) of the device and, hence, at its field effect mobility (μ). Such device-level parameters are ultimately influenced by (i) the intrinsic properties of the semiconductors-dielectrics-metals, by (ii) the combination of materials, by (iii) the interface between the gate dielectric and the semiconductor, and by (iv) the fabrication processes. The (i) has been discussed in the previous pages, while the (iv) will be described later in the chapter. It is worth highlighting the fact that the four mentioned points are interdependent. For example, the low-temperature polymeric substrates set constraints for the direct growth of crystalline materials and for their patterning and, eventually, limit the performance of the device.

Here, we will focus on some of the technological variables that must be considered to select the materials for the construction of a degradable transistor.

Dielectric Constant of the Gate Insulator In scaled transistor it is beneficial to adopt high-k gate dielectric in order to reduce the operating voltage and minimize the gate leakage. Among the inorganic and degradable dielectrics, Si_3N_4 has the highest constant (about 7) with SiO_2 and MgO that have 3.9 and 3.2, respectively. Among the organic materials, PVA has a dielectric constant in the range of 7–10 hence being suitable for the deposition of layers thinner than 50 nm. However, such thickness is hard to be achieved because of its low equivalent resistance at low voltage. Moreover, in organic transistors, the use of high-k gate dielectric layer may deteriorate the carrier transport. The energetic disorder caused by the dipoles in high-k dielectric tends to trap carriers from gate bias-induced conduction channel. The resulted localization

of charge carriers could cause not only mobility degradation but also increased hysteresis and device instabilities. It was shown that, by inserting a thin, low-*k* dielectric layer between the high-*k* one and the channel, the dipole field can be effectively screened for improved device performance [67].

Semiconductor-Dielectric Interface As the dielectric surface roughness increases, the morphology of the dielectric-semiconductor interface changes significantly, and the mobility of the transistors decreases rapidly. It is suggested that the increased lateral grain boundaries limit the transport between domains and reduce the field effect mobility. It is also found that the V_{th} shift caused by gate bias stressing was extremely sensitive to the dielectric surface roughness. The rougher dielectric surface afforded a larger V_{th} shift. The researchers suggested that the increasing amount of trap states enhanced by the rough dielectric surface is the original reason of this instable V_{th}. Other effects are the increase of the subthreshold swing and the appearance of the hysteresis in the transfer characteristic of the device [68].

In addition to the roughness, the performance of the transistors is highly affected by the surface energy of dielectric layers. Different from the dielectric roughness, the surface energy impacts the performances of organic transistors not by hindering the charges transport directly but by influencing the orientation of semiconductor molecules and the morphology of semiconductor layers. The researchers find the grain size of pentacene increased with the increase of dielectric surface energy. Consequently, depressed mobility of OFETs is observed on high surface energy dielectric layers even with larger-grain morphology [69].

In general, the above described effects are valid for both organic and inorganic materials, and they depend on the growth/deposition conditions, usually with larger effects in case of low-temperature processing on polymeric deformable substrates. The correct choice of the device structure, i.e., top or bottom gate, staggered or coplanar, may also play a role and, eventually, alleviate some of the listed issues.

Band Alignment The choice of the materials defines the band alignment. Of great importance is the alignment of the energy levels for the gate stack and for the source/drain metallization. Here, the focus is on the dielectric semiconductor bandgap, but many references are available on the other subjects [70, 71]. Figure 28.3 reports the band alignment for most of the semiconductors and dielectrics that have been chosen to build degradable transistors. Ideally the dielectric bandgap should be as large as possible and should be aligned with the semiconductor bandgap in order to minimize the gate leakage for both p- and n-type devices. The plot highlights how the shifted gap of indigo would result in higher leakage and, hence, in a smaller I_{on}/I_{off} ratio (see Table 28.4). In this regard, Si, Ge, and MoS_2 are better choices.

Anisotropy and Polarity The performance of the transistors, especially the V_{th} and the V_{on}, is to a great extent affected by the polar groups on the gate dielectric. Take p-type channel OFETs as an example; in case where the end groups at the interface are electron-withdrawing groups (e.g., -F), this means electrons from the semiconductor film will be attracted by the additional holes supplied by those groups in the channel. Thus, a more positive gate bias is needed to switch off the device [69].

The directionality of the semiconductor bonds also plays a role. For example, the excellent charge transport properties of indigoid dyes are attributed to the strong intermolecular interactions of π-stacking reinforced by hydrogen bonding. Due to the directionality of π-stacking (typically along the crystallographic b-axis for most indigoids), charge transport is highly anisotropic. In order to achieve good OFET performance, molecules must adopt a "standing-up" conformation, with π-stacking parallel to the gate dielectric. To achieve this, aliphatic dielectric materials are used, such as polyethylene or the natural oligoethylene tetratetracontane [54].

Table 28.4 contains a list of field effect transistors that have been reported over the last 20 years with the constituent materials and their main electrical properties. However, the excellent performance of inorganic transistors often comes at costs of serial and complicate fabrication process which involve multiple micro-transfer printing steps to move the silicon NMs from the native silicon on insulator (SOI) wafer to the final degradable substrate. So, while the use of organic semiconductors sets stringent constraint to the performance and stability of the transistors, the abstruse manufacturing of silicon NMs hinders the fabrication of complex circuits with only few examples limited to basic digital block-like inverter, AND, and NAND [72].

The developments of more complex circuits, both analog and digital, would be indispensable to build systems which are able to amplify, filter, digitalize the signal acquired by the sensors, and communicate the data wirelessly. These are all necessary requirements to build the next generation of resorbable medical implants and compostable deployable sensors.

Only a few examples of logic circuits have been reported, including basic logic functions like inverters, ANDs, and NANDs made of silicon nanomembranes as semiconducting layer [36, 72], ring oscillators, as well as analog amplifiers in stacked 3D assembly using foundry-based microcomponents [35, 73], a-IGZO-based ring oscillators working at 19 V and up to 57 kHz [28]. Gallium arsenide has been also used to fabricate microwave electrical components on flexible cellulose nanofibril paper proving that it is feasible to fabricate high-performance flexible electronics using ecofriendly materials.

"c-" stands for crystalline silicon, "a-" stands for amorphous indium gallium zinc oxide

28.2.2 Sensors

Resorbable or biodegradable sensors are probably the most appealing and important class of devices which can be developed by this technology, with applications spanning from biomedical and implantable devices to environmental deployed sensors [45, 74]. Recently, Salvatore et al. reported a fully biodegradable temperature sensors made of Mg microstructures encapsulated by compostable EcoFlex® thin layers [18]. Such devices have fast dynamic response and high flexibility prospecting their use in packaging for food monitoring.

In biomedical applications, the specially designed flexible transient electronics can be closely connected with tissues

and organs; thus it can detect abnormal physiological signals sensitively and accurately, which is of great help to human disease monitoring and rehabilitation. There are various single-functional or multifunctional biodegradable sensors reported. Rogers' group utilizes MoS_2, a 2D material with unique mechanical, thermal, electrical, and optical properties, to create a multifunctional biosensor with good biocompatibility and biodegradability for accurate measurement of pressure, temperature, strain, and motion [58], as shown in Fig. 28.4a–e. Here, the CVD-grown polycrystalline MoS_2 monolayer film (grain size ~200 nm) takes about 2 months to completely dissolve at 37 °C in PBS solution. Rogers' group also developed a set of biodegradable transient electronics using doped silicon nanomembranes [25]. Figure 28.4f, g shows the device architecture of a stretchable and biodegradable pH biosensor and electrophysiology (EP) biosensor. In addition, Yu et al. reported a soft and high-resolution electrocorticography (ECoG) recording system based on Si devices which records in vivo electrophysiological signals from the cortical surface and the subgaleal space [75]. The

flexibility allows the device to be in close contact with the cerebral cortex, ensuring high data accuracy. Furthermore, such device can be completely degraded in PBS solutions, thus avoiding the risk of re-surgery removal to the brain. Kang et al. also reported a bioresorbable pressure and temperature Si sensor for the brain [45]. Moreover, recent studies have reported optical sensors functionalized with binding elements (such as receptors, antibodies, nucleic acids, enzymes, etc.) integrated with the device to react with target molecules [76].

Thermal therapy platforms and drug delivery systems have also gained much attention from researchers. Certain bacteria, such as *Staphylococcus aureus*, are highly sensitive to environmental changes, and their survival is reduced with an increase in the temperature. Based on this principle, it is possible to heat the specific part by implanting devices to achieve the effect of promoting wound healing. As shown in Fig. 28.4j, Tao et al. developed a transient radio-frequency (RF) device based on a Mg heater embedded between silk fibroin layers [20]. Such therapeutic device made of fully biodegradable packaging materials and electronics can be remotely activated by radio frequency after implantation. In addition to being able to heat specific sites, such thermal therapy platforms can also be used to trigger drug delivery, such as enhancing ampicillin molecular release in the silk fibroin film by an increase in temperature. Another work done by Rogers' group provides a biodegradable device that combines thermally actuated lipid membranes loaded with multiple types of drugs in a spatial array, which can be remotely activated by radio frequency [77]. Such device enables external excitation while precisely controlling drug dose. A wireless and programmable bioresorbable electrical stimulation platform has also been proposed to facilitate peripheral nerve regeneration [78].

28.2.3 Optical Devices: LEDs

Researches of biodegradable LEDs to replace commercial LEDs (high chemical stability and the risk of releasing toxic heavy metals) for use in the medical and environmental sectors expand the range of applications for such electronics. There are already some works to explore the material choices for biodegradable LEDs, such as partially biodegradable riboflavin- and peptide-based organic devices [79, 80]. Lu reports the first examples of LEDs with full biodegradability in aqueous solutions [81]. The device is demonstrated by the use of a II–VI semiconductor, ZnO, and an ultrathin (8 nm) transparent electrode of Mo, with a maximum optical power density of 0.7 mW cm^{-2} at 9 V.

Another interest in optical devices is providing intimate optical coupling to biological tissues based on the interaction of light with biological materials [19, 82]. Macromolecular materials such as silk fibroin, PLGA, and PLA are demonstrated to serve as bioresorbable waveguide materials. The main drawbacks, however, include swelling due to water absorption and limited contrast in index of refraction [83]. Recently, a silicon-based, bioresorbable photonic platform is established, in which thin filaments of monocrystalline silicon encapsulated by polymers as flexible, low loss, dimensionally stable, and bioresorbable optical waveguides provide precise optical transmission and sensing at targeted sites in biological systems [84].

28.2.4 Powering Devices: Batteries, Photovoltaics,and Energy Harvesters

Power devices are an important part of biodegradable electronics as they are essential to ensure stable operation of the electronic system in the human body. For biomedical applications, power devices need to be flexible, stretchable, and miniaturized, while the constituent materials should be highly biocompatible and fully degradable in vivo [85]. Currently, biodegradable power devices are expanded into the following categories: batteries, supercapacitors, photovoltaic devices, radio-frequency (RF) power scavengers, piezoelectric harvesters, etc.

Batteries. Biodegradable batteries providing energy for self-powered electronics in vivo have high-energy density and excellent biocompatibility. At present, researches on biodegradable batteries mainly focus on galvanic cells using biocompatible metallic electrode systems and metal-ion battery systems. For the former, Fig. 28.5a, b shows a biodegradable primary battery system consisting four Mg-Mo cells, with polyanhydride serving as spacers and packaging material [86]. Such battery system can provide a stable output voltage up to 1.6 V for 6 h at a constant current density of 0.1 mA cm^{-2}. Another fully biodegradable battery using Mg and molybdenum trioxide (MoO_3) in Fig. 28.5c provides a highly stable output voltage up to 1.6 V and capacity up to 6.5 mAh cm^{-2} while having a lifetime of 13 days [87]. For the latter, Kim et al. have reported an edible sodium ion battery with biologically derived melanin as an electrode [88]. Magnesium-iron storage devices with polycaprolactone (PCL) as a packaging and functional material have been also demonstrated [89].

Supercapacitors. Supercapacitors are an important energy source choice because of their higher power density, charge/discharge rates, and longer cycle lifetime compared to batteries. They store energy by forming an interface bilayer between the electrode and the electrolyte either through ion adsorption or redox reaction. A supercapacitor can be fabricated by a variety of different materials (metals, oxides [13, 90, 91], silicon [92], and organic polymers [93]) combined in the form of thin films. Based on such process, biodegradable supercapacitors can be developed by considering the degradation properties, biocompatibilities, and flexibilities of materials. Lee et al. provided the first fully biodegradable and edible supercapacitor using metallic electrodes (W, Fe, or Mo) and hydrogel electrolytes made of NaCl/agarose, both of which are biodegradable materials [90]. The supercapacitor provides a capacitance of 1.6 mF cm^{-2} and power density of 1 mW cm^{-2}. Studies on eumelanin have also demonstrated that this biocompatible and biodegradable material may be an effective candidate for future supercapacitor electrodes [93], as shown in Fig. 28.5d.

Photovoltaic devices. Photovoltaic (PV) power generation is a technology that directly converts light into electricity by utilizing the photovoltaic effect of the semiconductor interface. As a clean energy technology that has been developed worldwide in recent years, the light conversion efficiency of PV cells has been greatly improved, which also laid the foundation for its functional devices as implantable electronic devices. Unlike photovoltaic power generation in vitro, photovoltaic cells implanted in vivo are completely encapsulated in biological tissues (such as skin, fat, muscles, etc.) and in most cases are inefficient due to the absorption and scattering of light. Currently, biological tissue has two optically transparent windows in a specific near-infrared spectral region (NIR), 650–950 and 1000–1350 nm, respectively [88, 94]. Kang et al. have reported a fully degradable amorphous silicon (a-Si) transient thin film solar cell consisting of zinc oxide and magnesium, which can be completely degraded in a few days [48]. Lu et al. studied the first fully biodegradable silicon solar cells working in vivo [44], which appears in Fig. 28.5e, f. The fabricated PV cell array generated ≈60 μW of electrical power under 4 mm of porcine skin and fat, with an optical power density of 200 mW cm^{-2} produced by a NIR (780 nm) light-emitting diode (LED). The entire photovoltaic system coated with polylactic acid-glycolic acid (PLGA)

((**e**) and (**f**) Reproduced with permission. [44] Copyright 2018, John Wiley and Sons)

matrix can be almost completely degraded by hydrolysis after 27 days, which proves the feasibility of biodegradable photovoltaic cell system. However, biodegradable photovoltaic cells currently have problems such as light source scattering, absorption, excessive depth limitation (several millimeters), and potential tissue heating [85].

Radio-frequency (RF) power scavengers. Power harvesting via radio-frequency transmission was reported by Rogers' group for the realization of resorbable implants such as the neural cuff. One of these devices demonstrated real therapeutic functionality for infection abatement [20]. After 15 days the device, constituted by a Mg planar coil, a drug reservoir, and silk layers as substrate and encapsulation, was fully resorbed by the body without any inflammatory response in the associated tissues. In addition to neurotherapy, radio frequency can also be used in offering power for thermal therapy platform [20] and drug delivery [69], as discussed in 28.2.2.

Piezoelectric energy harvesters. Piezoelectric energy harvesters (PEHs) directly generate electrical energy by con-

verting mechanical motion in the human body like heartbeat, breathing, etc. Due to the advantages of high-power density, simple structure, and good scalability, PEHs can also be potential energy supply devices in vivo. Most high-performance inorganic piezoelectric materials are inherently rigid and brittle; thus devices would require special design to be flexible and stretchable. Meanwhile, biocompatibility and biodegradability are also important indicators for selecting materials for biodegradable piezoelectric devices. Dagdeviren et al. used a variety of water-soluble materials to form a piezoelectric energy harvester: ZnO (semiconductor/piezoelectric), Mg (conductor), MgO (insulator), and silk (substrate) [49]. The voltage and current outputs of the system are 1.14 V and 0.55 nA. The entire system can completely dissolve in DI water within 60 min at room temperature.

28.3 Dissolution Mechanisms

In most of the devices that have been described in the previous paragraphs, the decomposition is controlled and tuned by designing the thickness of the encapsulation and its composition. The dynamics of degradation proceeds through hydrolysis, enzymatic degradation, or electrochemical dissolution and is governed by chemical reactions and diffusion mechanisms, and it is, hence, complicated to be accurately predicted. It depends on pH, temperature, and spatial distribution of the etchants, processing, and geometrical layout of the structure. Moreover, the desired time scale for transience depends on the application, and it ranges from days or weeks (post-surgery treatment) to weeks/months (environmental sensors) and to years (security systems and consumer electronic devices). Finally, in some cases (i.e., failure of the device), it would be important to trigger the immediate degradation process in response to external stimuli. Such requirements can be effectively addressed only if the electronics is combined with microfluidic devices in order to achieve a timely and spatially controlled dissolution. A temperature expandable polymer (Expancel 031 DU 40, AkzoNobel), which is activated by micro-machined heater, has been used to release water from a reservoir-based device [95]. Despite the difficulty in the assembly due to the heterogeneity of the components (heaters, microfluidic channels and reservoirs, electronics), this device constitutes the first example of triggered and remotely controlled dissolution. Although most on-demand degradation has so far been limited to non-biomedical application, fully degradable device capable of controlled drug release device has been achieved [69, 96]. Involving stimuli-responsive materials extensively explored as drug delivery vehicles could provide potential routes to combine triggered degradation with implantable biodegradable electronics, which will endow more versatile functionalities and further advance the technology.

Modeling of dissolution rates. In the study of the dissolution mechanisms of biodegradable electronics, the dissolution rates of materials are important parameters for judging the overall dissolution time of the devices. Considering the complexity of the actual dissolution process, a simplified one-dimensional reactive diffusion model is proposed to simulate the overall dissolution kinetics for Si and dissolvable metals [97]. The analytical solution to the model can be fitted to the measured data, and key parameters that are not existing in the literature can therefore be extracted, which could predict dissolution rates under the same conditions. The reactive diffusion model takes into account both chemical reactions and diffusion of water into the materials. The diffusivity of water in the metal film (D) and the reaction rate constant (k) are the two key parameters. With $y = 0$ as the bottom surface of the material, and $y = h_0$ as the top surface of the materials, water concentration $w(y, t)$ at time t and thickness y satisfies the reactive diffusion equation

$$D\frac{\partial^2 w}{\partial^2 y} - kw = \frac{\partial w}{\partial t} \quad (0 \le y \le h_0) \tag{28.1}$$

Conditions include a constant water concentration (w_0) at the top surface of the layer $w|_{y=h_0} = w_0$ $\left(w_0 = 1\ \mathrm{g\ cm^{-3}}\right)$ and zero water flux at the bottom surface $\partial w/\partial t|_{y=0} = 0$, as well as zero initial water concentration $w|_{y=0} = 0$ $(0 \le y < h_0)$. Thus, the analytical solution to Eq. (28.1) is as follows:

$$\frac{h}{h_0} \approx 1 - \frac{t}{t_c} \tag{28.2}$$

where h_0 represents the initial thickness and $t_c = h_0 q_\rho M_{H_2O}\left(\sqrt{kD}w_0 M\right)^{-1} \tan h^{-1}\sqrt{kh_0^2/D}$ represents the critical time when the thickness reaches zero, ρ is the mass density of the materials, and M and M_{H20} are the molar masses of the materials and water.

Dissolution mechanisms of Si nanomembranes. In Fig. 28.6a–c, Yin et al. revealed the effect of anion concentration and temperature on the hydrolysis of silicon nanomembranes at the near neutral pH and proposed an empirical model for predicting the dissolution rate of silicon [98]. The anions (chlorides and phosphates) in the solution promote surface silicon oxidation by weakening the bonding of atoms on the surface to the internal atoms. The dissolution rates can be written as

$$r^{\mathrm{model}} = k_0\left(-\frac{E_a(M)}{k_B T}\right)[H_2O]^4\left[OH^-\right]^{0.25}[M]^{0.25} \tag{28.3}$$

$$k_0 = 2480\ \mu\text{m h}^{-1}\left(\frac{\text{mol}}{\text{L}}\right)^{-4.5} \tag{28.4}$$

$$M = \text{PO}_4^{3-} \text{ or } \text{Cl}^- \tag{28.5}$$

where k_B is the Boltzmann constant, $E_a(M)$ is the activation energy for hydrolysis, $[H_2O]$ is the concentration of water and is approximately constant, and [M] represents the concentration of a specific ion (e.g., $[PO_4{}^{3-}]$, and $[Cl^-]$). Similar results were obtained by Wang et al. [99]. In Fig. 28.6d, they found that size and doping level of the silicon nanomembranes can affect the dissolution rates, and molecular dynamics simulations were used to support such conclusions. The dissolution rates can be written as the following to indicate the size effect:

$$R = r_{\text{model}}\left(1 - \text{e}^{-bx}\right) \tag{28.6}$$

where x represents the size of the silicon nanomembrane and b represents the coefficient of the size-dependent behavior.

28.4 Fabrication Examples

Constituent materials of biodegradable electronics are sensitive to temperature, solvent, or water, e.g., biodegradable metals have fast dissolution rates in water and etchants, and biodegradable polymers have low glass transition temperatures and can easily dissolve in solvents. Therefore, conventional photolithography process and thin film deposition techniques that involve harsh solvents and elevated temperatures can hardly be used for the fabrication. To address the issues, device patterning is either performed using shadow masks which constrains the spatial resolution or through a transfer printing technique by fabricating devices on stable substrates followed by a subsequent transfer onto a final biodegradable substrate which involves multistep processing. Currently, most of the demonstrated biodegradable electronics are based on mono-Si NMs due to its excellent electronic properties and fully biodegradable abilities [100]. A variety of works have been done to solve the problems in the fabrication of such biodegradable electronics. First of all, in order to harvest high-quality mono-Si NMs from a SOI source wafer onto a biodegradable substrate, researchers have developed a series of transfer printing techniques [101]. For example, Rogers' group has proposed a two-step transfer printing process to fabricate transient complementary metal-oxide-semiconductor (CMOS) on biodegradable substrates [102]. The fabrication of MOSFETs starts from silicon on insulator (SOI) wafers that are doped and HF under-etched to release the 100–300 nm nanomembrane of silicon. The silicon membrane is then transfer printed with a soft stamp (PDMS) onto a polyimide-spin-coated wafer with a sacrificial layer in between to complete the fabrication (gate oxide deposition and contact formation). A second transfer process is required to transport the devices with PI supporting layers onto the target degradable substrates. The PI layers are removed during the second transfer process to achieve the fully biodegradable devices. Foundry-based process has also been proposed as a possible method to fabricate integrated biodegradable electronics with more complexity. Water-soluble integrated circuit at the 90 nm node was produced through foundry-compatible fabrication processes, by thinning of a SOI wafer down to 1 μm and transfer-printing onto a silk fibroin substrate [35]. Tungsten acts as a bioresorbable metal for interconnects as well as vias in such electronic devices. Another work suggests to fabricate foundry-based ultrathin silicon components on SOI wafers and release the whole arrays by anisotropic etching in potassium hydroxide (KOH) or tetramethylammonium hydroxide (TMAH) solutions [36], as shown in Fig. 28.7. The device is then transfer-printed onto a PLGA substrate for planarization and metallization [36].

Printing of biodegradable metallic components has also been proposed for high-speed and low-cost manufacturing of biodegradable antennas and green electronics [100]. The initial work by Huang was limited by the relatively low conductivity because of the formation of surface oxides on metal powders [103]. Further strategies have been proposed to remove surface oxides such as Ball milling and photonic sintering [104], laser sintering and printing [56], and acid treatment [57]. On the other hand, high conductivity Zn nanoparticles (Zn NPs) are used to achieve highly conductive circuits, making the devices suitable for various eco-friendly circuits [56].

Encapsulation processes of biodegradable electronics have become critical to ensure reliable operation. It is also of great interest to effectively control the operational lifetime of the devices. Transient devices generally have a two-stage operation mode (stable operation and rapid degradation under specific external stimuli) [105]. A typical device of such type suggests a N-MOSFET encapsulated by MgO and crystallized silk, which has a stable operation for ~90 h immersed in DI water, with rapid degradation after water penetration. Introduction of various encapsulation materials can extend the functional lifetime to different extent, including biodegradable polymers, plasma enhanced chemical vapor deposition (PECVD) oxides, single crystal silicon membrane, and thermally grown oxide [55, 105–107].

28.5 Application, Grand Challenges, and Outlook

Degradable and transient devices have been envisioned to find application into three main fields: (i) medical implants, (ii) green environmental sensors, and (iii) security systems.

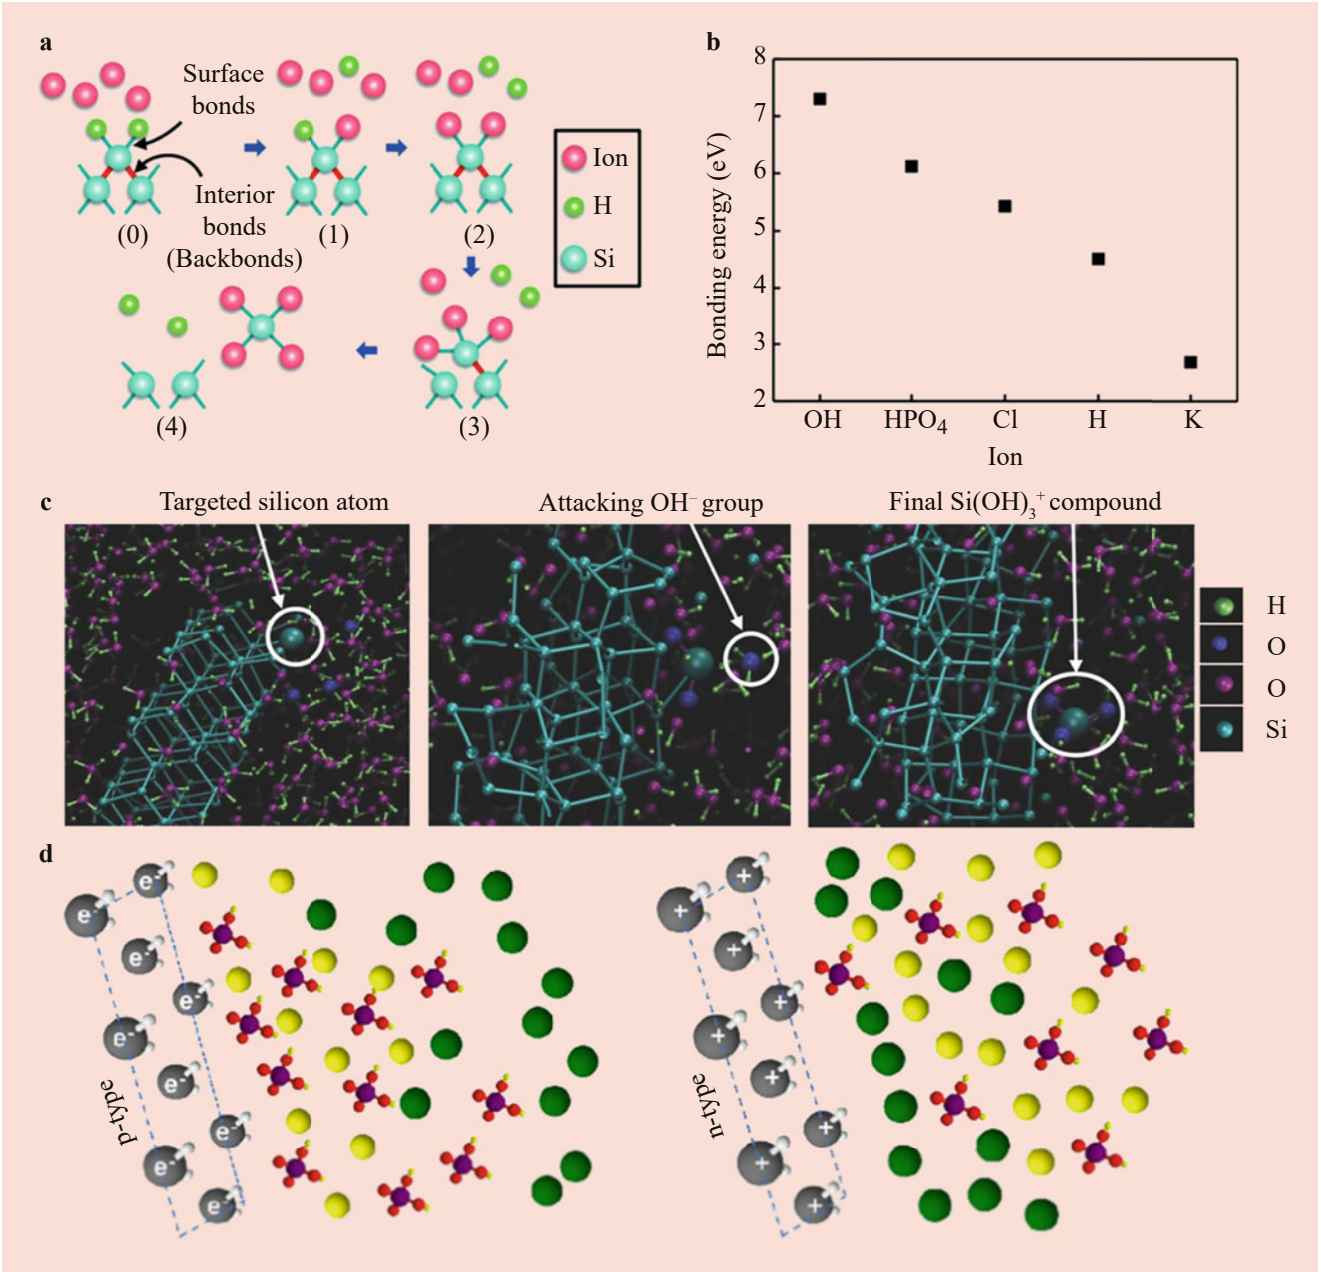

Fig. 28.6 Dissolution. Dissolution mechanisms for silicon. (**a**) Atomic configurations for each ion adsorption event in the dissolution process. (**b**) Strength of several ion-Si bonds. (**c**) Molecular dynamics images of silicon dissolution: (left) snapshot of the initiation of silicon dissociation; (middle) bonding of two OH^- groups to the targeted silicon atom; (right) bonding of the third OH^- group to the targeted silicon atom and generating $Si(OH)^{3+}$. Medical implants that can safely resorb in the body would be very beneficial in medical care scenarios that require the monitoring and medications of pathologies and diseases that are temporary and limited in time. A typical example consists of degradable drug release systems whose function is required only for a prescribed amount of time [59, 108]. Another example is a resorbable stent for coronary angioplasty [11, 42, 60]. Other devices may be envisioned in post-surgery treatments and care, i.e., heat delivery to accelerate healing processes. The reader would notice that such ideas are not new. However, they regained momentum, thanks to the developments in the construction of high-performance degradable electronics. The development of degradable high-performance circuits, wireless communication systems, powering devices, and actuators would generate a completely new class of medical implants. Of course, engineering efforts

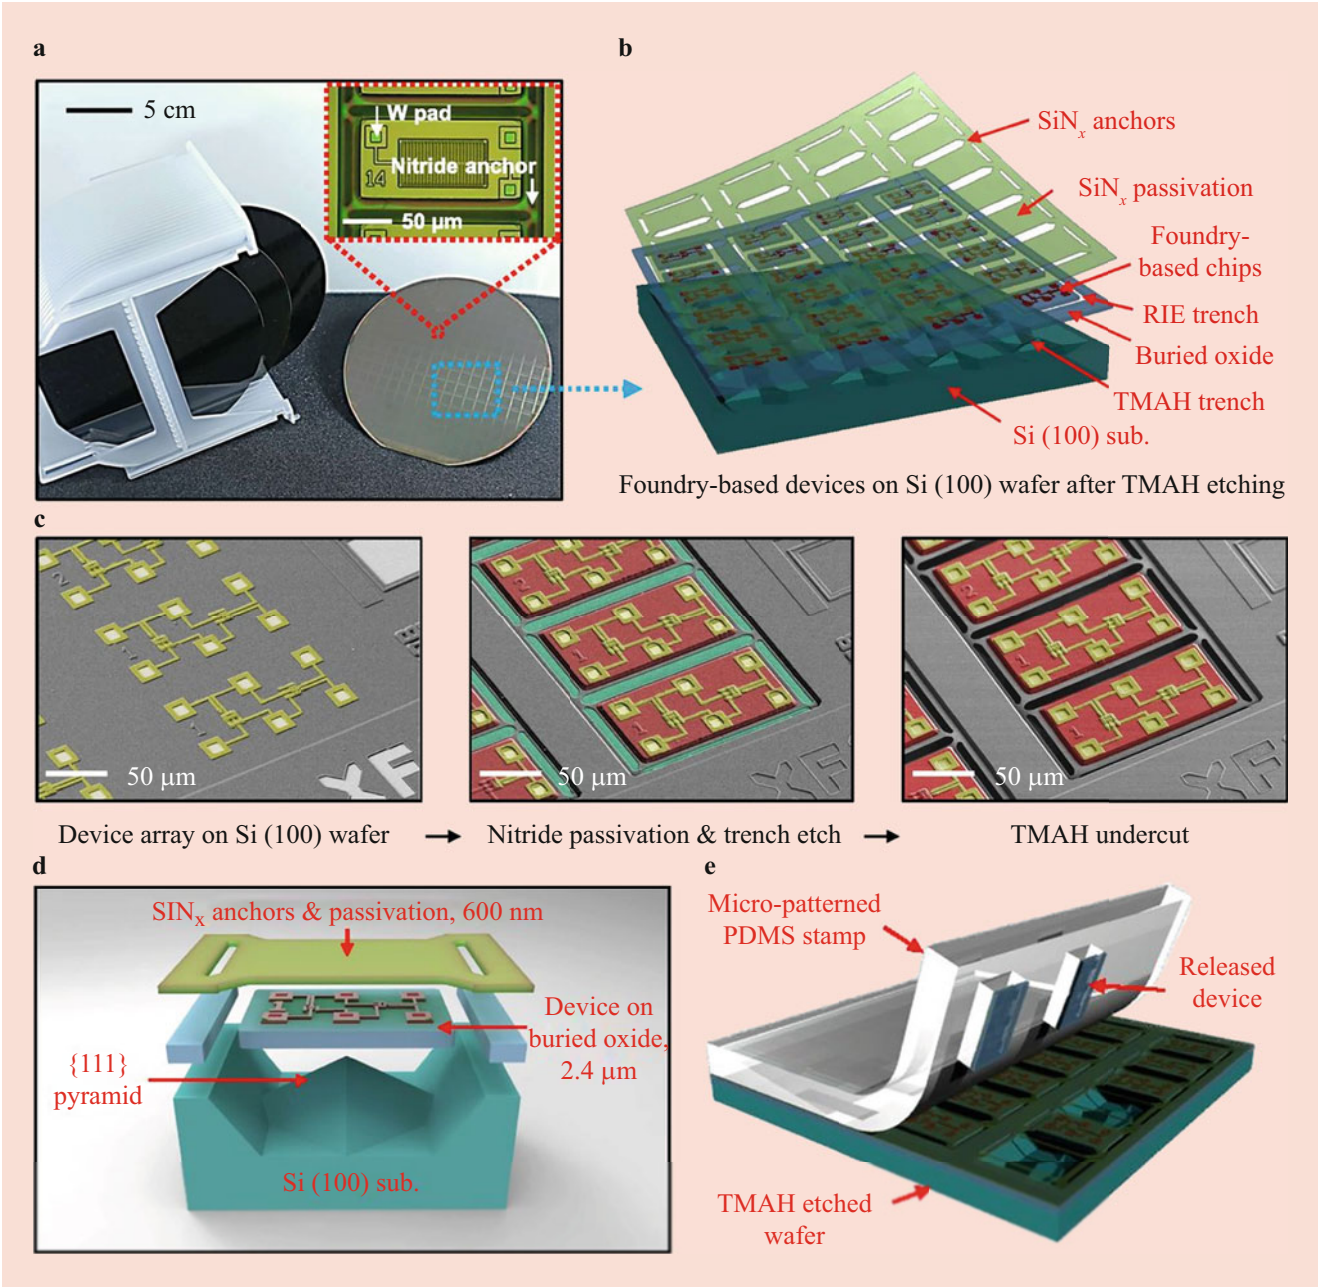

Fig. 28.7 Fabrication processes. (**a**–**c**) Device structure and wafer-scale release of foundry-based ultrathin silicon components. (**c**) SEM images of key processing steps for wafer-scale release. would need to be accompanied by more comprehensive studies of the effects on the health of the decomposition of the devices into their constituent materials and of their diffusion into the body.

Another picture that is very common in the recent engineering literature consists of realizing compostable sensors that can be deployed in the environment without any need to be retrieved and recycled. A longer-term view would even envision the fabrication of compostable printed circuit board and electronic packages to alleviate the problem of the disposal and recycling of the electronic waste. The current situation sees more than 50 million tons of waste from electrical and electronic equipment being produced per year worldwide. Developed countries have conventions, directives, and laws to regulate the disposal [109]. The European Commission has put in place two pieces of legislation: the di-

rective on waste electrical and electronic equipment (WEEE Directive) and the directive on the restriction of the use of certain hazardous substances in electrical and electronic equipment (RoHS Directive). As a result, today, European countries are able to recycle about 66% of their e-waste, but, they still deliver more than 10 million tons per year to incinerators or to the landfill, with the risk of leaching heavy metal in the ground water and with the emission of toxic fumes into the air [110]. Progress in the disposal has been hindered by the large palette of products available, where the variation in the materials and components makes e-waste one of the most complex waste streams [111]. The problem is further exacerbated by the presence of toxic and hazardous materials, such as lead and cadmium, which cannot be treated with conventional methods. The expense of proper disposal, hence, leads to the shipment of large amounts of e-waste to developing countries (i.e., China, India, Pakistan, Nigeria) where, despite the intents of national regulations, it is treated as general refuse with recovery of only a few materials of value. As dioxins, furans, and heavy metals are released, harm to the environment, workers, and area residents is inevitable.

The last application of transient devices is in the field of security systems. Here, the idea is to conceive systems that store sensitive information and that can disappear after a prescribed time or upon a remote command. In this contest, a major advancement consists in the implementation of mechanisms to trigger the dissolution process in response to external stimuli so as to ensure a spatially and timely controlled disintegration. One possible strategy to achieve such goal is to combine the degradable electronic components with microfluidic devices and functional/responsive materials. Ferromagnetic nanoparticles, UV, and thermal-responsive layers expand or rearrange their physical configuration to act as pumps or permeable membranes and release the liquid/etchants from 3D micro-reservoirs.

Transient or degradable or biodegradable electronics is an emerging technology that prospects the possibility to design new forms of devices and target applications which would be difficult to address with standard electronics. However, it inevitably faces challenges. Some of them are inherent to the nature of such technology: mechanical and functional reliability that are hard to design and predict and restricted palette of materials that may limit the performance of the devices. Here, the goal is to discuss the main ones and try to envision future research directions.

Restricted Palette of Materials The advancement in the study of materials that degrade in aqueous solution has been tremendous over the last 20 years. The list now includes organic and inorganic materials, and it is large enough to provide all key ingredients to build many optoelectronic devices. However, some of them could suffer of poor performance because of the restricted palette. Among the others, relevant examples include energy storage devices and passives for electronic circuits. Optical devices could also be challenging due to the limited choices of the semiconductors and their heterostructures.

Fabrication So far, the fabrication of degradable devices, especially those based on inorganic materials, have been achieved through multiple and tedious transfer steps from donor substrates/templates to the degradable ones. Recently, some research groups have started collaborating with industry and silicon foundries to establish transient-compatible processes. This is definitively an important step toward the realization of more complex and sophisticated devices and circuits on a large scale.

Dissolution Hard to Predict The control and prediction of the lifetime of the devices is probably the most challenging aspect of this technology. So far, the dissolution dynamics has been achieved through the design of the encapsulation layers and their thickness. Most of the time, such layers are constituted by polymers whose deposition and quality (uniformity, pinhole-free, etc.) are hard to control and reproduce. Some attempts have been also done to use higher-quality thin films that can be thermally grown or deposited by vacuum processes (PVD, ALD). However, thin film encapsulation remains challenging. Other strategies point toward the direction of combining responsive materials/devices with fluidic devices (reservoirs) that can be activated to trigger the dissolution at specific and desired point in time. Such approach could pave the way to military and security applications but would be probably even more challenging if the fluidic part should dissolve as well.

From Research Lab to Industry The technology is in its infancy, and most of the advancements have been achieved in university or research lab labs. In recent years more and more research groups have started publishing results about materials and new degradable devices. However, the involvement of industrial partners would be beneficial to both scale up the fabrication and to adopt some of the technologies/devices. Similarly, devices for biomedical applications would largely benefit from collaborations with clinicians and medical doctors both for a proper design and for in vivo tests.

RRAM is a novel device that is based on resistive switching. It has a typical MIM structure where the resistive-switching layer is sandwiched between the top electrode (TE) and bottom electrode (BE). The resistive switching indicates that the device can be reversibly switched between high resistance state (HRS) and low resistance state (LRS). The resistive-switching process from HRS to LRS is called SET, and the reversible process from LRS to HRS is called as RESET. Two kinds of modes including unipolar and bipolar have been observed to switch RRAM. For a fresh RRAM, a so-called Forming process is usually required to achieve the reversible and repeated resistive-switching behaviors. Generally, the Forming voltage is much higher than the switching (SET and RESET) voltage. If the Forming voltage is close to the switching voltage, this RRAM is referred to as Forming-free device.

For the physical origins of resistive switching in RRAM, the filament effect has been widely accepted. In this viewpoint, the resistive switching between HRS and LRS is due to the formation and rupture of conductive filament paths inside the resistive-switching layer. According to the composition of the conductive filament (CF), RRAM can be further classified into two types: (1) oxygen vacancy-based RRAM (Ox-RRAM) and (2) metal ion-based RRAM that is also called as conductive-bridge random-access memory (CBRAM).

RRAM was initially proposed for the memory application as the next generation of nonvolatile memory candidate in the early 2000s. Especially, Samsung presented a paper at the International Electron Devices Meeting that demonstrated the highly scalable characteristics in NiO memory cells integrated with conventional complementary metal oxide semiconductor (CMOS) with a one-transistor–one-resistor (1T1R) device structure. That further intensified the research activity on RRAM. Up to now, significant technical advances have been achieved in the device performance and integration, including great scalability (<10 nm), fast speed (<1 ns), low operation

voltage (<1.5 V) and current (<1 μA), high endurance (>1012 cycles), and long retention (>10 years at room temperature). The 3D integration approaches were also proposed for the high density of RRAM integration. The testing memory chips more than 16 G-bits have been reported and demonstrated.

In 2008, HP group published a paper to establish the link between RRAM and "memristor," where the concept of "memristor" was proposed and defined by L. Chua in the 1970s. Later, RRAM or memristor was proposed and demonstrated to implement the stateful logic, in which Boolean logic states were operated and stored in resistance of RRAM. In 2012, a collaboration work from Stanford University and Peking University reported a RRAM-based electronic synapse with multilevel states (>400 states) and ultra-low spiking energy (<1 pJ/per spiking) and then further demonstrated a 3D integration approach to achieve both high uniformity and low spiking energy in 2014. This strongly stimulates the RRAM research activities that extend RRAM to much wider areas beyond memory. Especially accompanying with the development of AI, the new computing paradigms beyond von Neumann such as brain-inspired computing are highly desired to overcome the bottleneck of so-called memory wall from the traditional von Neumann architecture. Research activity has been primarily driven by the search for ideal neuromorphic devices. RRAM was paid much more attention due to the featured functions of computing in memory, which is beneficial for the brain-inspired computing systems. More recently, while a lot of research efforts still remain focused on the device level, the demonstrations of the arrays in circuit/system level are increasingly common. Various RRAM array-based chips for both memory and brain-inspired computing applications were reported.

In this chapter, we will review the latest advancements in RRAM. Firstly, the physical mechanism on resistive-switching characteristics of both Ox-RRAM and CBRAM are discussed in Sect. 29.2. Then, the physics-based models and simulation methods are presented in Sect. 29.3. In Sect. 29.4, the array design and optimization technologies are addressed and discussed. The system applications of RRAM in emerged memory and novel computing paradigms for brain-inspired neural network are explored in Sect. 29.5. Finally, the prospect of future technological trend is highlighted in Sect. 29.6.

29.1 Introduction

In the past decades, resistive-switching random-access memory (RRAM) has been widely studied as one of the promising candidates for next-generation memory technologies [1–5]. Recently, innovation research on the novel devices for new computing paradigms beyond von Neumann architecture is emerging with the rapid development of artificial intelligence (AI) technologies. With its natural features that can both store and process data, RRAM has been also extensively explored to implement for the new computing paradigms such as brain-inspired computing and in-memory computing [6–10].

RRAM is a novel device that is based on resistive switching. The first report on resistive switching can be traced back to the 1960s. Hickmott published the first paper on electric field-induced hysteretic current-voltage (I-V) characteristics in thin anodic oxide films with metal-insulator-metal (MIM) structure [11]. The recent revival of interest in resistive switching began in the late 1990s originated from a report of resistive switching in $Pr_{0.7}Ca_{0.3}MnO_3$ (PCMO) by Asamitsu et al. [12]. Since that, resistive-switching (RS) phenomena have subsequently been reported in a wide variety of materials [1–7, 13–17] including metal oxides, nitrides, selenides, sulfides, and organic and low-dimensional materials. Meanwhile, the switching mechanisms [15–20] and the possible applications in the next generation of storage and computing started to be explored [21–29]. All these extensive researches were well reviewed in the published review articles [1–9].

RRAM has a typical MIM structure as shown in Fig. 29.1a, where the resistive-switching layer is sandwiched between the top electrode (TE) and bottom electrode (BE). The resistive switching indicates that the device can be reversibly switched between high resistance state (HRS) and low resistance state (LRS). The resistive-switching process from HRS to LRS is called SET, and the reversible process from LRS to HRS is called RESET. Two kinds of modes including unipolar and bipolar have been observed to switch RRAM as shown in Fig. 29.1b, c. For the unipolar switching, the same polarity of SET and RESET voltages can be used to switch the devices between HRS and LRS. In contrast to this, bipolar switching must use a pair of opposite polarity voltages to switch the device. For example, when we use a positive SET voltage to switch RRAM from HRS to LRS, a negative RESET voltage is necessary to switch the device from LRS to HRS. For a fresh RRAM, a so-called Forming process is usually required to achieve the reversible and repeated resistive-switching behaviors. Generally, the Forming voltage is much higher than the switching (SET and RESET) voltage. If the Forming voltage is close to the switching voltage, this RRAM is referred to as Forming-free device.

For the physical origins of resistive switching in RRAM, the filament effect has been widely accepted. In this view-

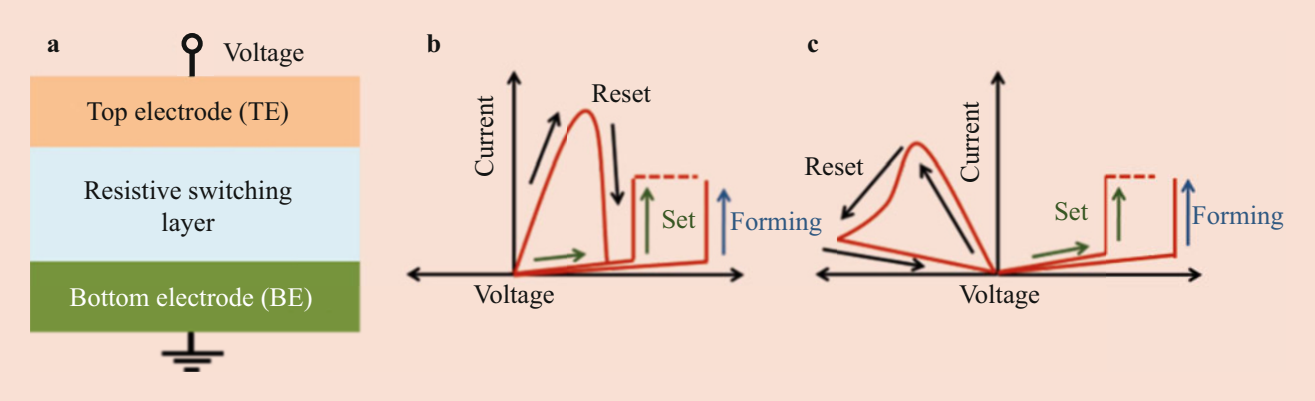

Fig. 29.1 (**a**) The MIM structure of RRAM device, (**b**) unipolar and (**c**) bipolar switching type depending on the voltage polarity

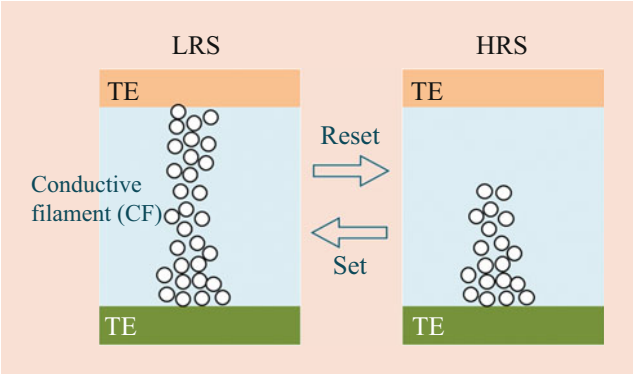

Fig. 29.2 The schematic view for the formation and rupture of a conductive filament (CF) path

point, the resistive switching between HRS and LRS is due to the formation and rupture of conductive filament paths inside the resistive-switching layer as shown in Fig. 29.2.

According to the composition of the conductive filament (CF), RRAM can be further classified into two types: (1) oxygen vacancy-based RRAM (Ox-RRAM) and (2) metal ion-based RRAM that is also called as conductive-bridge random-access memory (CBRAM).

RRAM was initially proposed for the memory application as the next generation of nonvolatile memory candidate in the early 2000s. Especially, Samsung presented a paper [30] at the International Electron Devices Meeting that demonstrated the highly scalable characteristics in NiO memory cells integrated with conventional complementary metal oxide semiconductor (CMOS) with a one-transistor–one-resistor (1T1R) device structure. That further intensified the research activity on RRAM. Up to now, significant technical advances have been achieved in the device performance and integration [31–38], including great scalability (<10 nm), fast speed (<1 ns), low operation voltage (<1.5 V) and current (<1 μA), high endurance (>10^{12} cycles), and long retention (>10 years at room temperature). The 3D integration approaches were also proposed for the high density of RRAM integration [39–41]. The testing memory chips more than 16 G-bits have been reported and demonstrated [42, 43].

In 2008, HP group published a paper [44] to establish the link between RRAM and "memristor," where the concept of "memristor" was proposed and defined by L. Chua in the 1970s [45]. Later, RRAM or memristor was proposed and demonstrated to implement the stateful logic [21], in which Boolean logic states were operated and stored in resistance of RRAM. In 2012, a collaboration work from Stanford University and Peking University reported a RRAM-based electronic synapse with multilevel states (>400 states) and ultra-low spiking energy (<1 pJ/per spiking) [22] and then further demonstrated a 3D integration approach to achieve both high uniformity and low spiking energy in 2014 [23]. This strongly stimulates the RRAM research activities that extend RRAM to much wider areas beyond memory. Especially accompanying with the development of AI, the new computing paradigms beyond von Neumann such as brain-inspired computing are highly desired to overcome the bottleneck of so-called memory wall from the traditional von Neumann architecture. Research activity has been primarily driven by the search for ideal neuromorphic devices. RRAM was paid much more attention due to the featured functions of computing in memory as demonstrated in Ref. [21–28], which is beneficial for the brain-inspired computing systems. More recently, while a lot of research efforts still remain focused on the device level, the demonstrations of the arrays in circuit/system level are increasingly common. Various RRAM array-based chips for both memory and brain-inspired computing applications were reported [46–50].

In this chapter, we will review the latest advancements in RRAM. Firstly, the physical mechanism on resistive-switching characteristics of both Ox-RRAM and CBRAM are discussed in Sect. 29.2. Then, the physics-based models and simulation methods are presented in Sect. 29.3. In Sect. 29.4, the array design and optimization technologies are addressed and discussed. The system applications of RRAM in

emerged memory and novel computing paradigms for brain-inspired neural network are explored in Sect. 29.5. Finally, the prospect of future technological trend is highlighted in Sect. 29.6.

29.2 Physical Mechanism of Resistive Switching

Since the early work in the 2000s, RRAM switching mechanisms have been attributed to the filamentary modification of conduction properties. It was possible to reveal the resistive-switching mechanism by several different techniques, including conductive atomic force microscopy (CAFM) measurements [51], area dependence of the LRS resistance [30], infrared thermal imaging of the device [52], and in situ microscopic imaging of the device during switching by transmission electron microscopy (TEM) [53]. Based on the experimental techniques, a large variety of physical mechanisms have been proposed leading to the resistive-switching effects such as the ion migration, charge trapping/de-trapping, thermal reaction, insulator-to-metal transition, charge transfer, and so on [4]. In this chapter, we will discuss the ion-based resistive-switching mechanism in detail, which can be further distinguished into two types. One type is based on the oxygen vacancies in the metal oxides, which is referred to as oxide-based RRAM (Ox-RRAM) [3, 17]. Both bipolar [54–56] and unipolar [57, 58] switching modes have been found in this kind of RRAM, and J. Kang et al. [17, 59] have proposed a unified mechanism for the bipolar and the unipolar modes, in which resistive switching is triggered by the generation and recombination of oxygen vacancies in the metal oxides. Another RRAM type is based on the bipolar electrochemical metallization mechanism, and the corresponding device is called the conductive-bridge random-access memory (CBRAM) or electrochemical metallization cell (ECM) [53]. The resistive switching of CBRAM relies on the active metal Ag or Cu penetrating (or dissolving) in the ion conducting layer which is oxide or chalcogenide to form (or rupture) a conducting path.

In this section, we will address the resistive-switching mechanisms of Ox-RRAM and CBRAM, respectively.

29.2.1 Ox-RRAM

We begin with the typical bipolar Ox-RRAM with single switching layer. The microscopic physical processes of switching in an Ox-RRAM are schematically shown in Fig. 29.3 [60]. During the SET process, the generation of oxygen vacancies (V_O) and the migration of dissociated oxygen ions (O^{2-}) to the top electrode cause the formation of CF connecting the two electrodes, which switches the cell from HRS to LRS. To specify, the excited state of ${V_O}^{2+}$ is firstly formed accompanying the generation of ${V_O}^{2+}$ and O^{2-}, and then the excited ${V_O}^{2+}$ state is relaxed to a stable V_O state. The generation probability of V_O under electric field is governed by [61].

$$P_g = f \cdot \exp\left(-\frac{E_a - \Delta\varphi}{k_B T}\right) \tag{29.1}$$

where f is the vibration frequency of oxygen atom, E_a is the average active energy of V_O, $\Delta\varphi$ is the barrier height reduction induced by electric field, and T is the local temperature. The hopping probability of the dissociated O^{2-} in the oxide layer can be described by [62].

$$P_h = f \cdot \exp\left(-\frac{E_h - \Delta\varphi}{k_B T}\right) \tag{29.2}$$

where E_h is the hopping barrier of O^{2-}.

During RESET process, firstly, the V_O state is excited to the ${V_O}^{2+}$ state, and then the O^{2-} is released by the top electrode and hop to the nearby ${V_O}^{2+}$ site and then recombine with ${V_O}^{2+}$, leading to the rupture of the CF. The probability of recombination between electron-depleted ${V_O}^{2+}$ and O^{2-} follows the equation [61].

$$P_r = f \cdot \exp\left(-\frac{\Delta E_r}{k_B T}\right) \tag{29.3}$$

where ΔE_r is the relaxation energy of recombination. The top electrode acts as an oxygen reservoir that can release O^{2-} with the probability governed by the following equation [62]:

$$P_m = f \cdot \exp\left(-\frac{E_i - \Delta\varphi}{k_B T}\right) \tag{29.4}$$

where E_i is the energy barrier of the electrode release O^{2-}.

The device uniformity and reliability of Ox-RRAM can be improved by adopting a bilayered electrolyte structure. A typical example is the widely used Ta_2O_5/TaO_X bilayer resistive-switching stack to improve the endurance characteristics [16, 63]. In the bilayer Ta_2O_5/TaO_X structure, the oxygen-deficient TaO_X layer, instead of TiN electrode in the HfO_X-RRAM, acts as the oxygen reservoir. The O^{2-} transportation in the Ta_2O_5/TaO_X stack is shown in Fig. 29.4. During SET process, the generated dissociative O^{2-} hop in Ta_2O_5 layer, and when they migrate to the Ta_2O_5/TaO_X interface, the O^{2-} can be absorbed by TaO_X layer. Within the TaO_X layer, some of the absorbed O^{2-} will continue hopping under the effect of electric field, while others get involved in the redox reaction with the oxygen-deficient TaO_X and then restored as lattice oxygen. During RESET process, the lattice oxygen in TaO_X will be thermally activated and released as

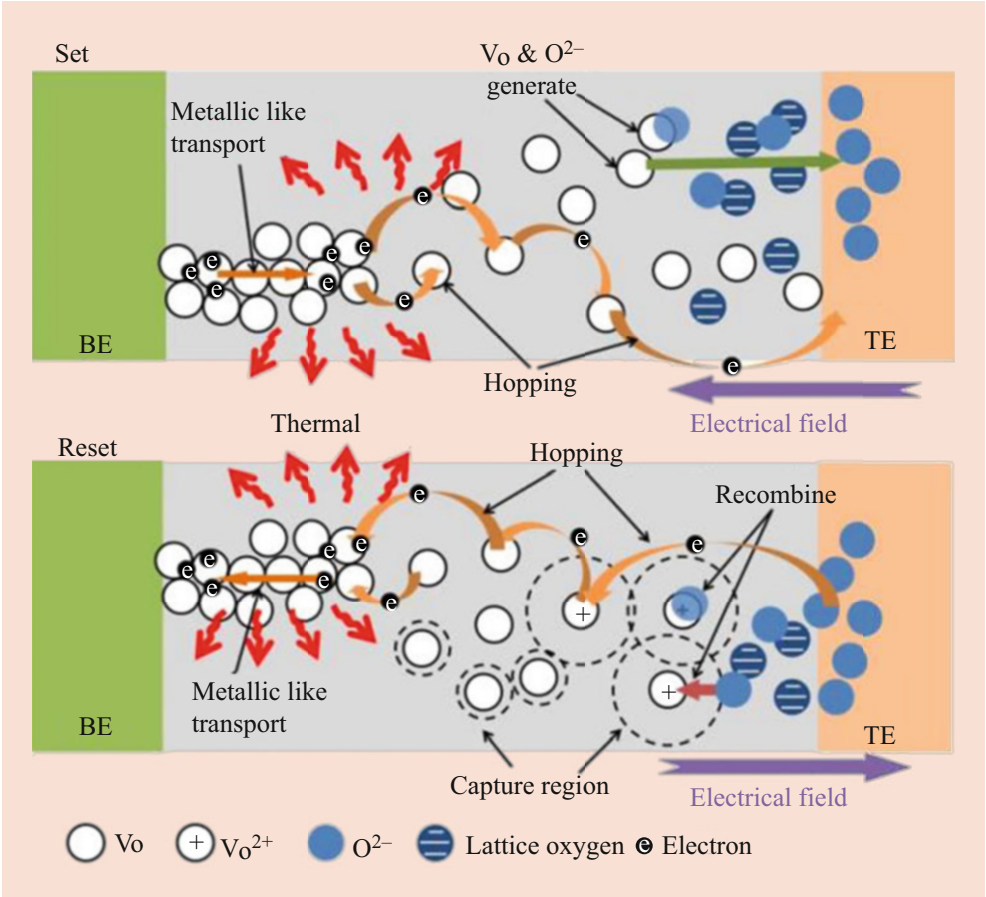

Fig. 29.3 Schematic physical processes of resistive switching in Ox-RRAM, including the generation of oxygen vacancies (V_O), hopping of oxygen ions (O^{2-}), electrode absorbing and releasing O^{2-}, recombination between V_O and O^{2-}, and increase of local temperature. (Reprinted from [60])

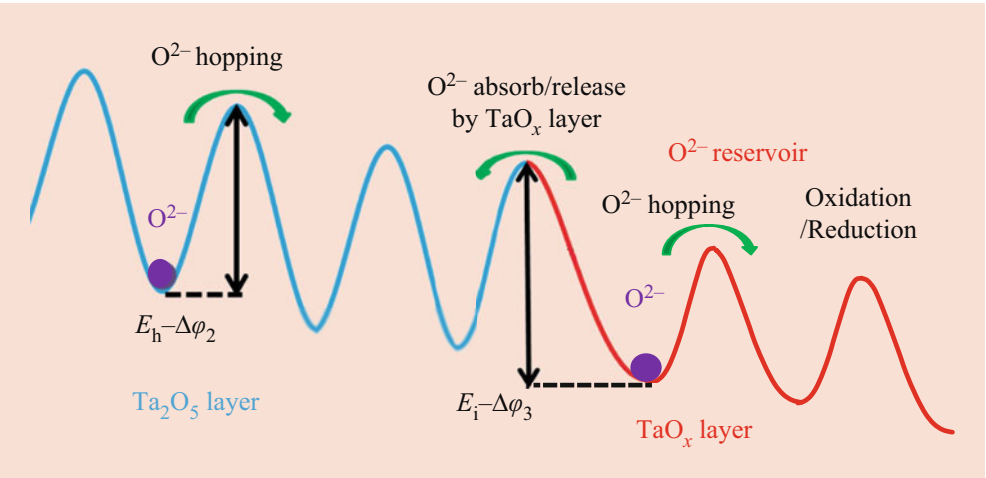

Fig. 29.4 Schematic of O^{2-} transportation in the Ta_2O_5/TaO_X stack

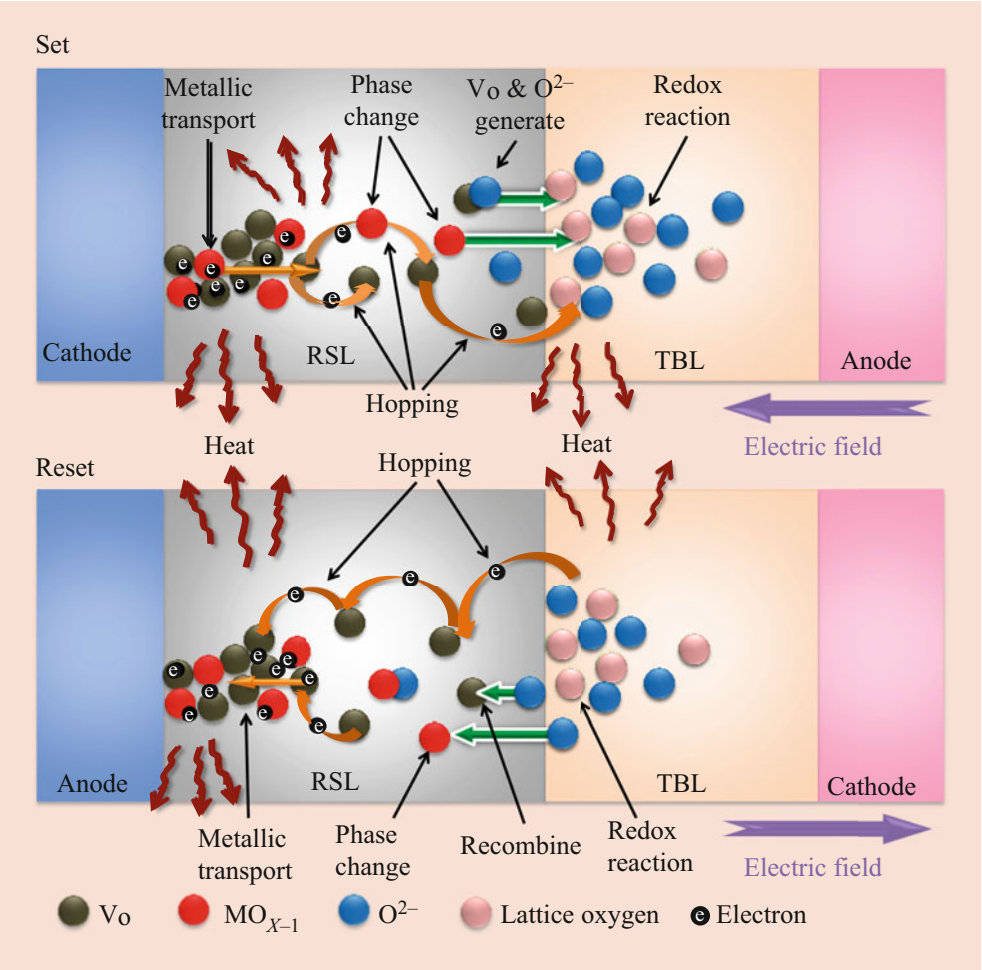

Fig. 29.5 Schematic resistive-switching model in bilayer Ta_2O_5/TaO_X RRAM. The two layers are the resistive-switching layer composed of Ta_2O_5 and TaO_X base layer. (Reprinted from [63])

dissociative O^{2-} which will migrate back to Ta_2O_5 layer to recombine with the oxygen vacancies [63].

Y. Zhao et al. have conducted ab initio calculations in the Ta-O system and found that besides the oxygen vacancy generation/recombination processes, phase transition also takes place in a Ta_2O_5-RRAM device [63]. The phase transition process takes place between Ta_2O_5 and TaO_2, which can be described by

$$Ta_2O_5 + 2e^- \leftrightarrow 2TaO_2 + O^{2-} \tag{29.5}$$

According to the ab initio calculation results, the Ta_2O_5 are semi-conductive, while the TaO_2 are metallic. The probability of the phase transition from Ta_2O_5 to TaO_2 can be described by

$$P_a = f \cdot \exp\left(-\frac{E_a}{k_B T}\right) \tag{29.6}$$

where E_a is the activation energy of Ta_2O_5 changing to TaO_2. It is a thermally controlled process. The reverse phase transition from TaO_2 to Ta_2O_5 can be described similarly. Hence the resistive switching in a bilayer Ta_2O_5/TaO_X RRAM can be depicted in Fig. 29.5. By applying a negative bias on the left electrode in Fig. 29.5, V_O is generated by ionizing O^{2-} from the Ta_2O_5 lattice. As the current increases, the phase transition between Ta_2O_5 and TaO_2 takes place, and a CF consisting of V_O and TaO_2 connects top electrode and the TaO_X base layer, switching the device from HRS to LRS. With positive bias on the left electrode, O^{2-} in the TaO_X base layer will be activated and migrate to the Ta_2O_5 layer to recombine with V_O or react with TaO_2, leading the rupture of CF, switching the device from LRS to HRS.

Next, we will discuss about the unipolar mode Ox-RRAM. The resistive-switching mechanism of unipolar Ox-RRAM is similar to the bipolar mode as shown in Fig. 29.6. It should be noted that the difference with bipolar is the storing and releasing modes of the dissociated O^{2-}. In the unipolar Ox-RRAM,

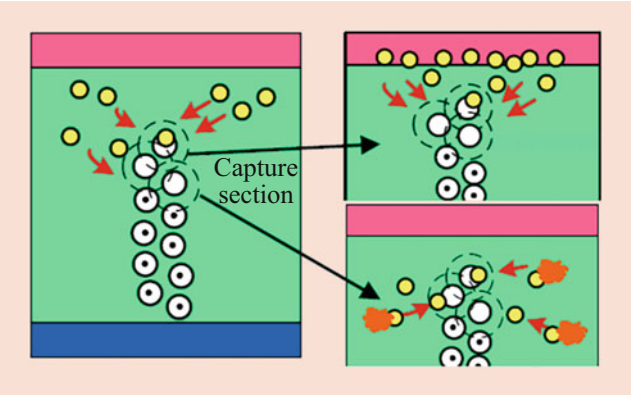

Fig. 29.6 Schematic RESET comparison between the unipolar and bipolar Ox-RRAM. For bipolar RESET, the O^{2-} is released by the O^{2-} reservoir and drifts from the interface to recombine with V_O. For unipolar RESET, the O^{2-} is released by Joule heating-induced thermal decomposition of the easily reduced oxide clusters or grains in the capture section region. (Reprinted from [59])

the dissociated O^{2-} will be absorbed and released from the easily reduced oxide clusters which are closely neighbored with the V_O-rich CF. In more details, several different phases of oxide clusters co-exist in the resistive layer [59]. One is the oxygen-rich phase. The oxygen-rich clusters can release O^{2-} mainly due to the thermal decomposition instead of electric field driving when the local temperature reaches a specific threshold [59]. The thermally released O^{2-} will then recombine with the V_O and consequently rupture the CF during RESET process. During SET process, the generation of V_O is similar with bipolar Ox-RRAM, but the dissociated O^{2-} will be absorbed by the nearby oxygen-rich phase rather than the anode.

For both bipolar and unipolar Ox-RRAM, the current conduction mechanism can be modeled as follows. For the CF region, the electron transport is metallic and the conductivity decreases with increasing temperature according to Arrhenius law [64], which can be described by

$$\sigma = \sigma_0 \exp\left(\frac{E_{AC}}{k_B T}\right) \tag{29.7}$$

where E_{AC} is the activation energy for conduction and σ_0 is the Arrhenius pre-exponential factor for conductivity. For the region without CF, the electron transport among the dispersive V_O is hopping, and the hopping rate between two V_O can be calculated by the Mott hopping model [65], which is

$$W_{m\to n} = f_{ph} \exp\left(-\frac{2\alpha R_{mn} + E_{mn}}{k_B T}\right) \tag{29.8}$$

where the f_{ph} is the vibration frequency of electron, R_{mn} is the distance between two V_O, α is the attenuation length of the electron wave function, and E_{mn} is the change of barrier height induced by the applied external field.

The local temperature plays an important role during the switching processes. The temperature distribution can be obtained by solving the Fourier heat-flow equation [66], which is

$$C\frac{\partial T}{\partial t} = \nabla (k\nabla T) + Q \tag{29.9}$$

where C is the specific heat per unit volume of the oxide layer, k is the thermal conductivity, and Q is the sum of multiple heat sources due to the inelastic electron-phonon.

29

29.2.2 CBRAM

The formation and rupture of CF are widely acknowledged as the resistive-switching effect in RRAM. Thus, understanding the dynamics of CF evolution is important to continue device research. The direct observation of CF in Ox-RRAM is difficult; however, in CBRAM, the formation of CF has been visualized in several device systems, which not only provide the origin of resistance change during switching operations but also reveal the CF evolution dynamics such as the CF geometry and CF growth direction. Figure 29.7 shows an example of CF growing from the inert electrode (IE) to the active electrode (AE) which is experimentally demonstrated by Y. Yang et al. [53]. Figure 29.7a shows the TEM image of an as-fabricated device using sputtered SiO_2 as the dielectric layer. To switch the device, a constant voltage is applied to Ag electrode. Image in Fig. 29.7b taken after the Forming process clearly revealed a well-defined CF with a typical conical shape. Detailed TEM study verified that the CFs are composed of Ag. The thinnest part of the CF is close to IE interface, with a much wider base formed near the AE. By applying a negative voltage on AE, all CFs, whether completely formed or partially formed, are found to first break at the filament/IE interface as shown in Fig. 29.7c. The dissolved parts of CF are reversely deposited on AE. The current-time characteristics during SET and RESET are shown in Fig. 29.7d, e, respectively.

However, different CF growth directions have been observed by experiments. H. Sun et al. observed the CF growth from AE to IE by SEM technique as shown in Fig. 29.8 [67]. In the Ag/SiO_2/Pt device, initially the gap between electrodes of fresh device is clean as shown in Fig. 29.8a. After constant voltage stress of 30 V with 10 μA compliance current applied on Ag electrode for 10 s, some Ag nanoparticles are generated near Ag electrode, as shown in Fig. 29.8b. After 150 s, more Ag nanoparticles are formed around Ag electrode, and

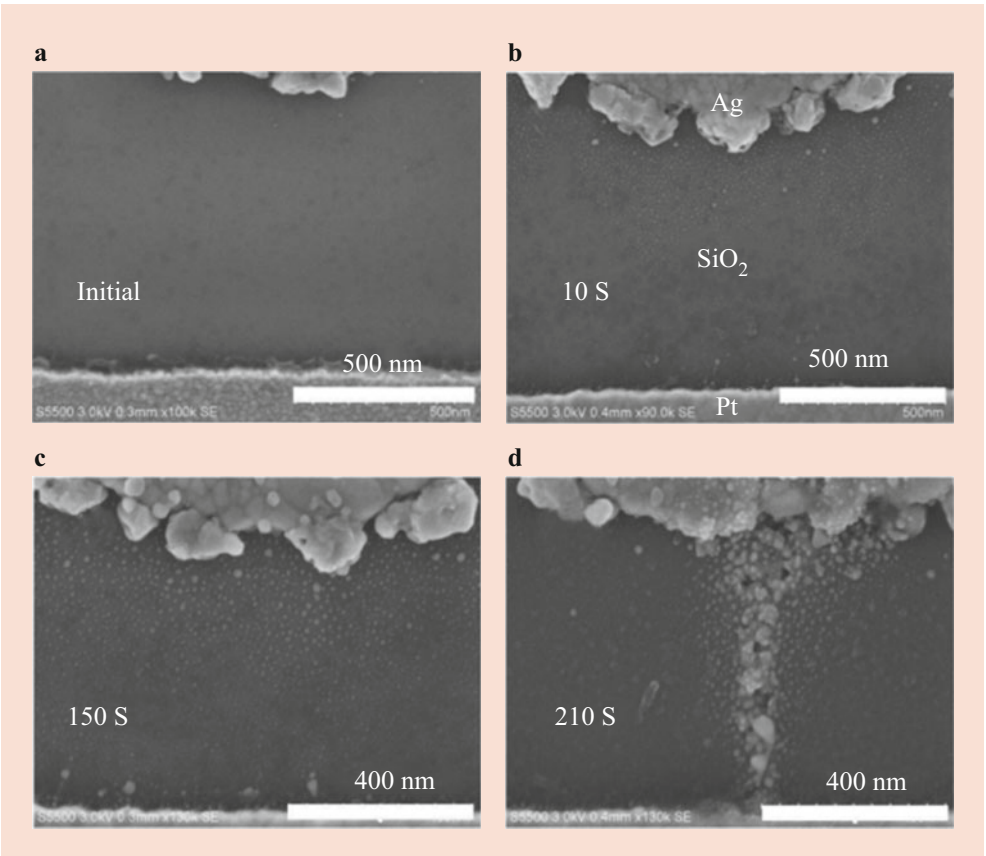

Fig. 29.8 SEM images capturing the dynamic CF growth in the Ag/SiO_2/Pt device. (**a**) Fresh device, (**b**)–(**d**) device after 10 s, 150 s, and 210 s under a 30 V constant voltage stress with 10 μA compliance current, respectively. (Reprinted from [67])

the nanoparticle chain extends toward Pt electrode, as shown in Fig. 29.8c. Finally, a continuous Ag nanoparticle chain is formed, and the device current reaches the compliance current due to the formation of Ag CF between two electrodes, as shown in Fig. 29.8d. The results clearly show that the initial Ag nanoparticle is firstly formed near the AE and then gradually extends to IE.

Based on the experimental observations, the resistive-switching mechanism in CBRAM is demonstrated as follows. Figure 29.9 shows the microscopic behaviors and

the correlated physical effects in CBRAM during resistive switching [68]. Here, the example of CF growth from IE to AE is demonstrated, while in the case of the other growth direction, the physical processes are likewise but their differences will be explained afterward. Generally, the following three physical steps would take place during resistive switching. Firstly, under the electric field of the applied voltage, the metal atoms from AE or CF may have the chance to be oxidized into cations, which can be described by

$$M \rightarrow {M_{\mathrm{ad}}}^{\mathrm{n+}} + ne^{-} \rightarrow {M_{\mathrm{ely}}}^{\mathrm{n+}} \tag{29.10}$$

where M represents the metal atoms, ${M_{\mathrm{ad}}}^{\mathrm{n+}}$ denotes the adsorbed cations on the surface of the CF or active electrode, and ${M_{\mathrm{ely}}}^{\mathrm{n+}}$ is the dissociative cations in the electrolyte. The oxidation probability of metal into cations can be described as [61].

$$P_{\mathrm{ox}} = f \cdot \exp\left(-\frac{E_{\mathrm{ox}} - \Delta\varphi}{k_{\mathrm{B}}T}\right) \tag{29.11}$$

where f is the vibration frequency of electrons, E_{ox} is the activation energy of oxidation, T is the local temperature, and $\Delta\varphi$ is the barrier height reduction induced by electric field.

After oxidation, the cations hop in the vacancy or interstitial sites of the electrolyte under electric field, with the probability of [62].

$$P_{\mathrm{h}} = f \cdot \exp\left(-\frac{E_{\mathrm{h}} - \Delta\varphi}{k_{\mathrm{B}}T}\right) \tag{29.12}$$

where E_{h} is the hopping barrier. Then when the cations collide with the electrons, the cations have the possibility to be reduced into metal atoms, which can be described by

$$M^{\mathrm{n+}} + ne^{-} \rightarrow M \tag{29.13}$$

The corresponding reduction probability is [61].

$$P_{\mathrm{red}} = f \cdot \exp\left(-\frac{E_{\mathrm{red}} - \Delta\varphi}{k_{\mathrm{B}}T}\right) \tag{29.14}$$

where E_{red} is the activation barrier of reduction. With the reduced atoms accumulated near IE, the atoms take nucleation reactions to form new nuclei on IE or within the electrolyte, depending on the particular material and experimental conditions. With application of an overpotential η_{nuc} on the atom, the Gibbs energy ΔG to form a cluster is a function of the atom number N and reaches its maximum for a critical particle number of [69].

$$N_{\mathrm{c}} = -\left(\frac{2\gamma a}{3ze_0\eta_{\mathrm{nuc}}}\right)^3 \tag{29.15}$$

where a is a constant depending on the cluster shape and the particle density and γ is the surface energy per unit area. The nucleation energy for a cluster with atom number N_{c} is

$$\Delta G_{\mathrm{c}} = \frac{4(\gamma a)^3}{27(ze_0\eta)^2} \tag{29.16}$$

Clusters with a number of particles smaller than N_{c} tend to dissolve, while larger clusters tend to grow further.

Based on these physical effects, the resistive-switching processes in CBRAM are shown in Fig. 29.9. During Forming or SET process, the positive bias is applied on AE, and the metal atoms on the surface of AE are activated into cations. Note that the oxidation barrier E_{ox} has different values according to the atom location on the AE surface. In the 2D example in Fig. 29.9, three different atom sites are considered and referred to as adatom, step, and vacancy sites. The corresponding oxidation barriers follow $E_{\mathrm{ox}}(1) < E_{\mathrm{ox}}(2) < E_{\mathrm{ox}}(3)$, where $E_{\mathrm{ox}}(1)$ is the oxidation barrier of atom in the adatom site, $E_{\mathrm{ox}}(2)$ is the barrier of step site, and $E_{\mathrm{ox}}(3)$ is the barrier of the vacancy site [65]. After oxidation, the cations migrate through electrolyte toward IE under electric field and get reduced near IE. Similar with the oxidation process, the reduction barriers also depend on the different locations of the cation being reduced. As the reduced atoms accumulate near IE, the filament gradually extends to the AE and finally forms a conduction path within the electrolyte. The device is then switched from HRS to LRS. During the RESET process as shown in Fig. 29.9b, negative bias is applied on AE, and the metal atoms in the CF are activated and migrated toward AE, finally redeposited near AE. The absence of atoms in the CF leads to the filament rupture, switching the cell back to HRS.

During resistive switching, the electrons are transferred at the metal/insulator interfaces due to the electrochemical reactions including the oxidation and reduction processes, and the electron transfer reaction can be mathematically described by the Butler-Volmer equation [70].

$$J_{\mathrm{et}} = j_{0,\mathrm{et}}\left(\exp\left(\frac{(1-\alpha)\,ze}{k_{\mathrm{B}}T}\eta_{\mathrm{et}}\right) - \exp\left(-\frac{\alpha ze}{k_{\mathrm{B}}T}\eta_{\mathrm{et}}\right)\right) \tag{29.17}$$

which exponentially relies on the electron transfer overpotential η_{et}. In the equation, z is the charge number, α is the charge transfer coefficient, and $j_{0,\mathrm{et}}$ is the exchange current density. The first and the second exponential terms describe the oxidation and the reduction processes, respectively. The cation transport within the electrolyte layer and the corresponding current density can be calculated with the Mott-Gurney law [70].

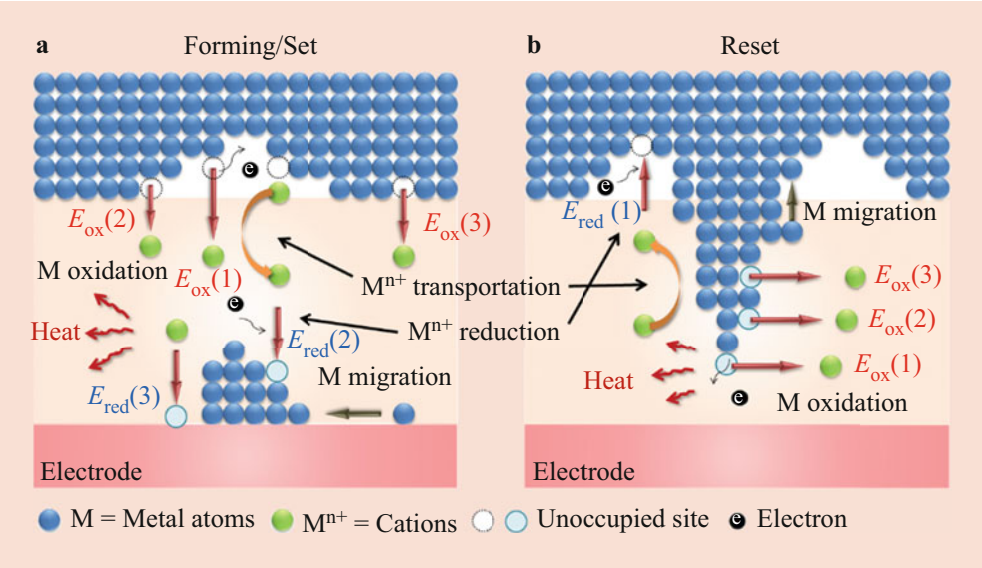

Fig. 29.9 The microscopic behaviors and the correlated physical effects in CBRAM during resistive switching. (Reprinted from [68])

$$J_{\text{hop}} = 2zecaf \exp\left(-\frac{E_{\text{h}}}{k_{\text{B}}T}\right) \sinh\left(\frac{aze}{2k_{\text{B}}T}E\right) \qquad (29.18)$$

where a is the mean cation hopping distance, E_{h} is the hopping barrier height, c is the cation concentration, and E is the applied electric field.

Under the same theoretical framework as shown in Fig. 29.9, Y. C. Yang et al. investigated the impacts of material parameters on the filament growth dynamics to explain the different filament growth modes observed experimentally [71]. According to Yang, the filament growth dynamics may fall into four different regimes depending on the kinetic factors based on the same theoretical framework as shown in Fig. 29.10. When the cation mobility μ and the redox rate Γ^{i} are high and homogeneous (case a), the cations can reach IE without agglomerating, thus avoiding nucleation within the insulating film so filament growth initiates from IE, and high Γ^{i} induced large amount of cation supply which leads to an inverted cone-shaped CF. Such CF growth dynamics are frequently observed in the conventional CBRAM in which electrolyte materials have high cation mobility. In contrast, in the case of low μ and low Γ^{i} (case b), the cations pile up and reach the critical nucleation conditions inside the dielectric, and further CF growth is fulfilled by cluster displacement. This case corresponds to electrolyte materials with very low cation mobility. If the cation mobility is low while the redox rates are high (case c), nucleation can occur inside the electrolyte, while large amounts of atoms can be deposited onto the cathode sides. This process is repeated thus again leading to an effective forward growth toward IE. Finally, if the cation mobility is high and the redox rates are low (case d), nucleation only occurs at IE, but the limited cation supply means reduction predominately occurs at the edges with high field strength, thus leading to branched CF toward AE. In general, the cation mobility determines the CF growth direction, while the redox rates determine the CF geometry.

29.3 Modeling and Simulation of Resistive-Switching Behaviors

29.3.1 Ox-RRAM

To capture the microscopic natures and the correlations with the electric and thermal properties during the switching process, numerical solutions such as the Monte Carlo methods have been developed to quantify and predict the switching, scaling, and reliability effects of RRAM. The Monte Carlo dynamic simulation is an efficient tool to study the atomic-scale evolution of a RRAM cell, which can benefit to deeply understand the underlying physics of resistive-switching behaviors and further propose optimization schemes for the RRAM cell. The Monte Carlo simulation method can be used to self-consistently simulate the microscopic processes happened during resistive switching under the external electric field and influenced by the local temperature. The general simulation algorithm flow is shown in Fig. 29.11.

For sake of simplicity, we will take 2D simulation as an example; the simulation is performed on an atomic matrix with a size of $m * n$, where m and n depend on the size of the fabricated device. Usually as the inputs of the simulation, the intrinsic defects are introduced and randomly generated when initializing simulation. After that, the potential and current distributions in the resistive-switching layer are solved by Poisson's equations or the resistor network [63], and

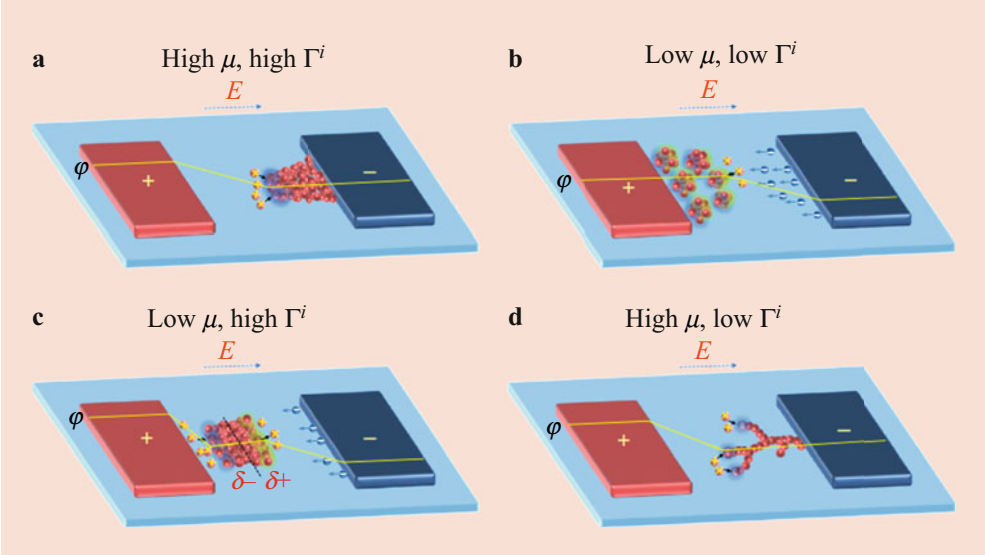

Fig. 29.10 Four different filament growth dynamics governed by kinetic parameters. (**a**) Filament growth from IE with an inverted cone shape, (**b**) filament growth from AE with discrete nanoclusters and a forward cone shape, (**c**) filament nucleation inside the dielectric and reconnection with the source, (**d**) filament growth from IE and a branched structure. (Reprinted from [71])

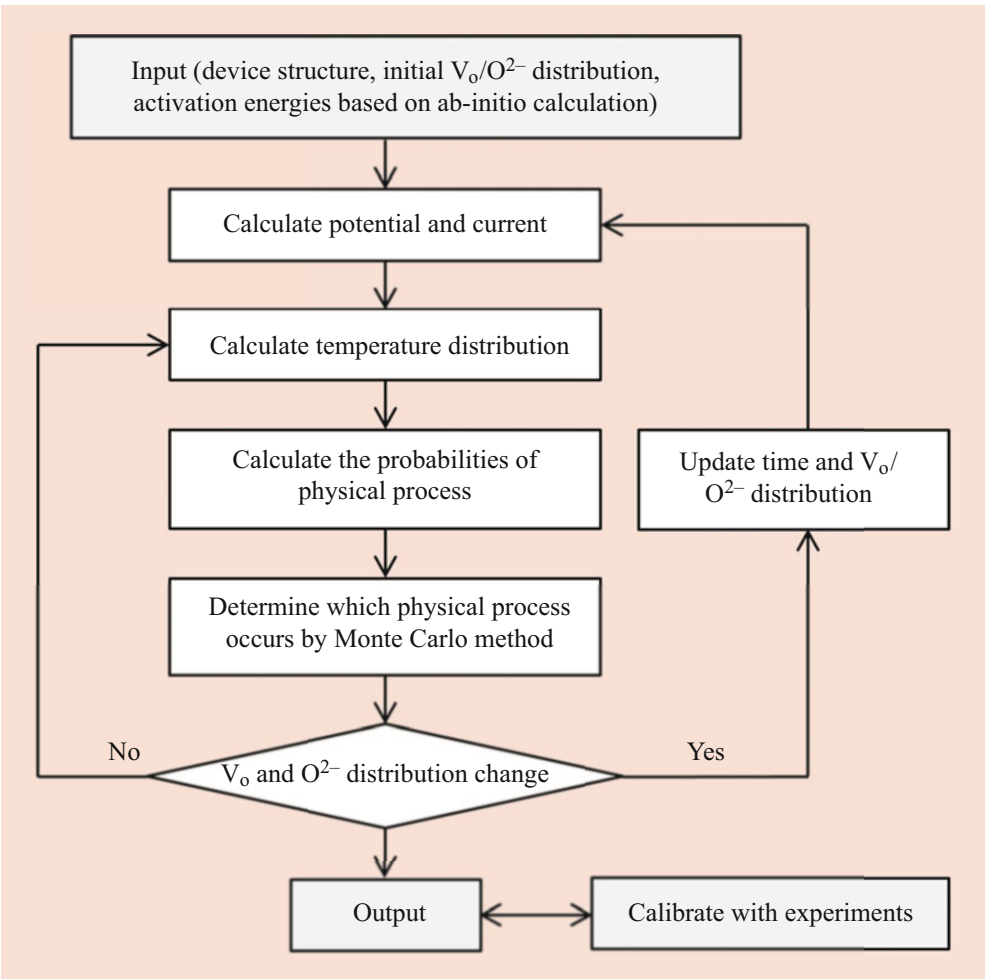

Fig. 29.11 Simulation flowchart of a typical Monte Carlo simulation algorithm for Ox-RRAM

then the local temperature distribution is calculated by the resolution pf the time-dependent heat diffusion equation [72].

$$\nabla\cdot\left[\kappa\left(\mathbf{r},T\right)\nabla T\left(\mathbf{r},t\right)\right]+g\left(\mathbf{r},t\right)=\rho C\frac{\partial T\left(\mathbf{r},t\right)}{\partial t} \quad (29.19)$$

where $T(\mathbf{r},T)$ and $g(\mathbf{r},t) = \boldsymbol{J}\cdot\boldsymbol{E}$ are the temperature and heat generation, respectively, at a given position $\mathbf{r}$ and time t, $\kappa(\mathbf{r},T)$ is the temperature-dependent thermal conductivity, ρ is the material density, and C is the specific heat capacity. Following these, the probabilities of the physical effects during resistive switching are calculated respectively. By precisely assigning different activation energies to particles according to their local structure, the probabilities of the physical processes can be calculated by Eqs. (29.1–29.4). The values of these activation energies can be either obtained through ab initio calculations or fitted with experimental results. After obtaining the probabilities, a random number uniformly distributed between [0 1] is generated and compared with these probabilities. Then a certain microscopic process is selected for each particle according to the comparison result. The time and particle distributions have to be updated in every time step. The field and temperature distributions are updated regularly, which are in turn used to update the V_O and O^{2-} configurations. For each time step, all the main physical processes are reevaluated to decide the next move. The above calculations will be repeated as the sweeping voltage changes.

Here, an example of TaO_X-RRAM is given to demonstrate the simulation results of the Monte Carlo method [63]. The simulated microscopic evolutions of CF in the Ta_2O_5 resistive-switching layer during switching are shown in Fig. 29.12. The filament configuration together with the corresponding current, temperature, and O^{2-} distributions is simulated. The simulation results indicate that the CF ruptures from the interface between the Ta_2O_5 layer and TaO_X layer and then reconnects to TaO_X layer gradually, revealing that the resistive switching is attributed to the rupture and formation of CF. More specifically, for RESET operation, the whole filament firstly disconnects at the Ta_2O_5/TaO_X interface and then extends to the interior as the sweeping voltage increases. For SET, a fine filament forms firstly in the rupture region and then gradually extends along the radius direction as current increases.

The simulated I-V characteristics of the $Pt/Ta_2O_5/TaO_X/Ta$ RRAM device are compared with measurements as shown in Fig. 29.13. The simulated results are in excellent accordance with experimental data. Points A–H in Fig. 29.12 represent each stage. The abrupt SET process and gradual RESET process can be reproduced by the simulations. From the simulation results, the 2D Monte Carlo simulation can capture the essential switching characteristics of RRAM with acceptable computation resources.

To more precisely gain the insights into the dynamics of the filament evolution, 3D simulation can be performed by Monte Carlo technique. Figure 29.14a–c shows the simulated

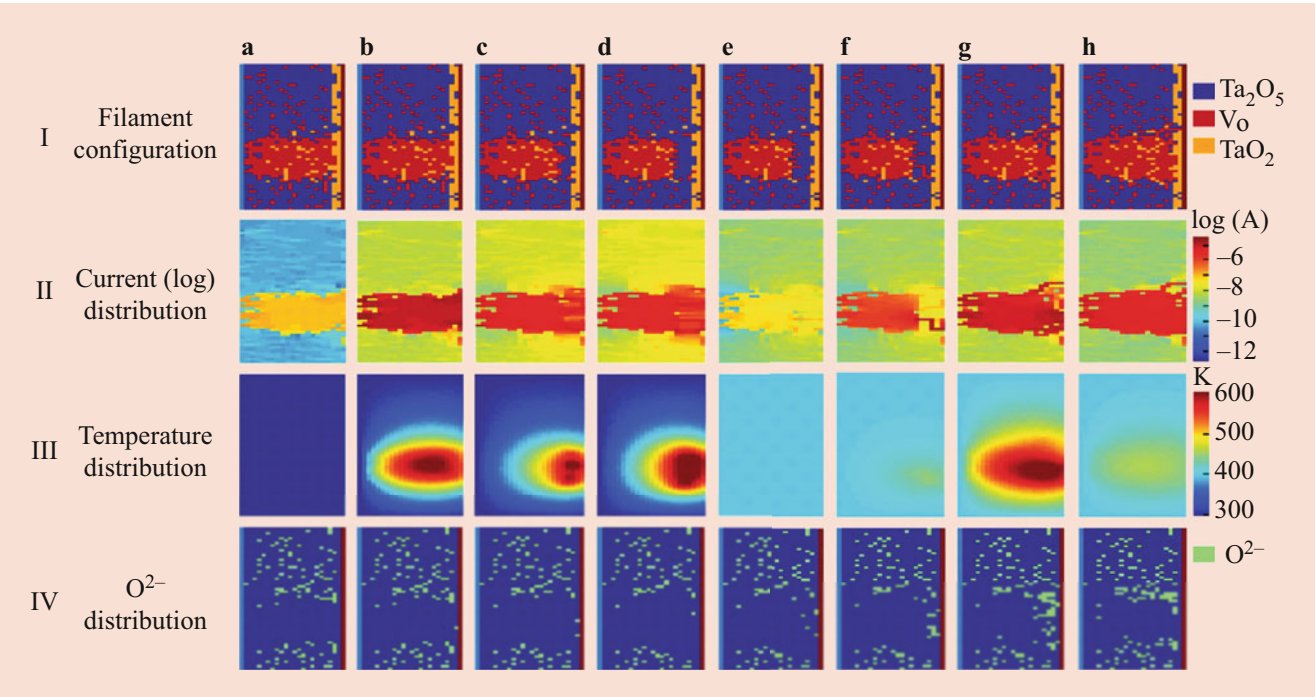

Fig. 29.12 Simulated microscopic evolutions of TaO_X-RRAM in the Ta_2O_5 resistive-switching layer during RESET and SET process. I, CF configuration; II–IV, the corresponding logarithmic current, temperature, and O^{2-} distributions. (Reprinted from [63])

3D evolutions of V_O and O^{2-} distributions during Forming process [73]. During the initial part of the forming voltage ramp, only few native defects exist, and the device is in HRS as shown in Fig. 29.14a. Since the current is small, the power dissipation is limited, and the local temperature is uniform and equal to the ambient one, as shown in Fig. 29.14d. As the sweeping voltage approaches a critical value, the higher electric field lowers the energy needed to break the Hf-O bond, thus increasing the defect generation probability, leading to a small increase of the local temperature as shown in Fig. 29.14b, e. At the third stage, a relevant change in the Forming process occurs when the generated V_O defects create a CF as shown in Fig. 29.14c, which strongly enhances the current and the local temperature as shown in Fig. 29.14f. Compared to 2D simulation, the 3D simulation can reproduce the particle reactions and evolutions more vividly, which would benefit the understanding of the underlying physics of RRAM.

The Monte Carlo simulation method can also be used to investigate the reliability issues of Ox-RRAM. Figure 29.15 plots the simulated CF evolution processes in endurance test and the corresponding resistance varying with switching cycle under different operation Schemes [74]. The experimentally observed typical endurance degradation can be reproduced by the simulations. Based on the simulation results, the over-SET and over-RESET will result in endurance degradation. The over SET endurance degradation is attributed to the extra V_O generation during SET process, which causes the extra growth of CF size, accompanying with the reduced R_{HRS} and R_{LRS}. The over-RESET originates from extra recombination between V_O and O^{2-}, which causes the widening of electron tunneling gap. This may cause SET failure due to the weakening of electric field in gap region, resulting in the reduced V_O generation. Results reveal that CF gap distance increases during over-RESET degradation, while the radius of CF increases during over-SET degradation. The results also reveal that the operation scheme will influence the endurance degradation. Retention is another important reliability aspect. Figure 29.16 shows the LRS retention degradation and the corresponding CF geometry evolution processes [75]. The migration of V_O from CF region results in the dissolution of CF, and therefore the conduction transforms from metallic to hopping. Additionally, the O^{2-} released by the electrode and sidewall oxide can recombine the V_O which reduces the amount of V_O and leads to the rupture of the CF. Therefore, the current decreases as the time goes on.

Besides the Monte Carlo simulation including the detailed microscopic information, the compact model of RRAM is also very important, which provides fast calculations of the device electrical characteristics for circuit design and evaluations. Among various compact models, the physics-based compact model can provide accurate results capturing the dependence on the material parameters and operation parameters, through which the critical parameters during switching can be extracted from the physical view, making the device optimization and device-circuit co-design possible. The physics-based compact model can bridge the resistive-switching behaviors with the evolution of CF geometry. Based on the simulated CF geometry evolution processes during the switching process as shown in Fig. 29.12, P. Huang et al. developed a physics-based compact model for RRAM operation in which the 3D CF evolution process is modeled as shown in Fig. 29.17 [60]. Initially, there is a cylindrical CF with a diameter w_0 bridging two electrodes. The RESET process is modeled as the changing of gap distance x between the CF tip and the top electrode. Thus the gap distance x determines the HRS resistance during RESET process. Hence, x and dx/dt are key factors for RESET process. The value of dx/dt is determined by three physical processes: (1) electrode release O^{2-}, (2) O^{2-} hopping in the oxide layer, and (3) recombination between O^{2-} and V_O. The reduction of x is determined by the slowest process among the above three processes.

When O^{2-} hopping is the dominant process, the O^{2-} flow rate of $J_{O^{2-}}$, which is the amount of O^{2-} flowing through unit area of cross section per unit time, can be written as

$$J_{O^{2-}} = 1/2\,(P_h\,(E, T, dt) - P_h\,(-E, T, dt)) / \left(a^2 dt\right) \quad (29.20)$$

where a is the distance between two V_O and the coefficient 1/2 results from two different directions of O^{2-} hopping. Thus the amount of O^{2-} hopping to V_O during dt is

$$N_{O^{2-}} = J_{O^{2-}} \pi\,(w_0/2)^2 dt \quad (29.21)$$

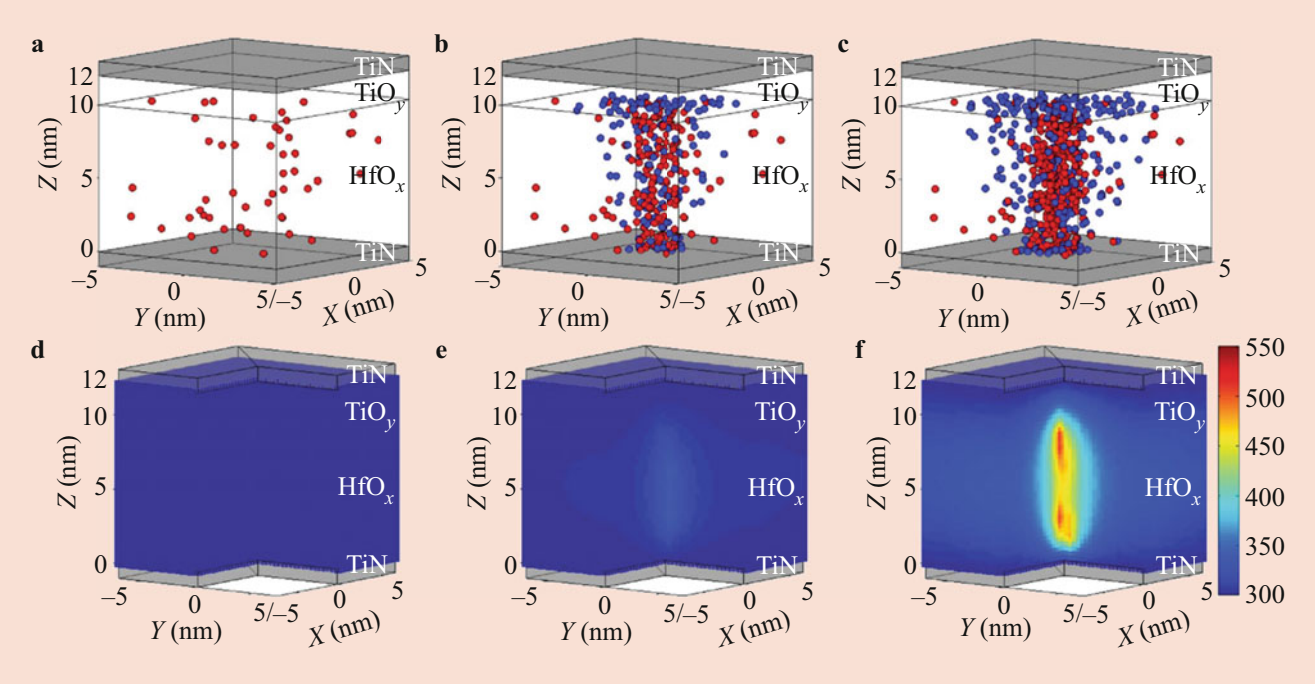

Fig. 29.14 Simulated (**a**)–(**c**) 3D V_O (red spheres) and O^{2-} (blue spheres) distributions, (**d**)–(**f**) the corresponding 3D temperature profiles. (Reprinted from [73])

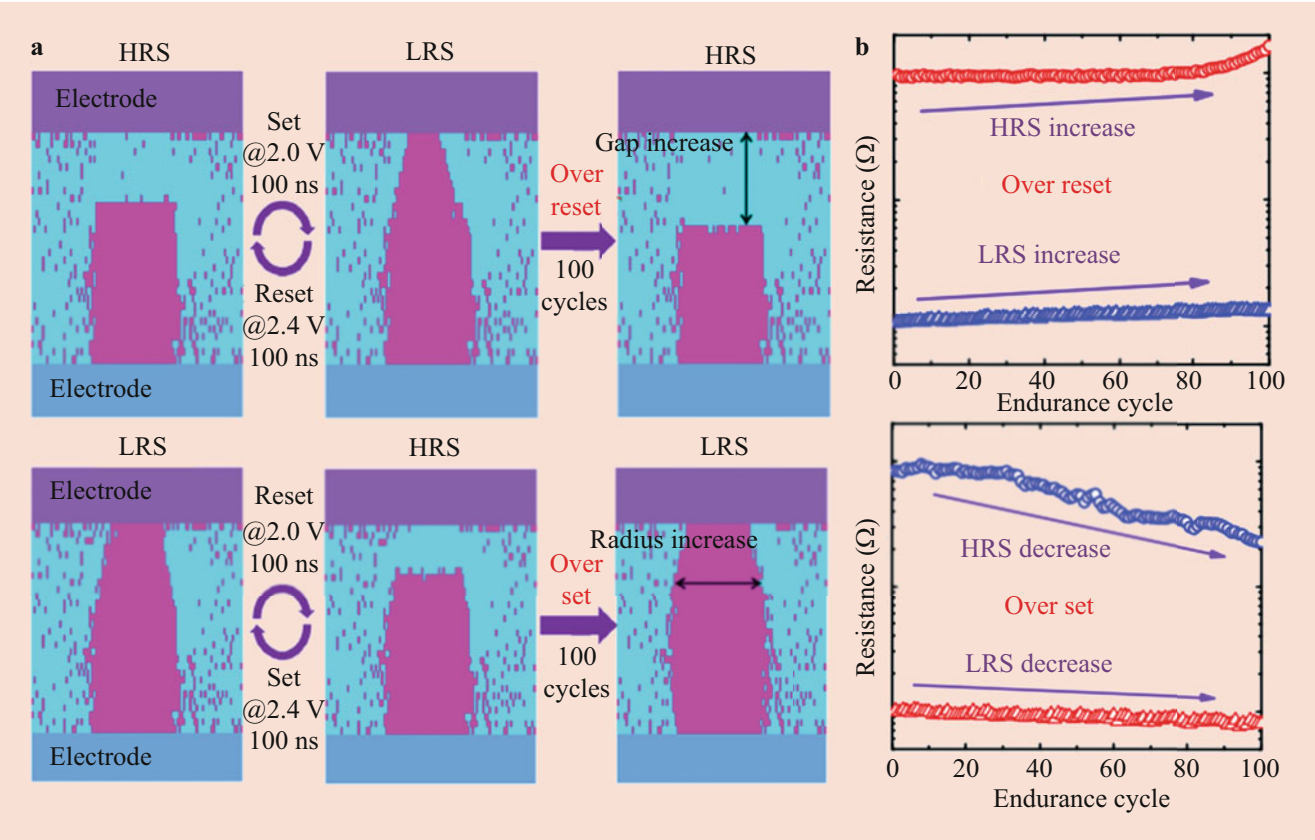

Fig. 29.15 (**a**) Simulated CF evolution in endurance test and (**b**) the corresponding resistance varying with switching cycle under different operation schemes. (Reprinted from [74])

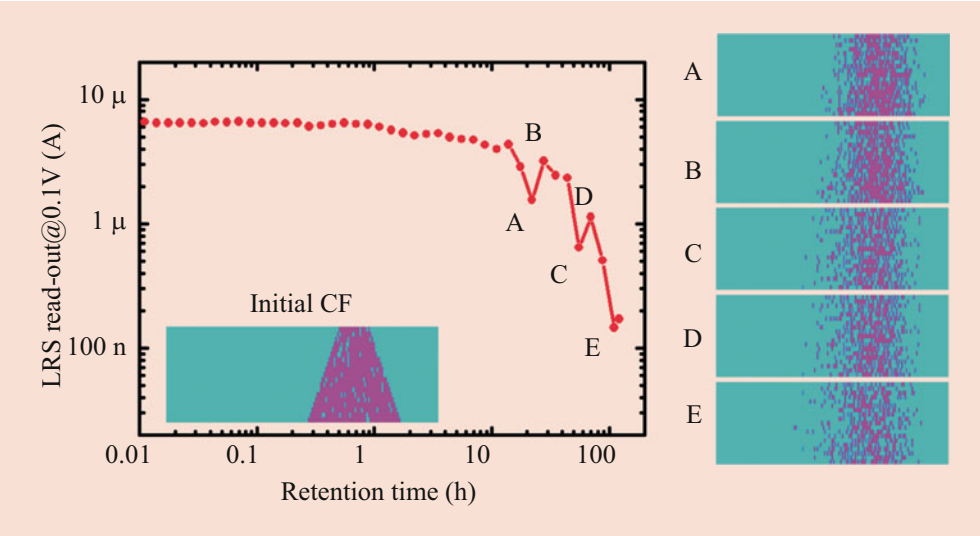

Fig. 29.16 Simulated LRS retention degradation of Ox-RRAM. The migration of V_O from CF region and the recombination of the V_O with O^{2-} released by the electrode/sidewall oxide will lead to the rupture of CF. (Reprinted from [74])

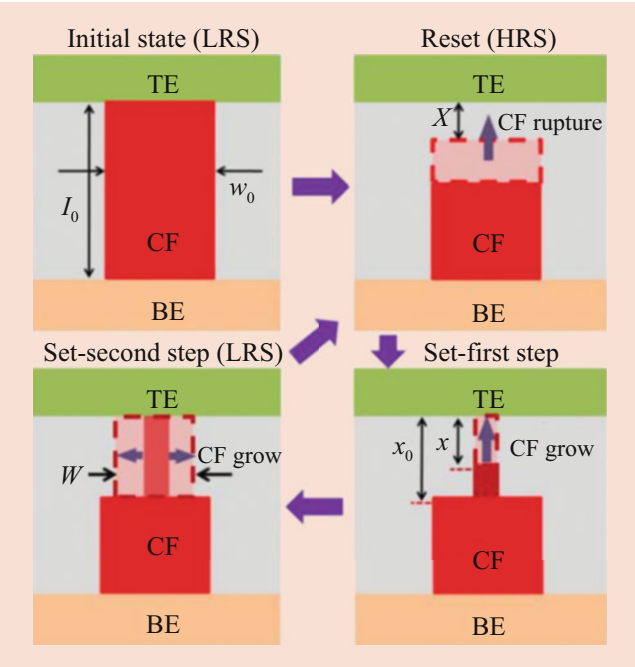

Fig. 29.17 Schematic of the CF evolution model during RESET and SET process. In RESET process, the gap distance x changes with applied voltage. The SET process is divided into two steps: CF growth from the rupture CF tip to the electrode and CF expanding along the radius direction of the formed CF. (Reprinted from [60])

and meanwhile the amount of V_O recombined with O^{2-} is

$$N_{V_O} = \pi (w_0/2)^2 \mathrm{d}x/a^3 \tag{29.22}$$

Combining (29.21, 29.22), dx/dt can be obtained as

$$\frac{\mathrm{d}x}{\mathrm{d}t} = af \exp\left(-\frac{E_h}{k_B T}\right) \sinh\left(\frac{\alpha_h Z e E}{k_B T}\right) \tag{29.23}$$

where E_h is the hopping barrier of O^{2-}, E is the electric field, α_h is the enhancement factor of the electric field for the lowering of E_h, and Z is the charge number of oxygen ion.

Similarly, when the process of electrode releasing O^{2-} is dominant, dx/dt can be written as

$$\frac{\mathrm{d}x}{\mathrm{d}t} = af \exp\left(-\frac{E_i - \gamma Z e E}{k_B T}\right) \tag{29.24}$$

where E_i is the energy barrier between the electrode and oxide and γ is the enhancement factor of the electric field. When the process of recombination between O^{2-} and V_O is the slowest, dx/dt is written as

$$\frac{\mathrm{d}x}{\mathrm{d}t} = af \exp\left(-\frac{\Delta E_r}{k_B T}\right) \tag{29.25}$$

where ΔE_r is the relaxation energy during the recombination process.

After RESET operation, x is fixed to x_0. During SET, the CF evolution is modeled by two steps: (1) a thin CF grows from the residual CF tip to the top electrode, and (2) the newly grown CF expands along the radius direction of the previously formed CF. The resistance change during SET operation is determined by the x_0 and w of the newly formed CF. Thus dx/dt and dw/dt are the key factors to model the SET operation. The key physical process during the SET process is the generation of V_O. The amount of V_O generated in the

rupture region during dt in the first step of SET process is as follows:

$$N_{V_{Og}1} = N_{sum} P_g\,(E, T, \mathrm{d}t) = P_g\,(E, T, \mathrm{d}t)\, a\pi r^2/a^3 \quad (29.26)$$

where r is the radius of newly grown thin CF. The absolute value of dx equals to the gap distance variation of the newly grown CF, which is

$$\mathrm{d}x = -\frac{N_{V_{Og}1} a^3}{\pi r^2} = -af \exp\left(-\frac{E_a - \alpha_a ZeE}{k_B T}\right) \mathrm{d}t \quad (29.27)$$

where E_a is the average activation energy of V_O. In the second step, the generation of V_O mainly occurs in the extended region along the radius direction. The changing rate of the width of CF is given as

$$\frac{\mathrm{d}w}{\mathrm{d}t} = \left(\Delta w + \frac{\Delta w^2}{2w}\right) f \exp\left(-\frac{E_a - \alpha_a ZeE}{k_B T}\right) \quad (29.28)$$

where Δw is the effective expanding width of CF.

Based on the CF evolution model, the conduction of the RRAM cell is modeled as shown in Fig. 29.18. Two major kinds of electron transport are identified in RRAM: the conduction in the CF region is considered as metallic, while the conduction in the gap region is hopping. The metallic current in the CF can be derived from Eq. (29.7) and Ohm's law. The hopping current is correlated with the voltage and gap distance by [76].

$$I = I_0 \exp(-x/x_T) \sinh(V/V_T) \quad (29.29)$$

where I_0 is 10 μA/nm^2 and x_T and V_T are the characteristic length and voltage. The LRS is modeled by the conduction of CF with a width of w parallel with a nonlinear hopping current as shown in Fig. 29.18a. Under ultralow current condition, w is small and the nonlinear I-V characteristics at LRS can be reproduced as shown in Fig. 29.18b. On the other hand, conduction in HRS can be equivalently modeled as two parallel nonlinear hopping currents with different x and the I-V characteristics of HRS are shown in Fig. 29.16c.

During resistive switching, the formation and rupture of CF are very sensitive to local temperature, and therefore it should be properly considered. For simplicity, we assume uniform temperature in the electrolyte layer. An analytic model for temperature at LRS can be adopted, which is [66].

$$T = T_0 + IVR_{th} \quad (29.30)$$

where T_0 is the ambient temperature and R_{th} is the effective thermal resistance. It should be noted that this temperature model is based on a quasi-static approach, which means

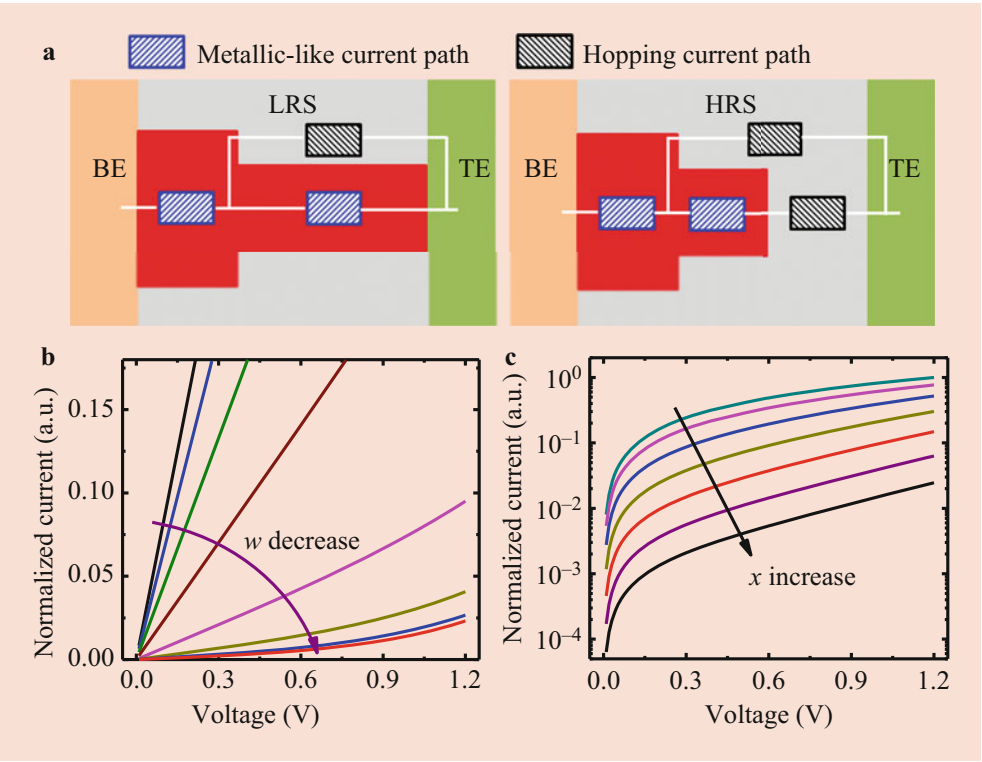

Fig. 29.18 (**a**) Equivalent circuit of conduction in LRS and HRS. (**b**) LRS and (**c**) HRS I-V curves reproduced by the conduction model. (Reprinted from [60])

the thermal equilibrium is assumed to be reached once the operation voltage is applied on the cell.

The equivalent circuit of the Ox-RRAM cell is shown in Fig. 29.19. It consists of a parallel capacitance (C_p), a large parallel resistance (R_p), and contact resistance (R_c) together with the resistive-switching elements (R_s). C_p results from the intrinsic MIM structure. R_p includes the conduction associated with the leakage current between two electrodes. R_c represents the total resistance of the electrodes itself and the contact resistance between CF and electrodes.

Utilizing the above model, the electrical characteristics of Ox-RRAM can be reproduced. Figure 29.20a shows the measured and calculated DC I-V curves during RESET and SET processes of the TiN/HfO$_X$/Pt/AlO$_X$/Pt bilayer devices. The compact model can successfully reproduce the gradual RESET and the abrupt SET processes that match perfectly with the measured data. It can be also found that the HRS resistance is high with large stop voltage during RESET process and will cause high SET voltage in the following SET process. Figure 29.20b shows the calculated and measured transient response current waveforms for the two RESET programming schemes in the TiN/HfO$_X$/Pt/AlO$_X$/Pt bilayer device. Excellent agreements between the modeling and measured data show the validity and universality of this compact model to capture the main features of the Ox-RRAM under both DC and AC operations.

Besides the physics-based model, S. Kim et al. propose a numerical electro-thermal model using the finite element method to quantitatively describe the electrical characteristics of Ox-RRAM [77]. The model is based on a V_O migration mechanism in a bilayer Ta_2O_5/TaO$_X$ device. During the Forming process, the charged V_O is attracted from the TaO$_X$ layer to the TE, where the TaO$_X$ layer only serves as the role of the V_O reservoir. The CF is described as a doped region where V_O acts as dopants and thus contributes to local electrical and thermal conductivity values. The migration of V_O is simulated by the local temperature and electric field derived from carrier continuity and heat equations fully coupled in a 3D geometry, which considers a complete bilayered structure that includes the top and bottom electrodes as shown in Fig. 29.21a. After the Forming process, the SET and RESET processes are described through V_O migration induced by the local electric field and temperature due to Joule heating. Thus, simulation of SET and RESET requires the self-consistent solution of three partial differential equations:

(1) A drift/diffusion continuity equation for V_O transport, which is

$$\frac{\partial n_D}{\partial t} = \nabla \cdot (D\nabla n_D - \nu n_D) + G \qquad (29.31)$$

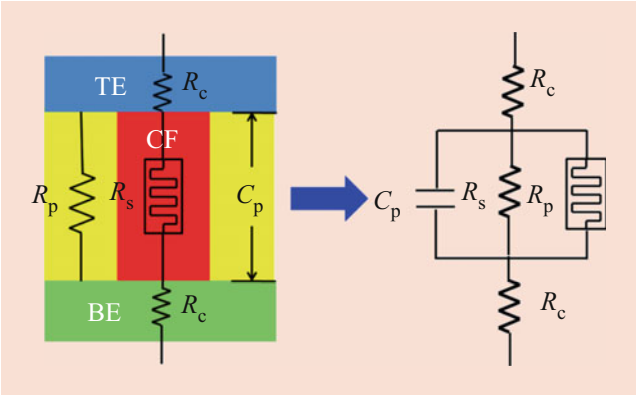

Fig. 29.19 Equivalent circuit of the Ox-RRAM cell with parasitic resistance and capacitance. (Reprinted from [60])

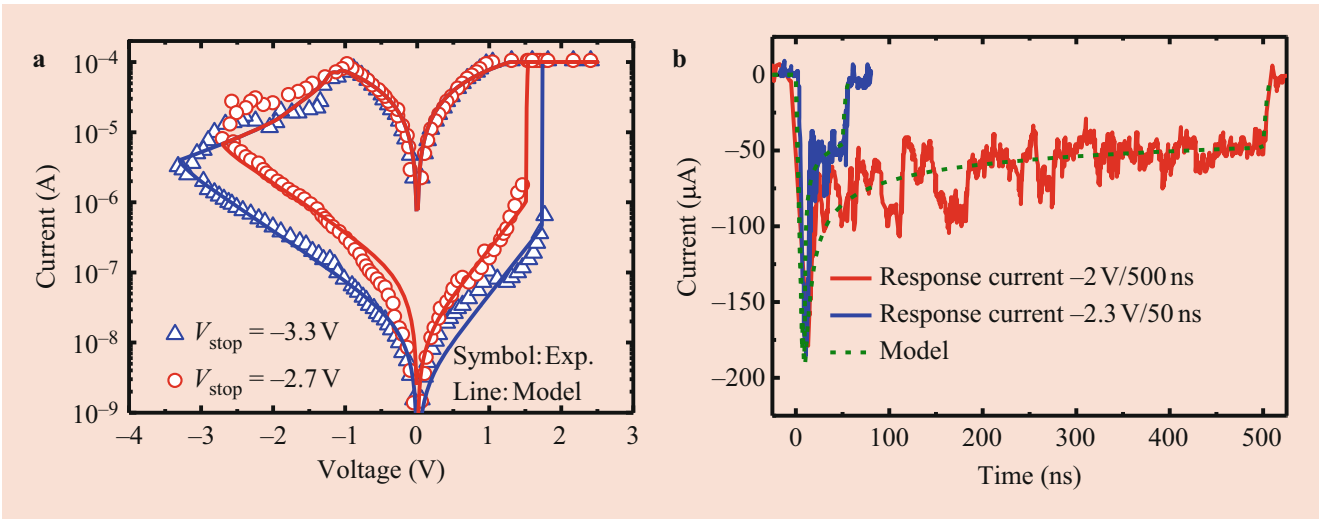

Fig. 29.20 (**a**) Measured and model calculated DC I-V characteristics of the TiN/HfO$_X$/Pt/AlO$_X$/Pt bilayer devices. (**b**) Measured and model calculated transient response current waveforms for the two RESET programming schemes. (Reprinted from [60])

where n_D is the concentration of V_O and D is the diffusivity of V_O, which can be described by

$$D = \frac{1}{2}a^2 f \exp\left(-\frac{E_a}{kT}\right) \tag{29.32}$$

where a is the V_O hopping distance and E_a is the diffusion barrier. v is the drift velocity of V_O, which is

$$v = af \exp\left(-\frac{E_a}{kT}\right) \sinh\left(\frac{qaE}{kT}\right) \tag{29.33}$$

and G is the generation rate of V_O, which is

$$G = A \exp\left(-\frac{E_b - q\beta E}{kT}\right) \tag{29.34}$$

where A is the coefficient of generation rate and β is the mesh size.

(2) A current continuity equation for electrical conduction

$$\nabla \cdot \sigma \nabla \psi = 0 \tag{29.35}$$

where ψ is the potential.

(3) A Fourier equation for Joule heating

$$-\nabla \cdot k_{th} \nabla T = J \cdot E = \sigma |\nabla \psi|^2 \tag{29.36}$$

Figure 29.21b shows the simulated region. In the calculations, the axisymmetric geometry allowed the 3D problem to be reduced to a 2D solution with a radial coordinate and a vertical coordinate. Figure 29.21c shows the measured and calculated I-V characteristics during the SET and RESET processes. The SET and RESET transition points show good consistency with the measured data.

The similar modeling method can be used for the reliability projection of Ox-RRAM and the crossbar array. P. Huang et al. have developed an analytic model for the endurance degradation of Ox-RRAM [74]. The endurance degradation behaviors under various operation modes can be predicted by the model and verified by the measurements. Based on the simulation results in Fig. 29.15, the analytic model including over-SET and over-RESET effects is proposed as shown in Fig. 29.22. An over-rupture region and an over-grow region during the switching process are introduced to model the endurance degradation. The parameters to characterize those regions are Δx and Δr. Δx and Δr are the difference of gap distance and CF radius between two consecutive cycles, respectively. $\Delta x/\Delta r$ is determined by the intrinsic effects, and the interaction effect between Δx and Δr. Δx can be described by

$$\Delta x_{n-1} = (1 - 1/\gamma_r)\, t\, v_x|_{x=x_{n-1}} - \eta \left(r_{n-1}^2/r_{n-2}^2 - 1\right) x_{n-1} \tag{29.37}$$

where x_n is the gap distance in HRS after n switching cycles, r_n is the radius of CF in LRS after n switching cycles, t^* is the time of residual CF tip growing to connecting the two electrodes, γ_r is the over rupture factor, and v_x is the x

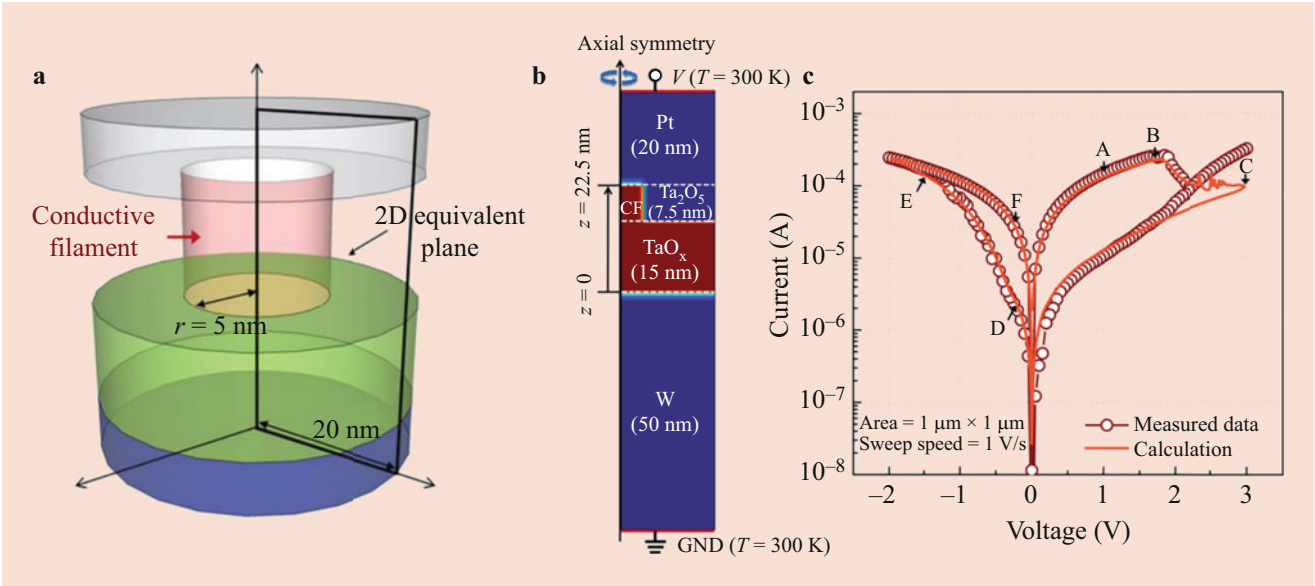

Fig. 29.21 (**a**) Simulated geometry used in calculation of the Pt/Ta_2O_5/TaO_X/W RRAM, (**b**) simulated boundary conditions, (**c**) measured and calculated I-V characteristics. (Reprinted from [77])

changing rate during RESET process. Δr can be deduced as

$$\Delta r_{n-1} = (\gamma_s - 1)\left(t^* v_r|_{r=r_{n-1}} + r_{n-1} - 2a\right) - \left[\Delta x / \left(v_x|_{x=x_n}\right) + (\gamma_r - 1)\, t^*\right] v_r|_{r=r_{n-1}} \quad (29.38)$$

where γ_r is the over-grow factor and v_r is the rate of CF growth.

By combining the endurance degradation model with the compact model of RRAM transient operations described by Eqs. (29.23)–(29.28), the endurance degradation can then be investigated. The model calculated and measured dependence of ratio degradation of over-SET on SET voltage and RESET voltage in TiN/Ti:HfO_X/Pt RRAM structure are shown in Fig. 29.23. The results imply that proper high RESET voltage and low SET voltage can suppress the ratio degradation caused by over-SET. This is because low SET voltage and high RESET voltage are not beneficial for the accumulation of extra O^{2-} during the switching cycle.

29.3.2 CBRAM

The device characteristics of CBRAM can be modeled and simulated similarly with Ox-RRAM, and the main difference is the resistive-switching mechanism. In this section, we will introduce some examples of various modeling and simulation methods to better illustrate the characteristics of CBRAM.

As mentioned previously, for CBRAM, various CF geometries, growth directions, and CF dissolution positions in different materials have been observed by experiments. Simulations can help to clarify the critical issues such as the impacts of the materials on the CF properties, which will help to understand the underlying physics in the CBRAM cell. Based on the physical effects, Y. Zhao et al. have developed a Monte Carlo simulation platform to capture the essential features during switching and the correlated microcosmic properties of the CBRAM device [68]. Figure 29.24a shows the simulated I-V characteristics of the Cu/Al_2O_3/TiN cell, in good agreement with the experimental data from [78]. The corresponding CF geometry can also be simulated by the simulation platform as shown in Fig. 29.24b, which is consistent with the experimental observation after SET by AFM in [78]. Based on the simulation results, in the case of Cu/Al_2O_3/TiN, the CF dissolves at the thinnest part due to the thermal-electric effect near IE.

Using the Monte Carlo simulation platform, by adjusting the material parameters and operation schemes, different CF geometries and growth directions can be simulated, which are summarized in Table 29.1 [79]. The simulation results reveal that the CF geometry is associated with the probabilities of oxidation, hopping, and reduction processes which are represented by P_o, P_h, and P_r. These probabilities highly rely on the activation energy (which varies with different materials) and the electric field (which depends on the operating schemes according to Eqs. (29.11, 29.12, and 29.14)). When choosing the electrolyte material with high cation mobility, P_o is usually less than P_h. In this case, the CF grows from IE to AE during Forming process. By contrast, if the cation mobility in the electrolyte is low, the CF grows from AE to IE during the Forming process. The CF geometry is determined by the competition between P_h and P_r: when P_r is larger than P_h, the CF is a converted cone; when P_r is smaller than P_h, the CF is a forward cone. The simulated CF geometry is consistent with the experimental observations in Refs. [67, 80, 81]. As shown in Table 29.1, the CF evolution is summarized as three modes labeled as Modes I–III according to the CF growth direction and geometry.

The simulation results show that the CF evolutions in the three different modes are quite similar. During RESET process, the CF first laterally narrows at the thin end, and then it shortens vertically once it ruptures. During SET process, the CF first grows vertically to connect two electrodes, and then it laterally expands near the thin end. The simulated DC I-V characteristics in Table 29.1 shows that the switching voltage and the resistance window are small in Mode II compared with Modes I and III.

The mechanical response of the electrolyte layer can also be investigated by simulations [82]. In liquid, the CF growth can take place in any direction. However, in a solid ion conducting layer, the filament growth induces mechanical stress in the host matrix, which would constrain the CF to some finite small size in general. To model the mechanical stress, a radial two-spring model is proposed in Fig. 29.25a. The small spring (I) model relaxation processes within the nanotemplate and yields a nonlinear Young's modulus that changes from a lower value $E_{1,0} = 500$ MPa to a $E_{1,max} = 1$ TPa within the first $l_1 = 5$ nm according to

$$E_1 = E_{1,0} \exp\left(\frac{r}{l_1} \ln\left(\frac{E_{1,max}}{E_{1,0}}\right)\right) \quad (29.39)$$

Spring (II) describes the mechanical properties of the electrolyte, and a constant Young's modulus E_2 is assumed. The young's modulus is related to the spring constant k according to $k = EA_k/L$, where A_k denotes the cross section on which the force works, i.e., the grid size is a^2, and L is the cell thickness. The overall radial spring constant is then calculated using $k_{ser} = k_1\, k_2/(k_1 + k_2)$. The mechanical work ΔW_{mech} that is stored when the spring is compressed by r results from the integration of Hooke's law, which is

$$\Delta W_{mech} = e \int_0^d r k_{12}\left(d'\right) \mathrm{d}d' \quad (29.40)$$

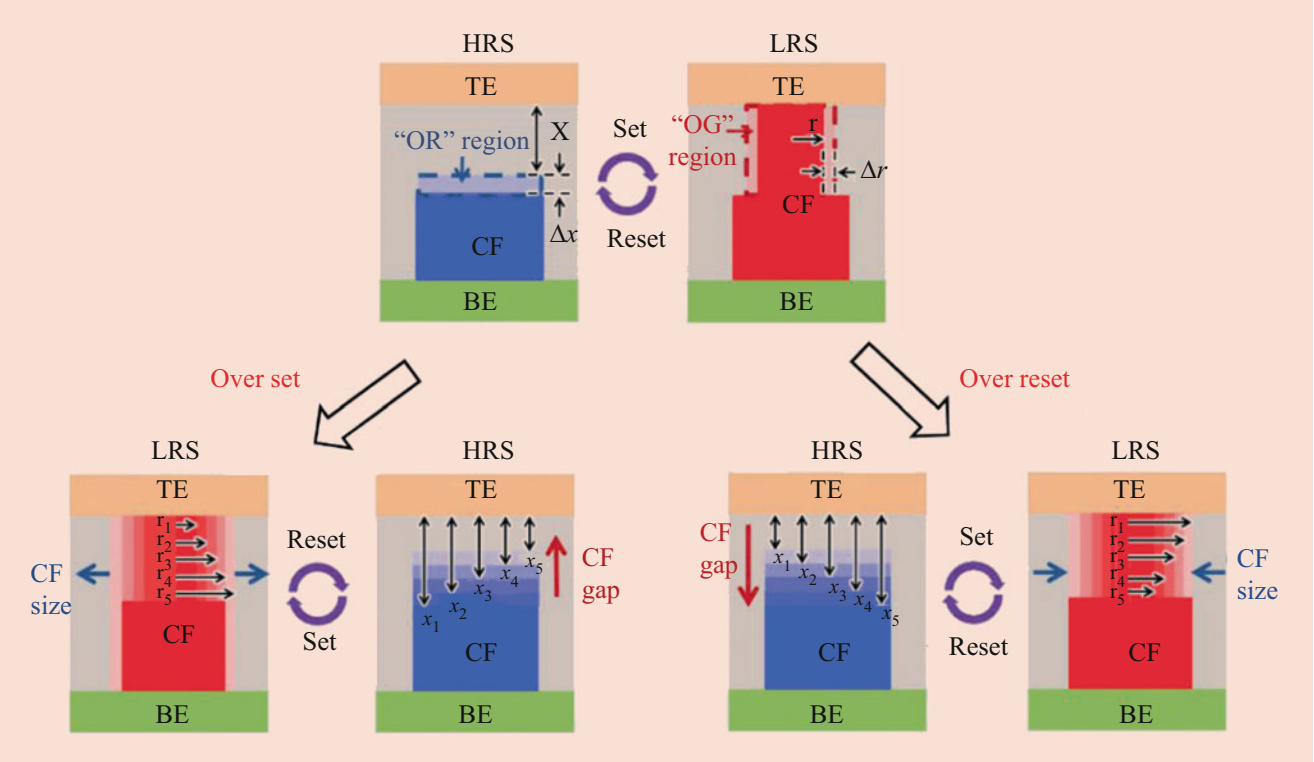

Fig. 29.22 Schematic of the endurance degradation model. (Reprinted from [74])

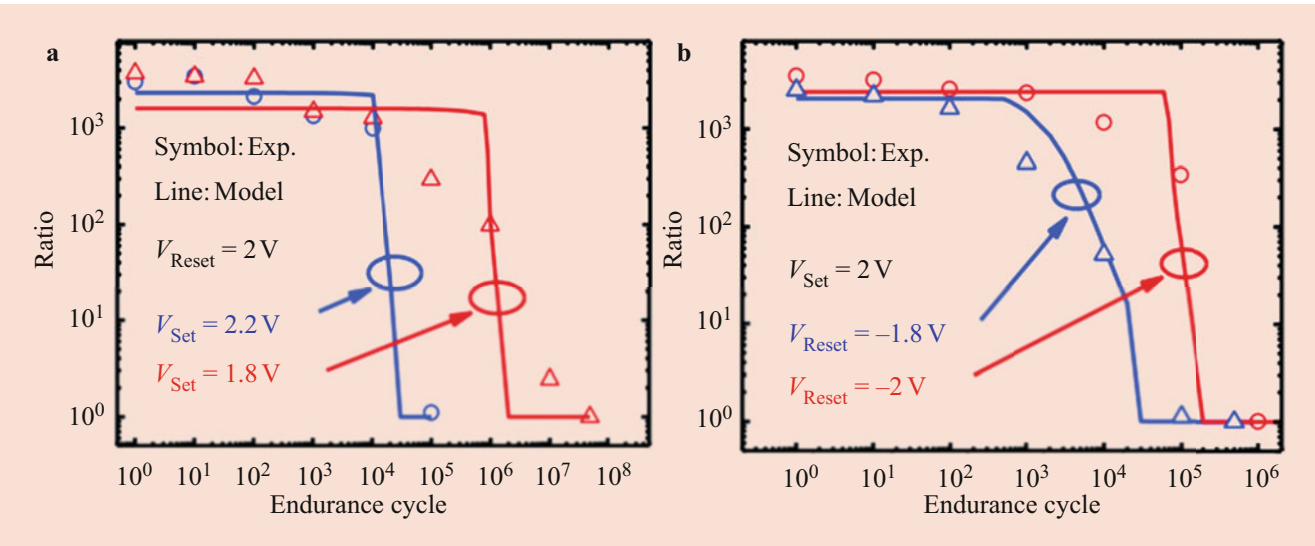

Fig. 29.23 Calculated and measured dependence of ratio degradation of over-SET on (**a**) SET voltage and (**b**) RESET voltage in TiN/Ti:HfO_X/Pt RRAM. (Reprinted from [74])

where d equals the CF diameter along the vertical axis. Figure 29.25a shows the mechanical work as a function of CF diameter for $E_2 = 10$ GPa and 500 MPa. The mechanical work is added to the reduction rate which is

$$\Delta W_{\mathrm{red,eff}} = \Delta W_{\mathrm{red}} + \Delta W_{\mathrm{mech}} \tag{29.41}$$

SET simulations were performed as shown in Fig. 29.25b, c. The diameter of the grown CF depends on Young's modulus of the electrolyte. If the Young's modulus is high, the mechanical stress applied on the filament is big resulting in a small CF diameter.

Simulations can also help to reveal the role of electrode work functions (Φ) in the switching kinetics [83]. For both

electrodes, an increase of Φ leads to a reduction of Forming time as shown in Fig. 29.26. Φ induces a flat band voltage shift but also affects the chemical reactions: increasing Φ_{TE} (or Φ_{BE}) reduces the effective oxidation (or reduction) energy barrier. While in the case of the TE, the reduction of Forming voltage is essentially due to the oxidation barrier decrease. For the BE, the reduction of Forming voltage results from the variation of the flat band voltage (neglecting the reduction barrier change). The schematic illustration of the TE case is shown in Fig. 29.26a. In terms of the relationship between the pulse voltage and Forming time, the increase of Φ_{TE} shows a shift of the characteristics, favorable to low-voltage operation but with a stronger effect for Φ_{TE} as shown in Fig. 29.26b.

The Monte Carlo simulation is also employed to investigate the HRS and LRS retention behaviors [83]. The same physical properties and parameters as for the switching are used; the only difference resides in the main accelerating factor, being the voltage for Forming/SET and the temperature for data retention. Figure 29.25 shows the measured and simulated retention characteristics under 100 °C for both the HRS and the LRS. The results indicate that the higher the compliance current, the lower the initial resistance, and the better the retention. This can be explained by the fact that the core of CF remains intact longer for a thick filament, which enhances its retention capabilities. HRS is described by the presence of a residual filament. HRS resistance decreases over time as the dissolution of the CF tends to recreate a conducting path in the electrolyte. The reformed conductive path can be simulated in Fig. 29.27a showing only little differences with the final LRS. Figure 29.27b shows the temperature impacts on the retention with the corresponding simulated final states. An increase of resistance value with

the time spent at high temperature is found. The resistance increase corresponds to the loss of data over time and is due to the CF dissolution. The higher the temperature, the more dissolved the CF, and the worst the retention.

Another method to simulate retention characteristics of CBRAM is to use a 2D numerical method [84]. The rectangular CF is assumed to be composed of metal atoms regularly distributed and each atom being treated independently. During bake, each metal atom starts to migrate following a random diffusion vector, which is

$$\overrightarrow{d_{x,y}} = \sqrt{2D} \cdot \text{Rand}\left(\overrightarrow{x}, \overrightarrow{y}\right) \tag{29.42}$$

where Rand is a randomly generated value following a normal distribution and D the diffusion coefficient in agreement with Fick's law

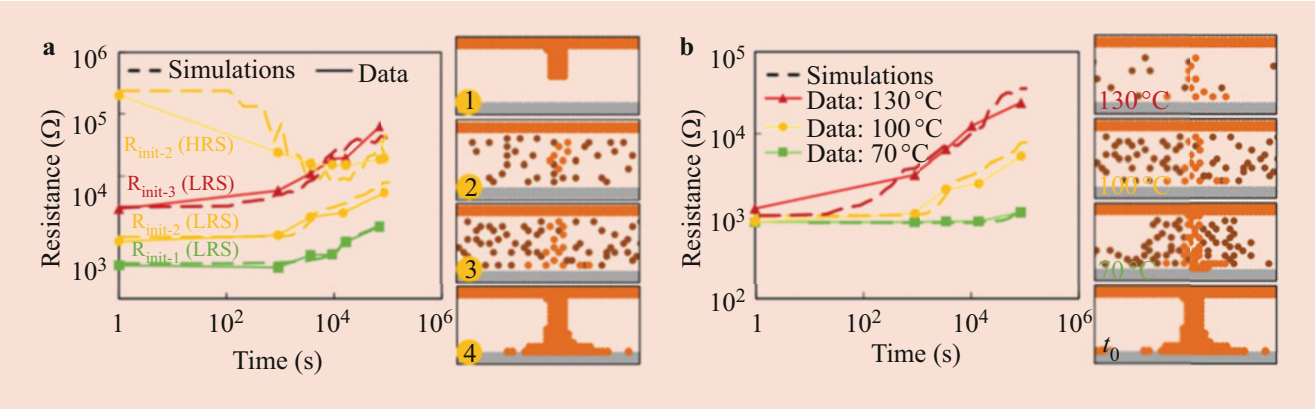

Fig. 29.27 (**a**) LRS and HRS retention degradation simulations and experimental data. (**b**) LRS retention experimental results and simulations. (Reprinted from [83])

$$D = D_0 \cdot \exp\left(-\frac{E_A}{kT}\right) \tag{29.43}$$

where D_0 is the diffusivity pre-factor, E_A is the activation energy, and T is the temperature. The cell resistance is then computed with a percolation model in a resistance network as shown in Fig. 29.28a. Figure 29.28b illustrates typical simulated LRS and HRS retention curves with the corresponding evolution of the CF morphology.

For the quick evaluation of the CBRAM characteristics in the array and circuit level, the detailed particle evolution can be neglected by highlighting the essential electrical characteristics. One way to model the switching kinetics of CBRAM is to use the electrochemical method proposed by S. Menzel et al. [70]. Depending on the electrode and electrolyte materials and also the thermodynamic conditions, the rate-limiting steps in the switching kinetics are (1) the nucleation process prior to CF growth, (2) the electron-transfer reaction at the metal/insulator interfaces, and (3) the cation transport within the electrolyte material. To model the switching kinetics, these processes can be divided into two steps: nucleation and the CF growth. For the first nucleation step, the nucleation time t_{nuc} can be written as [70]

$$t_{nuc} = t_{0,nuc} \cdot \exp\left(\frac{\Delta G_c}{k_B T}\right) \cdot \exp\left(-\frac{(N_c + \alpha)\, ze}{k_B T} \eta_{nuc}\right) \tag{29.44}$$

where $t_{0,nuc}$ is a leading factor, and here $\eta_{nuc} = V_{app}$. At time t_{nuc} the CF starts to grow. During the CF growth procedure, the equivalent circuit can be depicted as shown in Fig. 29.29a. The CF growth is modeled by the change in the tunneling gap between the filament and AE. The cylindrical CF has a cross-sectional area A_{fil} and a resistance R_{fil}. The dynamic evolution of the gap is assumed to be one dimensional and can be expressed using Faraday's law

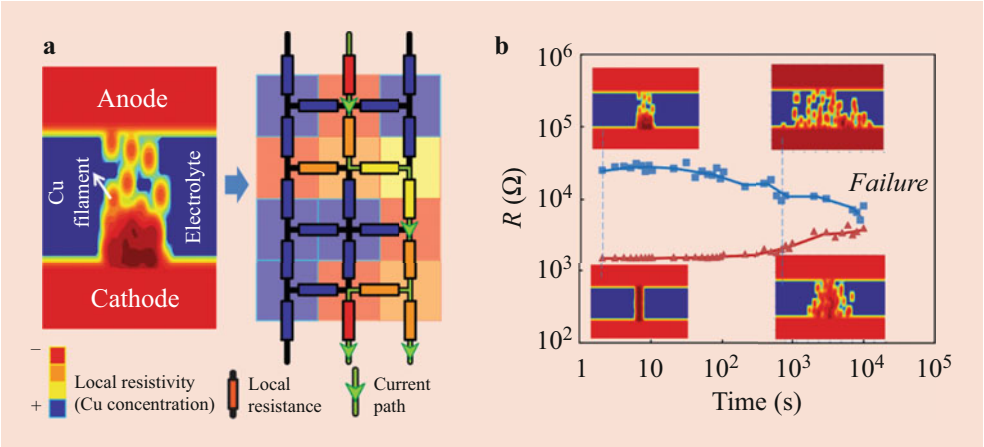

Fig. 29.28 (**a**) The resistance network used to compute the cell resistance during bake for a given metal atom distribution in the electrolyte. (**b**) Simulations of typical HRS and LRS retention characteristics at 100 °C with the CF morphologies at 2 s and 1000s. (Reprinted from [84])

$$\frac{\partial x}{\partial t} = -\frac{M_{\mathrm{Me}}}{ze\rho_{\mathrm{m,Me}}} J_{\mathrm{ion}} \tag{29.45}$$

Here, M_{Me} is the atomic mass of the deposited metal and $\rho_{\mathrm{m,Me}}$ is its density. The current density J_{ion} can be obtained by Eq. (29.18) for hopping current or Eq. (29.17) which is the Butler-Volmer equation. The electron tunneling current in the gap region can be expressed by

$$I_{\mathrm{Tu}} = C\frac{3\sqrt{2m_{\mathrm{eff}}\Delta W_0}}{2x}\left(\frac{e}{h}\right)^2 \exp \left(-\frac{4\pi x}{h}\sqrt{2m_{\mathrm{eff}}\Delta W}\right) A_{\mathrm{fil}} V_{\mathrm{Tu}}. \tag{29.46}$$

where m_{eff} is the electron effective mass, ΔW_0 is the effective tunneling barrier, h is Planck's constant, and V_{Tu} is the tunneling voltage. According to the equivalent circuit in Fig. 29.29a, the overall cell current is calculated by the sum of the ionic current and the tunneling current

$$I_{\mathrm{cell}} = I_{\mathrm{Tu}} + I_{\mathrm{ion}} \tag{29.47}$$

which is only a function of the overpotential η_{fil} and the gap distance x. Applying Kirchhoff's law, the cell voltage is

$$V_{\mathrm{cell}} = I_{\mathrm{cell}}\left(\mathrm{R_{el}} + R_{\mathrm{s}} + \rho_{\mathrm{fil}}\left(L - x\right)/A_{\mathrm{fil}}\right) + V_{\mathrm{Tu}} \tag{29.48}$$

which is also only a function of the overpotential η_{fil} and the gap distance x. The set of Eqs. (29.45–29.48) describes the dynamic behavior of the CF growth. The ordinary differential Eq. (29.45) can be solved numerically using an advanced Euler method. In each time step, the overpotential η_{fil} is calculated numerically using Eqs. (29.47 and 29.48) under different operation conditions.

Using this model, the simulations of switching kinetics have been conducted. During the simulation, first the nucleation time is calculated, and afterward the filament growth is simulated starting at the nucleation time. Figure 29.29b shows the simulated switching times as a function of the applied voltage for different temperatures and compared with experimental data. The model fits perfectly to the experimental data.

In order to bridge the electrical characteristics with the microscopic behaviors of CBRAM, a physics-based compact model is developed by Y. Zhao et al., which can clarify the impacts of CF evolution on electrical behaviors step by step based on the underlying physics. Due to the various CF growth modes, the modeling process of CBRAM would be different with that of Ox-RRAM. According to the simulated microscopic configurations of CF evolutions of the three modes in Table 29.1, The CF evolution can be modeled in Figs. 29.30 and 29.31 [79].

During the three CF evolution modes of RESET, the CF first narrows at the thin end and then dissolves from the weakest part toward the interior of the electrode along the direction of electric field as shown in Fig. 29.30. The CF geometry can be described by the following parameters: the small radius r_{t}, the wide radius r_{w}, and the filament height h, which determines the resistance of LRS. The gap distance x determines the resistance of HRS, which is modeled by the CF reduction length dh and the increase of the effective AE thickness dl. CF height reduction rate dh/dt is controlled by the slower process between oxidation and hopping. If oxidation is the dominant process, the CF height reduction rate is described by

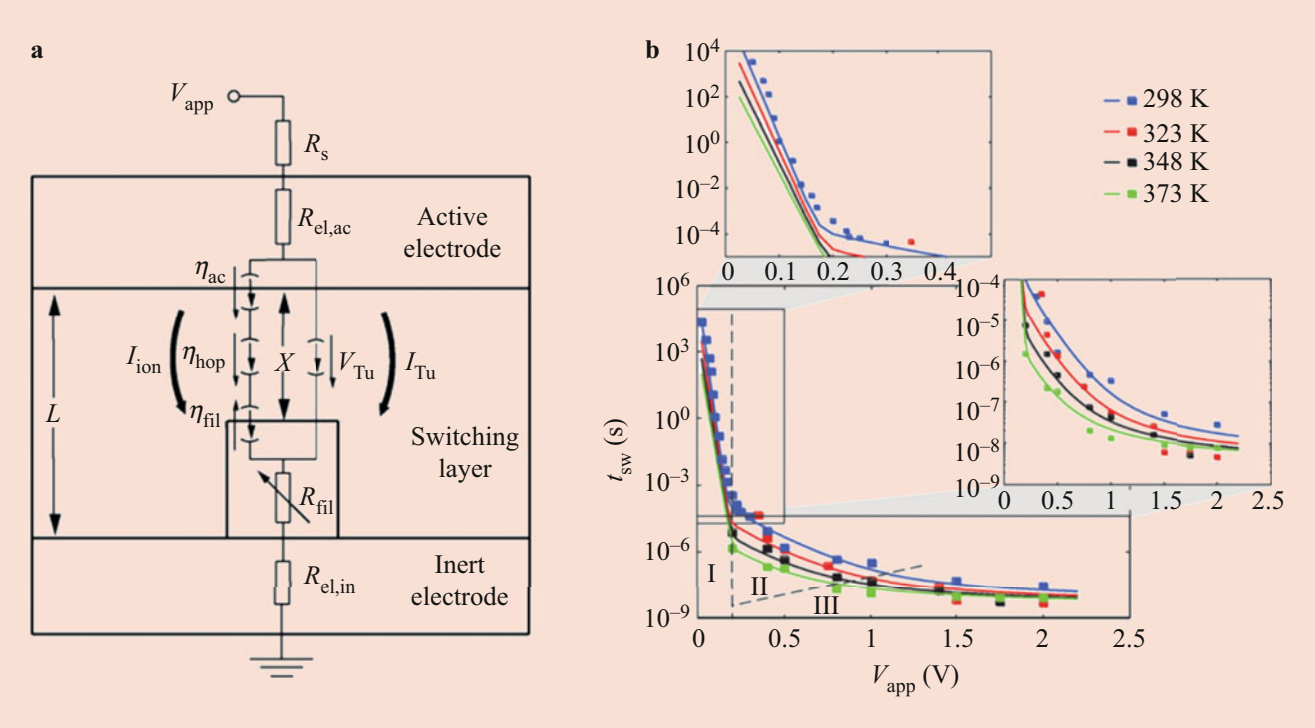

Fig. 29.29 (**a**) The equivalent circuit in the switching model, (**b**) transient SET switching kinetics of the AgI-based CBRAM for different ambient temperatures. (Reprinted from [70])

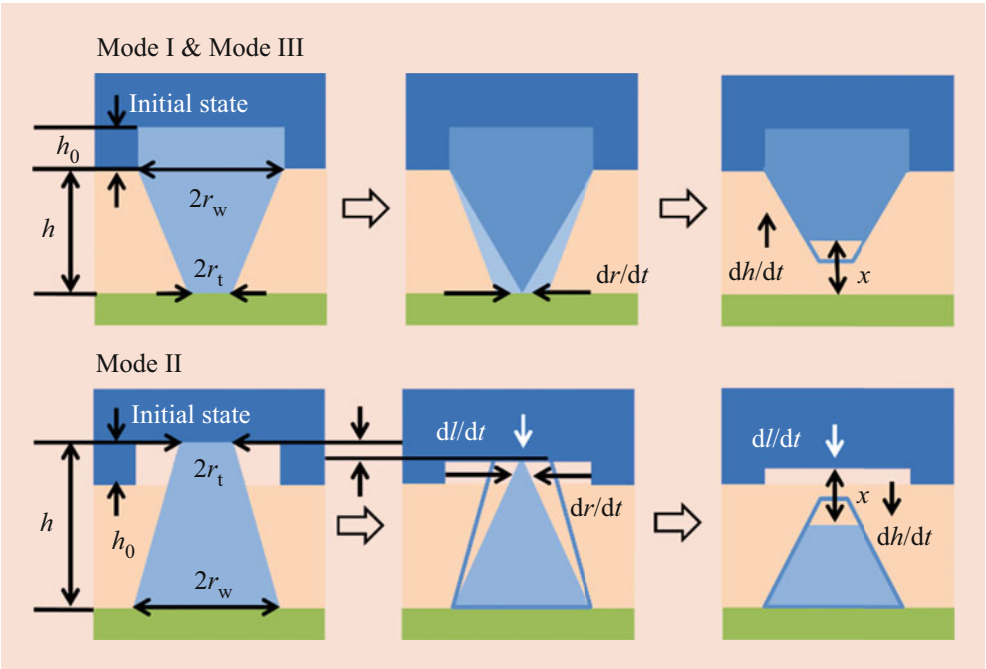

Fig. 29.30 Schematic of CF evolution model during RESET in different CF evolution modes. (Reprinted from [79])

$$\frac{\mathrm{d}h}{\mathrm{d}t} = af \exp\left(-\frac{E_{\mathrm{ox}} - \alpha_{\mathrm{o}} ZeE}{k_{\mathrm{B}} T}\right) \tag{29.49}$$

while when hopping is the dominant process, dh/dt follows

$$\frac{\mathrm{d}h}{\mathrm{d}t} = af \exp\left(-\frac{E_{\mathrm{h}}}{k_{\mathrm{B}} T}\right) \sinh\left(\frac{\alpha_{\mathrm{h}} ZeE}{k_{\mathrm{B}} T}\right) \tag{29.50}$$

and the variable dl/dt is decided by the competition between the reduction and hopping processes. The increased rate of effective AE thickness dl/dt is governed by

$$\frac{\mathrm{d}l}{\mathrm{d}t} = af \exp\left(-\frac{E_{\mathrm{red}} - \alpha_{\mathrm{r}} ZeE}{k_{\mathrm{B}} T}\right) \tag{29.51}$$

The narrowing rate of thin radius dr/dt which determines the RESET speed is modeled by the slower process between oxidation and hopping. When oxidation is the dominant process, dr/dt is described by

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{3f\Delta h}{h\,(2r_{\mathrm{t}} + r_{\mathrm{w}})} \sum_{i=0}^{h} \left(r_1(i)\Delta r + r_2(i)\Delta r - \Delta r^2\right) \exp\left(-\frac{E_{\mathrm{ox}} - \alpha_{\mathrm{o}} ZeE(i)}{k_{\mathrm{B}} T(i)}\right) \tag{29.52}$$

where Δh and Δr are parameters in the integrating process, r_1 and r_2 are the radii of the integrating cone, $E(i)$ is the local electric field, and $T(i)$ is the local temperature. When hopping is the dominant process, dr/dt is described by

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{3af}{h\,(2r_{\mathrm{t}} + r_{\mathrm{w}})} \sum_{i=r_{\mathrm{t}}}^{r_{\mathrm{w}}} \pi \left(r_2(i)^2 - r_1(i)^2\right) \exp\left(-\frac{E_{\mathrm{h}}}{k_{\mathrm{B}} T(i)}\right) \sinh\left(\frac{\alpha_{\mathrm{h}} ZeE(i)}{k_{\mathrm{B}} T(i)}\right) \tag{29.53}$$

where a is the distance between two atoms.

During SET process, a thin filament first connects AE and IE and then expands in the thin end as shown in Fig. 29.31, which is a reverse process of RESET. Compared with RESET, the dr/dt and dh/dt in SET operation are controlled by the slower process between reduction and hopping, and dl/dt is governed by the slower process between oxidation and hopping. When using the model, there is no need to presume in which mode the device is operating. Taking the material parameters and operation schemes as inputs, the model can automatically decide the CF evolution mode.

The compact model can reproduce the electrical characteristics in DC and AC operations, which are verified by experimental results with various material stacks. Figure 29.32a shows the measured and calculated DC I-V curves of the Cu/SiO_2/W during RESET and SET processes [79], where the abrupt switching can be accurately reproduced. By considering the parasitic effects such as the parasitic resistances and capacitance, the AC characteristics can be calculated by the model. Figure 29.32b is the calculated relationship between switching time and ambient temperature, which is in good agreement with experimental data from [85]. The physics-based compact model would benefit for the co-design of the device and circuit, serving as a powerful tool for the performance evaluation and optimization of the large-scale CBRAM array.

29.4 Array Design and Optimization

29.4.1 Crossbar Array

Unlike front-end-of-line (FEOL) eFlash/EEPROM, RRAM is a back-end-of-line (BEOL) memory and does not require revalidation of the existing circuit IPs due to its lower temperature integration process. Moreover, RRAM can achieve high-density integration due to its simple structure. Figure 29.33 shows the crossbar RRAM array with high-density integration. The array is composed of bit lines (BL) and word lines (WL), and every cross point of BL and WL is positioned with a RRAM device. To perform the read operation, a small voltage, such as 0.2 V, is applied on the WL of the selected cell, and the BL of the selected cell is grounded. Meanwhile the other BL and WL are floated, and the state of the cell is read out according to the current through the BL of the selected cell. Current difference (ΔI), which is obtained by reading R_{LRS} and R_{HRS}, is then sensed by connected sense amplifiers (SAs), which act as current-to-voltage converters, and thus, the resistance states can be detected in this way. An example of an SA is a simple current mirror or an operational amplifier with a feedback resistor to sense the current. The design of SAs is not a part of this chapter, and thus the peripheral sensing circuits are not introduced in detail. The BL of N cells can be simultaneously connected to CMOS sense circuits to increase the read speed. The voltage difference sensed by the CMOS circuit is defined as readout margin, which is one of the key parameters to characterize the read performance. To write the RRAM cell, the operation voltage is applied on the WL of selected cell, and the BL of selected cell is grounded. Meanwhile all other WL and BL are floated. The write operation of RRAM can also be performed in parallel like NAND flash.

Generally, the bias schemes for read and write operation are not workable due to the sneak current path as illustrated in Fig. 29.33. The sneak path causes the degradation of the readout margin and the misreading of the selected cell [86]. For write operation, the RRAM cell can't be switched and the unselected cell may be miswriting due to the sneak path. What's worse, these issues will be aggravated with the increase of array size. To mitigate the sneak current path, different bias schemes are proposed [87]. The most popular bias scheme is the "V/2" bias scheme for write and grounding bias scheme for read as illustrated in Fig. 29.34a, b. For "V/2" bias scheme, half of write voltage is applied on the BL and WL of the unselected devices to avoid the miswriting of unselected devices. However, the write disturbance is still not solved because about half of write voltage is applied on half self-selected cells. For grounding bias scheme, the BL and WL of the unselected cells are grounded to increase the readout margin. However, the energy consumption will increase for the read operation with grounding bias scheme. There are some other bias schemes for write operation, such as "V/3" bias scheme, in which 2/3 of the operation voltage is applied on the BL of unselected cells and 1/3 of operation voltage is applied on the WL of unselected cells. Consequently, the write disturbance can be effectively migrated because the voltage across the unselected cell decreases from V/2 to V/3.

Under the proposed bias scheme, the RRAM cells can be correctly read and wrote if the interconnect resistance is neglected. However, the interconnect resistance is usually comparable to the resistance of RRAM device, and it sharply

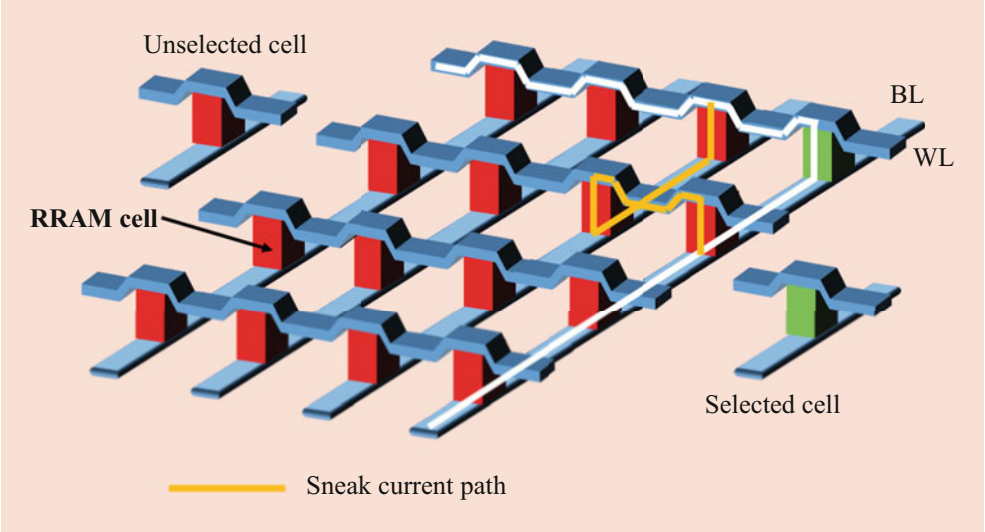

Fig. 29.33 Schematic show of the crosspoint RRAM array and the sneak current path

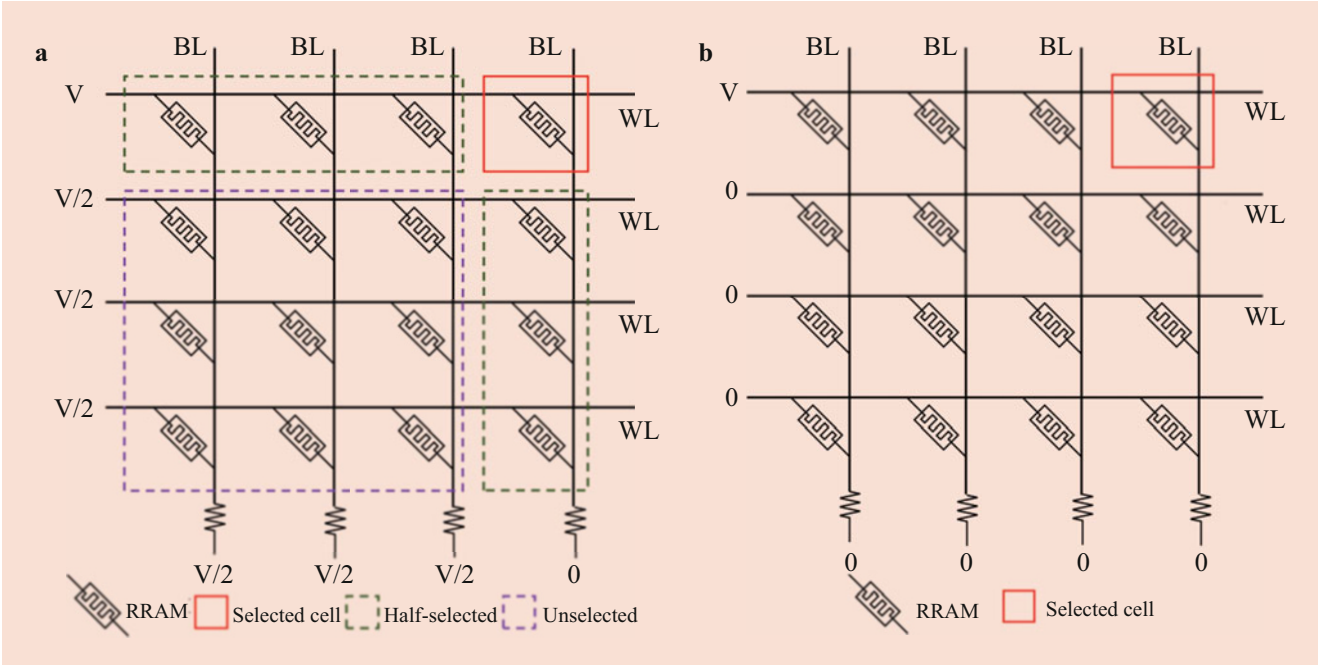

Fig. 29.34 Schematic illustration of (**a**) "V/2" and (**b**) grounding bias schemes

increases with the scaling down [88]. Therefore a selector device or highly nonlinear I-V characteristic for RRAM is required for the integration of crossbar RRAM array. Diode is the most common selector device, but it is useful only for unipolar. Unfortunately, the performance of unipolar RRAM is much worse than that of bipolar device; thus bipolar RRAM devices are widely used for the array integration. Transistor is another candidate for selector of RRAM. Up to now, most demonstrations of RRAM arrays are based on the 1T1R structure due to the nature of CMOS transistor process and the excellent behaviors as a selector without considering the scalability. A common 1T1R array structure is shown in Fig. 29.35. Generally, the RRAM cell is integrated with the drain terminal of transistor by bottom electrode. The gates of transistor in the same column are connected to the same WL, the source terminals of transistor in the same row are connected to the same source line (SL), and the top electrodes of RRAM in the same row are connected to the same BL. To read the selected cell, the high voltage is applied to the selected WL to turn on the selected transistor. Meanwhile, a small read voltage is applied to the selected BL, and the selected SL is grounded. The state of the selected cell is read

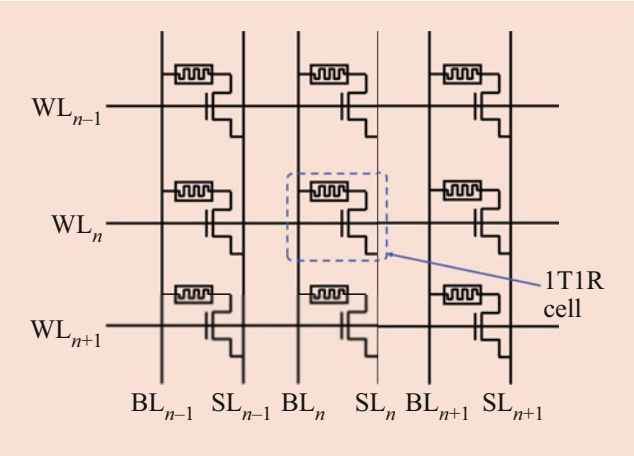

Fig. 29.35 Schematic diagram of the 1T1R RRAM array structure

out according to the current of selected SL. The sneak path is shut down since the transistors with unselected WL are all in turn-off state. To write the selected cell, the selected transistor is turned on by applying a high voltage on the selected WL. To SET the cell, the SET voltage is applied on the selected BL, and the selected SL is grounded. On the other hand, RESET voltage is applied on the selected SL, and the selected BL is grounded for the RESET operation. The transistor not only mitigates the sneak current path but also served as current compliance for SET operation. It seems that 1T1R array is a good choice for the integration of RRAM array. However, due to the intrinsic drawback of more than $8F^2$ cell size, the 1T1R structure cannot be scaled down to an ideal size. What's worse, 3D integration with 1T1R structure is hard. Therefore, a highly compact two-terminal bidirectional selector device is required for the high-density integration of RRAM array, which is discussed in the next section.

29.4.2 Selector Devices for RRAM Array

For the integration of RRAM array, the selector device should satisfy various technical requirements from both the array level and the individual RRAM cell. Firstly, the on-state current should be large enough to switch the RRAM cell, and the off-state current should be low enough to shut down the sneak path. Moreover, the fabrication process of the selector should be compatible with CMOS. It is better to be compatible with the BEOL process so that the RRAM array can be stacked three dimensionally [5]. Other specifications, such as cycling endurance, switching voltage, speed, etc., should also match with the RRAM cell.

Various attempts have been done to propose selector with different mechanisms and optimize its performance to reach the requirements. According to their IV characteristics and physical mechanisms, the proposed selectors can be roughly categorized into ovonic threshold switching (OTS) [89, 90], insulator-metal transition (IMT) [91, 92], mixed ionic-electronic conduction (MIEC) [93, 94], field-assisted superlinear threshold (FAST) [95, 96], tunneling [97], and Cu/Ag ionic selector [98]. The IV characteristics of OTS-, IMT-, MIEC-, and FAST-type selector are similar, where an abrupt increase of current can be observed at the threshold voltage (V_{th}) and abrupt decrease of current occurs when the voltage is smaller than the hold voltage (V_{hold}). Generally, the V_{th} is larger than the V_{hold}, and abs(V_{th}-V_{hold}) should be large enough to guarantee the switching of the RRAM cell. The mechanisms and material stacks of these four type selectors are different. The OTS depends on the phase change assisted by the joule heat or electrical field. The IMT relies on the insulator-metal transition of material, such as NiOx. MIEC and FAST as well as Cu/Ag ionic selectors are correlated with the movement of fast metal ion, such as Cu. However their details have some differences which are still under debate. The tunnel selector is utilized the Schottky barrier to achieve the rectifying effect. Table 29.2 summarizes the representative development for each type of selector together with their key characteristics. It can be found that all on/off ratio for the selectors is larger than 10^6, which is enough to build a crossbar RRAM array with size >10 M [86]. The on-state current of most selector is above 1 MA/cm^2, which can switch RRAM with 100 μA operation current when the feature size is 100 nm. Moreover, the operation voltage is optimized within a reasonable range. Other features such as off-state current, switching speed, and endurance also match with the mainstream RRAM cell.

Among these selectors, the FAST selector seems to be one of the most promising candidates and has been demonstrated by different groups [99, 100]. So we will introduce the FAST selector in detail next. In 2014, S. H. Jo et al. proposed a superlinear threshold layer-based selector, in which a conduction path is formed at the threshold electric field and the conduction path is dissolved when the electric field is below a value. Figure 29.36 shows its I-V curve with extremely sharp switching slope <5 mV/Dec, which is beneficial to the read and write operation of RRAM array. Moreover, the on/off ratio is larger than 10^7, which can shut down the sneak path. The threshold voltage of FAST selector is about 1 V and can be tuned by controlling either the STL thickness or device structure as discussed in [95, 96]. Additionally, the variability of threshold voltage is about 0.075 V, which is very important for integration of 1S1R RRAM array. The cycle-to-cycle performance of the selector exhibits good uniformity. The selector can reliably switch over 100 M cycles as shown in Fig. 29.37a. The selector can't switch under a disturbance of constant DC at half of threshold voltage for 2 h. Once the voltage applied on the FAST selector exceeds the threshold voltage, the FAST selector will turn on in 30 ns. The FAST selector can recover to the off state in 5 ns after removing the

Table 29.2 Various types of selectors with their key characteristics

Selector type	OTS [90]	IMT [91]	MEC [93]	FAST [95]	Tunneling [97]	Cu/Ag ionic [98]

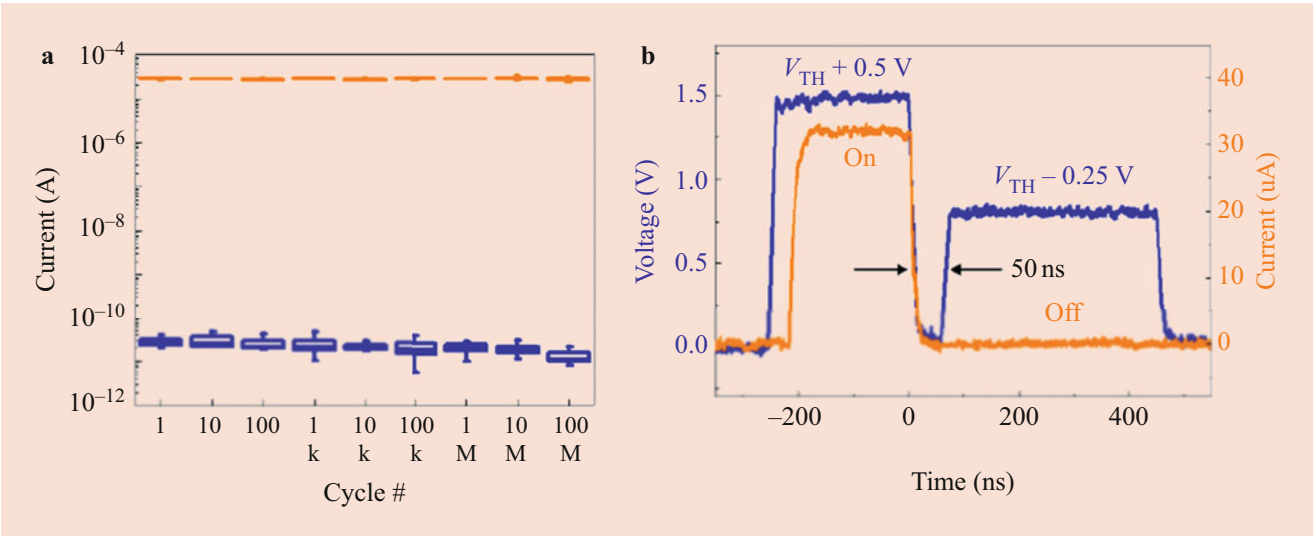

Fig. 29.37 (**a**) Cycling test of FAST selectors. The selectors can be reliably cycled over 100 M cycles which is limited by the test. (**b**) Switching speed of a FAST selector. The selector can be turned on within 30 ns in response to a 2 V pulse. Off-to-on transition time is about 5 ns for over 300 μA of passing current through the selector. (Reprinted from [95])

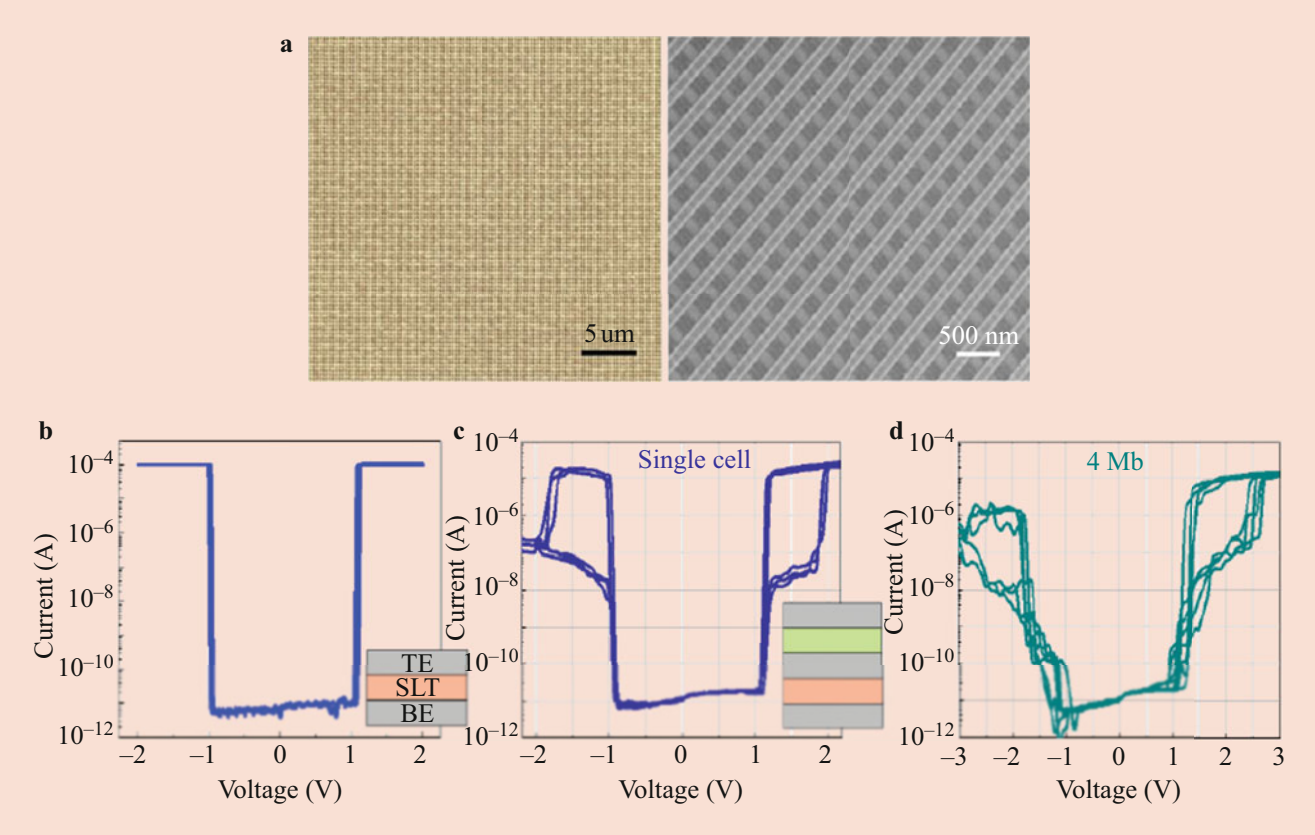

Fig. 29.38 Passive crossbar array integration of FAST selectors. (**a**) Images of the fabricated selectors. I-V characteristics of (**b**) selector, and (**c**) integrated 1S1R device. (**d**) I-V characteristics of 1S1R device in 4 Mb passive crossbar array. (Reprinted from [95])

applied voltage. Hence, the switching speed of FAST selector is less than 50 ns as shown Fig. 29.37b. The hold voltage of the FAST selector is smaller than 0.3 V for 300 uA on-state current, and it decreases with the on-state current.

S. H. Jo et al. also integrated the FAST selectors with RRAM for a 4 Mb passive crossbar array as shown in Fig. 29.38. The sneak current of single FAST selector is below 0.1 nA at both 25 °C and 125 °C with high device yield. In addition, the integrated RRAM is Forming-free with a low switching current. Hence, the IR drop of voltage and power consumption will decrease. The threshold voltage of the fabricated selectors is larger than half of RESET and SET voltage but smaller than RESET and SET voltage as shown in Fig. 29.38b. Such the sneak path can be suppressed during both the read and write operations. The integrated single 1S1R device shows $>10^2$ memory on/off ratio and $>10^6$ selectivity as shown in Fig. 29.38c. The 1S1R device in the 4 Mb crossbar array can also correctly switch as shown in Fig. 29.38d. In addition, it can reliably switch more than 100 K cycles with pulse operation. The designed and fabricated FAST selector shows a promising prospect of high-density RRAM array integration.

29.4.3 3D Integration

Although current RRAM is hard to replace 3D NAND flash in terms of existing technology, it is still one of the most promising candidates for the 3D high-density-integrated storage class memory to fill the speed and capacity gap between the DRAM and NAND flash memory in the current memory hierarchy [5]. Three possible approaches were proposed for 3D integration of RRAM. One is the 3D horizontal stacking RRAM array (HRRAM) architecture [101], in which 2D crossbar array is vertically stacked layer by layer as shown in Fig. 29.39a. This architecture has many attractive advantages in lateral scaling, and its process is more mature. Unity demonstrated a 64 Mb HRRAM test chip built with 0.13 μm technology [102]. SanDisk demonstrated a two-layer 32 Gb crossbar chip by 24 nm process, in which the memory cell is 1D1R structure [42]. However, the lithography steps will linearly increase with the number of layers as shown in Fig. 29.39b, which means a linearly increasing cost of fabrication [40].

To further decrease the cost, 3D vertical RRAM (VRRAM_1) architecture is proposed as shown in Fig. 29.39c

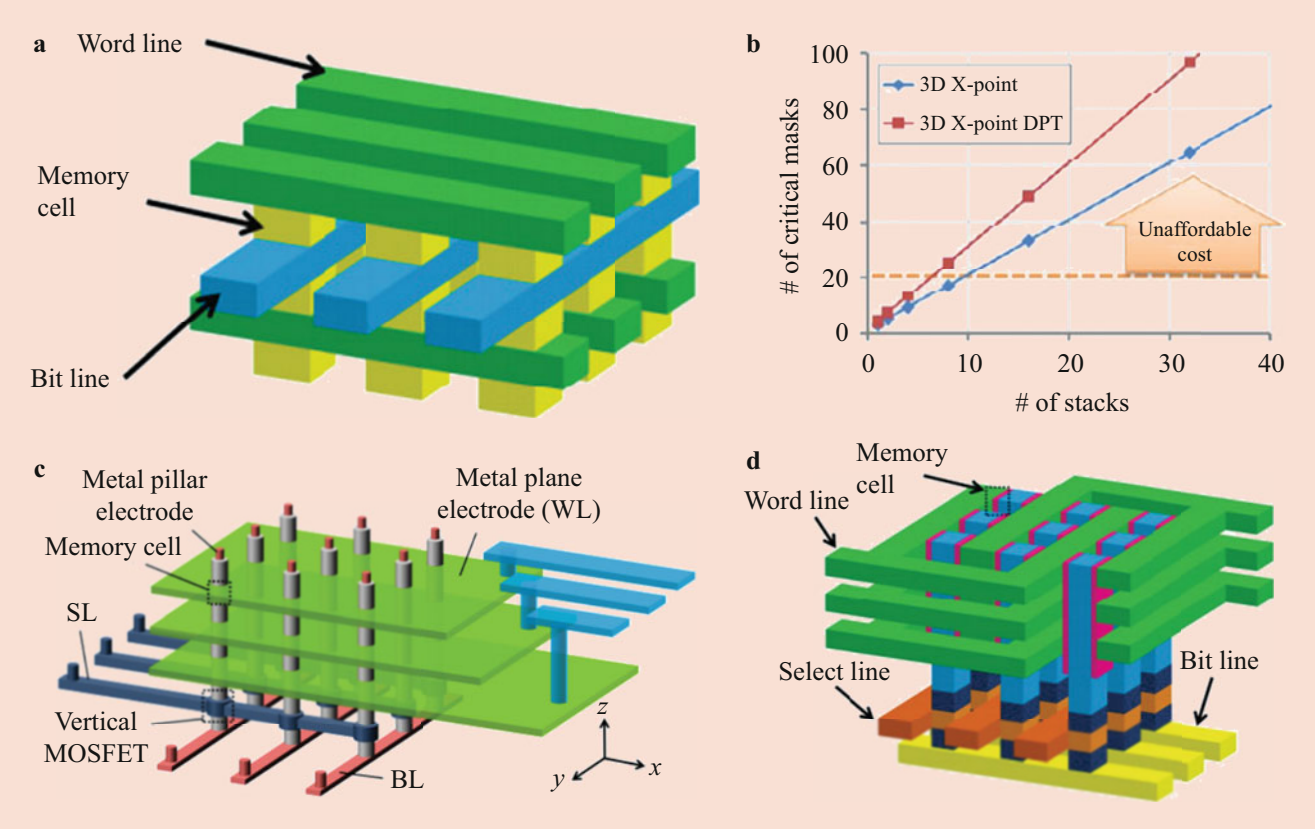

Fig. 29.39 (**a**) The schematic of 3D horizontal stacking RRAM array (HRRAM). The memory cell is located at the intersection between bit line and word line. (**b**) Minimum number of critical masks necessary for 3D horizontal stacking arrays as a function of stacked layer number. (**c**) The schematic of 3D vertical RRAM array (VRRAM_1). The RRAM cell is located at the intersection between pillar electrode and metal plane electrode. (**d**) The schematic of 3D vertical RRAM array (VRRAM_2). (Reprinted from [39, 40, 103])

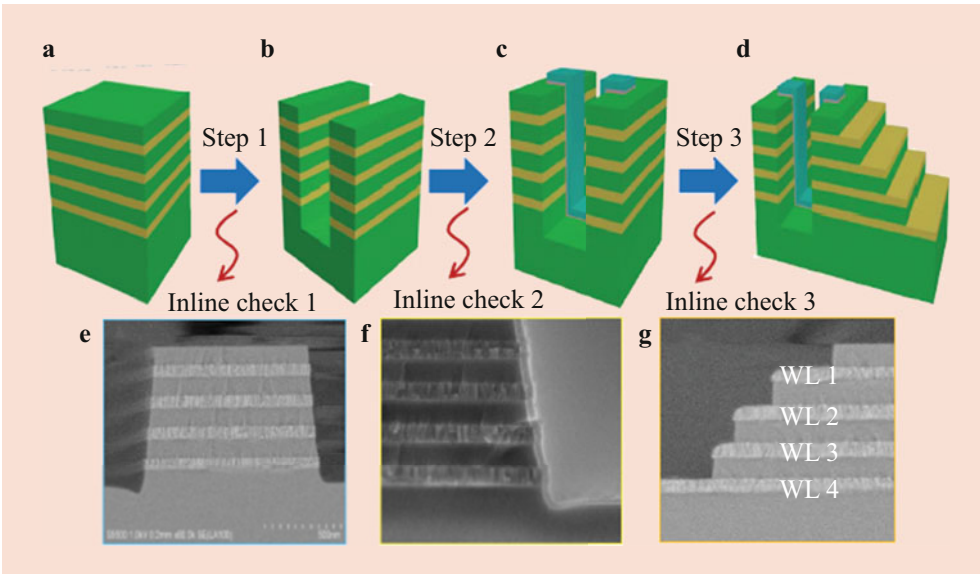

Fig. 29.40 (**a**)–(**d**) The integration process flow of 3D integration of VRRAM_2. (**e**)–(**g**) The inline check at each step of the process flow. (Reprinted from [105])

[39]. The memory cell is located between the plane electrode and the vertical pillar, which is similar to bit-cost-scalable 3D NAND. Thanks to simple one-step pillar fabrication process, this vertical 3D structure only requires one to three critical lithography steps regardless of the layer number. In addition, the IR drop will decrease due to the ultralow interconnect resistances of the metal plane and vertical metal pillar with core-shell structure. To further increase the density, another

vertical RRAM (VRRAM_2) structure is proposed by dividing the plane electrode into line electrodes with a single additional etch step as shown in Fig. 29.39d [104]. The memory cell is located between the horizontal odd/even metal word line and vertical pillar. Comparing with VRRAM_1, the leakage current path of VRRAM_2 is decreased. Therefore the energy consumption of write or read operation will decrease.

If the selector is required for these two structures, the array density may decrease due to thickness of selector. Therefore thin selector or RRAM cell with self-rectifying characteristics is more suitable for these structures. As feature size scaling down to <20 nm, the intermediate electrode would shorten the cells in the same pillar, leaving behind the self-rectifying as the only choice to prohibit the sneaking current. Luo et al. proposed a four-layer VRRAM_2 structure array by combining HfO_x resistive layer and MIEC selector layer [105]. The fabricated process of the four-layered VRRAM_2 is schematically shown in Fig. 29.40a–d. Firstly, TiN (60 nm)/SiO_2 (100 nm) layers were deposited layer by layer by PVD and PECVD. Then one-step etching was applied to form the WL after the patterning. Following is the deposition of resistive switching and selector layer HfO_2/CuGeS along the sidewall. Lastly, the top electrode was deposited on the sidewall by magnetron sputtering at room temperature, followed by lift-off process to form BL. The SEM images of inline checks for each step are shown in Fig. 29.40e–g. It can be found that profile of the sidewall is smooth, which can avoid the coverage issue and point discharge problem during write operation. Figure 29.41a shows the transmission electron microscopy (TEM) image and the spectrum of EDX line scan over the cross section of the device. Well-distinguishable layers with interface can be clearly observed. The EDX shows small amount of O signal overlap with the TiN layer, which implies that a thin TiON has formed between the TiN top electrode and HfOx layer. Figure 29.41b shows the I-V characteristic of 1S1R cell, which shows stable resistive-switching behavior and high selectivity. The SET voltage is about −3.5 V, and the RESET voltage is 6 V, which decreases with the thickness of CuGeS as shown in the set of Fig. 29.41b. The nonlinearity of LRS is larger than 10^3 with 1 V selective voltage due to the threshold switching characteristics of CuGeS layer. In addition, the operation current of the device is sub-nA with self-compliance characteristics, which is beneficial to increase the access voltage during the write operation. Figure 29.42a shows the typical.

I-V characteristics of the 1S1R cells of different layers in the VRRAM_2 array. The cells of each layer device exhibit similar stable and self-selective switching behavior. The distributions of the program (SET) and selective voltages are shown in Fig. 29.42b. The average voltage window is about 1 V, which can guarantee the correction of the read operation. The fabricated 1S1R cell can switch for more than 10^7 cycles with sub-μs pulse operation as shown in Fig. 29.42c. Figure 29.42d is the retention behaviors of LRS/HRS at different read voltages, which is stable for more than 10^4 s at 85 °C. Although four layers of the 1S1R RRAM array have been demonstrated with accepted performance, it is still far from replacing the 3D VNAND as the standalone memory.

29.5 Applications

29.5.1 Embedded Memory

Although RRAM is difficult to replace the 3D VNAND in the standalone storage case, it may be suitable for embedded memory due to its CMOS compatibility, low operation voltage, satisfactory endurance, and retention. Unlike FEOL eFlash/EEPROM, RRAM can be easily integrated into the CMOS process with limited additional masks. H. W. Pan et al. have proposed and demonstrated 1Kb FinFET RRAM in pure 16 nm FinFET CMOS logic process by utilizing the dielectric as the resistive-switching layer in 2015 [106]. The operation voltage of RRAM is smaller than 3 V, which means the charge pumps circuit can be simplified. In addition, sub-nm RRAM has been demonstrated, indicating the high scalability of RRAM [38].

A lot of effort has been done to develop various BEOL integration schemes by different researchers. In 2008, Z. Wei et al. fabricated an 8 kbit 1T1R memory array with long retention and high endurance using the standard 0.18 μm CMOS process [16]. RRAM is integrated between M2 and M3 by reactive RF magnetron sputtering using a Ta target in the oxygen environment. In 2012, S.-S. Sheu proposed an embedded mega-bit scale (4 Mb) TiN/TiOx/HfOx/TiN RRAM macro with sub-8 ns read-write random access time using 0.18 μm CMOS technology [107]. The RRAM can operate with sub-8 ns read-write speed in binary and 160 ns write speed for multilevel storage, respectively. In the same year, W. C. Shen et al. developed a high-density RRAM cell with a very small 35 nm × 35 nm contact hole realized in pure high-k metal gate 28 nm CMOS logic process [108]. No extra mask or process step is required for the fabrication of the RRAM cell by depositing in the patterned drain contact hole. Therefore, it is the most economical way to integrate the RRAM into CMOS circuit. The fabricated device can switch more than 1 M cycles together with the stable data retention. In 2015, M. Ueki et al. developed a high-speed and low-power 2 Mb ReRAM with macro-practical memory window for 10 years ranging from −40 to 85 °C in 90 nm CMOS platform [109]. The thin RRAM cell structure is integrated between M1 and M2 by the plasma oxidation of Ta with Ru as the BE. In 2016, C. H. Ho et al. fabricated 1 Mb HfO_2-RRAM between the M1 and M2 only with two extra masks between

metals for BEOL thermal stress immunity by 90 nm CMOS fully compatible process [110]. The resistive-switching layer is deposited by atomic layer deposition (ALD), and other layers are deposited by standard PVD processes. Reliable 20 k endurance and 85 °C 10-year retention are achieved by the stoichiometric engineering. The array offers potential applications of embedded IoT systems due to energy consumption reduction (80%) and cost-effective benefit (50% area) compared with eFlash.

In 2014, D. C. Sekar et al. proposed a low-power and robust 256 kb TiN/conductive TaO_X/HfO_2/TiN RRAM chip by controlling the capacitive surge currents during write operation. Generally, the SET and Forming process of RRAM is abrupt due to current overshoot even though the current is limited by the integrated transistor. The current overshoot mainly results from the discharge of the capacitive current as shown in Fig. 29.43a. When the applied voltage on the top electrode decreases from SET voltage to zero, the charge stored on the capacitance of RRAM will discharge via the CF and lead to the over-growth of the CF and high RESET current. To mitigate the overshoot current, a conductive metal oxide electrode (TaO_X) is introduced with optimized bulk resistivity of the TaO_X layer. It can achieve ~33% lower worst-case RESET current and 23× less fail bit count. Since the TaO_X layer can prevent heat flow and increase the temperature of CF as shown in Fig. 29.43b, the RESET voltage does not increase much despite the increase of IR drop due to the TaO_X layer. In addition, a write scheme is proposed and designed as shown in Fig. 29.43c, and the gate voltage of the selected transistor is biased near threshold voltage to limit the overshoot current. To overcome the mismatch between T1 and T2, transistor T3 and T4 are added to form the overshoot current for the current mirror. Forty percent reduction in RESET current is obtained by implementing the proposed circuit to the 256 kb RRAM array as shown in Fig. 29.43d.

The current available industrial solutions of RRAM for production mainly focus on the embedded memory application. The Panasonic Ox-RRAM processes are already available to be embedded with CMOS logic technology. In 2017, Panasonic introduced TaO_X-RRAM integrated into its 130 nm MCU product line and cooperated with foundry United Microelectronics Corporation to develop a 40 nm process, which is the first to start mass production in the industry [111]. In 2020, Panasonic announced a multifunctional secure IC that protects critical data on IoT and industrial devices by using 256 K 40 nm embedded RRAM as the memory which is highly resistant to radiation [112]. TSMC is also developing embedded RRAM for mass production. 40 nm ULP embedded RRAM has begun risk production at the end of 2017 and has completed consumer-grade qualification test for 10,000 cycles of endurance in 2018 [113]. The TSMC embedded RRAM technology is fully CMOS compatible for PDK and IP reuse for applications such as wireless MCU, IoT, and wearable devices. The CrossBar company developed the 40 nm RRAM process, both as a standalone memory and as an embedded memory. In 2018, CrossBar announced collaboration with Microsemi Corporation to integrate CrossBar's embedded RRAM in Microsemi products manufactured at the 1× nm node [114]. The Adesto company brought commercial RRAM devices to market with its trademarked CBRAM technology, and in 2018, European Solid-State Device Research Conference indicated the RRAM potential as embedded NVM for high-reliability applications such as automotive [115]. Adesto estimated that, compared to existing commercial-grade embedded NVM at 55 nm, the product using a 55 nm automotive-grade CBRAM macro could save 5–20% cost per die. In 2019 Symposia on VLSI Technology and Circuits conference, Intel announced an industry-leading combination of RRAM-based embedded NVM and 22FFL FinFET technology [116]. 22FFL is an ultra-low power and high performance technology for mobile and RF applications. It provides extensive high-voltage, high design flexibility, analog support, and low manufacturing costs. Embedded RRAM achieves 10^4 cycle endurance, 85 °C 10-year retention, and high die yield on 7.2 Mbit arrays and full 300 mm wafers.

29.5.2 Computing in Memory

In the conventional computing system, the computing unit and memory unit are separated. It leads to the huge energy-hungry and time-consuming data movement, called von Neumann bottleneck. To meet the requirement of future information evolution, developing energy-efficient parallel information processing systems beyond von Neumann architecture is highly desirable. RRAM can execute the logic operation and store the logical output in the same physical location [21, 117], which is a promising solution to overcome the von Neumann bottleneck.

The first proposal of computing based on RRAM is in 2010 by HP Inc., called stateful logic [21]. The basic logic operation demonstrated by HP Inc. is the implication (IMP), which is a university logic operation. The sub-circuit to execute the IMP logic operation is composed of two RRAM devices, P and Q, and one resistor (R_G), as shown in Fig. 29.44a. The bottom electrodes of device P and Q are connected by a common line, which is grounded via a resistor. The resistance state stored in the RRAM devices is the logical value. Two voltage pulses, V_{COND} and V_{SET}, are simultaneously applied to the top electrodes of P and Q, respectively, to trigger the logic operation. The output of logic operation is stored in the RRAM device Q after the operation. The magnitude of V_{SET} is little larger than the SET voltage, and the V_{COND} is half of V_{SET}. The resistance of R_G is chosen such that

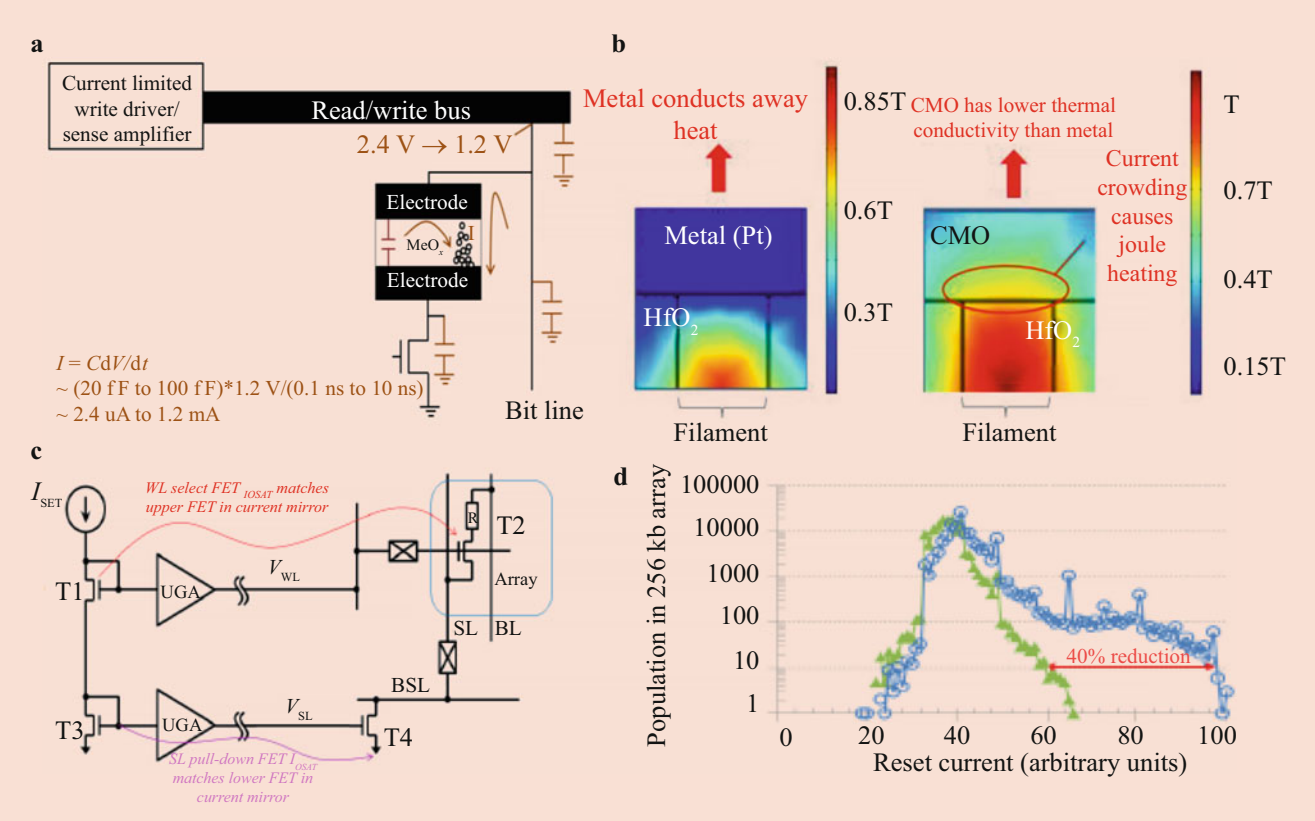

Fig. 29.43 (**a**) Overshoot current in 1T1R cell. (**b**) Simulation of the temperature distribution in the device with/without TaO_X layer for the same write current. (**c**) Proposed peripheral circuit for mitigating the overshoot current. (**d**) RESET current distributions for a 256 kb RRAM array. (Reprinted from [117])

$R_{LRS} < R_G < R_{HRS}$. If the initial state of Q (q) is LRS, it will not be switched regardless of the state of P (p). Q will be switched according to the p when the q is HRS. If p is HRS, it has little influence on the voltage divider formed by Q and R_G, and thus Q is SET to LRS. But if p is LRS, the V_{COND} pulse on P "shorts out" the voltage divider, and Q remains unchanged. During the operation process, the voltage across the P is not enough to change the state regardless of states of Q and P. We define the HRS as logical value "1" and LRS as logical value "0." The logical relation between the Q and P is summarized in Fig. 29.44b. It can be found that the IMP logical operation is performed, which can be experimentally demonstrated [21]. Other arbitrary logic computations can be performed based on the proposed logic operation. For example, NAND logic operation can be executed in three sequential steps by a circuit with three RRAM devices. However, the initial state of Q is covered during the logic operation, which hinders the logic cascading. Moreover, if the initial of Q is useful in the subsequent operation, a copy operation is required [118], which increases the computational time.

P. Huang et al. proposed a method to execute NAND and AND logic operations via resistance state interaction in one step without covering the input values in [26]. Figure 29.45a shows the sub-circuit to execute the NAND operation, where TE of the RRAM devices is connected by a common WL. A large voltage pulse is applied to the WL via a reference resistor (R_G), and a small voltage pulse is applied to the BL of devices A and B. The BL of device Y is grounded. Inputs are the resistance states of devices A and B, and the output logic

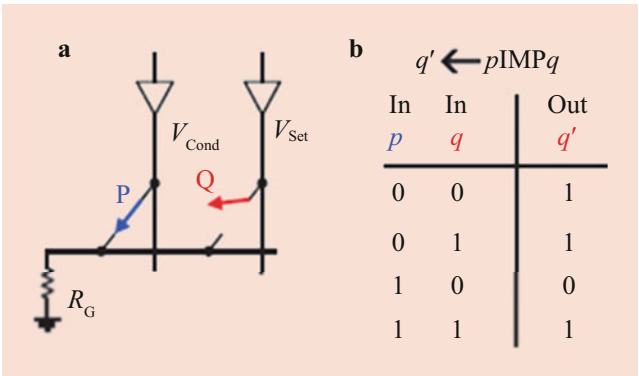

Fig. 29.44 Illustration of the IMP logic operation based on the RRAM. (**a**) IMP is performed by two simultaneous voltage pulses, V_{COND} and V_{SET}, applied to switches P and Q, respectively, to execute conditional toggling on Q depending on the state of switch P and Q. (**b**) The truth table for the IMP operation. (Reprinted from [21])

state will be stored into device Y after logic operation. The output device Y is initialized to HRS before the operation. Here we defined the HRS as logical "1" and the LRS as logical "0." If the input devices A and B are both logical "1," the potential of common WL is more close to V_{DD}, and the output device Y will be programmed to logical "0" after logic operation. If any input devices are logical "0," the potential of common WL is more close to V_R; thus the output device will still be in logical "1" after the logic operation. In this case, a NAND logic operation is performed. To guarantee the validation of the NAND logic operation , the V_R, V_{DD}, and R_G should be carefully selected. The magnitude of V_{DD} should be larger than the SET voltage to compensate the voltage drop across the R_G. Because the voltage across the input device can be close to V_{DD}-V_R, V_R should be large enough to not switch logic inputs. Meanwhile, the V_R should be small enough not switch the device Y. Therefore, the V_R is chosen to $V_{DD}/2$. Roughly, R_G can be selected as the $(R_{LRS}R_{HRS}/2)^{0.5}$. More detailed discussion about the selection of R_G can be found in [26].

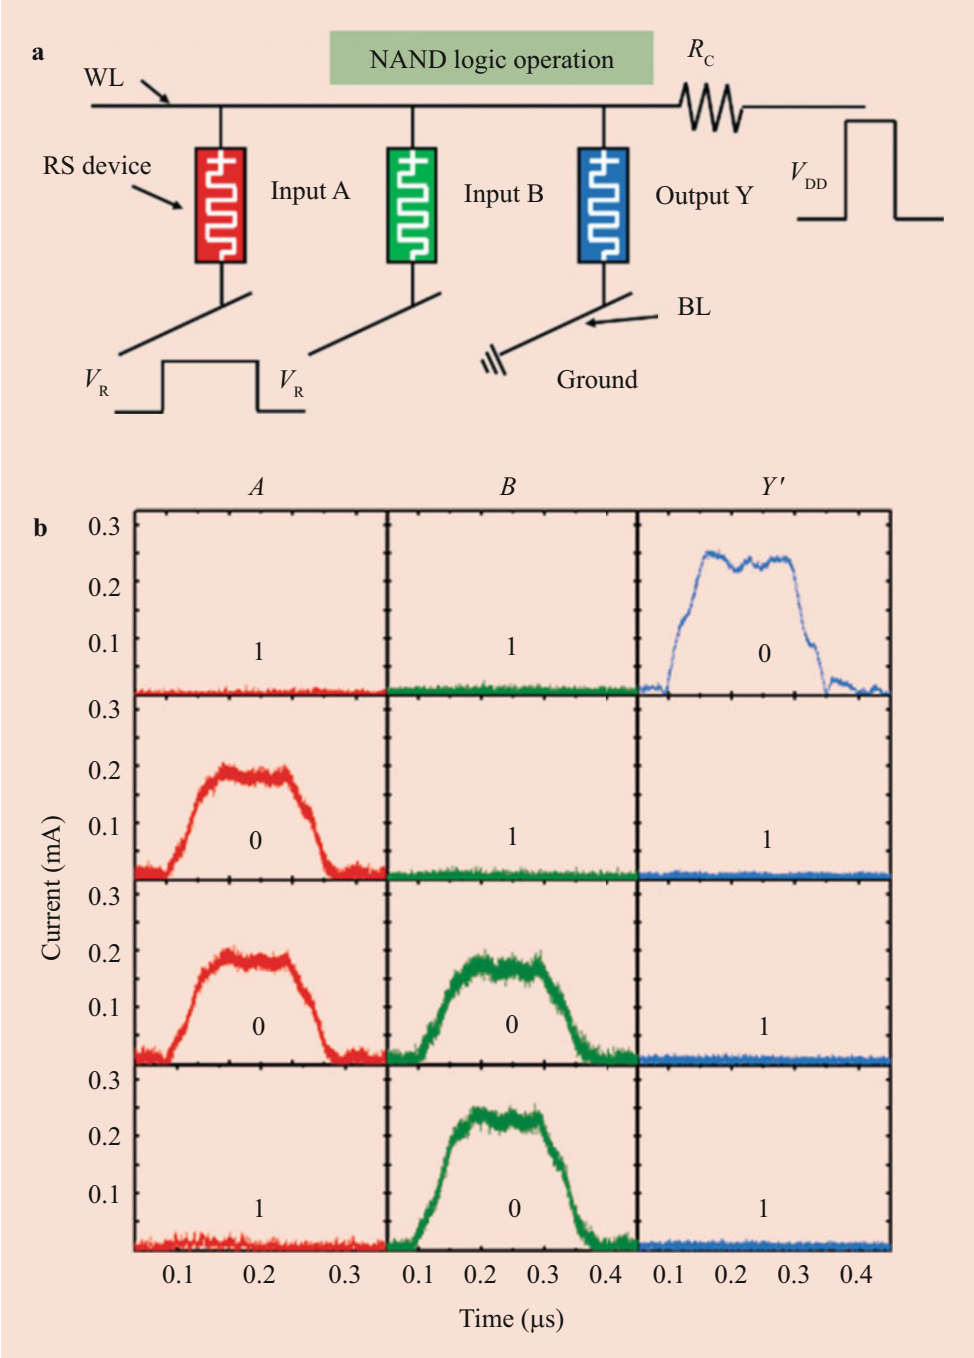

Fig. 29.45 (**a**) Sub-circuit of NAND logic operations executed by three RRAM devices with common WL. Logic inputs are stored in devices A and B, and Y will store the logic output depending on the states of devices A and B. Voltage pulses V_{DD} and V_R are applied to trigger logic operation. (**b**) The measured result of the NAND logic operation. (Reprinted from [26])

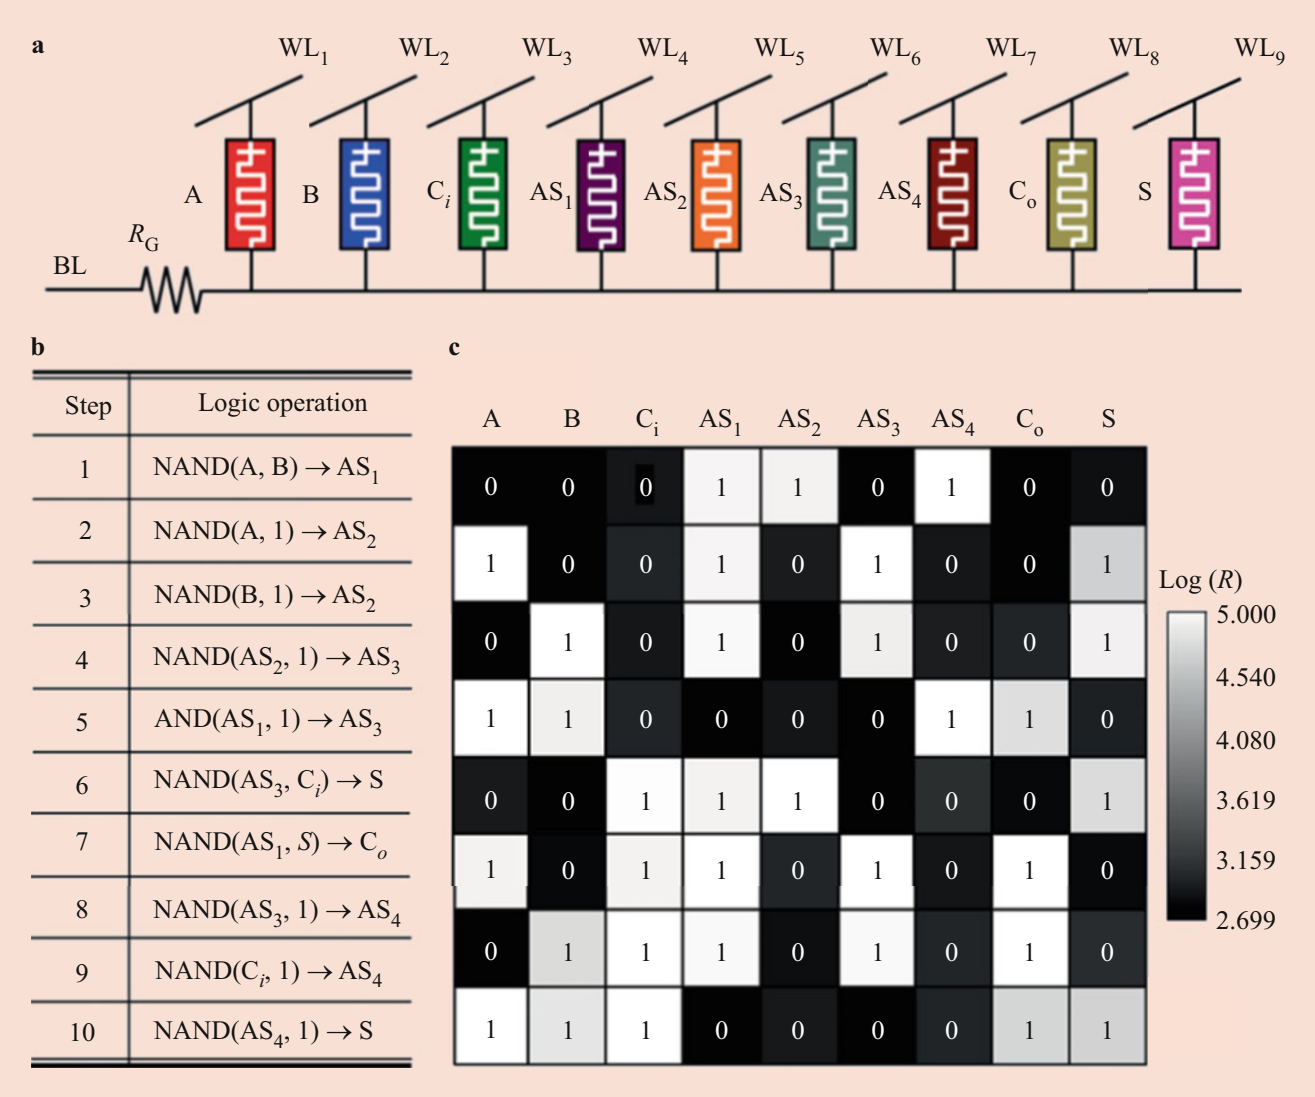

Step	Logic operation
1	NAND(A, B) → AS_1
2	NAND(A, 1) → AS_2
3	NAND(B, 1) → AS_2
4	NAND(AS_2, 1) → AS_3
5	AND(AS_1, 1) → AS_3
6	NAND(AS_3, C_i) → S
7	NAND(AS_1, S) → C_o
8	NAND(AS_3, 1) → AS_4
9	NAND(C_i, 1) → AS_4
10	NAND(AS_4, 1) → S

A	B	C_i	AS_1	AS_2	AS_3	AS_4	C_o	S

Fig. 29.46 (**a**) Array configuration of one-bit full adder circuits. (**b**) Computation procedure of one-bit full adder. Here formula "NAND(A, B) → Y" is used to represent that states of devices A and B executed the NAND logic operation and the logic output is stored into device Y. (**c**) Experimental result of logic operation of full adder for all eight input combinations. (Reprinted from [26])

To demonstrate the proposed logic executing method, a 16 × 8 array is fabricated and the measured result is shown in Fig. 29.45b. It can be found that NAND logic is successfully performed. By exchanging the V_{DD} and V_R, another frequently used logic operation AND can be executed by the same sub-circuit. It means that the logic function of the sub-circuit can be reconfigured at run-time by altering the applied voltage pulses. If the output device Y is LRS before the logic execution, its logical value will not be changed after the operation. Therefore the logic function should be revised as $Y' = \overline{AB}Y$ and $Y' = ABY$, respectively, if the logical value of Y is treated as an input. By cascading along the time dimension, any other logic functions can be realized using a finite number of NAND logic operations. Figure 29.46 shows the sub-circuit and computation procedure to perform the full adder, which is an example to show how to execute the compound logic operation with latching NAND logic operation. The sub-circuit is composed of nine RRAM cells including three input cells (addend A, summand B, and carry-in C_i), two out cells (summary S and carry-out C_o), and four assisted cells (AS_1–AS_4). The full adder logic operation requires ten sequential steps as shown in Fig. 29.46b. The logical states of input cells before operation and assisted devices and output devices after operation are read out by small voltage and are pictured as grayscale maps as shown in Fig. 29.46c. The measured results show that all eight possible input combinations correctly yielded the logical values of C_o and S that corresponded to the truth table for a full adder operation.

To execute logic operation between the states of devices in arbitrary positions of RRAM array, the previous discussed

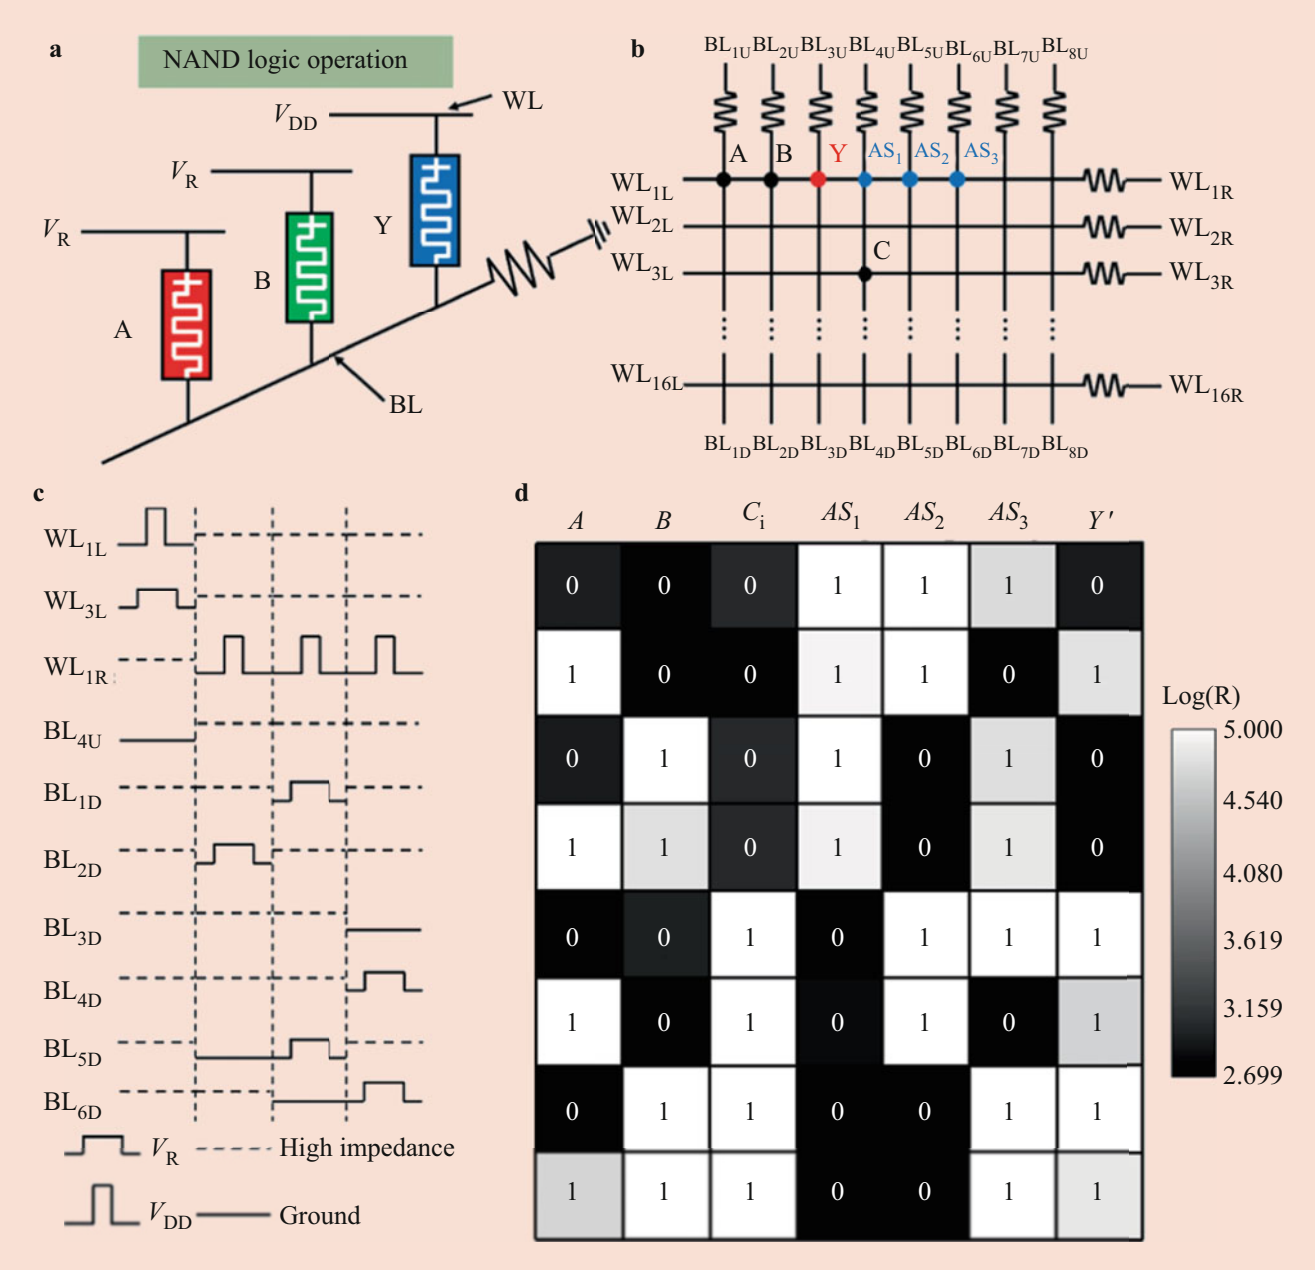

Fig. 29.47 (**a**) The array configurations of NAND logic operation executed by RRAM devices with common BL. (**b**) Location of input device in RRAM array to execute the logic operation $Y' = A\overline{B} + C$. (**c**) Time sequence of voltage pulses applied to the ports of RRAM array to perform $Y' = A\overline{B} + C$ logic operation. (**d**) Measured truth table. (Reprinted from [26])

method is not enough because the circuit structure of cells with the same BL (Fig. 29.47a) is different from the sub-circuit discussed in Fig. 29.45a. To execute the logic operation in the cell with the common BL, voltage pulses V_{DD} and V_R are applied to the TE of cell Y and A&B, respectively. Meanwhile, the common BL is grounded via the R_G. The validation of this method can be experimentally demonstrated as discussed in [26]. Figure 29.47b–d show an example how to perform arbitrary logic operations with the states of devices in different columns and rows of RRAM array. The time sequence of voltage pulses assigned to each port of RRAM array is illustrated in Fig. 29.47c. The measured results are pictured as grayscale map as shown in Fig. 29.47d, which means the defined computing task is correctly performed. Cells in different rows or columns of RRAM array can perform the same computing task in parallel by simultaneously applying the voltage pulses to the corresponding ports of BL and WL [25].

Besides the stateful logic, there are two other methods to execute Boolean logic with RRAM. In 2012, R. Rosezin et al.

used single RRAM cell as finite-state machines to perform the IMP logic operation in three steps [119]. The input of logic operation is transferred to the magnitude of voltage pulse applied to the BE or TE, and the output of the logic operation is stored in the device. The input and output physical variables of this method are different, which is difficult to cascade. Another way is using the RRAM as switch to build a reconfigurable logic array, which is proposed by B. Chen et al. in 2015. The logic operation is executed by readout based on the data matching method, which is similar to the content-addressable memory function [120]. In 2017, W.-H. Chen et al. fabricated 16 Mb ReRAM concept chip to achieve sub-14 ns computing speed with this method [121]. The variability of resistance is mitigated by the self-write termination scheme, which enhances the robustness of logic operation.

Compared with other new computing paradigms such as brain-inspired computing and quantum computing, Boolean logic computing is more close to the off-the-shelf system, which does not require developing new algorithms or software. However, the development of this field is very slow due to limited interest compared with other new computing paradigms. It still lacks the demonstration of complete computing and memory unit with input and output.

29.5.3 Brain-Inspired Computing

Another promising solution to overcome the von Neumann bottleneck is brain-inspired computing. Generally, there are two approaches for brain-inspired computing depending on the hardware used to compute. The first approach is mapping the algorithm of brain-inspired computing to the conventional CPU/GPU-SRAM/DRAM system or CMOS-based application-specific integrated circuit. This solution is still based on von Neumann architecture. Another solution is exploiting the unique properties of emerging nonvolatile memory (NVM) technologies to better emulate the analog synapses and utilize its crossbar structure for the hardware acceleration in the neural networks. The NVM uses its resistance or conductance to represent the weight of synapse. Among all emerged NVM, RRAM is one of most promising candidates due to its fast switching speed, high-density integration, low power, and COMS compatibility [24, 49, 122].

Neural network is composed of neurons and synapses. The neurons are connected by synapses with different weights. A two-layer neural network can be directly mapped to a RRAM crossbar array as shown in Fig. 29.48. The WL of the RRAM array is connected to the pre-neurons, while the BL of the array is connected to the post-neurons. The signals sent by the post-neurons are transmitted to the post-neurons via the RRAM-based synapse. The weights in the neural network are mapped to the conductance of the resistive synaptic devices. According to Kirchhoff's laws, the output current I_j at the j_{th} column can be written as

$$I_j = \sum_{i=1}^{m} V_i G_{i,j} \tag{29.54}$$

where V_i is the voltage pulse applied to the i_{th} row of WL from the pre-neurons and $G_{i,j}$ is the conductance of RRAM in the intersection of the i_{th} row and j_{th} column. Therefore, the weighted sum, which is the most time-consuming computing step for brain-inspired computing based on conventional computing system, can be performed by this crossbar RRAM array in one step. Generally, the integrated current at each column will be converted to voltage pulse by the neuron circuit and sent to the post-neuron.

The weights of RRAM-based synapses can be tuned row by row. There are two mainstream principles of weight update. One is the working mechanism of biological neural networks, in which the weight can be updated based on certain rules, such as spike time-dependent plasticity (STDP) and spike rate-dependent plasticity (SRDP) [122–126]. Such the goal is to emulate the synapse function of biological neural networks. For a STDP synapse, the weight update direction depends on the time difference Δt of the voltage pulses or spikes from the pre-neuron and post-neuron. When spikes from the pre-neuron before (after) the post-neuron, the RRAM-based synaptic weight increases (decreases). In 2010, S. H. Jo et al. fabricated a nanoscale RRAM device exhibiting the STDP synapse function as shown in Fig. 29.49a [126]. It can be found that the relation between the change in the synaptic weight and the Δt can be well fitted with exponential decay functions, which is similar to the STDP characteristics of biological synaptic systems as shown in Fig. 29.49b. In addition, this synapse can be repeated potentiating and depressing for more than 10^8 cycle. In 2017, N. Panwar et al. fabricated a PCMO-based RRAM, which shows a quasilinear relationship between analog conductance change and applied programming pulse voltage magnitude [127]. Arbitrary STDP behaviors, such as anti-STDP, symmetric STDP, and STDP with sin decay function, are achieved by leveraging this feature. In the same year, Z. Wang proposed a Ag:SiO_XN_Y-based RRAM to emulate the diffusive dynamic of biological synapse [28]. By utilizing the metal atom diffusion and spontaneous nanoparticle formation, multiple synaptic functions for both short-term and long-term plasticity, such as PPF, PPD, PPD following PPF, SRDP, and STDP, are successfully emulated. Besides the analog STDP function, binary STDP protocol was also experimentally demonstrated in the fabricated RRAM array [128]. Although various functions of biological synapse have been achieved by the RRAM, large neural network based on such synapse update rule is still lacking due to the fact

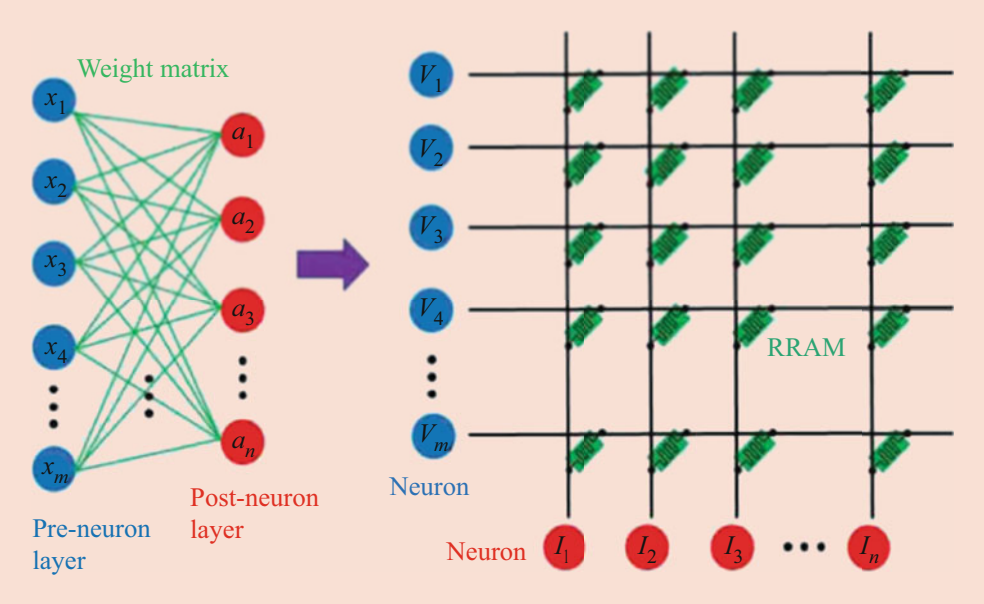

Fig. 29.48 Illustration of mapping a two-layer neural network to a RRAM array. (Reprinted from [5])

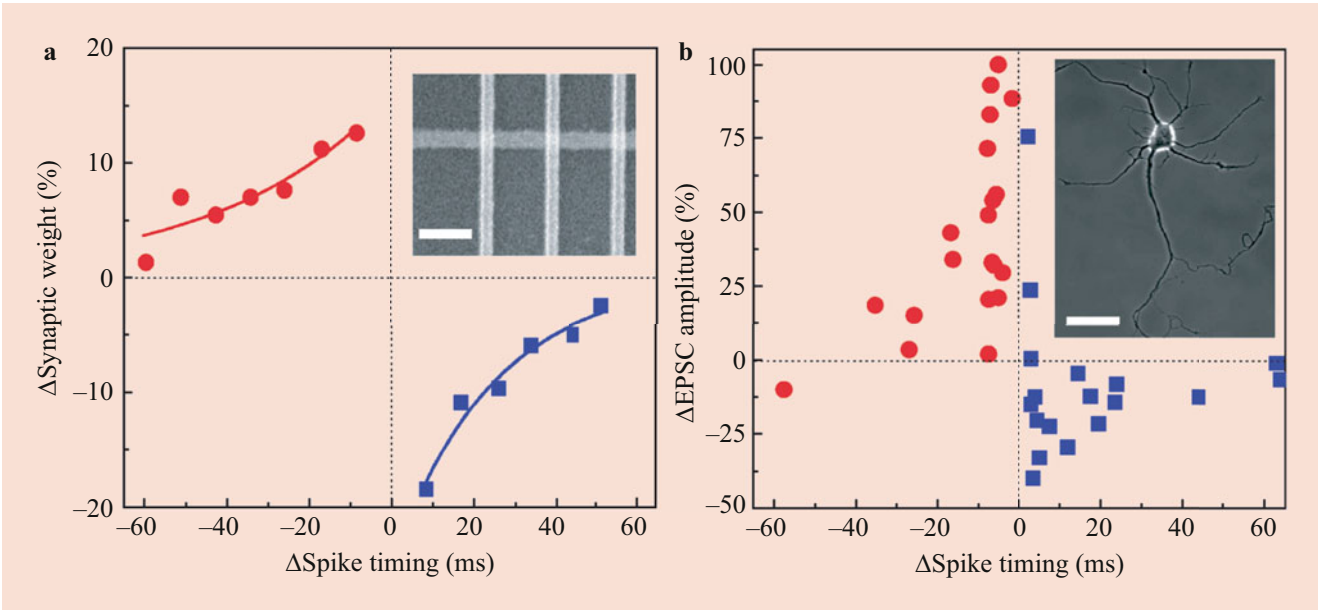

Fig. 29.49 Demonstration of STDP in the RRAM-based synapse. (**a**) The measured change of the memristor synaptic weight vs the relative timing Δt of the neuron spikes. Inset: scanning-electron microscope image of a fabricated memristor crossbar array. Scale bar: 300 nm. (**b**) The measured change in excitatory postsynaptic current (EPSC) of rat hippocampal neurons after repetitive correlated spiking (60 pulses at 1 Hz) vs relative spike timing. (Reprinted from [126])

that the working mechanism of brain is not clear. However, these achievements are helpful to the researcher of biological neural network and will significantly enhance the intelligence of neuromorphic hardware once a suitable algorithm is developed.

Another principle to update the weight is backpropagation (BP) learning rule, which has shown its advance in pattern and speech recognitions. The desirable characteristic of RRAM synapse for BP learning rule is multilevel (states > 64) and low-power (<0.1 pJ/spiking) switching, linear for update and good uniformity. In 2012, S. Yu et al. fabricated an HfOx-based RRAM synaptic device with sub-pJ energy to build a neuromorphic visual system as shown in Fig. 29.50a [76]. Z. Chen demonstrated the RRAM-based synaptic device with more than a hundred states in crosspoint array as shown in Fig. 29.50b, which can be utilized to recognize

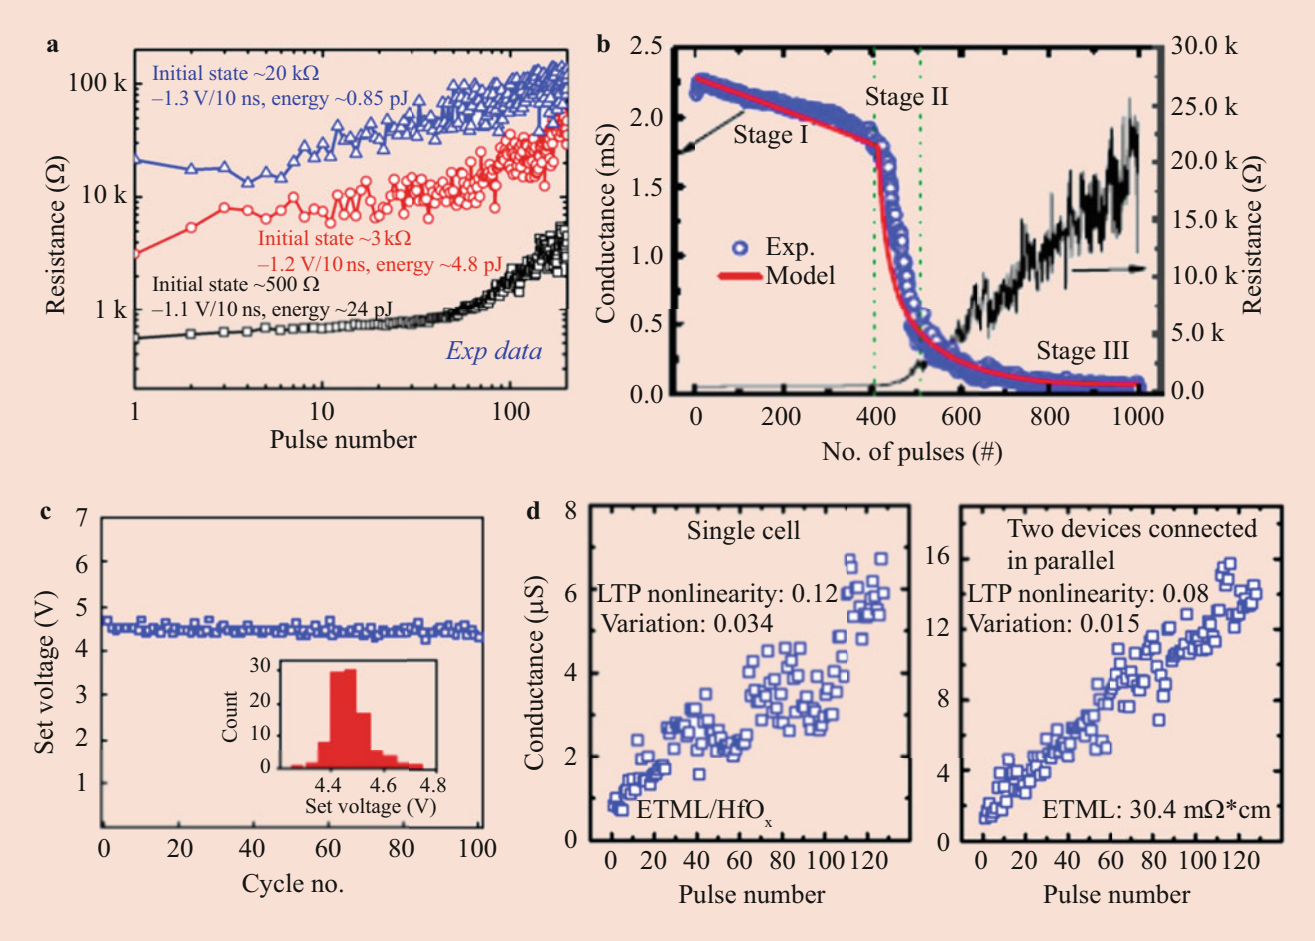

Fig. 29.50 (**a**) Dependence of energy per spike on the initial resistance states for the training process. (**b**) Measured gradual training process of resistive-switching device under consecutive identical pulses. (**c**) SET voltage with minimal temporal variations. (**d**) RRAM devices with good linearity, which is improved by introducing an electro-thermal modulation layer. (Reprinted from [76, 128, 130, 131])

the grayscale image [129]. S. Choi proposed an RRAM synaptic device with minimal spatial/temporal variations by confining the CF into widened dislocations in SiGe as shown in Fig. 29.50c [130]. By inserting an electro-thermal modulation layer between the TE and resistive layer to control the distribution of electric field and temperature in the filament region, conductance tuning linearity of RRAM synaptic device is improved by W. Wu et al. in [131]. However, the dynamic range decreases as shown in Fig. 29.50d. Z. Zhou et al. proposed a new hardware implementation approach to utilize the nonlinear synaptic cells to achieve high efficient online training [132]. Based on the presented implementation approach, the conductance tuning nonlinearity has little impact on the recognition accuracy of neural network.

Up to now, there are also a few experimental implementations of small-scale neural network based on RRAM array. In 2015, M. Prezioso et al. reported the experimental implementation of transistor-free Al_2O_3/TiO_{2-x} crosspoint array with low variability to allow operation of integrated neural networks for the linear classification [24]. The fabricated 12×12 crosspoint array was used to implement a single-layer perceptron with 10 inputs and 3 outputs, fully connected with 30 synapses. The neural network is used to classify three black-and-white images with 3×3-pixel, which corresponds to the nine inputs $V_1 \sim V_9$ as shown in Fig. 29.51a. V_{10} is the constant bias of nonlinear activation function. Thirty patterns, including three stylized letters ("z," "v," and "n") and three sets of nine noisy versions of each letter, are used to train and test this small-scale neural network. Each input signal was represented by a voltage V_j equal to either $+0.1$ V or -0.1 V according to the color of the pixel. The bias input V_{10} was equal to -0.1 V for the balance of the input. Each synaptic weight was implemented with a pair of memristors, so that $w_{ij} = G+ ij - G- ij$, enabling negative weights values. The network was trained with the Manhattan update rule in situ. The weights are updated in parallel for each column using two sequential voltage pulses. After 23 training epoch, the neural network can classify the 3 different letters by initializing the RRAM cell in the middle of their conductance (Fig. 29.51b). P. Yao et al. built a single-

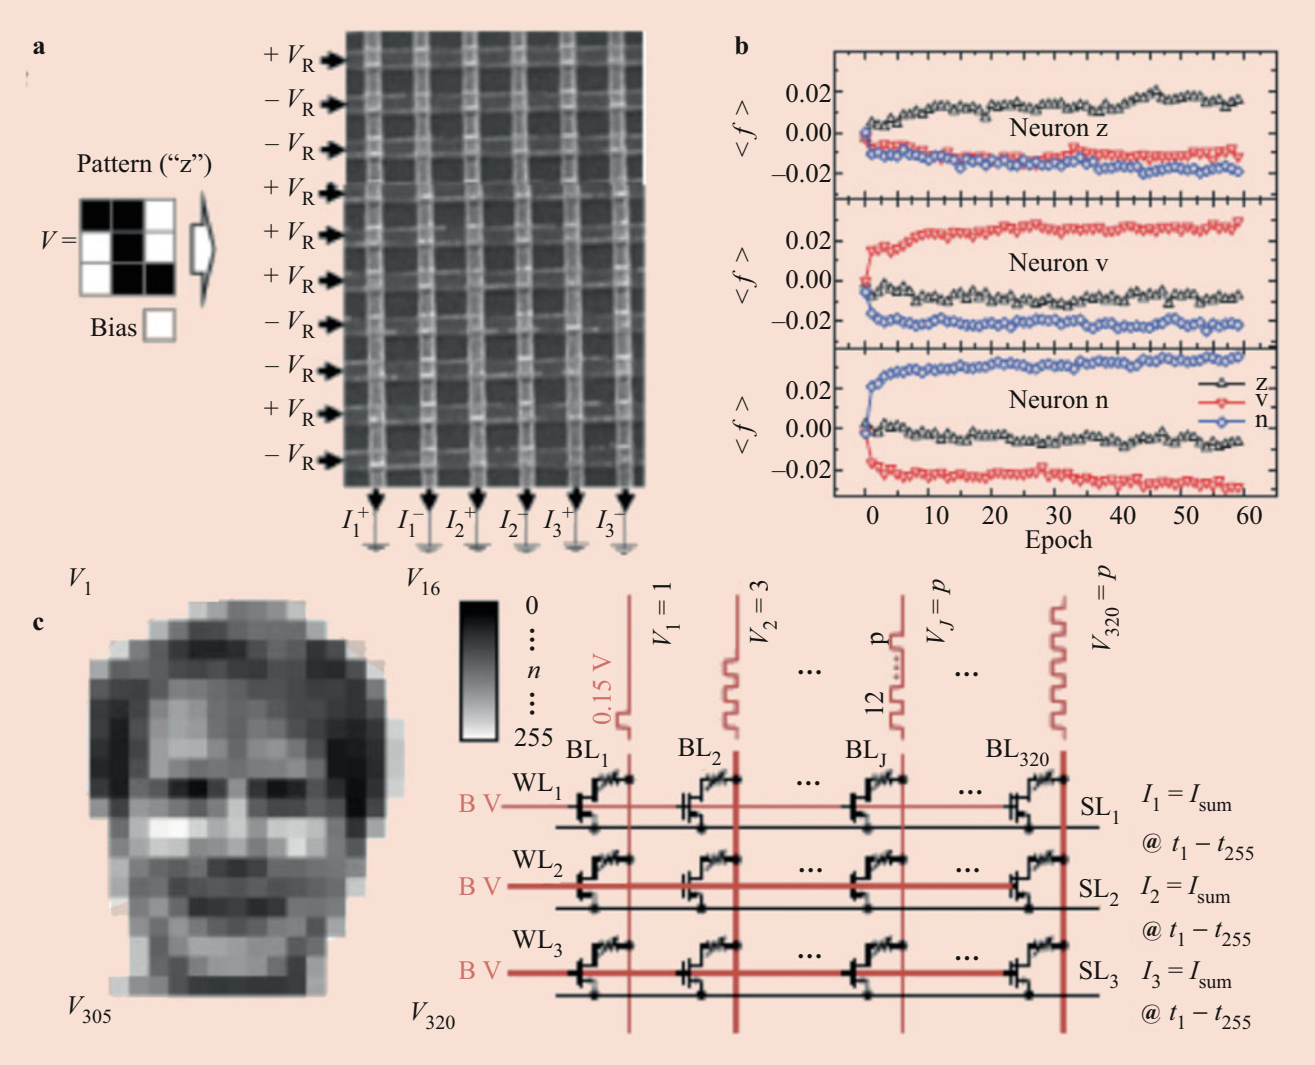

Fig. 29.51 (**a**) An example of the classification operation for a specific input pattern (stylized letter "z"), with the crossbar input signals equal to $+V_R$ or $-V_R$, depending on the pixel color. (**b**) The evolution of output signals, averaged over all patterns of a specific class. (**c**) The schematic of parallel read operation and how a pattern is mapped to the input. (Reprinted from [24, 49])

layer perceptron for grayscale face classification with 1T1R crosspoint array capable of bidirectional continuous weight modulation [49]. The fabricated $TaO_X/HfAl_yO_x$ RRAM array is 128 × 8, which is used to train the face pattern with 20 × 16-pixel as shown in Fig. 29.51c. In the training of neural network, two update rules were adopted: (1) without write-verify which only points out the switching direction depending on the errors sign, following the Manhattan rule, and (2) with write-verify which implements both direction and amplitude based on the errors sign and value, following the delta rule. There is a tradeoff between these two schemes. The scheme without write-verify can simplify the control circuitry since it is not necessary to calculate the specific analog value of the error between the targeted weight and the current weight, but it may slow down the converging speed due to the programming stochasticity, and the recognition rate is relatively low compared with the scheme with verify. The activation function of the output neurons is realized by measuring the total currents on SL to obtain the weighted sum and applying the sum to a nonlinear activation function. Nine images are chosen from the Yale Face Database and cropped down to 320 pixels to train and test this small-scale neural network. The image is in grayscale ranging from 0 to 255, which was converted to the number of voltage pulse applied to the BL (Fig. 29.51c). The average recognition rate on the total 9000 augmented noisy test patterns is 88.08% and 85.04% for the write-verify and without write-verify scheme, respectively.

Although some small-scale neural networks based on RRAM array have been demonstrated, it is still far from being applied. Challenges such as material optimization, variation suppressing, neuron circuit design, and algorithm

modification according to the practical device are needed to be solved.

29.6 Summary and Prospect

The RRAM has achieved remarkable progresses in the past decades. The significant advances include the following:

1. Physics understanding of the underlying mechanisms on resistive-switching behaviors. Various mechanisms have been proposed to clarify the physical origins of resistive switching in RRAM.
2. Physics-based models and simulation methods and platforms have been developed to quantify the device characteristics for the design and optimization of devices and circuits.
3. A variety of technical approaches for the integration and design of RRAM arrays and circuits were presented to achieve high performance with high-density integration and low-cost manufacturing.
4. The fabrication processes of RRAM-CMOS hybrid circuits were investigated.
5. The comprehensive visions of RRAM have been explored for future information processing technologies such as emerged memory and brain-inspired computing. RRAM testing chips for memory and brain-inspired computing have been demonstrated, indicating the feasibility of RRAM technologies for data storage such as embedded memory and brain-inspired computing systems.

These achievements highly promote the advances of RRAM technologies both in research and commercial activity.

Facing the research and application requirements, RRAM technologies still have some key challenges.

1. Physical mechanism: The development and application of RRAM technology demands a deep and predictive understanding of its underlying mechanisms. Even if the filament effect has been widely accepted for resistive switching, the physical origins of the conductive filament evolution during switching processes are still debated on, especially for Ox-RRAM. The main reason is due to the lack of direct experiment evidences in microscopic characterizations to identify the proposed mechanisms. Therefore, the final solution is to have the aid of breakthrough in atomic-level characterization technologies in the future.
2. Device optimization: The significant advances on device performance improvements have been achieved in Ox-RRAM. However, some key issues have to be addressed such as device variability from switching cycle to cycle and from device to device, peak switching current, forming voltage, and multilevel resistance states. Further optimization on these characteristics is desired to meet the requirements of the circuits and systems. The effective solutions may depend on the design and optimization of structures, materials, and operation schemes in device level by means of the deeply physical understanding and innovative device-engineering methods.
3. Selector: In the implementation of RRAM arrays, the array cell, in which a select device or selector is connected with a RRAM in series, is required to avoid or suppress the sneak path current issue in the crossbar arrays. It is key to develop a high-performance selector that can be easily stacked with RRAM and fabricated by CMOS-compatible process. For a selector, the required characteristics should include high on-current, high on/off-ratio, bipolar switch with high endurance, matching switch voltage with RRAM, and robust reliability. The optional selectors may be a transistor or a nonlinear device. From the viewpoint of high-density integration, a two-terminal selector is preferential for RRAM array. For this kind of selector, high nonlinearity, bipolar switch with high on-current, robust switching capacity with high endurance and anti-breakdown is highly desired. However, to develop the available selector for RRAM technology is still one of the major challenges.
4. Array cell: RRAM arrays usually utilize a crossbar structure, in which a basic cell includes a select device and a RRAM. Three types of optional cell structures have been proposed for RRAM arrays: (1) 1T1R, (2) 1R, and (3) 1S1R. For the 1T1R cell, a transistor is used as the selector at each cell. A transistor may be an ideal selector from the functions, but it limits the footprint of each cell and three-dimensional integration capability. 1R structure may be a plausible solution for ultrahigh density of crossbar array, in which the I–V nonlinearity of RRAM devices is utilized. In this structure, high I–V nonlinearity is needed. Additionally, the hard breakdown of RRAM cells during operation process is a key factor, which may cause unrecoverable damage to the array performance and reliable operation. The best solution is to use 1S1R structure, in which a two-terminal nonlinear device is stacked with RRAM to achieve small footprint of each cell and three-dimensional integration capability. However, 1S1R cell solution is stuck by selector technology. In this case, 1T1R or 2T2R cells with complementary structure will be the available solution for high volume of array integration in the near future.
5. Hardware architecture implementation: For brain-inspired neural networks, hardware implementation is emerging as one of the key challenges. In deep neural networks (DNNs), the key technical challenges are from two aspects. One is associated with the acceleration computing

using RRAM array, in which the design and fabrication of high performance RRAM arrays are key factors. Another is about the nonlinearity/symmetry and variability of RRAM-based synapses. According to the BP algorithm, the linear and symmetric responses of synapses to electric pulses are required for training process. However, that is a quite difficult task for RRAM-based synapse. Regarding this issue, the possible solutions may be from the interaction and optimization between devices and algorithm or architectures. For example, incorporating with recently proposed binarized neural networks (BNNs) based on modified BP algorithm, the impact of nonlinearity in RRAM-based synapses on system performance can be effectively eliminated.

In addition, programmable and reconfigurable physical fabrics using the intrinsic natures of RRAM are highly demanded.

As we look forward to the future, RRAM has emerged its great potential as one of most promising candidates for future information processing technologies past the von Neumann and Moore's law era. When the information processing technologies come to the data-centric era, it is necessary to develop the brain-inspired neural networks. While RRAM has the potential to be a nonvolatile memory technology both in standalone and embedded cases, it may be even more suitable for brain-inspired computing, especially considering its computing capacity beyond data storage. RRAM-based computing paradigms might provide a promising solution for the hardware implementation of brain-inspired neural networks. Specifically, RRAM arrays in crossbar structure can provide a native solution to implement massively parallel and power-efficient vector-matrix operations that form the basis of the core-computation in brain-inspired neural networks such as DNNs.

For the brain-inspired computing, RRAM devices are widely studied not only as function cells to mimic the dynamic behaviors of the basic cells-synapses and neurons in artificial neural networks (ANNs) but also as the data processing cells to perform the complex computing function such as convolution computing in deep learning convolution neuron networks. In DNNs, the backpropagation algorithms and corresponding architectures have been successfully developed and implemented for various application systems including image/speech recognition and natural language processing. The state-of-the-art DNN networks require a large memory capacity and high memory bandwidth. The massively parallel and power-efficient vector-matrix operations featured in a RRAM crossbar structure may provide an effective solution to DNN with high-performance acceleration for convolution computing. In the spiking neural networks (SNNs), the typical biological characteristics of spike timing-dependent plasticity (STDP) have been demonstrated, and a STDP-based learning rule is studied. However, the corresponding architectures and algorithms that can be utilized to construct a power-efficiency and operable SNN computing systems are still being developed. It is highly desired to develop the applicable algorithms or architectures based on the biological behaviors such as STDP. That will require persistent and creative research for RRAM technologies but must include insights from neuroscience, physics, chemistry, computer science, and electrical and computer engineering beyond any single discipline.

RRAM-based low-power embedded chips may be promising for edge-computing such as Internet of Things. Further advances in device technology and algorithm/architecture developments may lead to large-scale implementation of RRAM-based brain-inspired computing systems. This will drive RRAM into new research upsurges in the near future beyond memory.

Peng Huang received a B.S. degree from Xidian University, Xi'an, China, in 2010 and a Ph.D. degree in microelectronics from Peking University, Beijing, China, in 2015. He is currently a Research Associate in the Institute of Microelectronics, Peking University. His current research interests include model and simulation of Ox-RRAM, stateful logic, and RRAM-based neural network.

Yudi Zhao received a B.S. degree from Xidian University, Xi'an, China, in 2013 and a Ph.D. degree in microelectronics from Peking University, Beijing, China, in 2018. She is currently a postdoc in the Institute of Microelectronics, Peking University. Her current research interests include modeling and simulation of RRAM and brain-inspired computing.

Jinfeng Kang received his Ph.D. degrees from Peking University in 1995. He is a full-time professor of EECS School at Peking University. His research interests include nano-devices and materials for computing and data storage, brain-inspired computing, resistive-switching memory devices (ReRAM), and other innovative solutions to semiconductor technologies.

Abstract

This chapter is devoted to phase-change memories that have entered the market of non-volatile memories at the verge of the new millennium as a possible replacement for ultra-scaled flash memories. Rather than replacing conventional flash memories, the phase-change memory technology is now paving the way to the new market segment of storage-class memories.

Phase-change memories rely on chalcogenide alloys, which have been studied for more than a century now. After revisiting the most important historical and technological achievements of the last 50 years, the second part of the chapter summarizes the most relevant fundamental physical properties of chalcogenide alloys that influence their exploitation by the semiconductor industry. Besides pure phase-changing alloys for data storage, Ovonic materials for selectors are also considered.

The last two sections are more focused on the real-device performances. At first, the properties of chalcogenide alloys are reviewed in view of their influence on the performances of devices, and the most common device architectures are presented. Emerging cross-point arrays are also described. Finally, the most relevant reliability issues affecting phase-change memories are analyzed. New perspectives that are being pursued to achieve faster and more reliable phase-change memories are briefly outlined in the concluding paragraph.

Keywords

Properties of chalcogenide alloys · Ovonic threshold switching · Memory switching · Phase-change memory architectures · Selectors and cross-point arrays · Reliability issues

30.1 Introduction

Phase-change materials have historically received great interest from the community of optical and electronic engineers. At first, they were exploited for optical data storage; then, more recently, in the last couple of decades, they experienced a kind of second life as electronic non-volatile memories (NVM). Such an interest is based on their speed, data retention, endurance, and scalability, mainly due to the physical properties of the chalcogenides, the main materials they are made of.

A vast literature has been published in 50 years by research centers and, partially, by semiconductor industries. The present chapter contains a general, broad presentation of the physics and the technology of phase-change memories (PCM), as a detailed, exhaustive description would largely go beyond the scope of this chapter. Thus, in the following pages, only the main ideas on which these devices are based will be considered and illustrated. Readers willing to enter more deeply into the physics, material properties, and technology of PCM can find more detailed information in many good books specifically devoted to these topics [1–3], in review papers (e.g., [4–8]), and in the references therein.

30.2 PCM Development

30.2.1 A Historical Overview

In 1917 A.T. Waterman [9] published a paper entitled "*On the positive ionization from certain hot salts, together with some observations on the electrical properties of molybdenite at high temperatures*." Such observations sound, today, very peculiar, and it is worth reporting some of the original wording. They refer to the fact that "*With small applied potential differences the resistance of the strips is very high, but diminishes rapidly with increasing potential differences. No doubt this alteration in conductivity is partly due to the rise in temperature caused by the electric current*." Furthermore, "*The diminution of resistance with increasing potential difference continues uniformly up to a certain potential difference, […] at this point, which will be referred to as – 'the break', the resistance diminishes suddenly […] Before the voltage has been raised sufficiently for the break to occur the resistance diminishes […] with increasing voltage, whereas after the break the resistance diminishes with diminishing voltage. This difference may be regarded as characteristic of two states, α and β, of the material […] The phenomenon of the break is reversible […] The substance also tends to persist in the state in which it was when the current was turned off*." Figure 30.1, taken from the original paper of 1917, shows the results reported above. Waterman returned to the subject a few years later [10]. The new, more detailed, results confirmed the idea of the two forms of the molybdenite, α and β. The first form is characterized by a much higher conductivity than the second one. Part of these results, whose general aspects are very familiar to the present-day researchers in the field of PCM, are reported in [11].

The results of Waterman did not contain, of course, any indications of possible applications, and there were no relevant follow-ups.

The topic was investigated again many years later, in the sixties of the last century [12–15]. In his PRL paper of 1968, Ovshinsky reported "*a rapid and reversible transition between a highly resistive and a conductive state effected by an electric field … observed in various types of disordered materials, particularly amorphous semiconductors*." Despite not being the very first paper on this topic, this PRL paper is universally considered the first milestone of the PCM technology. In fact, this work had a particular impact on the scientific and technological literature, also because the analysis was soon extended to the optical properties of the same materials [16]. Since then Ovshinsky has been considered the founder of the applications of such materials, generally called *Ovonic* materials. He himself proposed this adjective to advertise his business, as for his previous important invention, which he called Ovitron switch [17].

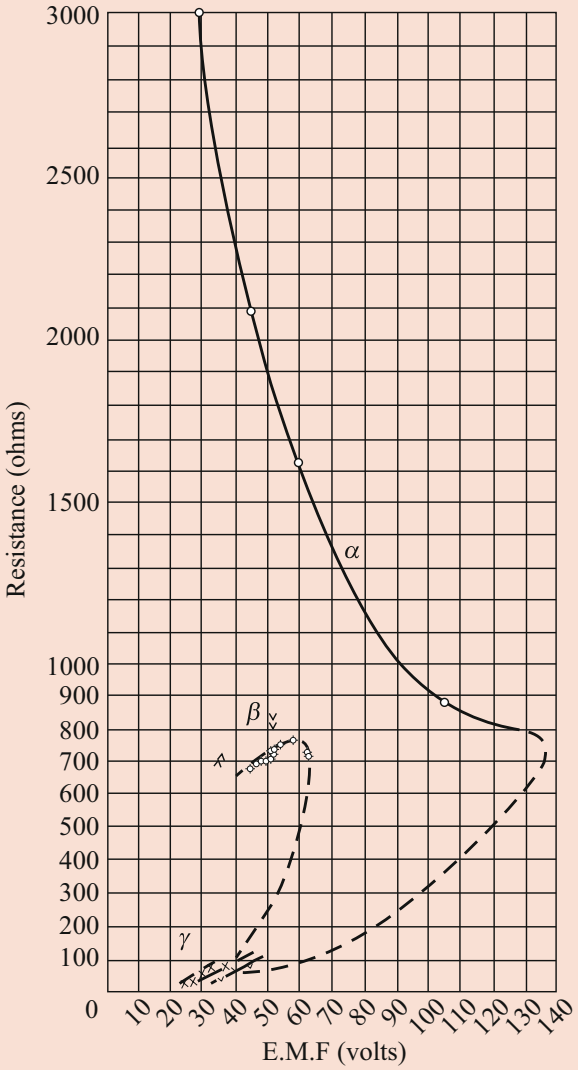

Fig. 30.1 Resistance of a sample of molybdenite as a function of the applied potential. (Reprinted, with permission, from [9] © Taylor & Francis Ltd., http://www.tandfonline.com)

In 1964 Eaton suggested that "*the transformation from one resistance state to another is due to a thermal breakdown of the dielectric during which melting occurs. Subsequently, either a high-resistance, glassy state, or low-resistance, crystalline state develops depending on the rate of cooling of the specimen*" [13]. In 1969 Pearson and Miller [18] mention "*well known semiconducting glass diodes […] which can exhibit negative resistance, […] undergo reversible electrical switching, and display a memory function*." They also report on "*the formation of a liquid phase and what appear to be conducting filaments […] with current densities* $> 10^4$ *A* cm^{-2}." Such filaments had been already suggested [13] and were coherent with the general theory of Ridley [19], according to which semiconductors with current controlled negative resistance might be expected to show filamentary current paths as a consequence the principle of least entropy production. The technological importance of fast and reversible variations of physical properties of such materials was already very clear to the above authors as evidenced by the fact that the publication of their results took place only after the request of patent registration [11]. In fact, several attempts to produce electronic memory chips of PCM have been made by some electronic industries in the following years. Such attempts, however, did not succeed mainly because of the large energy required to realize the phase change at each switch. Furthermore, chalcogenide-based memory prototypes were bigger and slower than conventional memories.

In addition to these objective difficulties, at that time there was also a certain *ideological* opposition from the establishment to Ovshinsky's new proposals: on the one hand, Ovshinsky was an outsider, without any academic credit, and this gave him little credibility; on the other hand, at that time scientific and technological activities were concentrated on the physics of crystals, and it did not seem possible that amorphous materials could be fruitfully exploited for the development of electronic devices owing to their intrinsic disorder [17].

Electronic PCM acquired a renewed interest and popularity at the turn of the millennium. On the one side, the reduction of the dimensions of the single devices drastically cut the power necessary to their working; on the other side, new chalcogenide alloys with fast crystallization times, high endurance, and long data retention were synthesized and studied. In addition, PCM proved to be less vulnerable to radiation, which makes them suitable for space and military applications. These reasons paved the way for making PCM competitive as replacements for conventional NVM, and in 2002 a 4Mb demonstrator array at the 180-nm technology node was presented by Ovonics and Intel [20].

Since then, most of the main semiconductor industries revealed their interest in PCM, and mass production was initiated by Numonyx (now Micron) [21] and Samsung [22, 23] with denser chips that reached 1 Gb at the 45-nm technology node in 2009, and 8 Gb after scaling down to the 20-nm technology node in 2012. Moreover, manufacturers investigated the exploitation of Ovonic materials also for new selectors, and Intel announced in 2009 a prototype of a stackable cross-point PCM [24].

Finally, in 2015 Intel and Micron unveiled the 3D XPoint™ technology, a commercial non-volatile 3D memory solution entirely based on chalcogenide materials for both the selector and the storage element [25, 26].

Optical memory devices had a better and faster success. The Ovshinsky group, in the same years of the research on the electrical properties of amorphous semiconductors, performed an analogous research on their optical properties [16]. They reported "*a high-speed crystallization of amorphous semiconductor films and the reversal of this crystallization back to the amorphous state using short pulses of laser light and evidenced by a sharp change in optical transmission and reflection. This optical switching behavior is analogous to the memory-type electrical switching effect in these materials*."

The first attempts to manufacture optical memories date back to the early 1970s; in the 1980s, write-once optical disks were released to the mass market. Owing to the possibility of being programmed with a suitable flashlamp exposure, phase-change materials, and chalcogenides in particular, became in the late 1990s key enablers for rewritable CDs and DVDs, under the impulse of Panasonic as leading industry. In 2003, high-capacity Blu-ray disks were also introduced into the market [27].

In recent years, new perspectives have opened up for the application of PCM (as well as other memories based on a controllable resistance change like RRAM) in the field of neuromorphic computation, a form of non-von Neumann, brain-inspired, computing where the same device acts both as memory element and processing unit. This subject is treated in details in Chap. ▶ 32. It must be said that also in this field Ovshinsky was a far-sighted anticipator. In fact, already in 1955 he was strongly interested in neurons and in the possibility of duplicating their functioning with electronic devices. There is little written testimony of his old proposals [17], while, more recently, one devoted to cognitive computing, developed in cooperation with Pashmakov, can be found in [28].

30.2.2 PCM Placement in the Non-volatile Memory Market

When PCM commercialization began in the late 2000s, a lot of expectations arose around this technology. The initial product development aimed at replacing NOR flash memories, targeting cellular phones as the driving application. According to Fantini [29], millions and millions of PCM

Table 30.1 Taxonomy of memory technologies on the basis of their key attributes

	PCM	NOR-flash	NAND-flash	DRAM
Non-volatility	Yes	Yes	Yes	No
Scaling	1× nm	45 nm	1× nm	1× nm
Granularity	Small/byte	Large	Large	Small/byte
Power	∼ Flash	Flash	Flash	> Flash
Write bandwidth	1–>15 MB/s	0.5–2 MB/s	>10 MB/s	>100 MB/s
Read latency	50–100 ns	70–100 ns	15–50 µs	20–80 ns
Endurance	$>10^6$	10^5	10^4–10^5	Unlimited

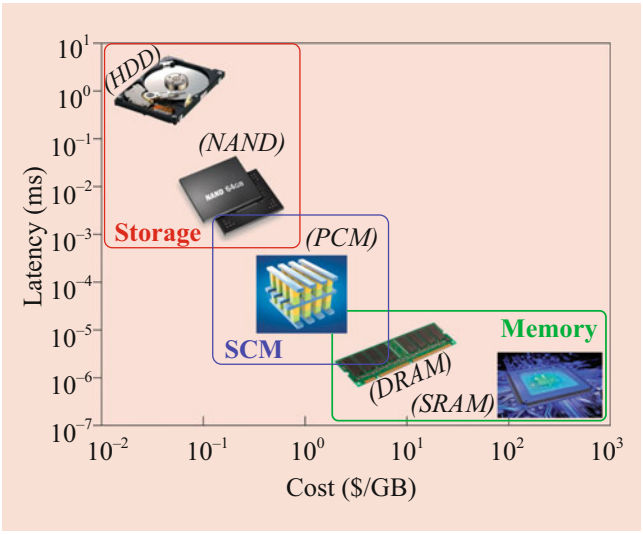

Fig. 30.2 Access time and cost for various memory technologies

cells were used, representing "*the largest volume of bits ever shipped on a non-charge based solid state memory physics*." The advent of smartphones turned the tables on the mobile phone scenario, and at that time it was clear that the huge demand of memory elements favored the transition to the NAND architecture. The use of PCM was then discontinued; PCM devices would turn competitive again only if they could be aggressively scaled down to reach data densities superior to those achieved by 3D-NANDs and justify the large investment costs to implement a new technology option.

Nevertheless, PCM still represent a viable choice for the embedded non-volatile memory technology, taking also into account their potential for computation. Currently, when these notes are being written, the integration of a conventional embedded non-volatile memory (e-NVM) at the 28-nm node is challenging, whereas PCM have already demonstrated the feasibility of such a solution at the production stage. Embedded PCM have the potential to quickly become the mainstream solution for automotive applications thanks to their single-bit alterability, which is a key enabler for a much simpler data handling with respect to flash-based memories, and to their reliability properties [30].

Besides the interest for automotive applications, manufacturers are seeking new market opportunities for PCM. During the early stages of development, the promising features of PCM devices led to envisaging PCM as a potential *universal* memory able to replace on one side flash memories and on the other side DRAMs. As knowledge progressed, neither of these two options became viable: PCM proved slower and with a worse endurance than DRAM and with a higher cost per bit than NAND flash. However, as reported in Table 30.1 and in the memory hierarchy of Fig. 30.2, a large gap in terms of latency (access time) and cost per bit exists between DRAM and NAND flash. Filling this gap is a clear opportunity for PCM, which can enter the memory market as a new complementary system usually referred to as storage class memory (SCM) [31], featuring an access time <10 µs and a moderate cost < 1 $/GB. PCM can thus compete as a faster, higher endurance NAND flash in the form of a storage-type SCM, where cost is the primary driver, and also as a non-volatile, though slightly slower, DRAM in the alternative form of a memory-type SCM, whose main focus is on write speed and read latency. At present, the main limitation for a storage-type PCM-based SCM is represented by the cost per bit, which can be reduced with the significant enhancement of the density offered by cross-point stacked 3D architectures.

30.3 Basics of the PCM Technology

A class of alloys including elements of the VI-A group, called chalcogenides, can easily and reversibly be switched between the amorphous and the crystalline phase upon the application of a heat source, like a laser spot or an electric current. Despite the intrinsic thermodynamic instability common to all glasses, the amorphous phase requires up to some years to spontaneously recrystallize at room temperature so that the amorphous state is considered stable as well in any practical application. On the contrary, crystallization becomes very rapid when the material is heated above the crystallization (or the glass transition) temperature.

Moreover, the amorphous and the crystalline phases exhibit in general a very large contrast in reflectivity and resistivity. These features make chalcogenide layers as the key component of a non-volatile phase-change memory, which is basically a thin-film resistor whose low-field resistance varies by at least two orders of magnitude depending on the phase state of the active region.

A ternary diagram of common chalcogenide alloys used by the semiconductor industry is shown in Fig. 30.3; among them, the most exploited compositions lie along the GeTe-Sb_2Te_3 tie line or are derived from it by doping and stoichiometry alteration [27].

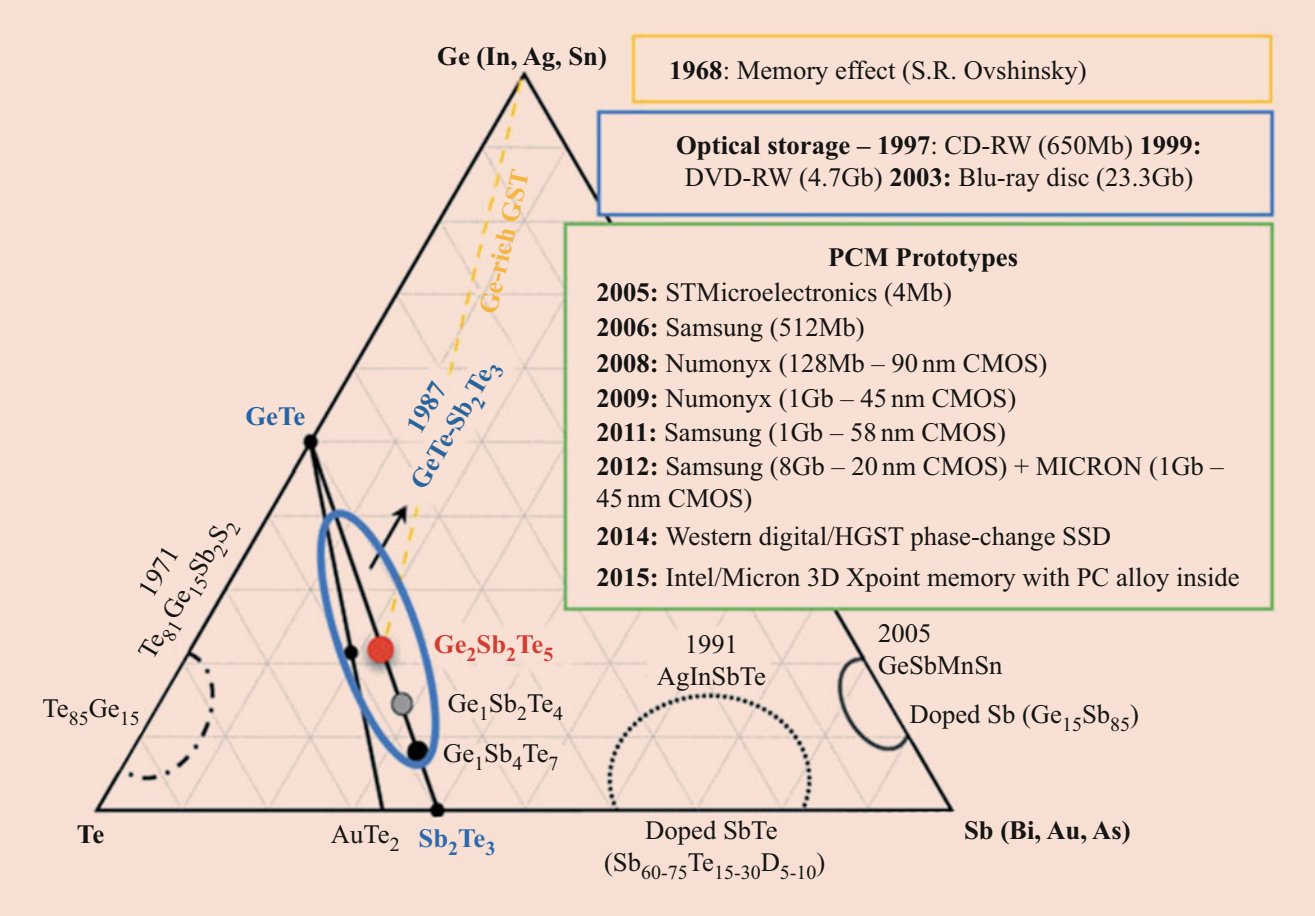

Fig. 30.3 Ternary phase diagram of most common chalcogenide alloys. The insets list the most important technological achievements reported also in Sect. 30.2.1. (After [33])

30.3.1 Optical and Electrical Properties of Chalcogenide Materials

The knowledge of the optical and electrical properties of chalcogenide materialsis of the utmost importance for unraveling the physics of the switching and their behavior in an NVM device. Some of these properties are often derived, either directly or indirectly, from optical experiments on thin films, which make them dependent also on the deposition parameters and the film microstructure. As a consequence, data published in the literature regarding, e.g., the optical bandgap, may be scattered (the interested reader can compare data cited in [33]), though they all lead to the same common interpretation and to the same trends. Most of the results disclosed in the literature have been determined for the $Ge_2Sb_2Te_5$ (also known as GST-225) and for the GeTe alloys, which are prototypical chalcogenides.

The amorphous GST-225 crystallizes into a rock-salt-like cubic phase, where one site is occupied by Te and the other site is occupied by Sb, Ge, and a 20% of stoichiometric vacancies [34], which are useful to stabilize the structure. This phase is metastable and transforms at about 600 K into a stable hexagonal phase. The sharp transition of the electrical resistivity between the amorphous and crystalline states is shown in Fig. 30.4a, where an initially fully amorphous layer of GST-225 (GeTe) is slowly heated up to the melting temperature. The abrupt changes highlight the amorphous-to-crystalline transition; a smaller drop is also present for GST-225 at higher temperature, coinciding with the transformation to the hexagonal phase. After the amorphous-to-crystalline transition has occurred, the material preserves the high-temperature resistivity also during cooling.

Analogous diagrams can be obtained also for the optical reflectivity (Fig. 30.4b), with a very pronounced increase in correspondence of the amorphous-to-crystalline transition, as for the resistivity. On the contrary, the cubic-to-hexagonal transition has limited effect on the optical reflectivity. The refractive index n and the extinction coefficient k for the two crystalline structures are, in fact, quite similar with small to

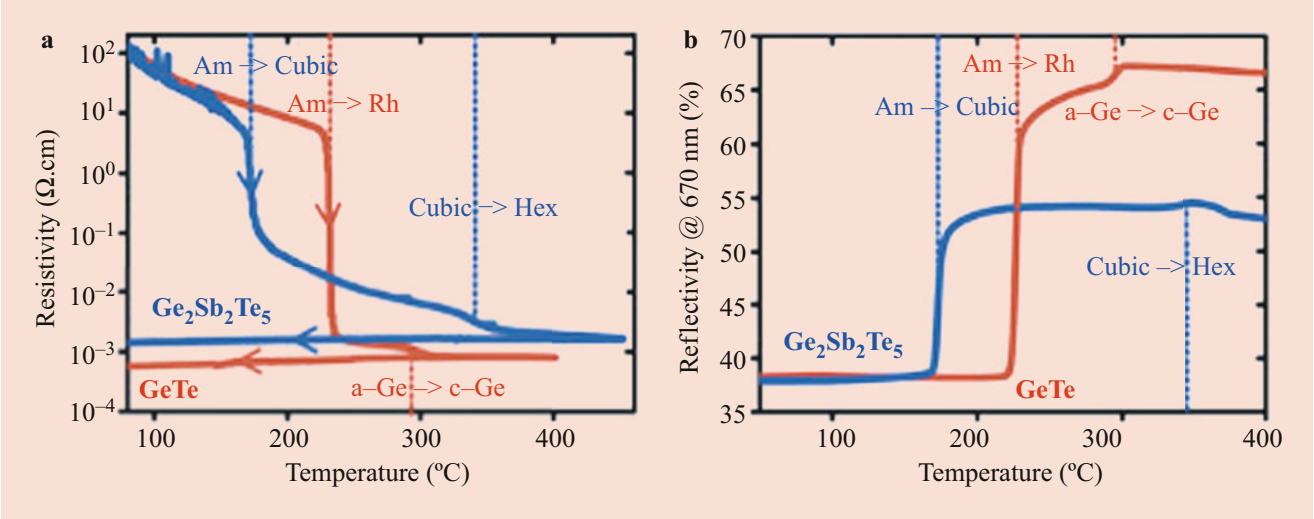

Fig. 30.4 Resistivity (**a**) and reflectivity (**b**) of GST-225 and GeTe during phase transitions as a function of temperature. (Adapted from [33])

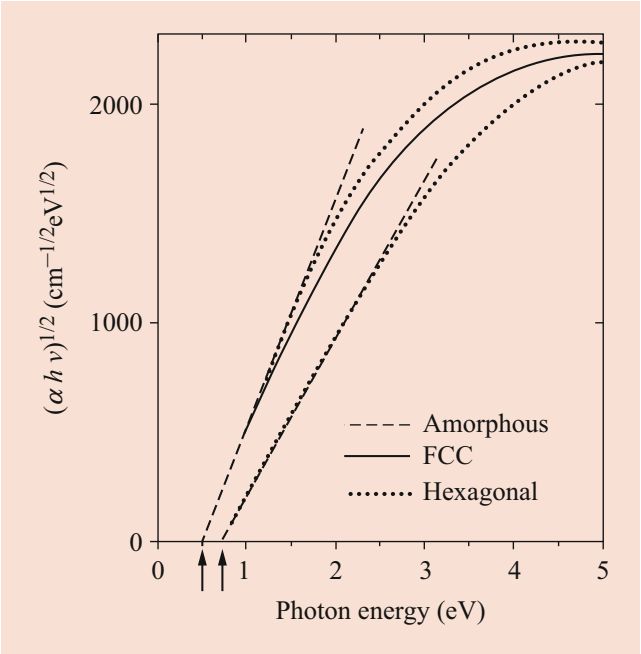

Fig. 30.5 The two arrows point at the optical bandgaps obtained as extrapolations to zero of the absorption coefficients, as from the Tauc equation 30.1. Values of 0.5 eV and 0.7 eV are obtained for crystalline and amorphous GST-225, respectively. (Reprinted from [35], with the permission of AIP Publishing)

negligible differences, but a significant change is found if they are compared to the amorphous phase [35].

The same applies also to the absorption coefficient α (Fig. 30.5), whose steep drop at the lowest energies indicates the band edge. By using the Tauc equation

$$\alpha h\nu \propto \left(h\nu - E_{\mathrm{g}}^{\mathrm{opt}}\right)^{r}, \tag{30.1}$$

with $r = 2$ (indirect bandgap), and extrapolating to the abscissa, an optical bandgap about 0.5 eV is found. Similarly, an optical bandgap about 0.7 eV is found for the amorphous phase; however, in this latter case, a deviation from linearity occurs at energies lower than 0.9 eV [35], which is the typical signature of an exponentially decaying Urbach tail connected to a high density of localized states.

Two sketches of the band diagrams (with associated densities of states, DoS) for the two phases of these prototypical chalcogenide semiconductors are shown in Fig. 30.6. Besides the larger gap of the amorphous phase, there are two more main differences. First, the amorphous phase features a large concentration of localized states spanning the entire gap, which are instead absent in the crystalline counterparts. These localized states significantly modify the density of states, which can be approximated by a continuous function joining the band states, the Urbach tails, and the midgap, deep, localized states. As long as carriers occupy states far from the band edges, their mobility decreases exponentially, thus giving origin to a mobility gap, i.e., an energy region where the mobility of carriers is negligible.

Next, the position of the Fermi level is different. Due to the large number of localized states, the Fermi level in amorphous chalcogenides is pinned close to midgap [36], i.e., amorphous chalcogenides behave like an intrinsic semiconductor with an activation energy for conduction about half of the mobility gap. On the contrary, crystalline chalcogenides are p-type semiconductors with a Fermi level lying close to the top of the valence band, which enables a thermal activation energy for conduction, compatible with a self-doping behavior that can be associated to the large number of stoichiometric vacancies of the crystalline structure. This picture is also confirmed by the hard X-ray photoemission spectroscopy (HXPES) spectra shown in Fig. 30.7 for GST-

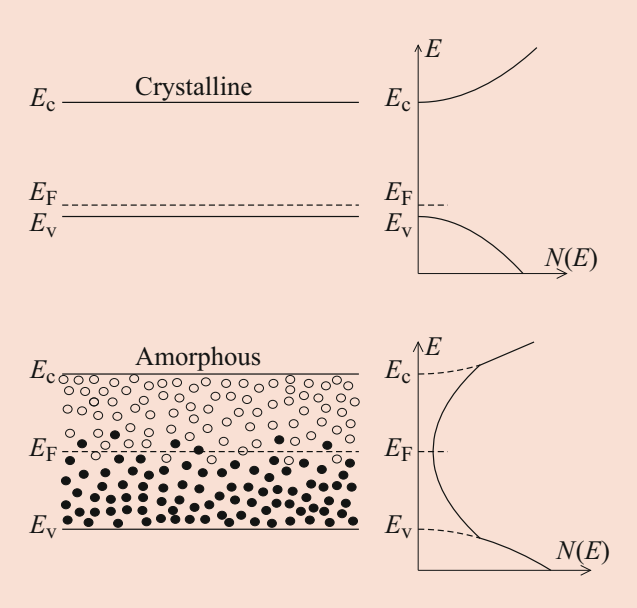

Fig. 30.6 Schematic band structure and DoS of crystalline and amorphous chalcogenide alloys at room temperature. White and solid circles represent empty and filled traps, respectively; the large number of traps originates a continuous DoS within the band gap. The band edges and the position of the Fermi level are also shown

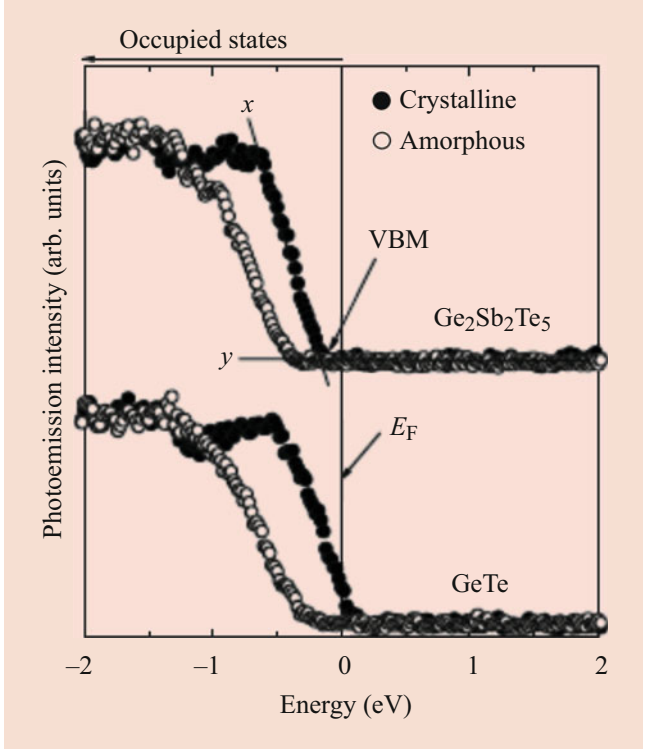

Fig. 30.7 Photoemission spectra near the valence-band maximum of amorphous and crystalline GeTe and GST-225. (Reprinted with permission from [37] © (2007) by the American Physical Society)

225 and GeTe, showing the occupation of the valence band with respect to the Fermi level [37].

The p-type conduction of crystalline GST-225 is further confirmed by Hall mobility measurements [38] and is also claimed for amorphous GST-225 via Seebeck analysis [39]. However, as a result of the strong Fermi-level pinning, the intrinsic semiconductor behavior of the amorphous phase still seems more appropriate due to the negligible carrier concentration in the extended states.

30.3.2 Device Operation

At the end of the fabrication stage, the deposited chalcogenide layer is brought into the low-resistance crystalline, or SET, state. The RESET operation, i.e., the amorphization of the programming region (which usually corresponds only to a portion of the chalcogenide layer), is obtained by heating the material to more than 1000 K, largely above the melting temperature T_m, with a very short electric-pulse of suitable intensity and then rapidly cooling it down. The entire amorphization process can be as fast as few tens of picoseconds [40,41]. This procedure destroys the periodic atomic arrangement typical of the crystalline phase and freezes the atoms in a disordered configuration, because the very fast quenching hinders the atomic mobility and prevents the system from reaching an energy minimum. As a result, a high-resistive amorphous state, also known as RESET state, is reached.

To switch back the material into the SET state, an electric pulse bringing the system into the fast crystallization regime is required. If the temperature is kept between the crystallization temperature T_x and the melting temperature T_m for a sufficient long time, atoms are allowed to move, and the ordered crystalline state is progressively recovered. It is thus evident that the SET operation takes place at temperatures lower than the melting temperature, in the 500–600 K range, but needs a significantly longer time to complete, from some tens to a few hundreds of nanoseconds [40,41].

In order to READ the state of the programmed region, a low voltage, small current pulse that does not alter the actual state of the memory is applied, and the resistance of the cell is determined by a current sense amplifier. A schematic of the READ, SET, and RESET pulses is shown in Fig. 30.8. Note that the two terms SET and RESET are commonly used for both states and programming operations; in order to avoid ambiguity, we shall use SET/RESET state or SET/RESET operation wherever necessary.

Depending on the phase of the chalcogenide layer, two distinct current vs. voltage characteristics are found (Fig. 30.9a). The crystalline phase is basically a simple resistor, and the slope of the $I(V)$ curve is determined by the series of the low-resistive chalcogenide layer and the resistance of the circuit necessary to the memory operation.

The amorphous phase features, instead, a highly non-linear, S-shaped characteristic, in which a high-resistive branch at the lowest voltages and a low-resistive branch at high bias—the latter merging with the characteristic of the crystalline phase—are connected through a negative differential resistance (NDR) branch. The latter is quite unstable, and it is often identified, under current controlled measurements, only by the two portions very close to the switching points.

By deeply analyzing the $I(V)$ characteristic of the amorphous phase, two switching processes can be identified (Fig. 30.9b). In the so-called subthreshold, or amorphous OFF, regime, the current exhibits an Ohmic, an exponential, and a super-exponential regime as a function of the increasing voltage. At a given voltage V_{th}, or threshold switching voltage, the conductivity of the chalcogenide layer rapidly increases. This state is usually addressed as amorphous ON, since no phase transformation has occurred yet. The amorphous ON state corresponds to the NDR branch of the current-driven $I(V)$ characteristic (voltage snapback), whose slope is determined by the load resistance, or to a dramatic steep rise in the current level if the measurement is voltage-driven, as it happens in memory arrays. If the bias is removed with the material in the amorphous ON state, the amorphous OFF state is recovered.

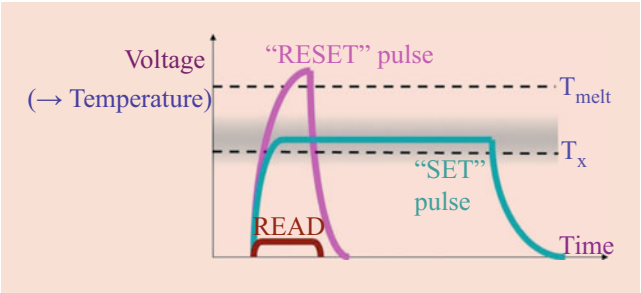

Fig. 30.8 Schematic voltage pulses, with the corresponding temperatures reached in the chalcogenide alloy, required for the operations in a typical PCM cell. (Reprinted with permission from [5] © (2010) American Vacuum Society)

This phenomenon is known as Ovonic threshold switching (OTS) and often triggers a second switching event, the memory switching. The strong increase in the current due to the threshold switching leads, in fact, to a high Joule heating of the chalcogenide layer which, in turn, activates the phase transition to the crystalline state, if the bias persists for a sufficient time.

Yet, OTS does not occur as soon as the bias is applied, and a certain delay time can be measured between the application of an electrical pulse and the beginning of the switching event. The delay time ranges from few nanoseconds to milliseconds, with an exponential dependence on the applied voltage, as shown in Fig. 30.10; in principle, if the applied voltage coincided exactly with the very threshold voltage, the delay time would be infinite, as reported also in [43].

While OTS is reversible, memory switching (MS) is permanent and is responsible for the non-volatile behavior of the PCM. The volume of the amorphous region depends on the temperature field achieved in the chalcogenide layer, whose distribution and maximum value can be tailored by applying electrical pulses of calibrated power. A typical programming curve, i.e., the mapping between the memory resistance and

the programming power, is reported in Fig. 30.11. This curve is obtained by setting the amplitude of the programming pulse, reading the PCM resistance and then reverting the PCM to its initial state for a higher programming pulse. The left half of the programming curve describes the sharp transition from a fully amorphized to a fully crystalline layer: after a threshold current is reached, the amorphous region is rapidly converted into a crystalline region with a small-to-negligible modulation of the crystalline volume. Once the SET process is completed, the PCM cannot be switched back to the high-resistive state with a pulse of the same amplitude, irrespectively of the pulse duration. The right half of the programming curve describes the opposite transition, from a fully crystalline to a fully amorphous layer. Such a transition is much broader and is dominated by the timescale of the melt-quench process: the higher the RESET pulse, the bigger the amorphous region, the more resistive the chalcogenide layer. Differently from the left half of the programming curve, the amorphous region can be transformed back to crystalline through a proper calibration of the falling edge of the electrical pulse. More interestingly, the possibility of modulating the PCM resistance in accordance to the programming current paves the way to multiple-level cells (MLC), and reliable solutions up to 4 bits per cell have been demonstrated [45, 46].

Though memory switching is common to all chalcogenides, for certain compositions the melting temperature is so high that in practice it is never reached, or the kinetics of the phase change is slower than the typical pulse duration so that the phase change does not immediately follow the threshold switching event. The material remains in the amorphous ON state even at voltages larger than the threshold switching voltage. If the voltage is progressively reduced, the amorphous ON state is kept down to the so-called holding voltage $V_h < V_{th}$, which is the minimum voltage that sustains the ON state, and then the current falls down to the amorphous OFF level. These chalcogenide materials are not used for storage but have a strong potential for selector devices.

While the physics of MS is well determined by the thermodynamics and the kinetic of the crystallization, that of OTS is still far from being completely understood, though it has been studied for more than 50 years now, and a number of models have been proposed. These models, in fact, are able to properly describe some features of OTS, but none of them provides the full picture yet.

30.3.3 The Ovonic Threshold Switching

The Ovonic threshold switching is undoubtedly the key enabling mechanism of phase-change memories, as it provides the high current necessary for the amorphous phase to switch to its crystalline counterpart. Ridley pointed out in 1963 that S-shaped $I(V)$ characteristics lead to filamentary conduction [19], which is the formation of low-resistance filaments connecting the electrodes within a high-resistance matrix. Most of the models developed up-to-date to interpret OTS are still coherent with such an observation, either by creating unstable crystalline filaments, or by thermal filaments, or by identifying preferred pathways where some kinds of enhanced tunneling/hopping among defective states occur. These models can be classified into three main categories: thermal, electronic, or structural. In the following, we shall summarize the main features of some of them; further information is reported in Chap. ▸ 40. The interested reader can also read more detailed reviews in [7, 8].

Thermal Models

The very first mechanism proposed to explain the threshold switching in phase-change materials is an electro-thermal instability that triggers the switching event [13]. In the thermal models, Joule heating boosts the conductivity, being the latter proportional to the thermal activation of the carriers: $\sigma \propto \exp[-E_a/(k_B T)]$. A positive feedback is established: the higher the current, the more the power dissipation, the higher the conductivity, and so on. If one assumes that Joule heating is predominant along a filament (whose origin basically depends on local non uniformities of the amorphous matrix that induce the initial current concentration), the threshold temperature T_{th} is approximately given by [8]:

$$T_{th} = \frac{E_a}{2k_B}\left(1 - \sqrt{1 - \frac{4k_B T_0}{E_a}}\right), \tag{30.2}$$

where E_a is the activation energy for conduction and T_0 is the ambient temperature. The relationship above requires $E_a > 4k_B T_0$, which is the minimum condition for obtaining a negative differential region in the $I(V)$curve. Interestingly, the same conclusion was also found in [47] for a pure electronic model. Thermal models were abandoned in the 1980s in favor of purely electronic switching mechanisms. Adler [48] observed that the switching event is triggered by a specific value of the electric field, not of a voltage, and for such a reason, the switching event occurs in an extremely small timescale, much lower than the time required for heating the lattice. However, an electro-thermal interpretation of the OTS was proposed again by Bogoslovskyi and Tsendin in 2011 [49] by combining thermal excitation to tunneling from ionized negative U-centers.

Electronic Models

Double-injection electronic models were initially proposed by Henish [50] and Mott [51] but were later abandoned in favor of the generation-recombination model proposed by Adler [52]. This model relies on the idea that valence alternation pairs (VAPs), i.e., pairs of three-fold coordinated, positively charged C_3^+ and one-fold coordinated negatively charged C_1^- chalcogen atoms, enhance the carrier generation and recombination rates, with different time constants for the two processes. Some years later, Pirovano [53] showed that a similar model can be applied to any kind of defects, and not only to VAPs.

In order to obtain the threshold switching condition, it must be assumed that the rates are proportional to the carrier concentration, as happens for impact ionization, the generation term is dependent on the electric field through the Okuto-Crowell equation [54], and the recombination time is modulated by trap filling. The switching point represents the limit condition where recombination is able to balance generation by simply filling traps. In the subthreshold regime, the recombination process is favored by the presence of empty traps, and an equilibrium is established with a generation process that is exponentially dependent on the current. At higher currents, when a vast majority of traps is already filled, the only way to let recombination balance generation is reducing the voltage, so that the generation rate is reduced as well. In order to sustain a high current, a large carrier concentration, as the one produced by impact ionization, must be considered.

The model consists of the standard drift-diffusion equations for electrons and holes, coupled to kinetic equations for trap filling, and to the Poisson and Fourier heat equations, which is also one of its main advantages in view of a possible implementation in TCAD simulators.

Two main shortcomings of generation-recombination models have been evidenced [55]. According to the original work by Adler, the mechanism above takes place in a micrometer-wide filament, which raises a natural skepticism about its applicability to much smaller devices as those made available by the semiconductor industry in the 2000s. Moreover, the model relies on impact ionization, which does not seem compatible in amorphous chalcogenides, as the typical mean free path for carriers is quite small and does not allow them to reach the energy required to ionize neutral defects.

Still bound to the idea of filamentary conduction, Karpov and coworkers proposed in 2007 a unified model for OTS and MS [56]. Their model assumes a field-enhanced nucleation rate that, in turn, decreases the energy barrier for crystallization so that a rod-like embryo of a crystalline filament is formed in the vicinity of the bottom electrode (BE). The very high contrast in the resistivity of the filament with respect to the surrounding amorphous matrix is such that the current is largely gathered by the embryo, thus concentrating the electric field at its edges, and the crystalline filament progressively grows until it connects the electrodes. Once the full filament is created and the field is removed, the filament can either be stable or dissolve according to its radius: if the latter is larger than the minimum thermodynamically stable radius, the filament is stable and MS is achieved, otherwise it dissolves and OTS takes place.

This model presents two strong points: the unified vision encompassing both OTS and MS, and the description of the delay time necessary for OTS to occur, including its dependencies on voltage and temperature. However, it is affected also by two important weaknesses: on the one side, an unstable filament should dissolve at a rather lower field (corresponding to the holding voltage) than the one required for its creation (corresponding to the threshold voltage); on the other side, parameters used to model crystallization do not fully cope with those stemming from its pure thermodynamical description.

Also in 2007, Ielmini proposed a model based on hopping from deep to shallow traps and the non-uniformity of the electric field [57]. At present, this model represents undoubtedly the most credited and used model for OTS nowadays. The model was later reworked by Ielmini himself [58] and mostly by Piccinini at al. [59,60], Buscemi et al. [47,61], Jacoboni et al. [43], and Brunetti et al. [62], who introduced also the self-consistent coupling to the Poisson equation and ended up in a hydrodynamic formalism. Interestingly, Buscemi et al. [47] found the same constraint for the activation energy holding for thermal models, once the carrier temperature replaces the lattice temperature. Cappelli et al. [63] developed also a 3D discrete version of the hydrodynamic model, by which they demonstrated the occurrence of filamentary conduction also with their model. All of these models share the same physical explanation and take into consideration a different level of complexity. Detailed descriptions are reported in Chap. ▶ 40; generally speaking, they can be referred to as hot-carrier models.

In essence, these models consider the co-existence of low-energy, thus low-mobility, states (e.g., deep traps) and states at higher energy, with a higher mobility (e.g., shallow traps and extended band states). In the subthreshold regimes, either Ohmic or exponential, carriers move according to trap-limited conduction, hopping from a low-mobility state to another by tunneling or thermal emission; the carrier distribution is close to the equilibrium distribution. In the super-exponential region, carriers are partially promoted to high-mobility states as a result of the action of the high electric field close to the BE. An out-of-equilibrium carrier distribution featuring a carrier temperature replaces the equilibrium distribution. Since the mobility of carriers in high-energy states is exponentially higher than the one of carriers in deep states, high currents can be sustained with a high field close to the BE and with a much smaller field far from the BE, as long as the carrier concentration in these states is large enough. This originates the positive feedback for OTS: the higher the field close to the BE, the larger the amount of carriers in mobile states, the higher the current that can be sustained with a low field far from the BE, and so on.

While hot-carrier models provide a good to excellent fitting of the $I(V)$ characteristics and of the threshold conditions, they all fail in explaining the measured switching delay time, which is much longer than the one predicted by the models [44].

Structural Models

Besides thermal and electronic models, a new interpretation of OTS was provided in 2020 by Noé et al. [64], who connected the switching mechanism to the presence of the metavalent bonding proposed by Wuttig, Raty, and coworkers [65,66].

Metavalent bonds have been introduced on the basis of many physical parameters, such as hybridization and ionicity, whose values are between those typical of covalent and metallic bonds, as shown in Fig. 30.12. Materials featuring metavalent bonds are also called incipient metals, since their conduction properties can progressively reach values close to those of metals upon the application of a proper driving force.

According to the proposed model, the change of the bonding configuration in chalcogenide glasses is triggered by a high electric field, which has a significant impact on the electronic properties of the OTS materials by increasing the degree of bond alignment. More specifically, states around the Fermi level delocalize and transform from low-conductivity defect states to high-conductivity delocalized channels. The latter are responsible for a dramatic change in the electronic DoS and, in turn, to a huge increase in the electronic conductivity. These changes are metastable and are mostly recovered after the removal of the excitation; however, since the mechanism involves structural modifications, part of them are irreversible and the amorphous structure is unable to recover the full pristine state. This behavior could thus explain the so-called forming (or first firing) of Ovonic materials, according to which the very first switching events occur at higher voltages than the subsequent ones.

30.3.4 Memory Switching and the Physics of Phase Change

The physics at the basis of the phase change in chalcogenide materials is nothing but the physics of a phase transition in a solid system, as described by Avrami in the late 1930s and early 1940s [67–69]. The driving force for crystallization is the difference in Gibbs free energy that exists between the amorphous (or the liquid) and the crystalline phase. At first, a crystalline nucleus is created. This can happen either in the bulk (homogenous nucleation) or close to a surface, an interface or an impurity (heterogeneous nucleation), but since heterogeneous-nucleation rates dominate over homogenous-nucleation rates, the crystallization process begins quite often at an interface between two materials [70].

According to classical nucleation theory, clusters of crystallites are created as a result of two competing phenomena: the addition of a new crystallite to an existing crystallite and the detachment of a crystallite from a formed cluster. The process of cluster formation is governed by the reversible work of formation, which is the result of two components: the energy gained by forming the crystal phase and the energy required by the surface formation between the crystalline and the amorphous phase. The critical quantity is the variation of the Gibbs free energy $\Delta G = G_{\text{crystal}} - G_{\text{liquid}}$ [70]:

$$\Delta G = -\Delta g V + \gamma S, \tag{30.3}$$

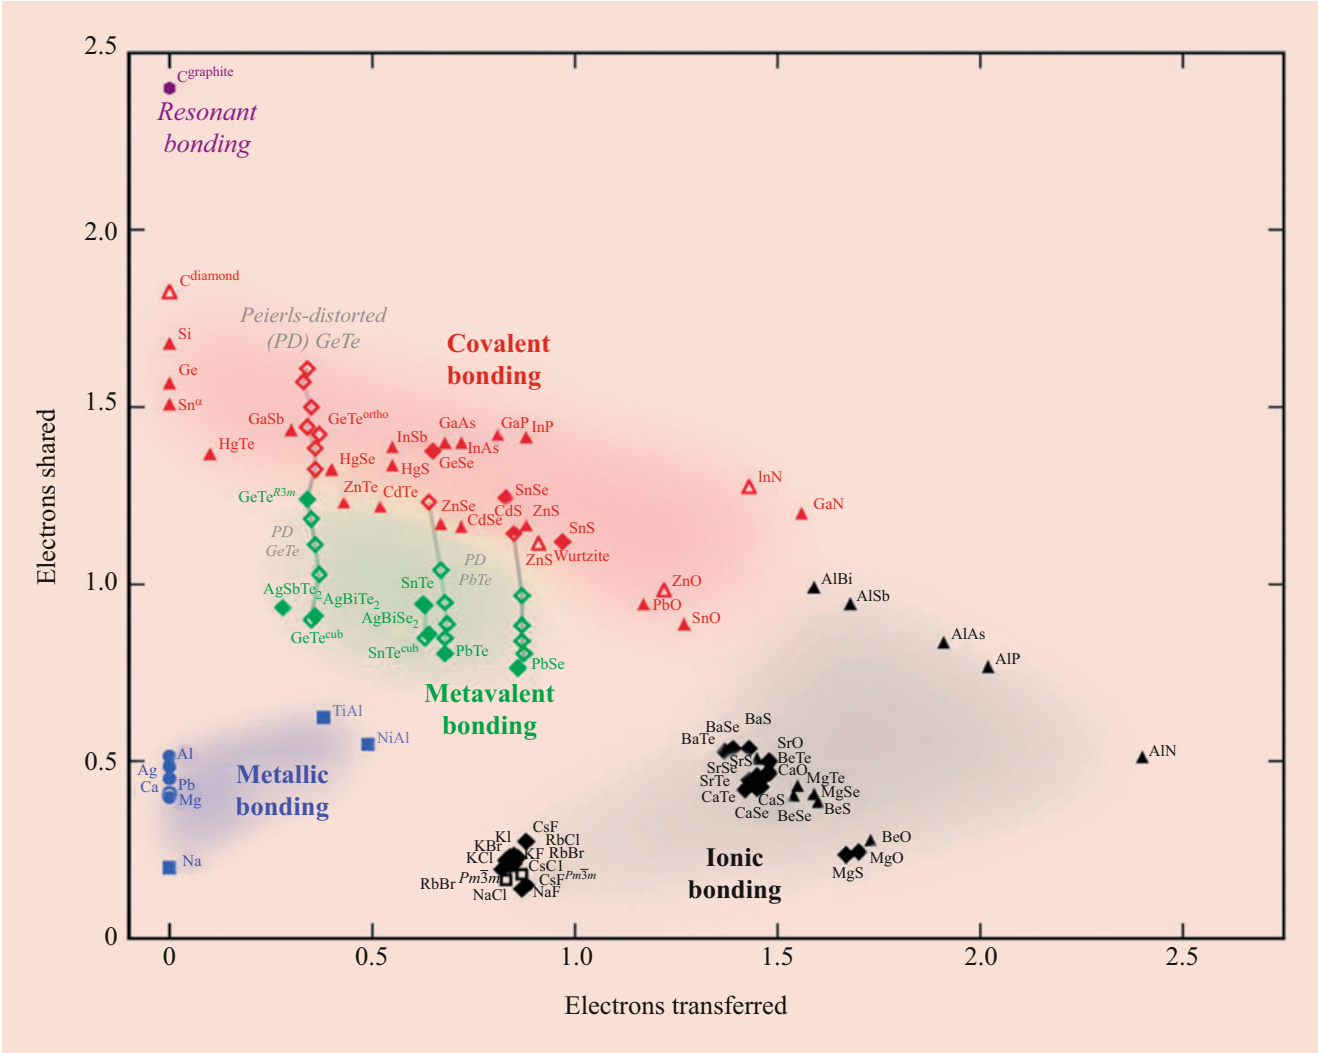

Fig. 30.12 Map of electronic interactions and bonding of many materials. The amount of electrons transferred between neighboring basins is a measure of the ionicity of the bond, while the amount of electrons shared is a measure of its covalent character. Metavalent bonding is collocated between covalent and metallic bondings. Adapted from [66], with permission from John Wiley & Sons Inc.

where $\Delta g = g_{\text{liquid}} - g_{\text{crystal}}$ and γ are the bulk-specific free energy difference between the amorphous and the crystalline phase and the surface-specific free energy, respectively, and V and S are the volume and the surface of the crystallite. Note that $\Delta g < 0$ above the melting temperature T_{m}, and γ is positive, thus unfavorable to crystallization. For spherical crystallites at $T < T_{\text{m}}$, ΔG has a maximum at the critical radius $r_{\text{c}} = 2\gamma/\Delta g$, which represents the minimum size for clusters to be stable. The nucleation rate reads [71]:

$$I = K \exp\left(-\frac{\Delta E_{\text{a}}}{k_{\text{B}}T}\right) \exp\left[\frac{-16\pi\gamma^3}{3(\Delta g)^2 k_{\text{B}}T}\right], \qquad (30.4)$$

ΔE_{a} being an activation energy at the surface, and the bulk free energy difference being expressed as $\Delta g = \Delta h_{\text{f}} f(T_{\text{m}}, T)$, with Δh_{f} the specific enthalpy of fusion. Several empirical approximations have been proposed for $f(T_{\text{m}}, T)$; among them, many authors agree on that by Singh and Holtz [72].

After nucleation has occurred, a stable cluster can grow. New atoms from the amorphous phase hit the cluster with frequency ω and can attach to the cluster if they are able to overcome the energy barrier $\Delta E'_{\text{a}}$, which may differ from the activation energy ΔE_{a} above. Similarly, some atoms can detach from the cluster if they overcome the same energy barrier $\Delta E'_{\text{a}}$ modulated by the difference in the Gibbs free energies of the clusters before and after detachment $\Delta G_n - \Delta G_{n-1}$. The cluster growth velocity can thus be expressed as [6]:

$$v = \beta\lambda\omega \exp\left(-\frac{\Delta E'_{\text{a}}}{k_{\text{B}}T}\right)\left\{1 - \exp\left[-\frac{\Delta g V}{k_{\text{B}}T}\left(1 - \frac{r_{\text{c}}}{r}\right)\right]\right\}, \qquad (30.5)$$

where λ is the typical crystallite size, β is a geometrical factor, and r is the cluster radius. When $r \gg r_c$, the growth velocity depends only on the temperature and has a maximum close to the melting temperature.

A phase-change alloy can be classified as growth-dominated if it features long incubation times, low nucleation rates, and high growth velocities. On the contrary, when relatively short incubation times, high nucleation rates, and moderate growth velocities prevail, the alloy is nucleation-dominated. As is evident from the formulas above, nucleation rates and growth velocity are functions of the temperature, so that the same compound can behave as a nucleation-dominated material at low temperatures and as growth-dominated material at high temperature. Typical activation energies for nucleation of chalcogenides along the GeTe-Sb_2Te_3 tie line lie in the range 2.5–4.0 eV, whereas slightly lower values have been derived for the growth process, according to growth velocities in the range tens of nm/s to few pm/s [6].

In order to account for memory switching, the thermodynamical model above must be coupled to any of the transport models summarized in the previous paragraph and to the Fourier heat equation. The full model is tackled only numerically, due to the strong non-linearity affecting the constitutive equations. While many numerical schemes can be applied to solve the transport equations, the thermodynamics of the phase change is mostly solved by means of Monte Carlo techniques that provide a very accurate description of nucleation, crystal growth, and dissociation [73, 74] and also take into account the intrinsic stochasticity of the process [71, 75].

30.4 Materials and Devices

30.4.1 Materials and PCM Performances

The key requirements for a PCM device may vary significantly upon the specific application the memory is designed for. Generally speaking, the PCM must have a fast SET speed (<100 ns), a limited RESET current (values lower than 200 μA whenever possible), a high endurance (typically $>10^8$ cycles), and a long data retention (more than 10 years at 85 °C; stricter requirements apply instead to embedded-PCM for automotive applications). Besides these properties that are mostly linked to the chalcogenide composition, a good scalability and a low intra- and intercell-variability of the threshold condition and of the ON and the OFF resistance are also a plus from the technological standpoint [8].

Demonstrators of PCM cells have been designed to largely overcome one or a few of these constraints, but none of these prototypes meets the entire set of requirements altogether, or can easily be moved to the fabrication stage at the industrial level.

Table 30.2 Most relevant phase-change material parameters and their influence on the PCM performances

Phase-change material parameter	Influence on PCM performances
Crystallization temperature and thermal stability of the amorphous phase	Data retention and memory lifetime
Melting temperature	RESET power
Resistivity in amorphous and crystalline phases	ON/OFF ratio SET and RESET current
Threshold voltage	SET and READ voltages
Thermal conductivity	SET and RESET power
Crystallization speed	SET pulse duration (power) Data rate
Melt-quenching speed	RESET pulse duration (power)

Reprinted with permission from [5], © (2010) American Vacuum Society

The most important material parameters that influence the performance of a PCM are listed in Table 30.2.

The crystallization temperature T_x is defined as the lowest temperature at which the crystallization takes place in a time scale compliant with the technological needs. The crystallization temperature represents the upper bound for data retention in the amorphous state, though it does not give any precise measure of data loss at lower temperatures after a sufficient long time from the programming operation. In other words, it is a measure of how hot a PCM cell can become before immediately losing the stored information. The crystallization temperature is strongly dependent on the material composition, the layer thickness, the presence of defects in the bulk of the alloy, or on the metallization lines at the boundary of the chalcogenide layer. Raoux et al. [76] reported that some chalcogenides are able to crystallize films as thin as 1.3 nm or in nanoparticles about 2 nm in diameter in a longer time with respect to their thicker counterparts, which is a key enabler for the extreme scalability of the PCM technology.

The melting temperature is also dependent on the composition, and to a lesser extent, on the size in ultra-thin films, nanowires, and nanoparticles. As a rule of thumb, the lower the melting temperature, the better the PCM. As a matter of fact, the melting temperature dominates the power required for the RESET operation, which is the most energy-demanding programming operation, and the reduction of the high energy consumption per bit is one of the most challenging open issues for the PCM technology.

The difference in resistivity between the amorphous and the crystalline phases contributes to defining the memory window of PCM, which is determined through the ON/OFF ratio, i.e., the ratio between the current in the SET and RESET states upon the application of a READ pulse. The best alloys for phase-change memories exhibit a very large theoretical contrast up to five orders of magnitude, even

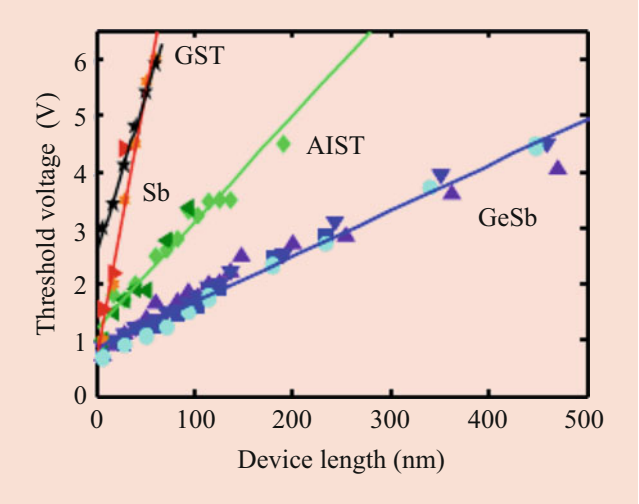

Fig. 30.13 Experimental threshold voltage vs. device length for various phase-change materials. The intersection with the *Y*-axis are attributed to the contact resistances. (Reprinted from [77], with the permission of AIP Publishing)

though, in practice, the ON/OFF ratio never exceeds two orders of magnitude due to technological constraints. In fact, from the one side, the series of the contact resistance and the circuitry resistance is higher than the resistance of the crystalline chalcogenide, thus becoming the dominant factor; from the other side, the resistivity of the amorphous phase is determined by the kinetics of the melt-quench process, yielding a different value than an as-deposited layer. A large ON/OFF ratio is a fundamental condition for designing multiple level (or multibit) cells, so that also intermediate resistances can be exploited for data storage. Moreover, the resistivity slightly increases for both phases with scaling: this is beneficial also in the reduction of the programming currents, as higher voltages drop across the chalcogenide layer and higher Joule heating is present.

Another parameter that has a strong influence on the programming currents is the threshold voltage or, more appropriately, the threshold field. Studies and theoretical models have in fact shown that the threshold voltage scales linearly with the thickness of the amorphous layer, and no deviations have been observed down to 10 nm (Fig. 30.13). The ideal value for the threshold voltage is about 1 V (corresponding to a threshold field about 10–100 MV/m), which is considerably higher than the typical reading voltage (few hundreds of mV to ensure a proper separation far beyond noise between the SET and RESET states of the $I(V)$ characteristic), sufficiently lower than the SET voltage, and compatible with the integration with an access device.

The thermal conductivity impacts the thermal response of a PCM cell to the programming conditions. In practice, the lower thermal conductivity, the lower the energy required for the RESET operation, and this is achieved by scaling rather than acting on the composition of the chalcogenide alloy [5].

Among these parameters, the crystallization speed and the melt-quenching speed are probably the most critical ones, as they define whether a material is suitable for being exploited in the PCM technology or not. In order to be competitive, PCM must be fast, with a crystallization time in the nanosecond time scale. The entire PCM technology relies on the possibility to modulate electrical pulses with *fast* or *slow* falling edges. The difference between what should be considered fast and what should be considered slow is given by the crystallization speed: pulses whose thermal effects are faster than the crystallization speed will amorphize the material, provided that a temperature higher than the melting temperature is reached, whereas slower pulses will lead to recrystallize the bit. Generally speaking, the melt-quenching speed should be at least one order of magnitude faster than the crystallization speed, which determines the achievable data transfer rate. Downscaling is beneficial for both the crystallization and the melt-quenching speed, as the transient components in the Fourier heat equation are shorter.

The elemental crystallization processes (nucleation, crystal growth, and dissociation) typically follow the Arrhenius law for activated processes. Due to activation energies in the 2–4 eV range [6], differences have been observed up to 15–20 orders of magnitude in the crystallization time between room temperature and the melting temperature. Such a large difference prevents the spontaneous recrystallization and leaves the amorphous phase unchanged for years after RESET (retention time), even though a continuous relaxation of the amorphous phase occurs leading to resistance drift. The latter is evidenced by a continuous decrease of the conductivity of the amorphous layer with time, whose effects are of null interest for single-bit cells, but can be extremely detrimental for a MLC where the information is encoded by means of intermediate and narrow resistance windows. As shown in Fig. 30.14, resistance drift is negligible in the crystalline phase. A more detailed explanation of resistance drift can be found in Chap. ▸ 40.

30.4.2 PCM Device Architectures

As reported above, the most serious concern for the PCM technology is given by the large current required for the RESET operation, whose average density has been estimated as $J_{\mathrm{RESET}} \sim 40$ MA/cm^2, which projects the energy consumption for the RESET operation at about 20 pJ/bit [79]. As shown in Fig. 30.15, with advanced prototypes of PCM obtained with carbon nanotube electrodes, it is possible to reduce the energy consumption down to ∼100 fJ/bit, and a theoretical limit as low as 100 aJ/bit has been estimated [80, 81].

The high current density required by the RESET operation is not only a challenge per se but strongly limits the compatibility with standard selector devices like FETs used in a memory array to address the single bits, unless very large transistors are used to drive the current. Alternatively, the dimensions of the phase-change volume are decreased sub-lithographically.

According to the way sub-lithographic features are implemented, PCM cell structures can be classified as [5]:

- *Contact-minimized* cells (Fig. 30.16a), where the sub-lithographic element is represented by a narrow BE, usually made of TiN, on top of which a chalcogenide layer is deposited. The reduced cross-section of the BE determines the high current density required to heat up the chalcogenide, so that the BE also acts as an external source of heat. This configuration is known also as mushroom cell, since the amorphized dome on top of the heater resembles the cap of a mushroom.
- *Volume-minimized* cells (Fig. 30.16b), where the sub-lithographic element is given by a confined chalcogenide volume. Contrarily to contact-minimized cells, the phase change in volume-minimized cells is guaranteed primarily by the power dissipated in the confined chalcogenide volume via Joule heating, so that these cells are also referred to as confined, self-heating cells.

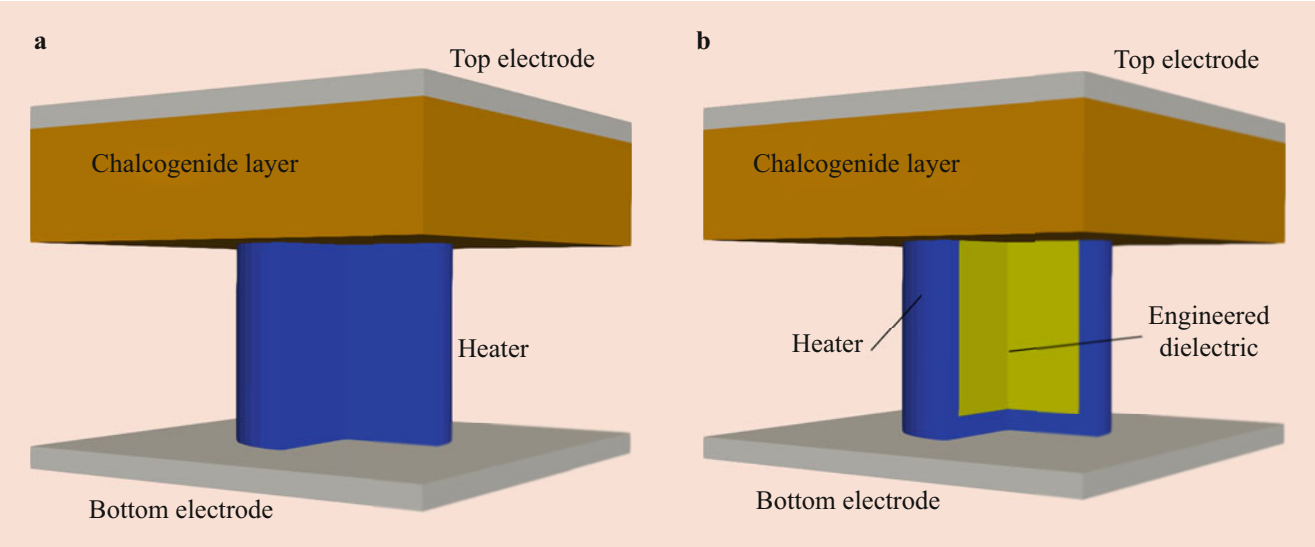

Fig. 30.17 (**a**) Matchstick and (**b**) ring architectures. A quarter of the heater has been removed to show the internal structure of the pillar; the surrounding oxide is not represented

Contact-Minimized Cells

In mushroom cells, the main thermal contribution to the phase change is generated outside the chalcogenide volume along the heater, owing to its purely resistive nature. The hottest spot has been estimated inside the chalcogenide material close to the BE, where self-heating adds to the thermal power flowing across the interface. Moreover, due to inefficient phonon scattering at the heater/chalcogenide interface, a thermal boundary resistance (TBR) also sets in, locally increasing the temperature. The presence of this additional element makes the cell more complex to manufacture and opens new challenges on the material side, as the heater must ensure good compatibility with the phase-change alloys both for mechanical adhesion and absence of cross-contamination. Furthermore, it must provide a good resistivity to induce the phase change and an endurance with cycling similar to that of the chalcogenide alloy.

The first developed PCM cell with a heater is the matchstick structure, where the heater is a simple pillar grown within a surrounding oxide, with a large chalcogenide layer on top (Fig. 30.17a). In order to engineer the heater/chalcogenide resistance and/or adhesion, or to hinder undesired species diffusion activated by the hot temperature, functionalized interfacial layers can be deposited in between.

Rather than filling the entire pillar of the matchstick structure, in the ring structure (Fig. 30.17b), the heater is made of an outer TiN layer and of an inner part filled by a dielectric material engineered to achieve the optimal thermal performance [83]. Using this architecture, an about 10% reduction of the RESET current is achieved.

The μ-trench architecture (Fig. 30.18) represents an effective alternative way to reduce the contact area [84]. Instead of depositing a planar chalcogenide on top of the heater, a dielectric layer is deposited first, and part of it is etched away in correspondence with the heater, so that the chalcogenide layer can fill the gap. The μ-trench geometry allowed an optimized RESET current about 300 μA at the 90 nm technology node. The most advanced contact-minimized PCM structure

that has been adopted so far by PCM manufacturers is the wall geometry (Fig. 30.19). In this case, an L-shaped heater connects the metallization to the chalcogenide layer on top of its thin vertical wall. With a wall structure, a RESET current of about 200 μA has been obtained at the 45-nm technology node [85].

Volume-Minimized Cells

Self-heating PCM devices rely only on the heat generated by the current flowing through the chalcogenide layer. The main advantage of this solution is given by the simplified layout, which gets rid of all the wear-out mechanisms related to the heater; however, these cells may require extremely high current densities to initiate the phase change, which always occurs in the middle of the chalcogenide layer. The maximal efficiency is pursued by means of a geometrical optimization.

The simplest volume-minimized cell is the so-called pillar structure (Fig. 30.20), where a prismatic volume of chalcogenide material is sandwiched between two metal contacts and is sealed on the sidewalls by an oxide. The high programming current (about 3 mA for a 45 nm wide chalcogenide [85]) limits the application of the pillar structure, unless a very high aspect ratio for the chalcogenide prism is considered.

In order to mitigate the impact of resistance drift and improve the reliability of the cell, preventing also void formation upon cycling, some manufacturers introduced a metallic liner to surround the chalcogenide volume [86].

A step further from the pillar structure is represented by the self-heating vertical wall structure (Fig. 30.21), where the chalcogenide material is deposited according to an L-shaped geometry, whose largest base is connected directly to the BE. The programming current can be reduced significantly by controlling the width of the chalcogenide wall. The limiting factor attaining the wall structure is the strict geometrical alignment to be achieved with a complex deposition of the chalcogenide and of the surrounding oxides.

Line and bridge cells (Fig. 30.22) are created by patterning a thin layer of chalcogenide on top of a dielectric substrate. In line cells, this layer grows wider far from the active region and is directly contacted by metal pads, whereas in bridge

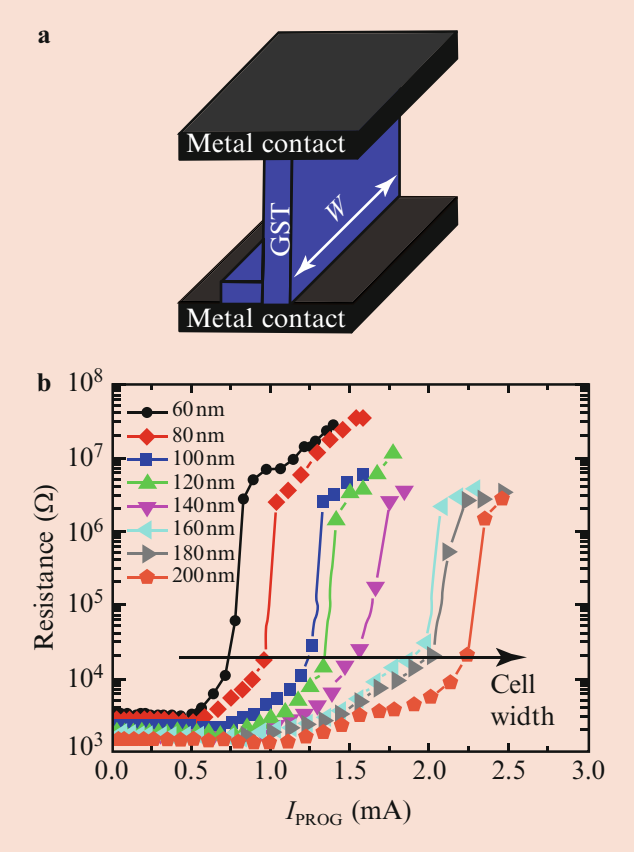

Fig. 30.21 (**a**) 3D sketch of the self-heating wall architecture and (**b**) $R(I)$ programming curves with different wall widths W. (Reprinted, with permission, from [85] © (2014) IEEE)

cells also the contacts are buried in the substrate under the chalcogenide thin layer. These cells do not allow for the creation of a dense array but are quite useful for material testing and early prototyping [85].

In Fig. 30.23 several figures of merit (high-density, efficiency, optimizations, easiness of integration, and manufacturing complexity) are pictorially evaluated in a radar plot. Self-heating cells slightly outperform heater-based solutions in terms of efficiency but introduce some manufacturing issues at the process, integration, and optimization levels. The wall structures, either self-heating or heater-based, allow for a high density due to their shape factor. The optimal trade-off is thus represented by the heater-based wall structure. On the one side, this architecture benefits from its aspect ratio, which is particularly interesting for dense packing, and on the other sides from multiple optimization knobs and a high integration level, suffering only from a limited lower efficiency and higher process complexity due to the larger number of manufacturing steps.

Cross-Point Arrays

Being two-terminal devices, PCM cells are arrangeable in cross-point arrays (i.e., arrays where orthogonal bit-lines and word-lines are created on two parallel planes, with the memory elements in between) with a footprint on the order of $4F^2$, provided that they can be addressed individually. As sketched in Fig. 30.24, even denser arrays can be reached when multiple layers are stacked on top of each other, further reducing the footprint to $4F^2/L$ where L is the number of layers considered, though this solution is limited by the wear-out connected to the necessary circuitry. In order to select single-memory cells, an access device, or selector, must be connected in series to the storage element so that, ideally, no disturb occurs in the neighboring cells when any operation (either READ, SET, or RESET) is performed on a *selected* cell. The selector acts then as a normally OFF switch, and it is temporarily activated only when its storage element in series is read or programmed. A selector must be capable to supply, in the ON state, the high current density required by the most critical programming operation, which means a current density on the order of several MA/cm^2. On the contrary, the OFF-state leakage current must be as low as possible, and a good selector should provide a very large ON/OFF current ratio, ideally as high as 10^5–10^6, though in real devices it is limited to 10^2–10^4. In order to satisfy these two constraints, the $I(V)$ characteristic of an access device should be highly non-linear with a steep rise of the current above a given voltage threshold.

Furthermore, the selector must match the voltage requirements of the memory element it is paired to. In particular, the voltage drop across *half-selected cells*, sharing the same word-line or the same bit-line with the selected cell, should always guarantee a low leakage current not to degrade the selectivity of the access device. The threshold voltage of the selector has to be stable and repeatable to minimize cell-to-cell variability and noise effects. Usually, this is achieved by finding a selector whose resistivity is much higher than the memory resistivity in the RESET state. Furthermore, the selector threshold voltage should also be sufficiently higher than the switching voltage of the partner memory and with a small stability window on the order of 0.3 V or less. It is also important that the holding condition, that defines the minimum current and/or bias to sustain the ON state, be significantly lower than the operation condition, in order to avoid undesired oscillations between the ON and the OFF states.

Finally, the access device should not limit the memory performance, i.e., the properties of the selector should outperform those of the companion memory cell in terms of switching speed, cycling endurance, and reliability.

As reported in [4], several memory-cell selectors have been tested to be paired to PCM cells. As it regards conventional devices, such as diodes or transistors, the large RESET current density points at diodes/BJTs or large-sized MOSFETs. The latter makes integration quite challenging due to the huge dimensions of the access device with respect to the small storage elements, nearly preventing dense arrays.

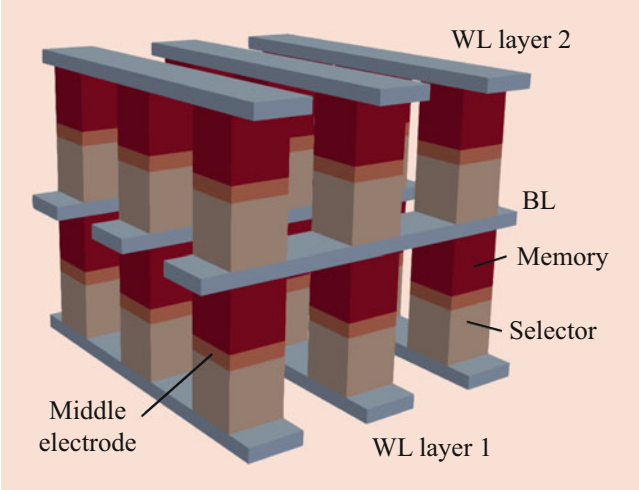

Fig. 30.24 Schematic of a cross-point array with two layers stacked one on top of the other. Each cell is composed of a selector and a partner memory, separated by a metal line to prevent the interdiffusion of the chalcogenide alloys

New configurations and new materials have been investigated to increase the bit density. Among them, Ovonic materials can be tailored to match many of the requirements above (Table 30.3), and in the last 10 years, they have intensively been studied as the most promising candidate for pairing a PCM device, after Intel revealed the integration of an OTS access device on top of a PCM cell in a stackable cross-point architecture [24]. In 2015 Micron and Intel jointly announced their 3D XPoint™ memory, a cross-point array with a vertically stacked double layer of GST-based PCM cells and As-doped Se-Ge-Si OTS selectors [26], and a similar announcement was made also by SKHynix 3 years later [87].

When an OTS selector is connected in series to a PCM, the two $I(V)$ characteristics merge. In Fig. 30.25, these $I(V)$ curves are reported when the PCM is either in the SET or

in the RESET state. When the PCM is in the SET state, the threshold voltage $V_{th,S}$ is close to the OTS threshold voltage, since the PCM is merely a low loading resistance; on the contrary, with the PCM in the RESET state, the overall threshold voltage $V_{th,R}$ is significantly higher than the OTS threshold voltage alone, as the voltage drop across the PCM must be sufficient *per se* to turn the memory to its ON state. By applying a voltage pulse between $V_{th,S}$ and $V_{th,R}$, the selector is always in the low-resistance state, and the PCM state is thus read; pulses larger than $V_{th,R}$ are instead used for programming the PCM. In practice, in order to prevent disturbances, the OTS material should be engineered to have a threshold voltage higher than half of the voltage required by the RESET operation, including the variability window of the threshold voltage itself.

The interested reader can find a comprehensive review about access devices, their figures of merit, and requirements in [89] and on the state of the art of cross-point PCM arrays in [88, 90].

Table 30.3 Main properties of a few cutting-edge selectors for PCM cross-point arrays

	OTS	MIEC	Doped α-Si
Material	AsTeGeSiN	Cu-based	As-SiO_2

30.5 Reliability and Perspectives

30.5.1 PCM Reliability

The superior performances of PCM devices in terms of speed and scalability reviewed in Sect. 30.4.1 must be accompanied by a high degree of reliability. Reliability primarily depends on the inherent instability of the amorphous phase, which spontaneously tends to recrystallize, and on the changes in the local alloy composition over time owing to component segregation induced by the electric field or temperature. Failure mechanisms can be classified according to the usage specifications that are impacted: data retention, read disturb, and thermal disturb, all connected to the nature of the amorphous phase, and cycling endurance, linked instead to the local composition and to the response of the whole device.

Data Retention

A data retention failure may occur when the resistance of a programmed bit shifts with time and affects only the RESET state, since the SET state is thermodynamically stable. After being programmed, the resistance of the cell initially increases with time (resistance drift), then, when spontaneous recrystallization begins, it progressively drops to low values. When the threshold that separates the SET and RESET states is crossed, the information is lost. While resistance drift is a concern only for phase-change MLCs, recrystallization is observed sooner or later for all chalcogenide alloys and impacts all kind of devices. The typical criterion adopted for data retention requires fewer than 1 ppb failures at the array

level after 10 years at 85 °C, independently of the previous stress history [5].

Data retention is strictly connected to the write speed, since both of them involve the crystallization process and its activation energy. To achieve a low write latency, the alloy must be able to crystallize in hundreds of nanoseconds when heated above the crystallization temperature; on the opposite side, crystallization must not occur in years at the operation temperature. In general, a high activation energy is a key property to ensure a good data retention over time, as long as it allows a fast SET operation within technologically-compliant temperatures.

To estimate the data retention capability, measurements are typically performed at multiple high temperatures (>150 °C), and data are fairly well extrapolated at lower temperatures assuming a reasonable Arrhenius activation model (Fig. 30.26). Pirovano et al. [91] measured in GST-225 samples a halving of the cell resistance in 10^2–10^4 s for temperatures ranging between 150 °C and 200 °C, with an activation energy about 2.6 eV. This leads to a data retention longer than 10 years for temperatures below 110 °C.

Repeated measurements on the same cell result in a large distribution of retention times according to a Weibull distribution [93], and the same occurs also across an array of cells. These evidences demonstrate the existence of a dominating stochastic component to crystallization. Redaelli et al. [93–95] interpreted the loss of data retention by means of a percolation model, where crystalline grains are stochastically nucleated in the amorphous dome and grow, until a percolation path finally crosses the whole amorphous dome, thus dramatically reducing the overall device resistance (Fig. 30.27).

Gleixner et al. [96] also observed an early failure of a tiny fraction of bits, irrespectively of the applied stress condition; this behavior was attributed to an insufficient RESET operation by which some of the nucleation sites require a limited growth to induce the resistance drop.

Cycling Endurance

Cycling endurance has long been recognized as one of the strengths of PCM devices, as from early studies on single cells, 10^{12} cycles have been demonstrated without a significant degradation of the resistance contrast [97]. Pirovano et al. [91] compared the endurance of a single optimized cell to the statistical behavior at the array level on a large dataset, finding that even at $\pm 4\sigma$ a sufficient separation between SET and RESET is still present after 10^6 cycles (Fig. 30.28). Cycling issues are common to both PCM cells and OTS selectors.

Two different failure modes have been observed: the *stuck-set* and the *stuck-reset*. In the former case, the RESET pulse is progressively less effective in amorphizing the chalcogenide layer until it fails to induce the resistance change, and the memory is left in the SET state; in the latter case, instead, the resistance remains very high, irrespectively of the SET pulse due to permanent local damages at the chalcogenide-electrode interface, like void formation and delamination.

In order to understand the degradation induced by cycling, it must be recalled that the PCM operation exposes the chalcogenide alloy at relatively high temperatures under the influence of high current densities. Both these two conditions favor atomic mobility and electromigration. Experiments

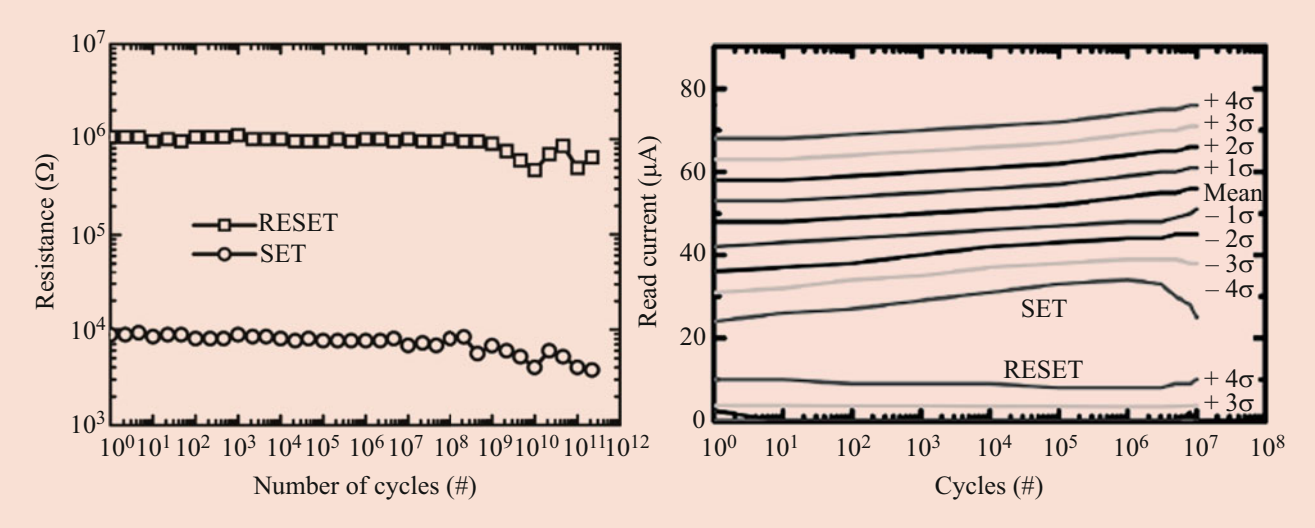

Fig. 30.28 Cycling endurance for the SET and RESET states and associated statistical distribution of the READ current at the array level. (Reprinted, with permission, from [91] © (2004) IEEE)

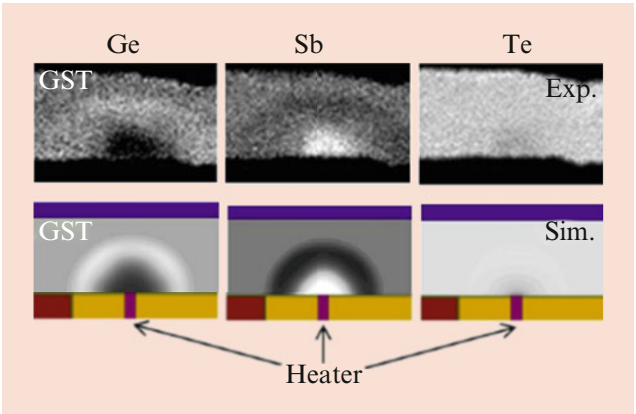

Fig. 30.29 Experimental and simulated concentrations of Ge, Sb and Te after a trapezoidal pulse with a falling edge about 1 μs on the central cut plane for a 45-nm wall cell. (Reprinted, with permission, from [99] © (2013) IEEE)

performed on test line cells showed that, once the molten state is reached, Te takes the form of an anion, and Sb and Ge that of a cation, moving in opposite directions [98]. Energy dispersive X-ray spectroscopy (EDX) analyses and electromigration simulations in a 45-nm wall cell evidenced Sb-richer and Ge-depleted volume in the cell core and a nearly invariant Te concentration (Fig. 30.29) [99]. This form of compositional segregation limits the ability of amorphizing the programmed region, and the cell is finally left stuck-set. On the other side, material depletion induced by temperature-accelerated, current-driven elemental migration results in void formation or delamination of the chalcogenide-electrode interface, and the cell becomes stuck-reset. Endurance measurements have found that the endurance increases when the time spent for melting is shortened [100].

To expand the life cycle of a PCM device, several protocols have been proposed to heal, either thermally or electrically, the damage produced by write cycling before reaching an irreversible condition. These protocols detect the accumulation of the damage by, e.g., monitoring a shift to higher values of the programming characteristic; after a given threshold value is crossed, a recovery operation is activated in order to bring the device back to its pristine state [101].

Read Disturb

The read disturb consists in an undesired recrystallization accelerated by the current flowing in the cell during READ pulses. It does not represent a severe issue for the PCM technology, as it can be controlled by modulating the READ current. As a matter of fact, READ operations, in general, are not able to increase significantly and uniformly the overall temperature of the cell and induce the phase change. However, Pirovano et al. [91] hypothesized that extremely confined local heating may occur, and in those portions of the amorphous dome the crystallization rates are larger than expected. Thus, there is a small, but non-negligible crystallization probability, whose magnitude depends on the time spent for reading. Since the READ pulse is fast, the event of crystallization during reading is unlikely, but sometimes it may happen. It is clear that a single event in a very confined volume would not appreciably alter the overall resistance of the amorphous dome, and it does not constitute any concern. However, multiple READs on the same cell without an intermediate programming pulse increase the possibility of local recrystallizations, as the cumulative time spent under biased conditions is much longer, and eventually the cell may fail (Fig. 30.30). The operating temperature may further accelerate the process.

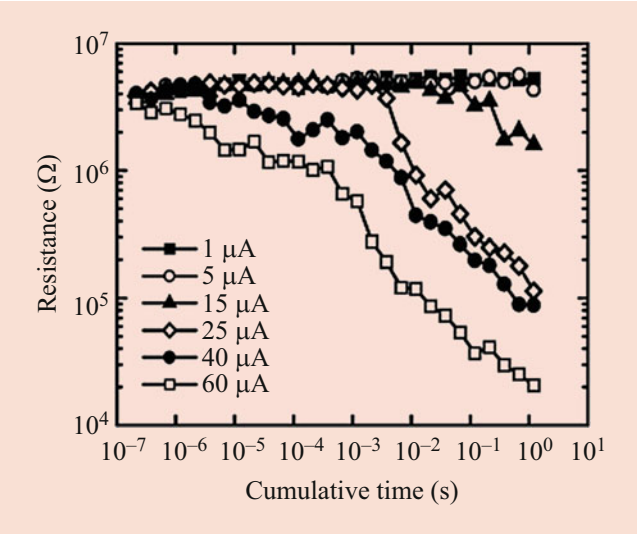

Fig. 30.30 Resistance decrease as a function of the cumulative time spent in the HRS after the last RESET operation. (Reprinted, with permission, from [91] © (2004) IEEE)

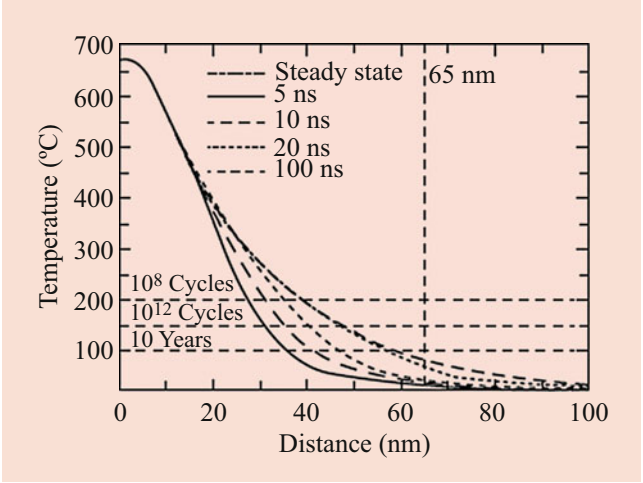

Fig. 30.31 Temperature profile during RESET as a function of distance and time for a μ-trench cell at the 65-nm node. The horizontal lines are the target conditions for the victim cell. (Reprinted, with permission, from [92] © (2003) IEEE)

The impact of the current on the read disturb can be assessed by suitable models combining carrier transport and stochastic crystallization. Given a PCM lifetime of about 10 years, and a reading pulse of about 100 ns, if a write-once single cell were continuously read over its lifetime, about 10^{15} cycles are counted. If reading were instead performed serially throughout all cells of an array, that number is greatly reduced to 10^4 cycles for Gbit arrays. In a typical write-once scenario (e.g., in automotive applications), where only few cells of the array are stressed by repeated READs, an intermediate result is obtained, and a lower limit of about 10^{10} cycles before failure is targeted at the memory design stage. Starting from this constraint, it is possible to estimate as about 1 μA the maximum reading current that can safely be applied during READ operations to prevent read disturbs.

Thermal Disturb

As reported in Sect. 30.3.2, during a RESET pulse, a very high peak temperature is reached and a side effect is the heating of the surrounding cells or thermal cross-talk. If this Joule heating is sufficient to give origin to an unwanted SET operation in one of the neighboring cells, a thermal disturb (also known as proximity disturb or programming disturb) occurs. The programmed cell is often referred to as the aggressor, and the disturbed cells are identified as victims. As for the case of the read disturb, the probability of inducing a recrystallization in a victim cell depends on the programming pattern of the aggressor and on the cumulative time spent under thermal stress. Under the likely condition that one aggressor cell is normally programmed a few percent of its endurance cycle before the victim is refreshed, it is possible to target that one victim cell should survive about 10^6 cumulative write cycles of its aggressors.

The impact of the thermal disturb is usually assessed by means of thermal simulations [92], combined with data-retention experiments. As shown in Fig. 30.31, thermal cross-talk in μ-trench cells undergoes a quick decline with distance from the aggressor cell and is low enough not to constitute a significant concern for recrystallization at the 65-nm node. Furthermore, Russo et al. [102] found that isotropic scaling (i.e., preserving the aspect ratio of the PCM cell) has no impact on the victim cell, but the temperature profile would be significantly different if only the lateral dimension is scaled down. Nevertheless, an aggressive scaling is not fully compatible with contact-minimized geometries, where a unique chalcogenide layer is deposited on top of multiple heaters: since the amorphous dome must always be larger than the heater, the inter-cell spacing cannot be reduced proportionally, increasing the risk of thermal cross-talk. On the contrary, volume-minimized cells benefit from scaling and mostly from the presence of the confining oxides separating neighboring cells. The TBRs at the interfaces, in fact, have the effect of cutting the thermal flow and do not reduce with scaling, minimizing the risk of thermal disturb.

Thermal cross-talk is probably a minor concern in a single-level PCM but can have a more pronounced effect in MLCs. The conduction in the amorphous phase is largely attributed to the presence of defective states within the mobility gap, whose annihilation with time is a thermally activated process. A temperature profile that is not a concern for recrystallization can however accelerate the annihilation of these defective states [103], enlarging the mobility gap due to structural relaxation, thus enhancing the resistance

drift, reducing the reliability of intermediate-resistance level and, eventually, leading to data loss.

30.5.2 Performance Improvements and Perspectives

The high potential of the PCM technology has been recognized for many years but is still jeopardized by the correlations existing between material properties, speed, performances, and reliability issues. By way of example, a material offering a high crystallization temperature leads to a better thermal stability and longer data retention but also to slower and more energy-demanding devices [82]. Depending on the application, engineers focus on one aspect or another: in SCM, where a high number of writing cycles is expected, a large cycling endurance is preferable, rather than thermal stability and longer data retention, which are instead key requirements for embedded PCM to maintain stored data after soldering. Since chalcogenides can be tailored to match specific technological needs, acting on materials and compositions is the primary source for PCM optimization.

Stoichiometric alloys like GST-225 suffer from important technological limitations due to the high RESET currents and to a low crystallization temperature that brings in a limited data retention at moderately high temperature. Many efforts have been made to improve the performances of these alloys by N or C doping, by Ge enrichment, and by considering new compositions along different tie lines [104]. Doping with light elements like C or N extends the thermal stability range and allows one to meet the specifications required by automotive applications (10 years retention at 150 °C), at the price of slowing down the switching speed. However, the achieved improvement is still insufficient for the soldering step, whose target is set to 2 min at 260 °C. Ge-rich alloys further extend the thermal stability of programmed states, and Sb ensures a very fast switching speed, but a limited endurance is reported for non-stoichiometric compositions due to a larger phase segregation that can be stabilized by N doping [105]. The performance achieved by the standard GST-225 alloy, the so-called golden composition (GST-212 with increased Ge concentration along a second tie-line between Ge and Sb_2Te_3) [104], and variants of the golden compositions obtained by N incorporation and Ge enrichment [106] are summarized in Table 30.4.

The reduction of the RESET current is often pursued by the optimization of the PCM cell design, aiming at a better thermal efficiency and a more efficient Joule heating. It has been estimated that in non-optimized cells up to 99% of the energy is inefficiently spent in heating oxides and metal lines, which can also increase the thermal cross-talk between neighboring cells. Two approaches to decrease the RESET current by maximizing the thermal efficiency have been proposed. On the one side, carbon nanotubes and graphene sheets have been tested as contacts [80, 107] or as thermal confining materials [108] for the minimization of the thermal budget owing to their strong non-isotropic thermal conductivity. On the other side, multilayer dielectric stacks, with a lower thermal conductivity (also alternated to air gaps), can replace the confining dielectric [109].

A completely different approach to PCM technology is provided by interfacial PCM (iPCM), which are a superlattice phase-change material stack formed by two alternating crystalline layers of different composition [110, 111]. A typical example is obtained for the $[(GeTe)_x(Sb_2Te_3)_y]_n$ alloys by aligning the ⟨111⟩ direction of a cubic GeTe layer on top of the c-axis of a hexagonal Ge_2Sb_3 layer. According to Tominaga et al. [112], iPCM switch between the HRS and LRS without melting, but with a short-range movement of some atoms, which flip between two configurations corresponding to the SET and the RESET states. The resistance contrast of an iPCM is comparable to that of a conventional PCM up to 10^6 cycles, but the programming currents are roughly halved, and about a 40% reduction of the average power consumption is achievable under standard usage conditions.

One more development direction deals with increasing the storage density, which is pursued in NVM in general by creating a 3D stacking as in cross-point architectures, or by exploiting the large resistance contrast with the implementation of the multi-level storage. As we have warned earlier in this chapter, resistance drift is the strongest challenge for MLC. In order to cope with it, besides taking into account the broadening of each resistance window with time, new sensing schemes making use of ramped READ pulses and evaluating the time required to reach some current reference values have been proposed [113]. An alternative strategy

Table 30.4 Material properties (crystallization temperature, RESET current, crystallization time needed to complete 90% of the transformation, and SET speed) for different compositions

Material	T_x (°C)	I_{reset} (μA)	Recryst. time (ns)	SET speed (ns)
GST-225	150	>400	55	<80
Golden composition (G-c)	253	≥150	200	80
Ge-rich G-c	295	100–150	560	80
N-doped Ge-rich G-c	316	100–150	1750	80
Enhanced N-doped Ge-rich G-c	413	50–100	3115	160–240

Reprinted, with permission, from [106] © (2012) IEEE

considers tailoring the chalcogenide layer. It has in fact been observed that Ge enrichment increases drift, but this effect is largely counterbalanced by the addition of dopants like N that contribute to form stable Ge-N bonds, as for the materials in the last two lines of Table 30.4. By tailoring the chalcogenide composition, a demonstrator with a material featuring a wider memory window and manageable resistance drift has been proposed also for MLC SCM applications [114].

In conclusion, as a consequence of great technological hopes, a lot of work on chalcogenide materials, PCM, and OTS devices was made in the last couple of decades. Following the Gartner hype cycle [115], the peak of inflated expectations was reached in the early 2000s, but, after that, disillusionment prevailed, as many difficulties about integration, performances, retention, and reliability quickly arose. Nevertheless, the interest of the semiconductor industry did not decline, and a deeper knowledge on PCM and OTS devices was recently achieved, renewing the interest back again. The present status of the technology, as well as promising projects sponsored jointly by academia, research centers, and the most important semiconductor companies, bodes well for reaching the plateau of productivity in the near future.

Abstract

Scaling of semiconductor devices is the main driving force behind an outstanding performance increase of modern integrated circuits. However, it is apparent that transistor scaling shows signs of saturation, and an introduction of new solutions for energy-efficient computation becomes paramount.

The electron spin offers additional functionality to digital switches based on field-effect transistors. SpinFETs and SpinMOSFETs are promising devices, with nonvolatility introduced through the relative magnetization orientation between the ferromagnetic source and drain. Although several fundamental problems including spin injection from metal ferromagnets to a semiconductor, spin propagation and relaxation, as well as spin manipulation by the gate voltage were successfully demonstrated, increasing the magnetoresistance ratio as well as achieving efficient spin control represent the challenges to be resolved.

Magnetic tunnel junctions are perfectly suited as key elements of nonvolatile CMOS-compatible magnetoresistive memory. Purely electrically addressable spin-transfer torque and spin-orbit torque magnetoresistive memories are superior compared to flash memories and will compete with DRAM and SRAM. MRAM possesses a simple structure, long retention time, high endurance, and fast operation speed. In addition, a combination of nonvolatile elements with CMOS devices allows to bring close or to even shift data processing capabilities into the nonvolatile segment. This paves the way for a new low-power and high-performance computing paradigm based on logic-in-memory and in-memory computing architectures, where the same nonvolatile elements are used to store and to process the information.

31.1 Introduction

31.1.1 MOSFETs: Recent Developments

Continuous miniaturization of metal-oxide-semiconductor field-effect transistors (MOSFETs) is one of the main drivers behind the recent tremendous increase in speed, performance, density, and complexity of modern integrated digital circuits. Although the name MOSFET was not modified since its invention until now, the transistor structure has become dramatically more complex. Numerous outstanding technological challenges have been resolved on the exciting journey of continuous transistor downscaling. The main challenge with transistor dimensions' reductions is to preserve a good electrostatic channel control by the gate to guarantee steep switching between the open (on) and closed (off) transistor states with several orders of magnitude current difference.

Modern MOSFETs feature channel strain as a mobility booster, which allows improving the on-current while maintaining other characteristics including the off-current unchanged. Strain first introduced in 2003 for the 90 nm technology node [1] is currently routinely delivered to the channel by appropriately engineering the capping layers and/or replacing silicon in the source and drain extensions with a material with larger (smaller) lattice constant, which stresses the channel compressively (tensely). As donor n- or acceptor p-doped silicon channels require tensile or compressive strain to boost the carrier mobility, in modern complimentary metal-oxide-semiconductor (CMOS), technology strain is independently delivered to each transistor. To boost the mobility in n-silicon channels, tensile capping materials are used, while in p-channels compressive capping layers are complemented by epitaxially regrown SiGe source and drain [1].

To continue shrinking the CMOS technology to the 45 nm technology node, the traditional SiO_2 gate oxide had to be replaced with a high permittivity (high-k) dielectric [2]. Since this replacement has required a major modification in the gate stack process technology, it also demanded the replacement of heavily doped silicon by a metal to negate the depletion length in the gate. These replacements have allowed to enhance the electrostatic channel control by reducing the effective dielectric thickness while maintaining the physical oxide thickness sufficiently large to inhibit parasitic tunneling leakage currents. However, to proceed to the 22 nm technology node and beyond, a new architecture of three-dimensional tri-gate transistors has been introduced [3]. By making the fins higher and thinner, this technology combined with strain techniques and high-k dielectrics/metal gates allows continuing the scaling down to 14 nm [4] and 10 nm [5] feature size and offers great performance and power advantages over planar structures. Combining the technology with pitch splitting, self-aligned patterning, and EUV lithography, the device miniaturization is continuing its pace down to 7 nm feature size.

To proceed with scaling to the 5 nm technology node, an introduction of a new channel material with improved characteristics, such as strained SiGe [6] for p-MOSFETs or III-V materials [7], is foreseen. To further improve the channel control, gate-all-around devices are considered. In order to sustain the high on-current through the transistor, the channel in such devices contains several nanosheets surrounded by the gate. The introduction of new materials with higher mobility combined with the gate-all-around nanosheet architecture for improved electrostatic control will potentially allow to proceed with scaling at the 5 nm technology node and beyond [8].

Although single devices with gate length as short as a few nanometers, which is close to what is believed to be an ultimate limit, were demonstrated [9] long ago, fabrication, control, integration, and reliability issues will slowly lead to unbearable hurdles. Growing critical technological challenges and soaring costs will gradually bring the CMOS scaling to a saturation. Another important limitation for transistor scaling is related to the heat generation. Even though the transistor size is scaled down, the load capacitance per unit area of a circuit stops decreasing. This suggests that the on-current must increase to boost the operation speed or stay the same to guarantee the same high clock frequency.

However, in ultra-scaled MOSFETs the current is close to ballistic and is determined by the number of transversal propagating modes in the channel, so that the channel conductance ceases to depend on the channel length. It then follows that with the transistor scaling the supply voltage must remain the same to maintain the same current through a transistor regardless of its channel length. This results in an approximately constant power dissipation of a single MOSFET. The generated heat increases rapidly with increased transistor size, which puts clearly foreseeable limitations to the continuation of the increase in the performance of integrated circuits, and research for finding alternative technologies and computational principles becomes urgently important.

Carriers in graphene are characterized by a mobility which can exceed silicon mobility by an order of magnitude [10], making this material very attractive for future electronic device applications. However, Dirac fermions do not possess a gap and can be transmitted through a classically forbidden region without any reflection. Therefore, applying a gate bias, which would normally switch off a traditional MOSFET, does not stop the current flow through a graphene sheet. A high on-off current ratio can be obtained, if the graphene sheet is used as a base of a bipolar-like transistor [11], albeit advantages steaming from the high graphene carrier mobility are not used. Nanoribbons may open a gap in

the Dirac spectrum, thus making reflection from a forbidden region possible [12]. However, in order to avoid strong edge roughness scattering [13], the edges of nanoribbons must be atomistically perfect, which makes the practical use of nanoribbons at the current technology level development hypothetical.

Recently, a single layer of molybdenum disulfide MoS_2, a purely two-dimensional material, has attracted interest [14]. In contrast to graphene, this is a direct gap semiconductor and is thus suitable for making a MOSFET. However, both electron and hole mobilities are limited by the carriers' interaction with homopolar phonons [15, 16]. It remains to be seen, if the electron mobility and current in this material can be sufficiently boosted [17] to make it competitive with CMOS.

Inspired by the continuing efforts in graphene and transition metal dichalcogenide monolayer devices, a search for novel two-dimensional monolayer semiconductors has intensified. Potentially, atomically thin-layered semiconductors free from dangling bonds possess excellent electronic properties and are suitable for the ultimate transistor scaling. Although a large number of two-dimensional semiconductors have been discovered and explored [18], they still suffer from reproducibility and scalability due to the lack of large-scale synthetic processes. At the moment, the best performing transistors reported are merely comparable to standard silicon devices as the performance of the current two-dimensional semiconductor transistors is compromised by defects at their interfaces or contacts [18].

31.1.2 Electron Spin as a Complement to Charge

The principle of MOSFET operation is fundamentally based on the charge degree of freedom of an electron. The electron charge interacts with the gate-induced electrostatic field. The gate potential can open or close the transistor by creating a potential barrier. However, it is well known that the electron possesses another intrinsic degree of freedom, namely, the electron spin. As the downscaling of charge-based CMOS devices is approaching its saturation, the electron spin attracts at present much attention as a possible candidate for complementing or even replacing the charge degree of freedom in future microelectronic devices [19–28]. Indeed, the electron spin state is characterized by one of the two possible spin projections on a given axis, a property which could be potentially used in digital electronics for information processing. In order to switch between the two aligned spin states, an amazingly small amount of energy is required, which is very attractive for low-power applications.

The electron spin may be pointing not only up or down along a certain axis. As a quantum mechanical property, spin can point at any direction on a unit Bloch sphere. The electron spin offers the whole Bloch sphere of states to process and store information by initializing, manipulating, and detecting the spin orientation. As the electron spin is a purely quantum mechanical property, the set of states on a Bloch sphere is termed a quantum bit, or a qubit, as opposed to a bit of classical, binary information. A computer using qubits for information processing is named a quantum computer. Due to their intrinsically quantum mechanical nature, qubits could form an entangled state. This state cannot be represented as a direct product of independent qubits, wherein a single qubit state is entangled with other qubits and thus cannot be described independently. Qubits' entanglement generates intrinsically quantum correlations between the qubits, which go beyond classical correlations and even cannot be described at a classical level.

Single-electron spin systems in semiconductors can be broadly classified into two large categories: atomic impurities [29] and spins in quantum dots [30]. A quantum computer consisting of interacting qubits potentially offers an advantage over traditional digital computers in resolving certain computationally involved tasks. A quantum computation scheme utilizing spins of electrons in quantum dots [31] was suggested almost simultaneously with a quantum-mechanical computer employing the nuclear spins of donors in silicon [32]. A review of group IV semiconductors' proposals for quantum computation is given in [33]. Carriers in quantum dots are strongly confined in all three spatial directions. If the confinement potential possesses a symmetry, the degenerate energy levels in quantum dots, like in real atoms, form shells. For this reason, the electron system in a quantum dot is often called an artificial atom. Properties of artificial atoms can be tailored by adjusting confinement so that the number of particles in a dot and the total spin can be controlled [34]. Single-atom qubits [29] offer a spin lifetime of several seconds [35] to 30s [36]. The single-atom technology was recently shown to have a potential toward large-scale quantum computers as it allows growing three-dimensional silicon quantum chips, in which precise interlayer alignment and highly accurate measurement of spin states are achieved [37]. A successful implementation of a quantum computer based on spins requires the possibility of efficient spin initiation, coherent manipulation, and reliable readout. An unprecedented advantage in these fields has been achieved [38, 39]. With two-qubit operation [40] a processor performing quantum algorithms [41] has already been successfully demonstrated; a pressing challenge is now to proceed to a larger computational network.

Silicon predominantly consists of ^{28}Si nuclei with zero magnetic spin, with a few percent admixture of magnetic ^{29}Si nuclei. In isotopically purified silicon cleaned from the magnetic isotope ^{29}Si, the dephasing of donors' electron spins is significantly reduced [42], resulting in a coherence time

of about 10 s at $T = 1.8$ K. Thanks to its unique properties for spin applications, silicon, the main material of modern microelectronics, is promising for spin-driven devices. Compatibility of spin-based devices with charge-based silicon CMOS technology would greatly facilitate their integration on the same chip. However, at least at the current level of the technological development, this integration requires the capability of room temperature operation, which at the moment excludes the use of quantum-mechanical properties of localized electron spins in silicon due to fast dephasing, causing the loss of quantum information at (sub)nanosecond scale before a quantum gate operation is performed.

More promising for room temperature quantum bit storage are the nuclear spins of the ionized shallow donors in purified ^{28}Si, because they display an unprecedentedly long spin coherence time close to 40 min [43]. This considerably exceeds the coherence time of two seconds demonstrated at room temperature in a quantum bit consisting of a single ^{13}C nuclei/nitrogen vacancy in an isotopically purified diamond crystal [44]. Spins of impurities in solids combined with nearby nuclear spins in the lattice form a quantum register [45]. Coherent coupling of the registers with photons results in high-fidelity state initialization, manipulation, and readout, yields long retention quantum memory, and allows long-distance transmission of quantum information [45]. These important ingredients institute impurity spins as unique building blocks for realizing quantum networks at room temperature. However, the technology also requires a controllable creation of high-density near-surface defects with given charge state and long-living spin state, which represents a significant challenge for modern semiconductor technology.

There exists yet another opportunity to employ the electron spin in digital electronics. The relaxation time for non-equilibrium spins of conducting electrons toward its equilibrium value is in the range of nanoseconds in undoped bulk silicon [46, 47]. As the corresponding spin diffusion length is in the micrometer range, the spin of conducting electrons can be used to encode, transfer, and process information. In this case, the electron spin degree of freedom is employed in its binary mode, as the information is stored as a positive or negative spin projection on a given axis usually defined by a ferromagnetic electrode's magnetization direction. As the spin does not interact with the electric field and diffuses from the spin accumulation region regardless of the electric field applied, transferring the spin information does not in general require any charge current to flow, although spins belong to the electrons which are of course the charged particles. The ability to decouple spin from charge and to generate pure spin currents makes the spin degree of freedom potentially promising for low-power digital applications.

Novel microelectronic devices have to be smaller and faster than the traditional ones and be more efficient, in order to reduce the power consumption of future integrated electronic circuits. Because the scaling of conventional MOSFETs is rapidly approaching its fundamental limits, new engineering solutions have to be introduced. Utilizing spin properties of electrons opens a great opportunity to design devices with superior characteristics which cannot be achieved with the present transistor technology.

An attractive path to mitigate the unfavorable trend of increasing power at standby is to introduce nonvolatility in the circuits. The development of an electrically addressable nonvolatile element, which combines fast operation, simple structure, and high endurance, is essential to mitigate the increase of the standby power and the power needed for data refreshment. Nonvolatile elements also enable instant-on architectures without the need of data initialization when going from the standby to an operation regime.

The spin field-effect transistor (SpinFET) [19] is a switch which employs the spin properties of electrons. The SpinFET is composed of a semiconductor channel region sandwiched between the two ferromagnetic contacts, source and drain. The source contact injects spin-polarized electrons in the semiconductor region. The gate voltage-dependent spin-orbit interaction in the channel is used to modulate the current through the SpinFET. It causes the electron spin to precess during the electron propagation through the channel. Only the electrons with their spin aligned to the drain contact's magnetization can leave the channel through the drain contact, thus contributing to the current. The spin-orbit interaction is controlled electrically by applying an external gate voltage.

In this chapter, we briefly review first the current status of spin-based digital switches including the recently demonstrated SpinFET and the SpinMOSFET, and we outline the exciting challenges still preventing the spin-based switches from entering mass production. Thereafter we document the present status in spin-based purely electrically addressable nonvolatile magnetoresistive memories, which are proven to be competitive with flash memory and possess a considerable potential to enter the dynamic and static RAM markets. We conclude the review with an outlook focusing on nonvolatile logic architectures.

31.2 Spin-Based Switches for Digital Applications

The idea of using spin to complement or even to replace the charge degree of freedom in digital computing was around for more than three decades. However, even a proof-of-concept demonstration of basic elements necessary for digital spin-related applications, such as injection of spin-polarized currents in a semiconductor, spin transport, spin manipulation by electric field, and spin detection, was extremely challenging. Conceptual and technological difficulties to inject spin-

polarized electrons in silicon were preventing researchers from studying spin propagation in silicon. One of the reasons is that, contrary to III-V semiconductors, silicon is an indirect gap semiconductor. Therefore, techniques based on optical excitations with the absorption/emission of circularly polarized photons used to introduce spins in, for example, GaAs, cannot be applied [46, 47].

Although it seems that injecting spin-polarized carriers from a ferromagnetic contact into silicon bypassing the current is straightforward, non-equilibrium spin accumulation was not seen in earlier attempts. The reason was understood just relatively recently [48]. It appears that all known ferromagnets at room temperature are metals. Due to a fundamental spin conductivity mismatch [48] between the ferromagnetic metal contact and the semiconductor, no spin accumulation is dynamically injected in the semiconductor, when the electric current runs from the ferromagnetic metal into the semiconductor. Even though there is a large difference in the densities of states between the spin-up and spin-down electrons in the metal, the density of states in silicon for either spin projection is still much lower than that for the minority spin in the metal. As silicon is a nonmagnetic semiconductor, the densities of states for spin-up and spin-down electrons are equal. Then, when the current runs through the interface between a ferromagnetic metal electrode and a semiconductor, the supply of both spin-up and spin-down electrons into semiconductor is overwhelmingly high so that both spin-up and spin-down channels are fully and therefore equally populated (Fig. 31.1a). It results in a total zero dynamically injected spin accumulation in silicon.

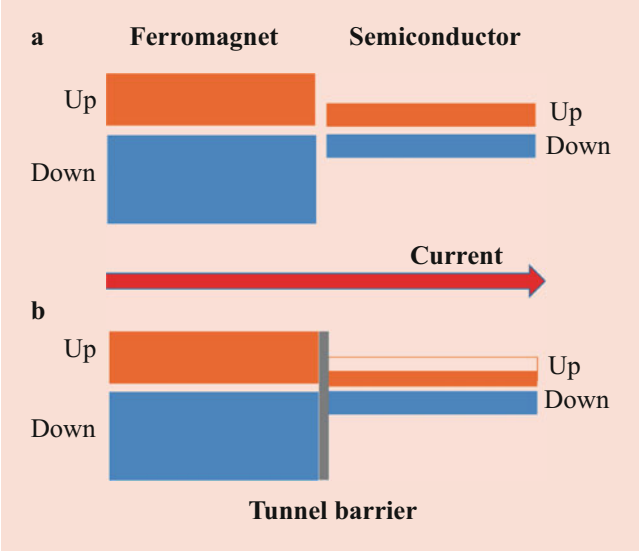

Fig. 31.1 Electric current-induced dynamic spin injection from a ferromagnetic metal into a semiconductor. (**a**) Regardless of a large difference in the density of states between the spin up/down electrons, both spin up/down channels in the semiconductor are equally populated due to their much smaller densities of states. It illustrates the spin impedance mismatch between a ferromagnetic metal and a semiconductor. (**b**) The introduction of the tunneling barrier reduces the electron flow, so that the spin channels in the semiconductor are proportionally populated resulting in a spin accumulation

31.2.1 Electric Spin Injection into Semiconductors

The problem of reliably injecting spins into silicon by electrical means was long without solution. Indeed, to resolve it, one employs either a ferromagnetic semiconductor or a half-metallic ferromagnet to inject spins. Although ferromagnetic semiconductors are known, their Curie temperature is around 100 K [49, 50], well below room temperature. Half-metallic ferromagnets are promising, because they contain only one spin polarization as the density of states for the minority spins at the Fermi level is zero. They are therefore characterized with maximal spin polarization. However, the interface between the half-metallic ferromagnet and a semiconductor is not well understood and not controlled, so typically the high spin current polarization impinging from the half-metal is lost [51] presumably at the interface due to intensive spin-flip events.

A different approach was adapted in [52]. A special technique based on hot-electron injection and a simultaneous attenuation of spins antiparallel to the magnetization of the ferromagnetic film allowed creating an imbalance between the electrons with spin-up and spin-down in silicon, thus injecting spin-polarized current. The spin-coherent transport through the device was studied by applying an external magnetic field which causes a precession of the spins during their propagation in silicon from source to drain. The detection is performed with a similar hot-electron spin filter. Therefore, the drain currents are small due to the carriers' attenuation in the source and drain filters. However, the experimental setup represents a significant breakthrough as it demonstrates the first spin-driven silicon device which can potentially operate at room temperature. The first demonstration of coherent spin transport through an undoped 350-μm-thick silicon wafer [53] has ignited a great interest and gave hope for silicon spintronics to be implemented within the next decade.

As a generalization of the hot-electron injection method [52, 53], an optically assisted method to achieve large spin injection into semiconductors including a monolayer MoS_2 from a ferromagnet with help of a femto-second laser is gaining momentum [54, 55]. A plausible explanation is as follows: a short laser pulse in the ferromagnet excites the large population of strongly out-of-equilibrium electrons with both spins. However, the minority spins are characterized by a much stronger relaxation rate and lose their energy quickly. So, in analogy with the hot carrier spin injection [52, 53] only the majority spins with their energy higher than the

conduction band minimum can diffuse into the semiconductor resulting in a giant, almost 100% spin polarization. It remains to be seen if this approach is competitive as it requires expensive and technologically involved equipment.

A purely electrical method to inject spins in a semiconductor was suggested by E. Rashba already in 2000 [56]. The current which flows into the semiconductor from a ferromagnetic metal is reduced by introducing a tunnel barrier. This allows to occupy the corresponding density of states for the majority and minority spins in a semiconductor proportionally to their ratio in the ferromagnet (Fig. 31.1b). However, this technique requires the tunnel barrier to be not too thick to have a signal nor too thin to avoid the spin impedance mismatch problem. In addition, the quality of the barrier and interfaces should guarantee a very low rate of spin flips in the stack [57]. Therefore, it took almost a decade until first experimental evidences of electrical dynamic spin injection in silicon appeared [58–61], which resulted in a systematic study of spin transport properties in silicon [27]. In particular, many promises were due to the large signal interpreted as a spin accumulation observed in the so-called three-terminal injection scheme [60, 61], where the same ferromagnetic electrode is used to inject and to detect the spin accumulation. However, it appears that the signal is orders of magnitude larger as compared to what a simple estimate would give [57, 60], which certainly rang the bells that a phenomenon different from spin accumulation generated the signal. It is currently established [62] that the spins are reliably injected into silicon from a ferromagnetic electrode through a tunnel barrier, with a value consistent with a theoretical estimate of spin accumulation. However, the main signal relating the additional voltage modulation with the magnetic field in the three-terminal injection scheme is determined by the magnetoresistance due to spin-dependent trap-assisted resonant tunneling [63] or hopping [64]. We briefly describe in what respect the spin-dependent hopping differs from its spin-independent counterpart and highlight an idea of a single-spin switch in the following.

Spin-Dependent Trap-Assisted Hopping from a Ferromagnet to Silicon

Single-electron hopping plays an important role in determining transport properties in undoped semiconductors and dielectrics. The Coulomb interaction plays an important role as well, as it leads to the repulsion of the charges on a trap and to the Coulomb blockade, thus forbidding the double occupancy of a trap. The Coulomb repulsion results in strong charge correlations at transport. Indeed, when electrons tunnel through a trap [65], a second electron from a metallic contact cannot enter the trap, if it is already occupied by an electron. However, when the electron is released from the trap to a contact, the Coulomb repulsion does obviously not prevent another electron entering the trap. Therefore, the electron transport is performed in sequences consisting of an electron hopping from the source electrode to the trap, followed by the electron escaping from the trap to the drain electrode. Because the Coulomb repulsion is a purely classical interaction, electron tunneling through the trap represents an example of classically correlated charge transport.

From the point of view of devices, the Coulomb blockade has led to the discovery of the single-electron transistor [65], which is a three-terminal device consisting of a small metallic island (dot) weakly coupled to the source and drain electrode by means of tunneling through the thick potential barriers. Because of the weak coupling, electrons are allowed to jump on the dot from the source and to escape to the drain one by one. However, due to the Coulomb blockade, the transport through the dot at small source-drain voltages is suppressed, unless the free energy to add an electron to the dot occupied with $(N - 1)$ electrons or to extract an electron from the dot occupied with N electrons is exactly zero [65]. As the potential of the dot and, therefore, the addition/extraction energies can be tuned by the gate electrode capacitively coupled to the dot, a current switch between the on and off states can be built. As the transport through the dot is carried out by a single-electron jumping on/from the dot, the switch is termed single-electron transistor.

In addition to its electron charge, the electron possesses spin. From the physical phenomena related to a single spin, the Pauli, or spin, blockade is known to the single-electron transport, in addition to the Coulomb blockade. The Pauli exclusion principle forbidding two electrons with the same spin projections to occupy the trap quantum state results in yet another correlation affecting the transport through the double-quantum dot system in a magnetic field [66].

The spin blockade is very sensitive to the spin decoherence and relaxation effects and is therefore typically observed at low temperature. However, recently spin correlations resulting in large magnetoresistance and magnetoluminescence effects in organic semiconductors and organic light-emitting diodes [67] were reported at room temperature. The transport is due to the variable-range spin-dependent single-electron hopping through a network of traps. Due to the Pauli blockade, the current is very sensitive to the strength of the external magnetic field which aligns the spins and inhibits the current.

In the case when the source and/or drain electrodes are ferromagnetic, the spin correlations are observed at the transport through a *single* quantum dot. Indeed, an electron impinging a ferromagnetic electrode from a trap has a larger probability to escape, if its spin is parallel to the magnetization $\mathbf{M}$ of the electrode [68]. In this case, the drain electrode plays a role similar to the second quantum dot in the Pauli spin blockade experiments [66], which results in a Pauli blockade-like trap-assisted tunneling transport between the ferromagnetic electrodes. The signal has been observed at temperatures as high as 500 K [61], envisioning that a single-spin switch seems conceivable.

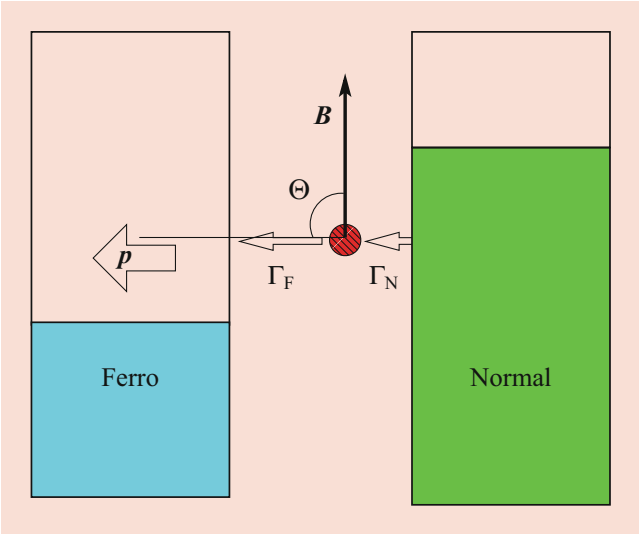

Fig. 31.2 Schematic illustration of trap-assisted tunneling from a semiconductor to a ferromagnet. The magnetic field $\boldsymbol{B}$ forms an angle Θ with the direction of the magnetization in the ferromagnet

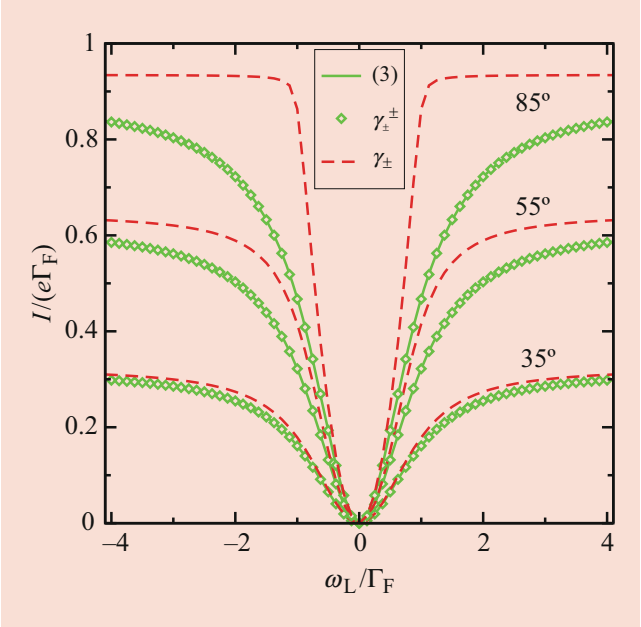

Fig. 31.3 Magnetoresistance computed with the stationary solution of (3) for spin-dependent sequential tunneling (diamonds). The results are compared with the findings in [63] (solid lines) and [69] (dashed lines)

Here we report on a three-terminal single-spin switching device employing for its operation both the spin and the Coulomb blockade. The switch consists of a trap weakly coupled to three ferromagnetic electrodes by tunneling transition rates. In this case, the spin on the trap is a vector quantity determined by the magnetic polarizations of the electrodes, transition rates, as well as the weak non-quantizing magnetic field, which results in unusual correlations in the three-terminal device. In order to describe the switch, we first elaborate on spin-dependent trap-assisted hopping between a normal metallic and a ferromagnetic electrode. We then generalize the description to spin-dependent hopping in a magnetic tunnel junction with both electrodes being ferromagnetic. After that we analyze a multiterminal device governed by spin-dependent hopping by considering an example of a three-terminal switch, where the source, the gate, and the drain are ferromagnetic.

We consider the transport due to spin-dependent trap-assisted tunneling. The trap is located between a normal metallic and a ferromagnetic electrode (Fig. 31.2). The trap can be empty or occupied by a single electron. The non-quantized magnetic field $\boldsymbol{B}$ is applied at an angle Θ with respect to the magnetization direction in the ferromagnetic drain contact.

The tunneling rate Γ_N from the normal metallic contact to the trap does not depend on spin, while the tunneling rate from the trap to the ferromagnet is spin-dependent and is determined by the two rates $\Gamma_\pm$ for the spin projection on the trap aligned and anti-aligned with $\mathbf{M}$. The rates can be expressed as

$$\Gamma_\pm = \Gamma_F (1 \pm p), \tag{31.1}$$

where the spin current polarization at the interface of the ferromagnet $p \leq 1$ is defined as [63]

$$p = \frac{\Gamma_+ - \Gamma_-}{2\Gamma_F}. \tag{31.2}$$

The equations for the site occupation probability n and the spin $\mathbf{s}$ on the trap are determined from the equations [64]

$$\frac{\mathrm{d}}{\mathrm{d}t} n = \Gamma_N (1 - n) - \Gamma_F n - \Gamma_F \mathbf{ps}, \tag{31.3a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t} \mathbf{s} = -\Gamma_F \mathbf{s} - \boldsymbol{p}\Gamma_F n + [\mathbf{s} \times \boldsymbol{\omega}_L], \tag{31.3b}$$

where $\boldsymbol{p} = p\,\frac{\mathbf{M}}{M_s}$, M_s is the saturation magnetization, and $\omega_L = \frac{eB}{mc}$ is the Larmor precession frequency. In the case $p = 0$, one obtains the standard balance equation for the occupation decoupled from the spin. The spin polarization of the ferromagnetic drain electrode couples the spin degree of freedom into the equation for the site occupation, which results in the resistance dependence on the magnetic field [63] shown in Fig. 31.3 by solid lines, for several values of Θ.

The transport process consists of two consecutive hops from the normal metallic source electrode to the trap and an escape from the trap to the ferromagnetic electrode [70].

The first step is characterized by a single-rate Γ_N. However, the escape from the trap is described by a matrix because of the coupling between the spin and the occupation at the trap. The escape probability $P(t)$ from the trap in the case of spin-independent hopping is described as

$$P_2(t) = 1 - n(t), \tag{31.4}$$

where $n(t)$ is the solution of the differential equation [64]

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} n \\ s_x \\ s_y \\ s_z \end{pmatrix} = -\mathbf{A}\begin{pmatrix} n \\ s_x \\ s_y \\ s_z \end{pmatrix} \tag{31.5}$$

The 4×4 relaxation matrix $\mathbf{A}$ is written in the coordinate system with the OZ axis parallel to the magnetic field $\boldsymbol{B}$:

$$\mathbf{A} = \begin{pmatrix} \Gamma_F & p\Gamma_F \sin\Theta & 0 & p\Gamma_F \cos\Theta \\ p\Gamma_F \sin\Theta & \Gamma_F & \omega_L & 0 \\ 0 & -\omega_L & \Gamma_F & 0 \\ p\Gamma_F \cos\Theta & 0 & 0 & \Gamma_F \end{pmatrix} \tag{31.6}$$

Because the trap is populated by hopping from the normal metallic electrode, spin-up and spin-down states are occupied with equal probabilities. Thus, the initial spin at the trap is zero, and the initial condition for (31.6) is

$$\begin{pmatrix} n \\ s_x \\ s_y \\ s_z \end{pmatrix}(t=0) = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}. \tag{31.7}$$

The charge transport consists of a series of repeated cycles. An electron jumps from the normal metallic electrode to the trap with the rate Γ_N and then escapes from the trap to the ferromagnetic electrode with the probability $P(t)$ (31.4). Double occupancy of the trap is prohibited by the Coulomb repulsion. One electron charge is transferred at each cycle during the time $\tau_1 + \tau_2$. The average time τ_1 is evaluated in accordance with the escape probability $P_1(t) = 1 - \exp(-t\,\Gamma_N)$. The time τ_2 is computed according to $P_2(t) = 1 - n(t)$. In contrast to spin-independent tunneling, the probability is not determined by a single exponential distribution. As it follows from the solution of (31.5, 31.6 and 31.7), the escape probability (31.4) is defined by the four eigenvalues of the 4×4 relaxation matrix $\mathbf{A}$ (31.6):

$$\gamma_{\pm}{}^{+} = \Gamma_F \pm \left(\frac{1}{2}\left(p^2\Gamma_F{}^2 - \omega_L^2\right) + \sqrt{\frac{\left(p^2\Gamma_F{}^2 - \omega_L^2\right)^2}{4} + \omega_L^2 p^2 \Gamma_F{}^2 \cos^2\Theta} \right)^{1/2} \tag{31.8a}$$

$$\gamma_{\pm}{}^{-} = \Gamma_F \pm \left(\frac{1}{2}\left(p^2\Gamma_F{}^2 - \omega_L^2\right) - \sqrt{\frac{\left(p^2\Gamma_F{}^2 - \omega_L^2\right)^2}{4} + \omega_L^2 p^2 \Gamma_F{}^2 \cos^2\Theta} \right)^{1/2} \tag{31.8b}$$

The solution of (31.5, 31.6 and 31.7) is then written as

$$\begin{pmatrix} n \\ s_x \\ s_y \\ s_z \end{pmatrix}(t) = \sum_{\sigma,\sigma'} C_{\sigma'}^{\sigma}\, \boldsymbol{u}_{\sigma}^{\sigma'} \exp\left(-t\gamma_{\sigma}^{\sigma'}\right), \tag{31.9}$$

where $\boldsymbol{u}_{\sigma}^{\sigma'}$ are the eigenvectors of $\mathbf{A}$ in (31.6). The coefficients $C_{\sigma'}^{\sigma}$ are uniquely determined by the initial condition (31.7).

The first component of (31.9) determines the escape probability $P_2(t) = 1 - n(t)$. The average time τ_2 can be calculated analytically. The stationary current I computed as

$$I = \frac{e}{\tau_1 + \tau_2} \tag{31.10}$$

which is shown in Fig. 31.3 with diamonds. The current from (31.10) coincides with the one obtained in [63] (Fig. 31.3, solid lines) but is significantly lower than the current computed with the expression from [69] shown with dashed lines in Fig. 31.3. In fact, the current values from [69] are too large for all directions of the magnetic field except the one, when $\boldsymbol{B}$ is parallel to $\boldsymbol{p}$. This implies that the escape times used in [69] are shorter. The escape time distribution probability in [69] is determined by the two tunneling rates (31.8a) from each of the Zeeman levels renormalized by coupling to the ferromagnetic contact. This approximation is appropriate only in the case when the magnetic field is aligned with the magnetization. In the general case, the consideration based on the matrix Eqs. (31.5, 31.6 and 31.7) is necessary to reproduce the correct transition probabilities and currents. This explains [64] the controversy between the results in [63, 69].

Spin-Dependent Hopping in Magnetic Tunnel Junction

The spin-dependent trap-assisted hopping between a ferromagnetic metal and a nonmagnetic semiconductor is the key to explain the peculiarities of the magnetic field-dependent signal [63] in electrical spin injection experiments [27, 57–61]. The main conclusion which can be drawn from [63] is that the observed voltage signal is not due to the nonequilibrium spin injection but rather due to the strong magnetoresistance effect (Fig. 31.3). Another important physical system is a magnetic tunnel junction (MTJ). A MTJ represents a sandwich made of two ferromagnetic metals separated by a tunnel junction. As the current properties through the structure are solely determined by tunneling, a proper description of spin-dependent trap-assisted tunneling is paramount.

We consider the spin-dependent hopping transport between two noncollinear ferromagnetic contacts (Fig. 31.4). The ferromagnetic contacts are characterized by the spin current polarizations $\boldsymbol{p}_{1,2} = \frac{\Gamma^+_{1,2}-\Gamma^-_{1,2}}{2\Gamma_{1,2}} \frac{\mathbf{M}_{1,2}}{M_{1,2}}$ and the saturation magnetization $\mathbf{M}_{1,2}$. The tunneling rates from the source to the trap and from the trap to the drain are defined as an average of the rates with the spin-up (+) and spin-down (−) projection on the magnetization direction in the corresponding electrode: $\Gamma_{1(2)} = \frac{\Gamma^+_{1(2)}+\Gamma^-_{1(2)}}{2}$. In order to determine the escape probability $P_2(t) = 1 - n(t)$ from the trap, one has to solve (31.4). The tunneling rate from the ferromagnetic source electrode to the trap defining the occupation is the sum of the tunneling rates with the spin-up and the spin-down projections on the axis oriented along the source polarization p_1:

$$\Gamma_{\mathrm{S}\to\mathrm{Trap}} = \Gamma^+_1 + \Gamma^-_1 = 2\Gamma_1 \tag{31.11}$$

The rate (31.11) plays a similar role as Γ_N in sequential tunneling considered in the previous section. Although $\Gamma_{\mathrm{S}\to\mathrm{Trap}}$ does not depend on the spin polarization of the source, the electron on the trap originating from the ferromagnetic source electrode exhibits nonzero spin defined by the spin polarization p_1 as the ferromagnetic source electrode injects electrons with the spin defined by the source polarization vector. The nonzero initial spin generalizes the initial condition (31.7) to the case of trap-assisted tunneling between the two ferromagnetic electrodes [64]:

$$\begin{pmatrix} n \\ s_\mathrm{x} \\ s_\mathrm{y} \\ s_\mathrm{z} \end{pmatrix} (t=0) = \begin{pmatrix} 1 \\ p_1 \sin\zeta\cos\varphi \\ p_1 \sin\zeta\sin\varphi \\ p_1 \cos\zeta \end{pmatrix} \tag{31.12}$$

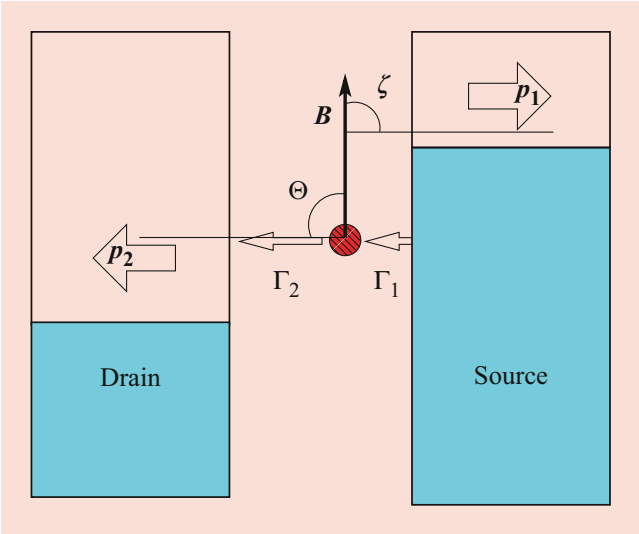

Fig. 31.4 For tunneling between two ferromagnetic electrodes, the direction of the source magnetization is specified by ζ and the polar angle φ, in addition to the angle Θ between the magnetic field and the drain magnetization

In order to evaluate the stationary current, it remains to solve (31.4, 31.5 and 31.6) with the initial condition (31.12) and the matrix $\mathbf{A}$ be modified so that $\boldsymbol{p}$ is replaced by $\boldsymbol{p}_2$ and Γ_F by Γ_2.

Results of the calculations are shown in Fig. 31.5. The magnetoresistance displays a more pronounced minimum at small magnetic fields as compared to tunneling from a normal metallic electrode. This is due to the fact that the probability to inject spins with the orientation opposite to p_2 causing the spin blockade is mostly determined by Γ^-_1 for the parameters chosen in Fig. 31.5 and is thus reduced as compared to the probability of tunneling of 50% from a normal metallic source electrode. The magnetoresistance also shows a dependence on the direction of the magnetic field in the case when $\boldsymbol{B}$, $\boldsymbol{p}_1$, and $\boldsymbol{p}_2$ are not lying within the same plane, although at high magnetic fields the symmetry with respect to the direction of the magnetic field is restored.

31.2.2 Single-Spin Transistor

We now analyze a three-terminal device in the configuration shown in Fig. 31.6, where the source "S," the gate "G," and the drain "D" are ferromagnetic, each described by the corresponding spin polarization $p_\alpha (\alpha = \mathrm{G(gate)}, \mathrm{S(source)}, \mathrm{D(drain)})$. The potential at the trap is determined by the gate voltage V_GS, the drain-source voltage V_DS, and the capacitances C_α, which are assumed equal to C. The current I_α is defined positive, if it flows from the electrode $\alpha = \mathrm{G(gate)}$,

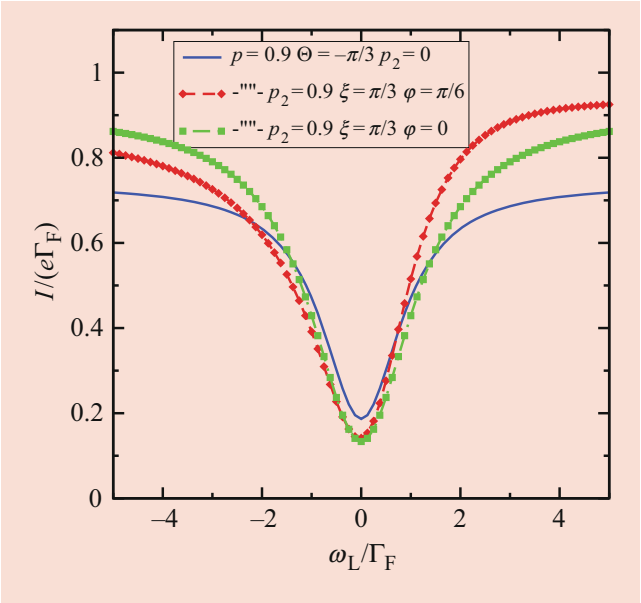

Fig. 31.5 Tunneling magnetoresistance for $p_1 = 0.9$, for different orientation and polarization p_2 of the source contact

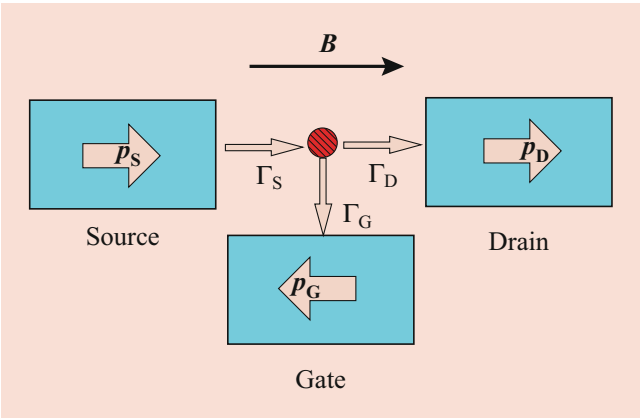

Fig. 31.6 A single-electron switch composed of an electron trap and three ferromagnetic contacts with an arbitrary relative magnetization orientation. Electron transport is due to trap-assisted spin-dependent hopping between the ferromagnetic contacts

S(source), or D(drain) to the trap. The current continuity $I_G + I_S + I_D = 0$ is thus automatically ensured.

In the case when there are several ferromagnetic terminals shown in Fig. 31.6, the spin correlations and thus the currents through each junction are determined by the generalized Eqs. (31.13a and 31.13b):

$$\frac{\mathrm{d}}{\mathrm{d}t}n = \Gamma_2\,(1-n) - \Gamma_1 n - \Gamma_1 \boldsymbol{p}_1 \mathbf{s},$$
$$\Gamma_{1(2)} = \sum_{\alpha'(\alpha'')} \Gamma_{\alpha'(\alpha'')} \tag{31.13a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{s} = \Gamma_2\,(1-n)\,\boldsymbol{p}_2 - \Gamma_1 \mathbf{s} - \boldsymbol{p}_1 \Gamma_1 n + [\mathbf{s}\times\boldsymbol{\omega}_\mathrm{L}],$$
$$\boldsymbol{p}_{1(2)} = \frac{1}{\Gamma_{1(2)}} \sum_{\alpha'(\alpha'')} \boldsymbol{p}_{\alpha'(\alpha'')}\Gamma_{\alpha'(\alpha'')} \tag{31.13b}$$

The sum is performed over the junctions $\alpha'(\alpha'')$ with the rates $\Gamma_{\alpha'(\alpha'')}$ of hopping from the electrode to the trap (from the trap to the electrode).

First we consider the single-electron transistor mode, where there is no tunneling between the trap and the gate $\Gamma_G = 0$ and all electrodes are non-ferromagnetic ($p_\alpha = 0$) (Fig. 31.7a). We apply a constant gate voltage $V_{GS} = e/C_G$. We evaluate the current by using the rates standard to single-electron tunneling as [71]

$$\Gamma_\alpha\,(V_\mathrm{eff}) = \Gamma_\alpha \left(\frac{V_\mathrm{eff}}{V_\mathrm{GS}}\right), \tag{31.14}$$

where $V_\mathrm{eff} = (V_\mathrm{b} + V_\mathrm{a})/2 > 0$ is the effective voltage of the junction α calculated as an average of the voltages before V_b and after V_a the electron jump.

For zero drain-source voltage V_{DS}, we are in the Coulomb blockade region with a single electron on the trap, and no current can flow between the source and drain (Fig. 31.7b). For $V_{DS} < V_{GS}/2$ the junction "trap-drain" is biased in opposite direction, and there is no source-drain current (Fig. 31.7b). As soon as $V_{DS} > V_{GS}/2$, the "trap-drain" junction is biased such that the electron can escape the trap. The Coulomb blockade is overcome by the drain voltage, and the current starts flowing (Fig. 31.7b).

If we now allow tunneling between the trap and the gate, $\Gamma_S = \Gamma_G = \Gamma_D \equiv \Gamma$, an electron from the trap can escape to the gate at $V_{GS} = e/(4C_G)$ (Fig. 31.8a). The electrodes are considered metallic with $p_\alpha = 0$. At $V_{DS} = 0$ the source is not biased with respect to the drain, and equal currents flow through the source and drain junctions from the electrodes, which then combine into the gate current (Fig. 31.8b). At $V_{DS} = V_{GS}$ the drain and gate junctions are equivalent, and the corresponding currents are equal. Making the source electrode ferromagnetic with high spin current polarization $p_S = 0.99$ does not modify the current-voltage characteristics as the escape from the trap is spin-independent in the case of a non-ferromagnetic gate and drain $p_G = p_D = 0$ (Fig. 31.8b).

However, when the drain is also ferromagnetic, $p_S = p_D = 0.99$, $p_G = 0$ (Fig. 31.9a), one observes an increase of the drain current at $V_{DS} > V_{GS}/2$ shown by the dashed-dotted lines in Fig. 31.9b. At these conditions the drain junction is positively biased, and the current flows easily between the source and drain since the magnetizations of the electrodes are parallel $p_S = p_D$. Therefore, the spin at the trap is also parallel to the magnetizations. Because the

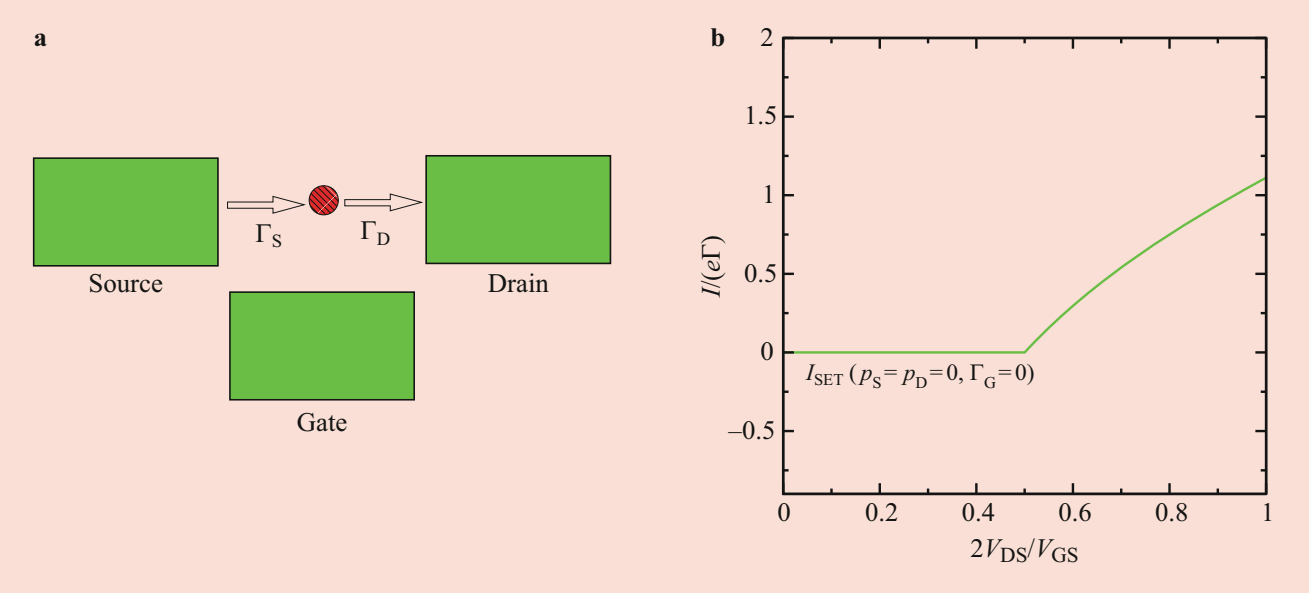

Fig. 31.7 (**a**) Single-electron transistor, (**b**) its source-drain current

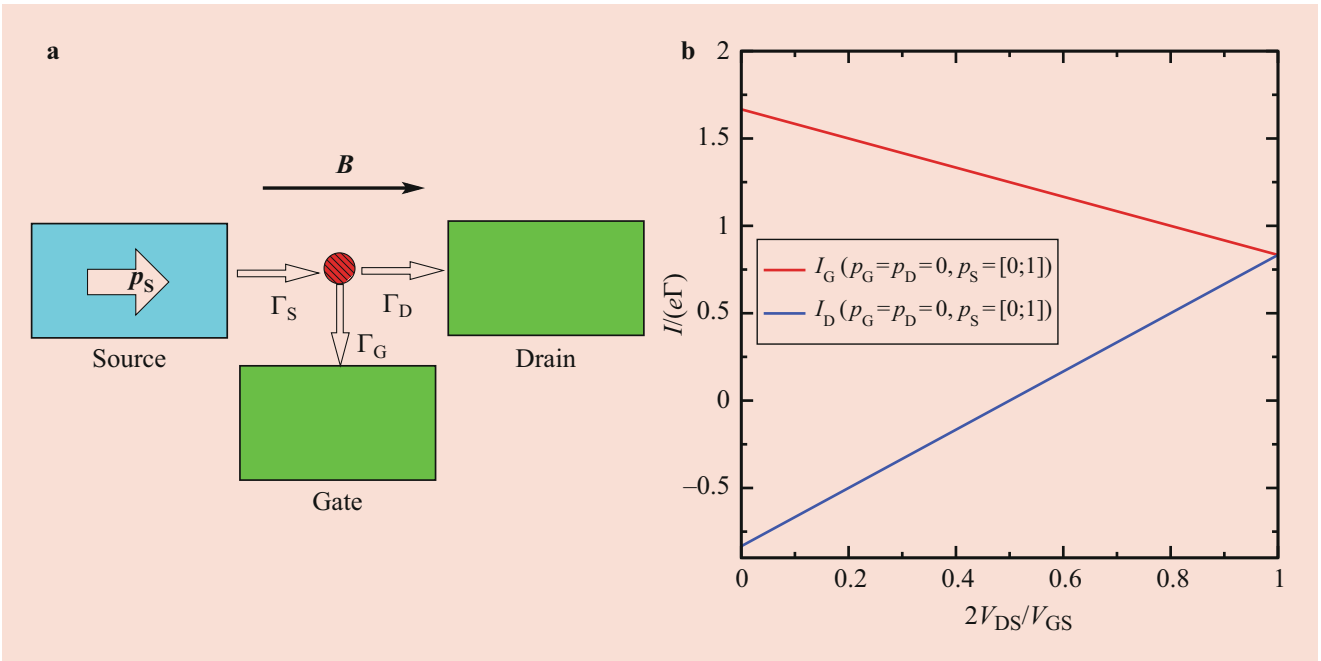

Fig. 31.8 (**a**) The source electrode is ferromagnetic, (**b**) currents through the gate and drain junctions

electron at the trap is spin-polarized, its probability to escape through the gate junction is reduced as only a single spin-polarized channel is open, in contrast to a spin-unpolarized electron, when both channels for spin-up and spin-down are open.

The situation changes dramatically when the gate is ferromagnetic, $p_G = 0.99$, $p_S = p_D = 0$ (Fig. 31.10a). At $V_{DS} < V_{GS}/2$, both the source and drain junctions are negatively biased, so that the electrons flow from these junctions to the trap and then try to escape to the highly polarized gate. The system is similar to the one with the trap-assisted tunneling between the normal metallic and the ferromagnetic electrode. In complete analogy to this case, the current suppression characteristic to spin-dependent hopping is observed in Fig. 31.10b.

At $V_{DS} > V_{GS}/2$, the drain junction is positively biased, and the spin blockade is lifted. An electron from the trap can always escape to the drain regardless of its spin. This leads

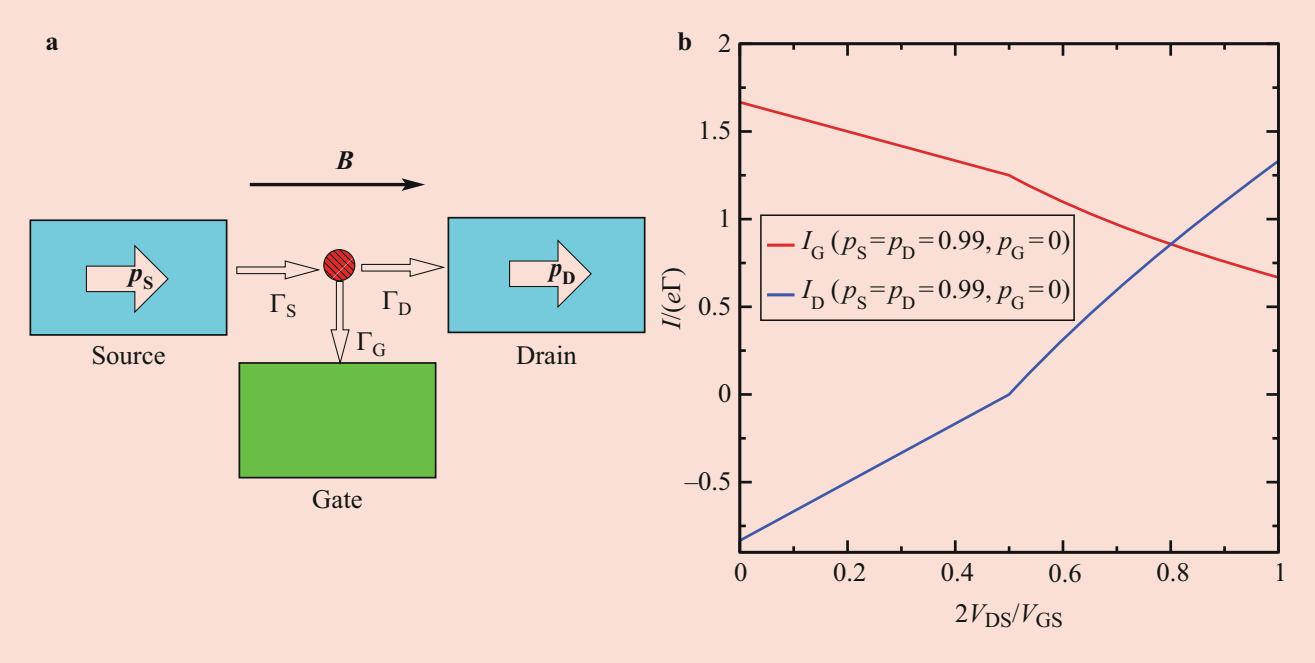

Fig. 31.9 (**a**) The source and drain electrode is ferromagnetic, (**b**) currents through the gate and drain junctions

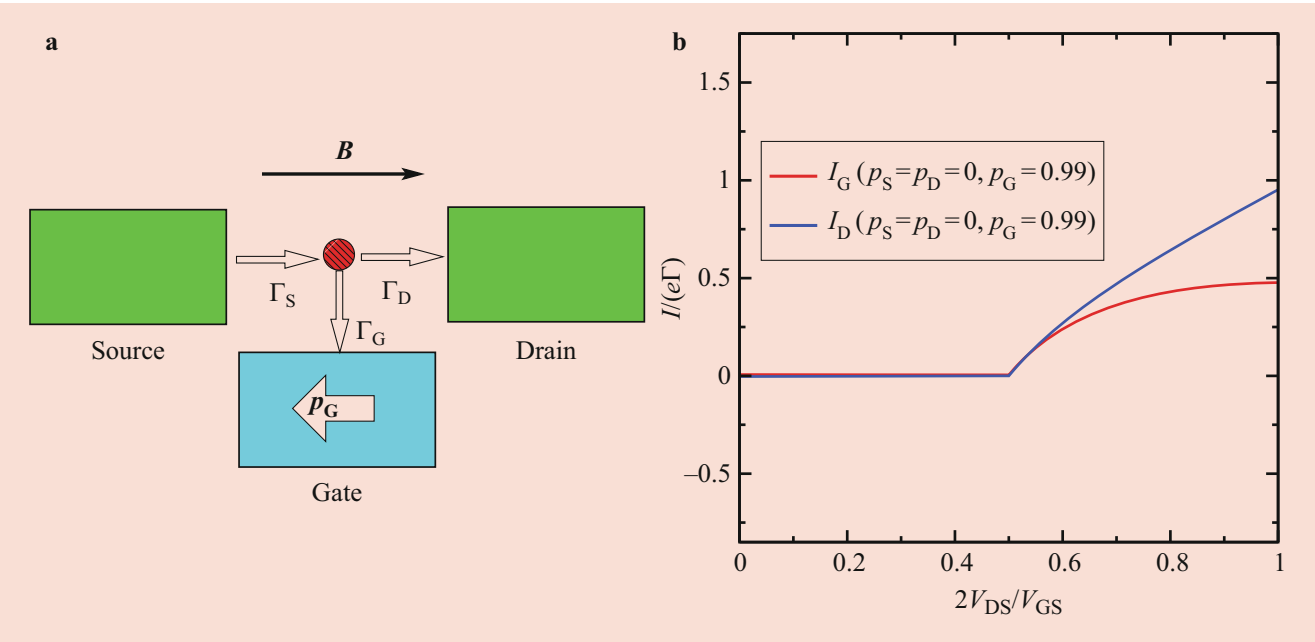

Fig. 31.10 (**a**) The gate electrode is ferromagnetic, (**b**) currents through the gate and drain junctions

to a nonzero drain current (Fig. 31.10b, solid line). Because the trapped electron with its spin opposite to p_G (which could not tunnel to the gate for $V_{DS} < V_{GS}/2$ and was responsible for blocking the gate current) can now easily escape to the drain, it does not block the current to the gate, and the gate current also starts flowing (Fig. 31.10b).

Adding ferromagnetism to the drain in the configuration shown in Fig. 31.11a ($p_G = -p_D, p_G = p_D = 0.99, p_S = 0$) does not alter the current-voltage behavior significantly (Fig. 31.11b). Since the source remains non-ferromagnetic, it provides electrons with spin parallel or antiparallel to p_G (or vice versa for p_D) with equal probability (50%). The

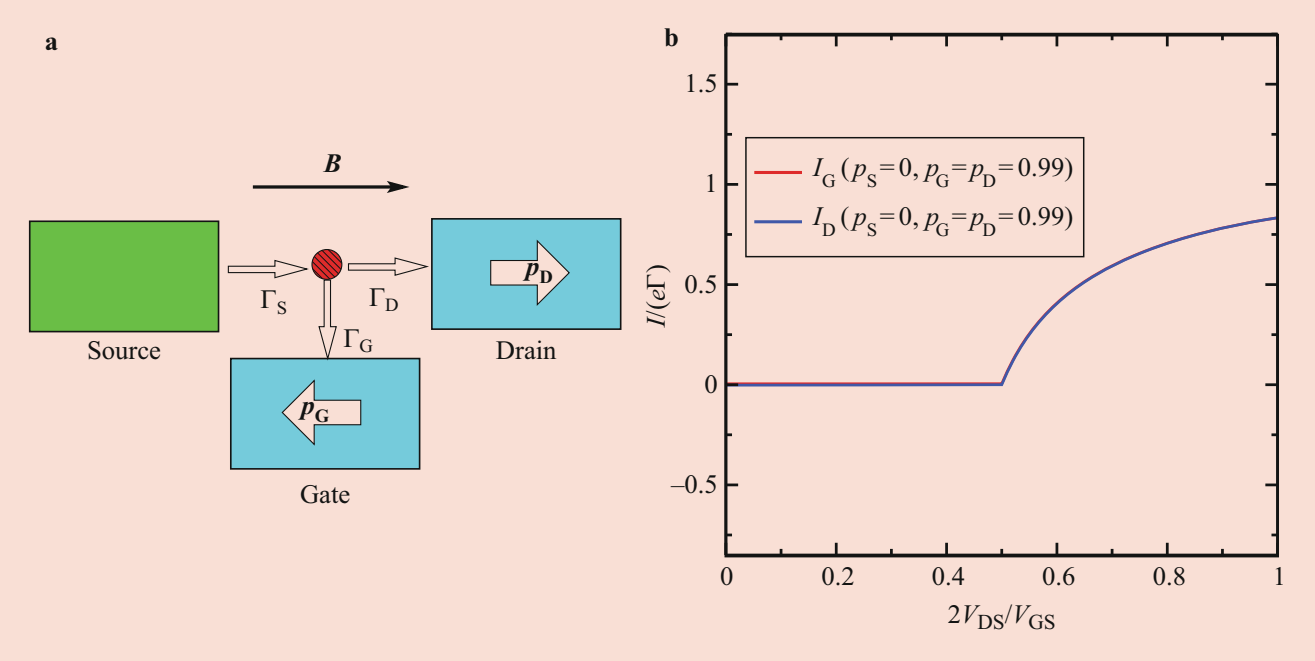

Fig. 31.11 (**a**) The gate and source electrodes are ferromagnetic, (**b**) currents through the gate and drain junctions

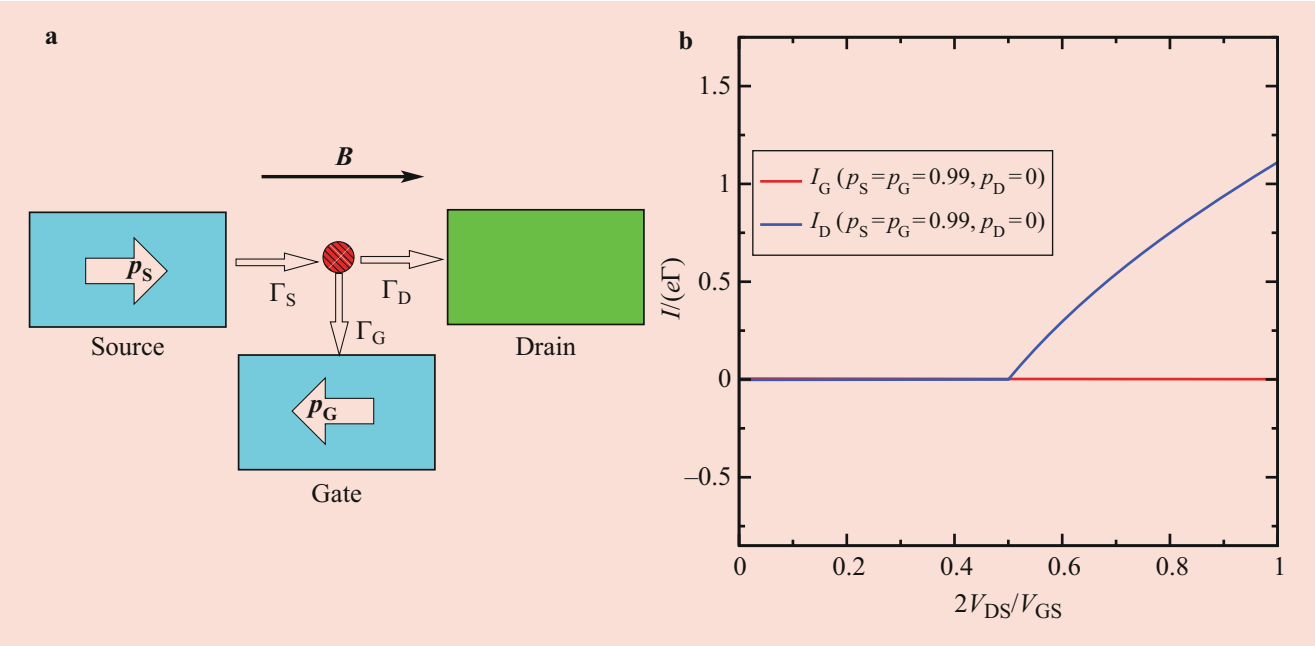

Fig. 31.12 (**a**) The source and gate electrodes are ferromagnetic, (**b**) currents through the gate and drain junctions

drain and gate currents are equal at $V_{DS} = V_{GS}$, although it is surprising that the currents are actually equal in the whole range $V_{DS} > V_{GS}/2$ (Fig. 31.11b).

Adding ferromagnetism to the source instead of the drain in the configuration in Fig. 31.12a ($p_G = -p_S$, $p_S = p_G = 0.99, p_D = 0$) does not alter the currents' blocking at $V_{DS} < V_{GS}/2$ (Fig. 31.12b). Indeed, the drain junction is negatively biased which prevents an electron to tunnel from the trap to the drain. The tunnel current into the gate is suppressed by the spin blockade as the drain electrode delivers electrons with the spin antiparallel to p_G with 50% probability, while the source delivers with probability 99%. These electrons cannot tunnel to the gate and thus block the gate current (Fig. 31.12b).

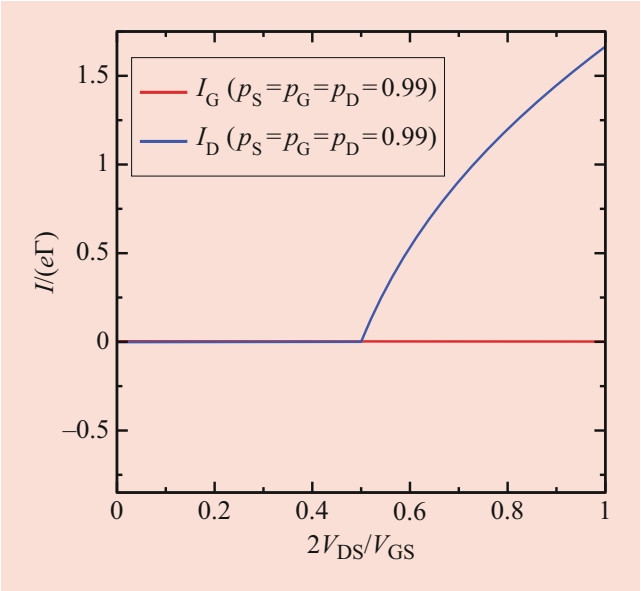

Fig. 31.13 Single-spin switch characteristics shown in Fig. 31.6. Electron transport is due to trap-assisted spin-dependent hopping between the ferromagnetic contacts

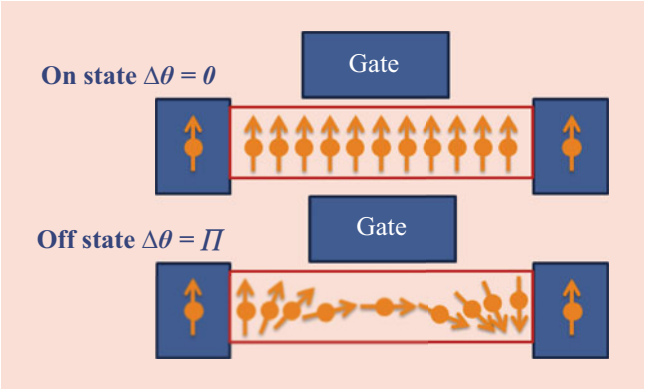

Fig. 31.14 Illustration of the SpinFET functionality [19]. Spin-polarized electrons are injected from a ferromagnetic source and absorbed by a ferromagnetic drain. The electron spins in the channel can be additionally manipulated by means of the gate voltage-dependent spin-orbit field

Because the source provides electrons with their spins mostly opposite to p_G, they cannot tunnel from the trap to the gate. The drain junction is positively biased at $V_{DS} > V_{GS}/2$, and the drain does not deliver electrons to the trap. Therefore, in contrast to Fig. 31.11b, the gate current remains negligible in the whole range of V_{DS} (Fig. 31.12b). The drain current is substantial at $V_{DS} > V_{GS}/2$ as electrons are allowed to tunnel to the normal metallic drain electrode.

Finally, if one considers all electrodes to be ferromagnetic in the configuration shown in Fig. 31.6 ($p_S = p_D = -p_G$, $p_S = p_G = p_D = 0.99$), mostly the electrons with their spins opposite to p_G are delivered to the trap. The gate current remains negligible in the whole range of V_{DS} Fig. 31.6. The drain current is blocked at $V_{DS} < V_{GS}/2$ (Fig. 31.13) as the gate junction is negatively biased, which prevents electrons tunneling to the drain. At $V_{DS} > V_{GS}/2$, the drain current flows. Since the source and the drain are strongly polarized with their magnetizations aligned, the current value shown in Fig. 31.13 is larger than in the case of a non-ferromagnetic drain (Fig. 31.12b) as only one-half of the states is now available in the drain to accommodate polarized electrons from the source. We stress that, although the current-voltage characteristic in Fig. 31.13 is qualitatively similar to that of a single-electron transistor (Fig. 31.7b), the suppression of the gate current and the switching is due to the spin correlations and the spin blockade at spin-dependent trap-assisted hopping in the considered three-terminal device with ferromagnetic electrodes.

31.2.3 Silicon SpinMOSFET and SpinFET

Successful injection and propagation of spins through a non-degenerate silicon channel lead to the first demonstration of a spin metal-oxide-semiconductor field-effect transistor (SpinMOSFET) [72] called by the analogy to a traditional charge-based MOSFET, the working horse of modern microelectronics. In contrast to the MOSFET, the current in SpinMOSFET flows between two ferromagnetic contacts. These contacts (source and drain) are connected by a nonmagnetic semiconducting channel region. Metallic ferromagnetic contacts serve not only as an injector/detector of the electron charge current in the channel. Because of their magnetization, these electrodes inject/detect electron spins [19]. The electron current is enhanced in the case of parallel alignment between the source/drain electrodes as electrons injected with spins parallel to the drain magnetization can easily escape from the channel to the drain. Alternatively, the current is suppressed for antiparallel magnetization alignment. As the magnetization of the source/drain can be manipulated by means of the external magnetic field and/or current (by means of the spin-transfer torque), the two on-current states for parallel/antiparallel magnetization alignment potentially enable the design of reprogrammable logic [73]. Importantly, the relative magnetization orientation between the source and drain is preserved without external power, which makes reprogrammable logic partly nonvolatile.

The spin signal is obtained as the current difference in parallel and antiparallel configuration of the source and drain magnetizations. For the first time, a high on/off ratio of spin signals was demonstrated [72] and, what is most important, at room temperature. However, the demonstrated device is different from the SpinFET first proposed in [19].

The SpinMOSFET differs from the SpinFET (Fig. 31.14) in one important aspect, namely, the gate voltage does not affect the spin polarization of the current. Indeed, the gate voltage is used to control the current through the channel. However, the spin orientation is solely determined by the injecting ferromagnetic contact orientation. The important ingredient of the SpinFET [19] is to employ the gate voltage-dependent effective spin-orbit field [74] to additionally manipulate spins propagating in the channel.

The idea is based on an earlier discovery of the gate voltage-dependent Bychkov-Rashba spin-orbit field [74]. In analogy with the magnetic field, the effective spin-orbit field acts on the electron spin and provides an additional momentum-dependent energy splitting between the opposite spin projections. This opens a possibility for a purely electrical way to manipulate the spin of a propagating electron. In a SpinFET the charge functionality is complemented and enhanced by the electron spin. In order to inject spins, the nonmagnetic source and drain electrodes are replaced by their ferromagnetic counterparts. The example of the SpinMOSFET demonstrates that the total current through the device depends on the relative orientation between the magnetization direction of the drain and the electron spin polarization at the end of the semiconductor channel. The electron current is maximal in the case of parallel alignment between the source and drain electrodes as electrons injected with spins parallel to the drain magnetization can easily escape from the channel to the drain. In contrast, the current is minimal when the source and drain are in antiparallel configuration. Therefore, the electron spin polarization orientation at the end of the channel relative to the drain magnetization direction additionally modulates the current through the SpinFET. As the spin polarization orientation can be manipulated by the gate voltage, it provides an additional knob to regulate the current through the device by means of spin.

Since the strength of the spin-orbit field depends on the potential gradient in the direction perpendicular to the channel, or the effective electric field, it can be conveniently controlled by the gate voltage. The fact that the spin-orbit field also depends on the electron momentum guarantees that all ballistically propagating electrons acquire the same spin rotation at the end of the channel [19]. This is in contrast to the case, where the spins are simply manipulated by the constant external magnetic field [52, 53], when the electron spin at the end of the channel depends on the time the electron travels through the channel. Because the electrons are injected with different velocity projections relative to the source-drain direction, the electrons reach the end of the channel with different spin orientations resulting in additional spin dephasing. Spin manipulation by means of the spin-orbit field is free from this unwanted dephasing, at least in the case of ballistic electron propagation through the channel. All electrons at the end of the channel acquire the same angle relative to the drain magnetization, the value of which is determined only by the strength of the spin-orbit field. The spin precession angle $\Delta\theta$ defined as the difference between the orientation of the spin of the electron at the end and at the beginning of the semiconductor region is [19].

$$\Delta\theta = \frac{2\alpha_R m^*}{\hbar^2} L, \tag{31.15}$$

where α_R is the strength of the spin-orbit interaction, which depends on the effective field, m^* is the effective mass of the electron, $\hbar$ is the reduced Plank's constant, and L is the length of the semiconductor channel. The strength of the spin-orbit interaction determines the minimum length of the semiconductor channel, sufficient to alternate the spin orientation.

The two dominant mechanisms of the spin-orbit interaction in well-investigated III-V semiconductor heterostructures are of the Rashba and the Dresselhaus type. The Rashba spin-orbit interaction is due to the geometrically induced structural asymmetry [74] in the system, while the Dresselhaus spin-orbit interaction is caused by the bulk inversion symmetry breaking [75]. The effective Hamiltonian of the spin-orbit interaction due to the confinement along the z-axis is in the form (Rashba type)

$$H_R = \frac{\alpha_R}{\hbar}\left(p_x\sigma_y - p_y\sigma_x\right), \tag{31.16}$$

where α_R is the effective electric field-dependent parameter of the spin-orbit interaction, $p_{x(y)}$ is the electron momentum projection, and σ_x and σ_y are the Pauli matrices. This is the typical gate-controlled contribution to the spin-orbit interaction in confined III-V semiconductor devices.

In silicon thin films, however, the Rashba spin-orbit interaction is relatively weak. Its strength is approximately one tenth of the value of the dominant contribution which, surprisingly, has a Dresselhaus form of the corresponding effective Hamiltonian [76, 77]:

$$H_D = \frac{\beta}{\hbar}\left(p_x\sigma_x - p_y\sigma_y\right) \tag{31.17}$$

This major contribution to the spin-orbit interaction is due to interfacial-induced disorder which breaks the inversion symmetry. The strength β of the Dresselhaus-like spin-orbit interaction depends almost linearly on the effective electric field, which is the case: $\beta \cong \beta^1 E_z$, where β^1 is the intra-valley coupling constant [77]. For a field strength of 50 kV/cm, the strength of the spin-orbit interaction is found to be $\beta \approx 2$ μeVnm [78], which is in agreement with the value reported experimentally [77], while $\alpha_R \approx 0.1$μeVnm. This

value of the Dresselhaus spin-orbit interaction in confined silicon structures is sufficient to consider them for applications as SpinFET channels.

To calculate the transport properties of the ballistic spin field-effect transistor, we consider a model similar to the one used in [79, 80]. The Hamiltonian in the ferromagnetic regions has the following form:

$$H = \frac{p_x^2}{2m_\mathrm{f}^*} + h_0\sigma_\mathrm{z}, \quad x < 0, \tag{31.18a}$$

$$H = \frac{p_x^2}{2m_\mathrm{f}^*} \pm h_0\sigma_\mathrm{z}, x > L, \tag{31.18b}$$

where m_f^* is the effective mass in the contacts, $h_0 = 2pE_\mathrm{F}/(P^2+1)$ is the exchange splitting energy with p defined as the spin polarization in the ferromagnetic regions, E_F is the Fermi energy, and σ_z is the Pauli matrix; $\pm$ in (31.18a and 31.18b) stands for the parallel and antiparallel configuration of the contact magnetizations. The spin-orbit interaction is taken in the Dresselhaus form relevant for silicon. The effective Hamiltonian in the channel is

$$H = \frac{p_\mathrm{x}^2}{2m^*} + \delta E_\mathrm{c} - \frac{\beta}{\hbar}\sigma_\mathrm{x}p_\mathrm{x} + \frac{1}{2}g\mu_\mathrm{B}B\sigma^*, \tag{31.19}$$

where m^* is the subband effective mass, g is the Landé factor, μ_B is the Bohr magneton, B is the magnetic field, and $\sigma^* \equiv \sigma_\mathrm{x}\cos\gamma + \sigma_\mathrm{y}\sin\gamma$ with γ defined as the angle between the magnetic field and the transport direction.

To calculate the dependence of the transport properties on the strength of the spin-orbit interaction, we take the wave function in the left contact as follows:

$$\Psi_\mathrm{L}(x) = \left(\mathrm{e}^{ik_\uparrow x} + R_\uparrow \mathrm{e}^{-ik_\uparrow x}\right)\begin{pmatrix}1\\0\end{pmatrix} + R_\downarrow \mathrm{e}^{-ik_\downarrow x}\begin{pmatrix}0\\1\end{pmatrix} \tag{31.20}$$

$$\Psi_\mathrm{L}(x) = R_\uparrow \mathrm{e}^{-ik_\uparrow x}\begin{pmatrix}1\\0\end{pmatrix} + \left(\mathrm{e}^{ik_\downarrow x} + R_\downarrow \mathrm{e}^{-ik_\downarrow x}\right)\begin{pmatrix}0\\1\end{pmatrix} \tag{31.21}$$

where (31.20) represents the incoming spin-up electrons and (31.21) the incoming spin-down electrons; correspondingly, $k_{\uparrow(\downarrow)} = \sqrt{2m_\mathrm{f}^*(E \mp h_0)/\hbar^2}$ is the wave vector of the spin-up (spin-down) electron, and $R_{\uparrow(\downarrow)}$ is the amplitude of the reflected wave. For the right contact, the wave function is given by

$$\Psi_\mathrm{R}(x) = C_\uparrow \mathrm{e}^{ik_\uparrow x}\begin{pmatrix}1\\0\end{pmatrix} + C_\downarrow \mathrm{e}^{ik_\downarrow x}\begin{pmatrix}0\\1\end{pmatrix}. \tag{31.22}$$

For the semiconductor region, the wave function can be written as

$$\begin{aligned}\Psi_\mathrm{S}(x) = A_+\mathrm{e}^{ik_{\mathrm{x1}}^{(+)}x}\begin{pmatrix}k_1\\1\end{pmatrix} + B_+\mathrm{e}^{ik_{\mathrm{x2}}^{(+)}x}\begin{pmatrix}k_2\\1\end{pmatrix}\\ A_-\mathrm{e}^{ik_{\mathrm{x1}}^{(-)}x}\begin{pmatrix}k_3\\-1\end{pmatrix} + B_-\mathrm{e}^{ik_{\mathrm{x2}}^{(-)}x}\begin{pmatrix}k_4\\-1\end{pmatrix},\end{aligned} \tag{31.23}$$

where $k_{\mathrm{x1}(x2)}^{(+)}$ and $k_{\mathrm{x1}(x2)}^{(-)}$ are the wave vectors obtained by solving the equations $\frac{\hbar^2k^2}{2m^*} + \delta E_\mathrm{c} \pm \sqrt{\left(\frac{Bg\mu_\mathrm{B}\cos(\gamma)}{2}\right)^2 + \left(\frac{Bg\mu_\mathrm{B}\sin(\gamma)}{2} - \beta k\right)^2} = E$, respectively. The constants k_1, k_2, k_3, and k_4 are calculated as

$$k_1 = -\frac{i\left(Bg\mu_\mathrm{B}\sin(\gamma) - 2\beta k_{\mathrm{x1}}^{(+)}\right) - Bg\mu_\mathrm{B}\cos(\gamma)}{2\sqrt{\left(\frac{Bg\mu_\mathrm{B}\cos(\gamma)}{2}\right)^2 + \left(\frac{Bg\mu_\mathrm{B}\sin(\gamma)}{2} - \beta k_{\mathrm{x1}}^{(+)}\right)^2}}, \tag{31.24}$$

$$k_2 = -\frac{i\left(Bg\mu_\mathrm{B}\sin(\gamma) - 2\beta k_{\mathrm{x2}}^{(+)}\right) - Bg\mu_\mathrm{B}\cos(\gamma)}{2\sqrt{\left(\frac{Bg\mu_\mathrm{B}\cos(\gamma)}{2}\right)^2 + \left(\frac{Bg\mu_\mathrm{B}\sin(\gamma)}{2} - \beta k_{\mathrm{x2}}^{(+)}\right)^2}}, . \tag{31.25}$$

$$k_3 = \frac{i\left(Bg\mu_\mathrm{B}\sin(\gamma) - 2\beta k_{\mathrm{x1}}^{(-)}\right) - Bg\mu_\mathrm{B}\cos(\gamma)}{2\sqrt{\left(\frac{Bg\mu_\mathrm{B}\cos(\gamma)}{2}\right)^2 + \left(\frac{Bg\mu_\mathrm{B}\sin(\gamma)}{2} - \beta k_{\mathrm{x1}}^{(-)}\right)^2}}, \tag{31.26}$$

$$k_4 = \frac{i\left(Bg\mu_\mathrm{B}\sin(\gamma) - 2\beta k_{\mathrm{x2}}^{(-)}\right) - Bg\mu_\mathrm{B}\cos(\gamma)}{2\sqrt{\left(\frac{Bg\mu_\mathrm{B}\cos(\gamma)}{2}\right)^2 + \left(\frac{Bg\mu_\mathrm{B}\sin(\gamma)}{2} - \beta k_{\mathrm{x2}}^{(-)}\right)^2}}. \tag{31.27}$$

The reflection and transmission coefficients are determined by applying the standard boundary conditions at the ferromagnet/semiconductor interfaces. We compute the current through the device as

$$\begin{aligned}I^{\mathrm{P(AP)}}(V) = \frac{e}{h}\int_{\delta E_\mathrm{c}}^{\infty}\left[T_\uparrow^{\mathrm{P(AP)}}(E) + T_\downarrow^{\mathrm{P(AP)}}(E)\right]\\ \left\{\frac{1}{1+\mathrm{e}^{\frac{E-E_\mathrm{F}}{k_\mathrm{B}T}}} - \frac{1}{1+\mathrm{e}^{\frac{E-E_\mathrm{F}+eV}{k_\mathrm{B}T}}}\right\}\mathrm{d}E,\end{aligned} \tag{31.28}$$

where k_B is the Boltzmann constant, T is the temperature, and V is the voltage. The spin-up ($T_\uparrow^\mathrm{P}$) and spin-down ($T_\downarrow^\mathrm{P}$) transmission probabilities for the parallel configuration of the contact magnetization are defined as

$$T_{\uparrow}^{\mathrm{P}} = \left|C_{\uparrow}\right|^2 + \frac{k_{\downarrow}}{k_{\uparrow}}\left|C_{\downarrow}\right|^2, \tag{31.29}$$

$$T_{\downarrow}^{\mathrm{P}} = \frac{k_{\uparrow}}{k_{\downarrow}}\left|C_{\uparrow}\right|^2 + \left|C_{\downarrow}\right|^2. \tag{31.30}$$

For the antiparallel configuration of the contact magnetization, the transmission probability is obtained in a similar fashion.

The conductance is defined as

$$G^{\mathrm{P(AP)}} = \lim_{V\to 0}\frac{I^{\mathrm{P(AP)}}}{V}. \tag{31.31}$$

In the limit of low temperatures, the conductance must coincide with the one obtained from the Landauer-Büttiker formula:

$$G^{\mathrm{P(AP)}} = \frac{e^2}{h}\left(T_{\uparrow}^{\mathrm{P(AP)}}(E_{\mathrm{F}}) + T_{\downarrow}^{\mathrm{P(AP)}}(E_{\mathrm{F}})\right) \tag{31.32}$$

Finally, the magnetoresistance ratio (MR) is computed as

$$\mathrm{MR} \equiv \frac{G^{\mathrm{P}} - G^{\mathrm{AP}}}{G^{\mathrm{AP}}}. \tag{31.33}$$

To facilitate the injection of the spin-polarized current into the channel, we introduce, following [79, 80], delta-function barriers of the strength U at the interfaces between the contact and the channel, which we characterize by the dimensionless effective strength $z = 2m_{\mathrm{f}}^* U/\left(\hbar^2 k_{\mathrm{F}}\right)$, where $k_{\mathrm{F}} = \sqrt{2m_{\mathrm{f}}^* E_{\mathrm{F}}/\hbar^2}$ at the interfaces between the contact and the channel.

The dependence of the MR on the strength of the spin-orbit interaction is shown in Fig. 31.15, for several channel lengths, at zero temperature. A more pronounced magnetoresistance modulation with the strength of the spin-orbit interaction is obtained for longer channels. In order to completely benefit from the magnetoresistance modulation, the channel length L should be larger than the inverse of the characteristic wave vector $k_{\mathrm{D}} = m^*\beta/\hbar^2$, which determines the dependence of the MR on the value of the strength of the Dresselhaus spin-orbit interaction β: $L \geq 1/k_{\mathrm{D}}$.

A thin silicon film channel of *[100]* orientation possesses a larger transport effective mass m^* [81, 82] compared to one which is *[110]* oriented. Therefore, a smaller variation of β is required in *[100]* oriented films to achieve the same k_{D} and thus the same variation of the MR. Thus, *[100]* oriented channels are best suited to be used as channels in silicon SpinFETs.

Figure 31.16 displays the magnetoresistance dependence on the strength of the spin-orbit interaction at different temperatures for a device with an 8-μm-long channel, for 1 meV source-drain voltage. The MR modulation is preserved at higher temperatures opening a practical possibility to modulate the current by changing the value of β at room temperature.

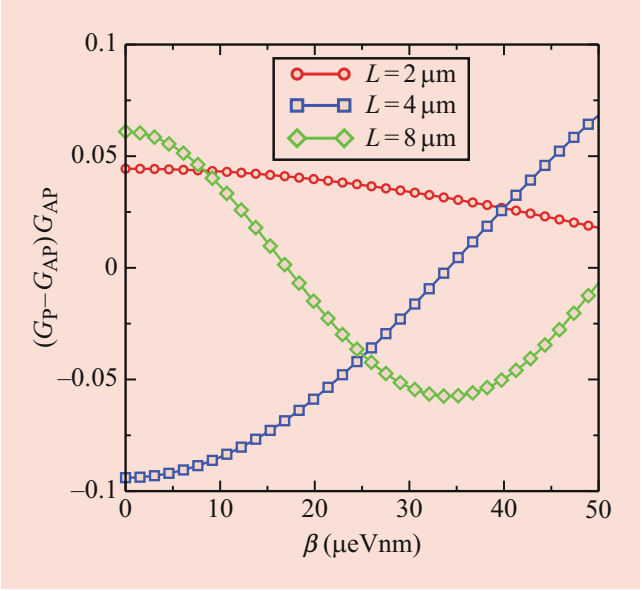

Fig. 31.15 MR dependence on the value of the Dresselhaus spin-orbit interaction for several channel lengths. The Fermi energy in the ferromagnetic source and drain is $E_{\mathrm{F}} = 2.47$ eV, the electrode spin current polarization $p = 0.4$, the silicon conduction band offset $\delta E_{\mathrm{c}} = 2.154$ eV, the tunnel barriers of the strength $z = 1$

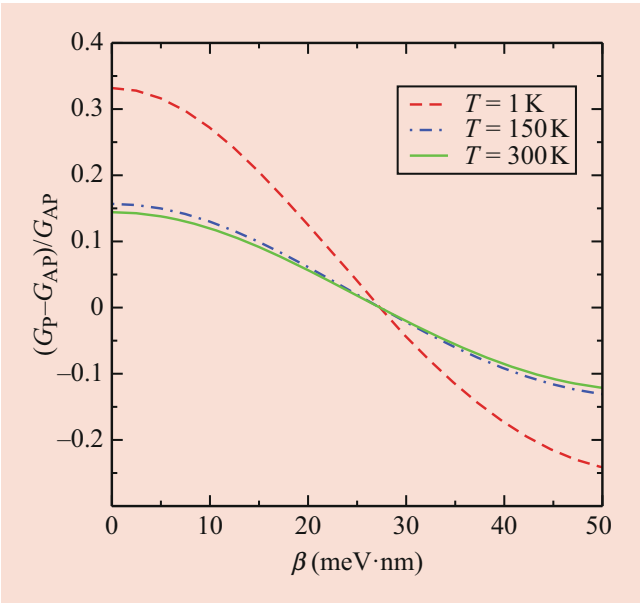

Fig. 31.16 Magnetoresistance dependence on the strength of the spin-orbit field for a *[100]* oriented channel with length $L = 8$ μm, for $E_{\mathrm{F}} = 2.47$ eV, $\delta E_{\mathrm{c}} = 2.154$ eV, $P = 0.4$, $z = 3$, $V = 1$ meV

Therefore, in principle, the spin-orbit field in silicon could be used to manipulate spins and to achieve the current modulation by means of spin. However, to potentially benefit from the current modulation due to the gate voltage-dependent

strength of the spin-orbit field, the silicon channel length must be as long as a few microns. Even if a silicon SpinFET were fabricated, it must compete with modern devices with a channel 100 times shorter. In order to decrease the channel length, the gate voltage-dependent spin-orbit field shall be increased.

The effective electric field-dependent parameter of the spin-orbit interaction is several orders of magnitude larger in III-V semiconductors, so the channel length needed for current modulation due to the voltage-dependent spin-orbit field can be shorter. However, the strong spin-orbit field needed for spin manipulation leads to a strong spin relaxation as well. Indeed, the spin-orbit field depends on the electron momentum. After a scattering event, the electron momentum changes, as does the direction of the spin-orbit field. Because the spin-orbit field defines the axis around which the electron spin precesses, the spin precesses around a different axis after scattering. After another scattering event, the field and the axis of precession are changed again. The most important scattering mechanism in bulk semiconductors at room temperature is electron-phonon scattering. As the electron-phonon scattering happens at random position and time, the information about the initial spin orientation and the angle it acquires while propagating along the channel are rapidly randomized. In order to avoid the randomization and maintain the spin precession coherence, one way is to reduce electron-phonon scattering. Therefore, a SpinFET made with a III-V semiconductor channel can only operate at cryogenic temperature.

An elegant solution to the problem of injecting spin-polarized electrons without using ferromagnetic contacts was proposed recently [83]. It resulted in the first demonstration of an all electrical SpinFET [83] with two gates. The idea is to employ again the spin-orbit field. The effective spin-orbit field guarantees that the electrons having their momentum along the propagation direction are spin-polarized. This idea allows to reliably inject spin-polarized electrons through the point contact created electrostatically by the corresponding additional gates [83]. By applying the potential difference between these gates, one ensures that the electrons moving from the contact to the channel and therefore having the momentum in this direction are spin-polarized. Using this innovative injection technique, the current modulation by means of the gate voltage-dependent spin-orbit field was confirmed. This provided the first successful demonstration of a SpinFET [83] 25 years after it had been predicted [19].

31.2.4 Spin Relaxation Suppression in Silicon Films

Before concluding the spin switches part, let us briefly discuss spin relaxation mechanisms in silicon. In contrast to the electron charge, the non-equilibrium spin accumulation injected into the channel relaxes to its equilibrium zero value while propagating through the channel and is not conserved. Spin relaxation is an important detrimental factor affecting the SpinFET functionality as it reduces the current modulation due to spin functionality. To avoid spin dephasing, the experiment [83] must be performed at an extremely low temperature of 30 mK.

The question then appears why silicon SpinMOSFET functionality was demonstrated at 300 K with a channel length of four micrometers [72]. Of course, the spin-orbit interaction is much weaker in silicon. In addition, the spin relaxation manifests itself completely different in semiconductors of the group IV, in which silicon belongs to, in contrast to III-V semiconductors. The crystal lattice of silicon obeys the inversion symmetry, while the crystal structure of III-V materials does not. If, in addition to the time-reversal symmetry, the structure obeys the inversion symmetry, then the electrons with spin-up and spin-down propagating with the same momentum are not allowed to have different energies, so the effective spin-orbit field causing the energy splitting in III-V semiconductors is zero in silicon. The spin relaxation in silicon is governed by a different mechanism [47, 84] called the Elliott-Yafet spin relaxation mechanism. A short explanation of the spin relaxation is as follows. Spins are injected with a fixed spin projection. However, the wave function with fixed spin projection is not an eigenstate of the Hamiltonian with the microscopic spin-orbit interaction included. In other words, the spin eigenfunction contains both a spin-up and a small spin-down part with respect to the axis of spin injection. Therefore, a small but finite probability to flip the electron spin appears at every scattering event, even if the scattering potential is spin-independent. This is the Elliott process [47] contributing to the spin relaxation in silicon. This process is complemented by the Yafet spin-flip events due to the spin-dependent contribution to the scattering potential. In bulk silicon the electron spin relaxation is determined by the transitions between non-equivalent valleys [47]. As uniaxial stress lifts the degeneracy between these valleys, the rates of the inter-valley transition are decreased, and the spin lifetime can be efficiently controlled by stress [84].

However, if a silicon SpinMOSFET is implemented in the future, it must be fabricated with the help of the technology used to produce modern CMOS transistors. In contrast to the experiment [72], where the current modulation through an 80-nm-thick silicon layer was performed by the back gate, the channel in modern CMOS devices is represented by a narrow fin or a thin sheet. As the electrons are transferred close to the interface, the role of the surface roughness in determining the spin relaxation in thin silicon channels must be understood. Indeed, it is known that the electron mobility in thin silicon body channels is determined not only by the

electron-phonon interaction but mostly by surface roughness scattering [85] and is significantly reduced as compared to the electron mobility in the bulk. An important question therefore is to determine how surface roughness scattering affects the spin relaxation in thin silicon films and what can be done in order to reduce the spin relaxation and to enhance the spin lifetime and the spin diffusion length.

In order to compute the spin relaxation, the rates must be evaluated. To do so, the scattering mechanisms as well as the corresponding wave functions and an effective Hamiltonian to determine the wave functions must be established. We adopt a **k**·**p**-based approach [86–88] suitable to describe the unprimed electron subbands in (001) silicon films in the presence of strain and spin-orbit interaction. The effective Hamiltonian includes only the relevant *[001]* oriented valleys with spin degree. The other valleys or, to be more precise, the corresponding subbands have larger energies due to a smaller effective quantization mass [86] and are disregarded.

Without the spin interaction, the unprimed subbands resulting from *[001]* oriented valleys are degenerate in the unstrained (001) film. The Hamiltonian is written in the vicinity of the X point along the k_z-axis in the Brillouin zone. The basis is conveniently chosen as $[(X_1,\uparrow), (X_1,\downarrow), (X_{2'},\uparrow), (X_{2'},\downarrow)]$, where $\uparrow$ and $\downarrow$ indicate the spin projection at the quantization $z-$ axis and X_1 and $X_{2'}$ are the basis function corresponding to the two *[001]* valleys. The effective **k**·**p** Hamiltonian reads as

$$H = \begin{bmatrix} H_1 & H_3 \\ H_3^{\dagger} & H_2 \end{bmatrix} \tag{31.34}$$

where H_1, H_2, and H_3 are defined as [28]

$$H_1 = \left[\frac{\hbar^2 k_z^2}{2m_l} - \frac{\hbar^2 k_0 k_z}{m_l} + \frac{\hbar^2\left(k_x^2 + k_y^2\right)}{2m_t} + U(z) \right] I_{2\times 2}, \tag{31.35}$$

$$H_2 = \left[\frac{\hbar^2 k_z^2}{2m_l} + \frac{\hbar^2 k_0 k_z}{m_l} + \frac{\hbar^2\left(k_x^2 + k_y^2\right)}{2m_t} + U(z) \right] I_{2\times 2}, \tag{31.36}$$

$$H_3 = \begin{bmatrix} D\varepsilon_{xy} - \frac{\hbar^2 k_x k_y}{M} & \left(k_y - k_x i\right)\Delta_{SO} \\ \left(-k_y - k_x i\right)\Delta_{SO} & D\varepsilon_{xy} - \frac{\hbar^2 k_x k_y}{M} \end{bmatrix}. \tag{31.37}$$

Here $I_{2\times 2}$ is the identity 2×2 matrix, m_t and m_l are the transversal and longitudinal silicon effective masses, $k_0 = 0.15 \times 2\pi/a$ is the position of the valley minimum relative to the X point in unstrained silicon, a is the silicon lattice constant, ε_{xy} denotes the shear strain component, $M^{-1} \approx m_t^{-1} - m_0^{-1}$, and $D = 14$ eV is the shear strain deformation potential. The effective spin-orbit term $\Delta_{SO}\,\tau_y \otimes (k_x\,\sigma_x - k_y\,\sigma_y)$ couples the states with the opposite spin projections from the opposite valleys. σ_x and σ_y are the spin Pauli matrices and τ_y is the y-Pauli-like matrix in the valley degree of freedom space. In the Hamiltonian (31.1) $U(z)$ is the confinement potential, and the value $\Delta_{SO} = 1.27$ meVnm computed by the empirical pseudopotential method (Fig. 31.17) is close to the one reported by Li and Dery [47].

The Hamiltonian H_3 describes the coupling between the two valleys along *[001]* direction. Shear strain term couples the two valley states with the same spin projection, while the spin-orbit term couples the two states from the opposite valleys with the opposite spin projections. In the case $H_3 = 0$, each eigenstate of the Hamiltonian (31.1) is four times degenerate with respect to the valleys and spin quantum numbers. The confinement potential does not lift the degeneracy. With the confinement potential included, one obtains the ladder of four times degenerate two-dimensional unprimed subbands.

It is known that shear strain lifts the degeneracy between the unprimed subbands [28]. Applying shear strain results in a stress-dependent mobility enhancement along the tensile stress direction. However, the electron mobility enhancement is determined by inter-valley scattering. Therefore, the electron mobility enhancement is due to the transport effective mass reduction with strain.

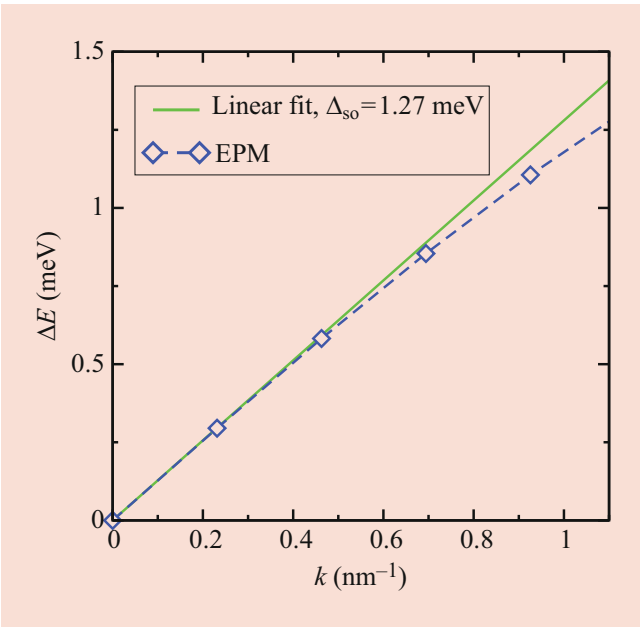

Fig. 31.17 Empirical pseudopotential calculations of the spin-orbit interaction strength by evaluating the energy difference between the *[001]* valleys at the X-point as a function of k_x. The linear fit is also shown

The spin relaxation in silicon is determined by inter-valley scattering. Therefore, the role of strain-induced valley splitting must be more pronounced regarding the spin relaxation time dependencies. The spin-orbit interaction couples the opposite valleys along the *[001]* crystallographic axis and should also result in valley splitting. However, in the case of a symmetric confinement potential, the spin degeneracy must be preserved, as it is required by the inversion and the time-reversal symmetries of the system.

To demonstrate this, we perform the unitary transformation of the Hamiltonian by transforming the four basis functions $X_{1\uparrow}$, $X_{1\downarrow}$, $X_{2\uparrow}{}'$, $X_{2\downarrow}{}'$,for the two [001] valleys with spin up and spin down as

$$\Psi_1 = \frac{1}{2}\left[\left(X_{1\uparrow} + X'_{2\uparrow}\right) + \left(X_{1\downarrow} + X'_{2\downarrow}\right)\frac{k_x - ik_y}{\sqrt{k_x^2 + k_y^2}}\right], \tag{31.38}$$

$$\Psi_2 = \frac{1}{2}\left[\left(X_{1\uparrow} + X'_{2\uparrow}\right) - \left(X_{1\downarrow} + X'_{2\downarrow}\right)\frac{k_x - ik_y}{\sqrt{k_x^2 + k_y^2}}\right], \tag{31.39}$$

$$\Psi_3 = \frac{1}{2}\left[\left(X_{1\uparrow} - X'_{2\uparrow}\right) + \left(X_{1\downarrow} - X'_{2\downarrow}\right)\frac{k_x - ik_y}{\sqrt{k_x^2 + k_y^2}}\right], \tag{31.40}$$

$$\Psi_4 = \frac{1}{2}\left[\left(X_{1\uparrow} - X'_{2\uparrow}\right) - \left(X_{1\downarrow} - X'_{2\downarrow}\right)\frac{k_x - ik_y}{\sqrt{k_x^2 + k_y^2}}\right], \tag{31.41}$$

$$X_1 = \Psi_1 \cos\left(\frac{\Theta}{2}\right) - i\Psi_3 \sin\left(\frac{\Theta}{2}\right), \tag{31.42}$$

$$X_2 = \Psi_2 \cos\left(\frac{\Theta}{2}\right) + i\Psi_4 \sin\left(\frac{\Theta}{2}\right), \tag{31.43}$$

$$X_3 = \Psi_3 \cos\left(\frac{\Theta}{2}\right) - i\Psi_1 \sin\left(\frac{\Theta}{2}\right), \tag{31.44}$$

$$X_4 = \Psi_4 \cos\left(\frac{\Theta}{2}\right) + i\Psi_2 \sin\left(\frac{\Theta}{2}\right). \tag{31.45}$$

Here $\tan(\Theta) = \frac{\Delta_{SO}\sqrt{k_x^2+k_y^2}}{D\varepsilon_{xy} - \frac{\hbar^2 k_x k_y}{M}}$. The transformation decouples the two degenerate sub-ladders. In the new basis, the Hamiltonian (31.34) can be recast as

$$h = \begin{bmatrix} h_1 & h_3 \\ h_3 & h_2 \end{bmatrix} \tag{31.46}$$

h_1, h_2, and h_3 are defined as

$$h_1 = \left[\frac{\hbar^2 k_z^2}{2m_l} + \frac{\hbar^2\left(k_x^2 + k_y^2\right)}{2m_t} - \delta + U(z)\right] I, \tag{31.47}$$

$$h_2 = \left[\frac{\hbar^2 k_z^2}{2m_l} + \frac{\hbar^2\left(k_x^2 + k_y^2\right)}{2m_t} + \delta + U(z)\right] I, \tag{31.48}$$

$$h_3 = \begin{bmatrix} \frac{\hbar^2 k_0 k_z}{m_l} & 0 \\ 0 & \frac{\hbar^2 k_0 k_z}{m_l} \end{bmatrix}, \tag{31.49}$$

where

$$\delta = \sqrt{\left(D\varepsilon_{xy} - \frac{\hbar^2 k_x k_y}{M}\right)^2 + \Delta_{SO}^2\left(k_x^2 + k_y^2\right)}. \tag{31.50}$$

It is straightforward to see that the 4×4 Hamiltonian (31.46) splits into the two 2×2 Hamiltonians

$$L_{1,2} = \begin{bmatrix} \frac{\hbar^2 k_z^2}{2m_l} + \frac{\hbar^2\left(k_x^2+k_y^2\right)}{2m_t} - \delta + U(z) & \frac{\hbar^2 k_0 k_z}{m_l} \\ \frac{\hbar^2 k_0 k_z}{m_l} & \frac{\hbar^2 k_z^2}{2m_l} + \frac{\hbar^2\left(k_x^2+k_y^2\right)}{2m_t} + \delta + U(z) \end{bmatrix} \tag{31.51}$$

acting on the independent sub-spaces with the basis functions X_1, X_3 and X_2, X_4, correspondingly. We note that the spin projection of X_1 (X_3) is opposite to that of X_2 (X_4). Therefore, the Hamiltonians $L_{1,2}$ define the two sub-ladders of the subbands. As the Hamiltonians $L_{1,2}$ have the same form, the energies of the corresponding subband from the two sub-ladder are the same. However, the degenerate states from the two different sub-ladders possess opposite spin projections. Although the degeneracy with respect to the spin degree of freedom between the two sub-ladders of subbands is preserved, within each sub-ladder the valley degeneracy is lifted by the spin-orbit interaction and/or shear strain. In the case when the confinement potential is approximated by an infinite square well, a quite accurate approximation [28] for the energy difference between the two unprimed subbands (the valley splitting) is obtained as

$$\Delta E_{\mathrm{n}} \approx \frac{2y_{\mathrm{n}}^2\delta}{k_0 t\sqrt{\left(1-y_{\mathrm{n}}^2-\eta^2\right)\left(1-y_{\mathrm{n}}^2\right)}} \left|\sin\left(\sqrt{\frac{1-y_{\mathrm{n}}^2-\eta^2}{1-y_{\mathrm{n}}^2}}k_0 t\right)\right|, \tag{31.52}$$

with y_{n} and η, defined as

$$y_{\mathrm{n}} = \frac{\pi n}{k_0 t}, \tag{31.53}$$

$$\eta = \frac{m_{\mathrm{l}} B}{\hbar^2 k_0^2}. \tag{31.54}$$

It follows from (31.52) that within each sub-ladder, the subband minima are two times degenerate in unstrained (001) silicon films. At finite momenta k_{x}, k_{y} the degeneracy is lifted. The splitting within each sub-ladder is determined by the spin-orbit interaction term alone, if the momentum is either along the *[100]* or *[010]* axis. Along these lines the spin-orbit interaction leads to a large mixing between the spin-up and spin-down states along these axes. Because of the large spin mixing, the regions in the momentum space close to these axes determine the spin relaxation and are called spin relaxation hot spots.

If the silicon film is stressed along the *[110]* direction, the shear strain component $\varepsilon_{\mathrm{xy}}$ is nonzero. The spin relaxation hot spots are determined by the condition

$$\left(D\varepsilon_{\mathrm{xy}} - \frac{\hbar^2 k_{\mathrm{x}} k_{\mathrm{y}}}{M}\right) = 0. \tag{31.55}$$

It then follows that the spin relaxation hot spots are moved toward higher energy in strained films as shown in Fig. 31.18. In the case when the hot spots are pushed higher than the Fermi (plus the thermal energy), the spin relaxation is significantly decreased, which must lead to the enhanced spin lifetime.

To compute the spin relaxation time, we consider surface roughness scattering as well as intra- and inter-valley scattering by acoustic [28] and optical phonons [88]. The wave functions are numerically calculated for an infinite square well potential in the basis X_1, X_2, X_3, X_4 and then transformed to the initial basis $[(X_1,\uparrow),(X_1,\downarrow),(X_{2'},\uparrow),(X_{2'},\downarrow)]$ with spin up or down relative to the axis z perpendicular to the silicon film. A proper linear combination of the eigenfunctions is taken [89] in order to obtain the wave functions with spin projections on a given axis.

Figure 31.19a, b show the total spin lifetime and partial contributions due to surface roughness, acoustic, and optical phonons scattering as a function of strain, for two different thicknesses (3 nm and 5 nm). The spin of the injected electrons is oriented along the z axis in *[001]* direction. For the thinner film of 3 nm thickness, the contribution due to electron-phonon scattering with longitudinal acoustic (LA) phonons is similar to the contribution due to surface roughness for small shear strain values. If the strain is increased, the LA phonons introduce the main contribution to the total spin lifetime.

For the thicker film shown in Fig. 31.19b, the role of the surface roughness scattering is reduced, and the total spin lifetime follows the same trends as the spin relaxation due to longitudinal acoustic phonons. The intersubband optical phonons calculated as g-process can be ignored for the film of 3 nm thickness, while their contribution for the thicker film is more pronounced at high strain. As a conclusion, the spin lifetime is significantly increased just by applying shear strain, which is today routinely used to boost the electron mobility in modern MOSFETs.

31.2.5 Perspectives of a Spin Silicon Switch

Silicon, the main element of modern microelectronics, is promising for spin-driven applications. Silicon is composed of nuclei with predominantly zero spin, which reduces the conduction electrons' spin relaxation due to their interactions with the nuclear spins. Silicon is also characterized by a weak strength of spin-orbit coupling, which results in long, approximately 10 ns, spin relaxation time at room temperatures suitable for SpinFET and SpinMOSFET operation. However, in electrically gated laterally confined silicon structures, the spin relaxation is enhanced [90], which could compromise

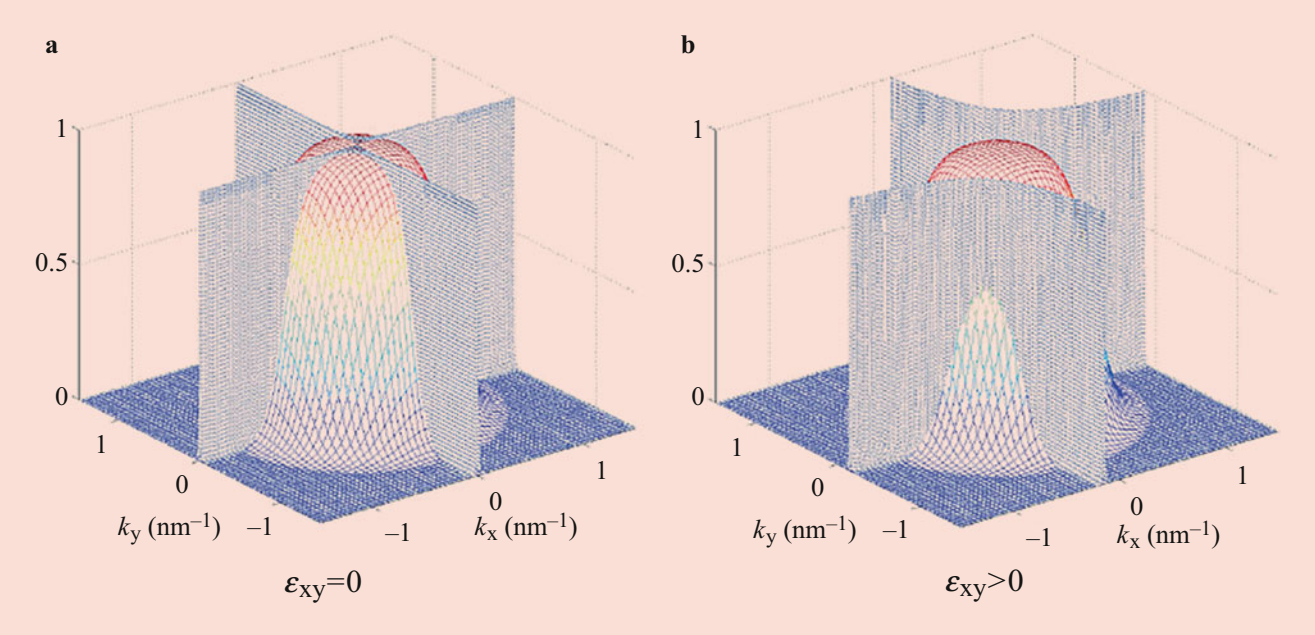

Fig. 31.18 (**a**) Spin relaxation hot spots in an unstrained silicon thin film and in a film stressed tensely along the *[110]* axis. (**b**) In the stressed film, the hot spots are pushed to higher energies toward unoccupied states

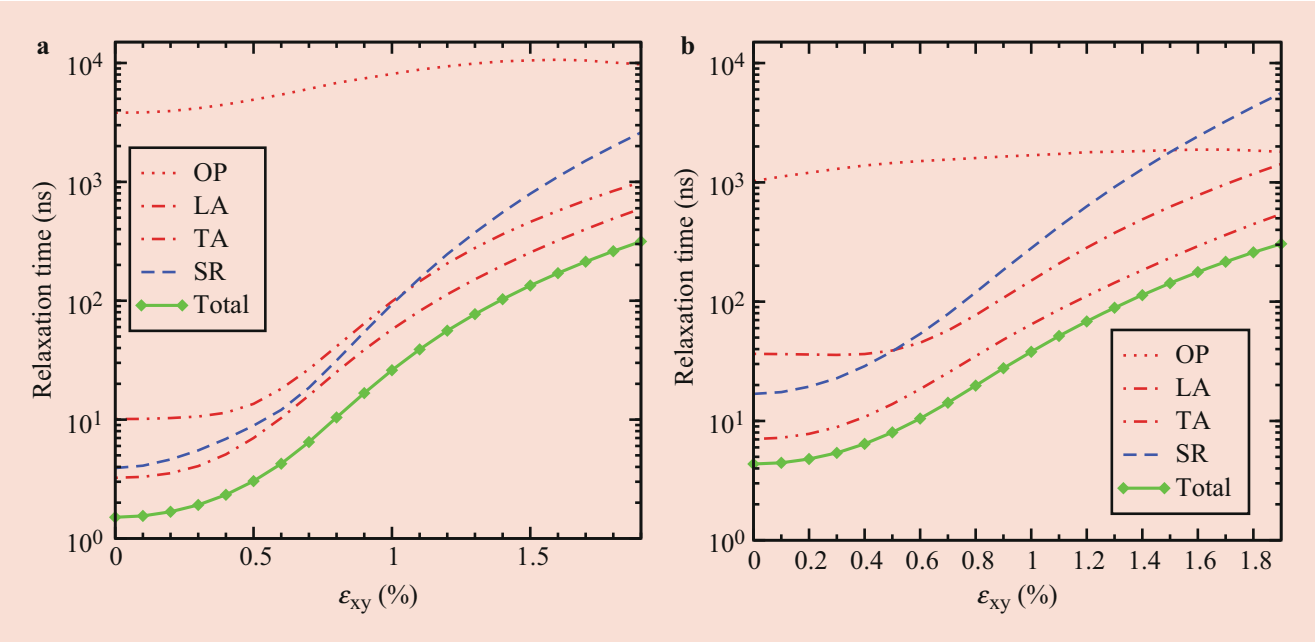

Fig. 31.19 The spin relaxation time in a (001) silicon film with a thickness (**a**) 3 nm and (**b**) 4 nm as a function of shear strain. Surface roughness (SR), longitudinal acoustic (LA), transversal acoustic (TA), and optical (OP) phonon-mediated scattering are considered

the reliability device and become an obstacle in realizing spin-driven devices. We demonstrate that shear strain is efficient to increase the spin lifetime by at least one order of magnitude. Shear strain is routinely used to boost the electron mobility in modern MOSFETs due to the strain-dependent transport effective mass. In contrast to the electron mobility determined by the inter-valley scattering processes, the spin relaxation is controlled by inter-valley scattering. Shear strain lifts the degeneracy between the valleys, which results in a substantial spin lifetime increase.

The increased spin lifetime leads to a longer spin diffusion length in thin silicon films. The inversion symmetry in thin

silicon films can be broken by applying a perpendicular electric field. This results in an electric field-dependent spin-orbit Rashba-like field which can be used to manipulate the electron spins while they propagate through the channel. It is therefore conceivable to perform an experiment at room temperature, which can demonstrate the spin manipulation in silicon, as the spin lifetime and the spin diffusion length can be significantly increased by applying shear strain. However, as the spin-orbit field in silicon is also weak, the channel length required for achieving a proper and useful spin manipulation is about several micrometers. In order to benefit from the gate voltage-induced spin and current manipulation in modern MOSFETS with a channel length of only 20 nm, a conceptually new method to manipulate spins by the gate voltage at such short distances is required.

The first experimental demonstration of a SpinMOSFET [72] confirmed that the electron spins are successfully injected into silicon. The spin diffusion length was a few microns at room temperature sufficient to demonstrate a large absolute difference between the currents in parallel and antiparallel source-drain magnetization configuration. However, the relative ratio of the on-currents, a characteristic similar to the tunneling magnetoresistance ratio, is still several orders of magnitude lower [72] than the tunneling magnetoresistance (TMR) in magnetic tunnel junctions, the main element of the magnetoresistive nonvolatile memory discussed later. In the experimental SpinMOSFET, a magnetoresistance ratio less than 0.1% was reported. In order to make a useful device, the ratio should be increased by at least two orders of magnitude to the level of the tunneling magnetoresistances in magnetic tunnel junctions. Our calculations show that the ratio depends on the source-drain spin polarization which must be increased. Another important ingredient is the tunnel barrier between the ferromagnet and the semiconductor. The defects apparently do not necessarily play a detrimental role. Spin-dependent trap-assisted transport study is in its incipient stage. However, it already reveals new concepts for devices, which, by analogy to a single-electron transistor, employ a single spin for their operation. More material research as well as experimental and theoretical work is needed in order to better understand the influence of the dielectric between the ferromagnet and silicon used to provide the spin injection.

Efficient spin injection is the key to boost the resistance difference between the two states with parallel and antiparallel alignment of the source-drain magnetization. New ideas to obtain a high spin polarization in the channel are urgently needed. One interesting option to boost the spin injection efficiency is to employ an electric field at the contact interface between the ferromagnet and the two-dimensional electron gas to increase spin-to-charge conversion [91]. Although a large MR of 80% was reported on a III-V surface layer at low temperature needed to avoid spin relaxation, the technique of boosting spin-to-charge conversion possesses potential for being also employed in silicon at room temperature.

New two-dimensional materials (graphene, transition metal dichalcogenides) are attractive for emerging microelectronics applications as they allow developing new concepts, in particular for spin switches [92]. Spin-polarized electrons injected into a graphene sheet propagate to the drain and remain spin-polarized as the spin relaxation in graphene is weak. However, if a MoS_2 single layer is introduced on the top of graphene, a parallel path for electrons through MoS_2, the material with strong spin relaxation, is open, and the current reaching the drain is not spin-polarized. As the chemical potential of the MoS_2 layer can be tuned from the conduction band to the gap, this opens the opportunity to have a switch between spin-polarized and spin-unpolarized drain currents depending on the gate voltage.

Although many fundamental problems and technological challenges have been resolved, and a SpinFET and a SpinMOSFET have been successfully demonstrated, both devices still rely on the charge current to transfer the spin, which may set some limitations for the applicability of such devices in mainstream microelectronics. In addition, the absence of an efficient and purely electrical spin injection scheme results in a small difference between the resistances in parallel and antiparallel source-drain configuration. New innovative ideas and physical principles which would allow an efficient spin manipulation by purely electrical means at ambient temperature are urgently needed to extend the functionality of modern MOSFETs by including electron spin. Nonvolatile devices based on magnetic tunnel junctions possess the tunneling magnetoresistance suitable for practical applications, in particular in memory devices discussed below.

31.3 Nonvolatile Magnetoresistive Memories

An attractive path to mitigate the unfavorable trend of increasing power dissipation, especially at a standby mode, is to introduce nonvolatility in the circuits. Nonvolatility is an ability to keep the data even if the supply power is turned off. Introduction of nonvolatility enables standby power-free integrated circuits. Indeed, if no information is lost, there is no need to recollect and recover the data, when the power is turned on. Nonvolatility is crucial for eliminating the leakage power dissipation and data refreshment cycles. Apart from standalone applications, e.g., critical program and data storage devices in extreme environments employed in the airspace industry, it is particularly promising to use nonvolatility in the main computer memory as replacement of conventional volatile CMOS-based dynamic random-access memory (DRAM) [93, 94]. In addition, this memory could be embedded on chip, which removes one of the bottlenecks of

the Von Neumann computing architecture, when memory is physically far away from the central processing unit (CPU). This way a lengthy and energy-consuming procedure of data exchange between the memory and the CPU is omitted.

In modern multicore processors, much of the energy consumption takes place in the hierarchical multilevel cache memory structure. To reduce this energy consumption, a viable approach is to replace the caches with a nonvolatile memory which desirably also offers a reduced memory cell size compared to static random-access memory (SRAM) [93, 94]. In addition, this helps bridging the speed gap between the last level caches serviced by fast CMOS SRAM and much slower main computer memory mastered by CMOS DRAM.

The development of a novel electrically addressable nonvolatile memory is essential to mitigate the increase of the standby power and to introduce instant-on architectures without the need of data initialization when going from a standby to an operation regime. To be competitive with the traditional, volatile memory technologies and also with nonvolatile flash memory, emerging nonvolatile memories must offer a fast switching time, a high integration density supported by good scalability, a long retention time, a high endurance, and a low-power consumption. At the same time, they must possess a simple structure to reduce fabrication costs. An important requirement is that emerging memories must be compatible with CMOS technology to benefit from the advantages provided by the well-developed CMOS fabrication technology.

Applications driven by magnetic moments and induced magnetic fields had a large share in typical information technology products in the past as the coupling between magnetic fields and currents in coils was employed in the first electronic devices. However, the coupling was weak, which resulted in low efficiency and high energy supply costs. An efficient coupling between the electrical and the magnetic degree of freedom is possible on a quantum mechanical level and was discovered in 1986 as a phenomenon called the giant magnetoresistance (GMR) effect. This facilitated a reliable, purely electrical read operation of the information encoded in the magnetization orientation. Based on this principle, hard disk drive storage devices with extremely high density appeared on the market. The tremendous impact of this discovery on the development of information technology was recognized by awarding the inventors the Nobel Prize in 2007 [95, 96].

The next generation of storage devices with even higher density was based on the unique properties of the MTJ. As was already briefly discussed, the tunneling current through the MTJ structure strongly depends on the relative polarization of the ferromagnetic contacts. The difference in the MTJ resistivity can reach several hundred percent at room temperature [97]. Using MTJs as data storage elements yields an efficient way of converting the spin (magnetization) degree of freedom into a charge (current) employed by CMOS devices. It is important that the typical resistance of an MTJ is similar to that of a MOSFET, which makes MTJ-based memory electrically compatible with CMOS circuitry without extra amplifiers needed. Thanks to this technology, a new generation of hard disk drives with even higher storage densities has been developed [98, 99].

In order to be fully compatible with CMOS circuitry, MTJs must be complemented with the ability to efficiently convert charge information into magnetic moment orientation. In earlier field-driven magnetoresistive random-access memories, the information writing was performed with the help of a magnetic field [100, 101]. Although a very fast switching of a specially designed free magnetic layer [102] has been achieved by applying carefully engineered orthogonal current pulses, MRAM with field-induced switching cannot be scaled beyond the 90 nm technology node [103]. Indeed, the magnetic field is generated by the electric current passing through the write lines next to the cell, which leads to an unbearable current density increase with scaling [101]. Therefore, in order to support the scaling, a new purely electrical way of MRAM information writing without magnetic field must be implemented.

Below we briefly discuss the three most prominent emerging concepts of nonvolatile magnetoresistive memories: spin-transfer torque MRAM, spin-orbit torque MRAM, and advanced magnetoresistive memories including racetrack memory.

31.3.1 Spin-Transfer Torque MRAM

The spin-transfer torque effect (STT) [104, 105] has been proven to be perfectly suited for purely electrical data writing by passing a current through the MTJ (Fig. 31.20a). When electrons pass through a fixed ferromagnetic layer, their spins become aligned with the magnetization. When these spin-polarized electrons enter the free magnetic layer, they become aligned with the magnetization of the free layer within a transition layer of a few angstroms. Due to the conservation of the total angular momentum, the change of the electron spin is compensated by the modification of the free layer magnetization. Therefore, the spin-polarized current exerts a torque on the magnetization of the free layer. If the current is sufficiently strong to overcome the damping, this torque causes magnetization switching. If the current tends to switch the magnetization from the parallel to the antiparallel configuration, altering the current direction will result in the magnetization switched from the antiparallel to the parallel state.

STT-MRAM is considered as a perfect candidate for future universal memory applications. STT-MRAM is fast (10 ns), possesses high endurance (10^{12}), and has a simple structure. It is compatible with CMOS technology

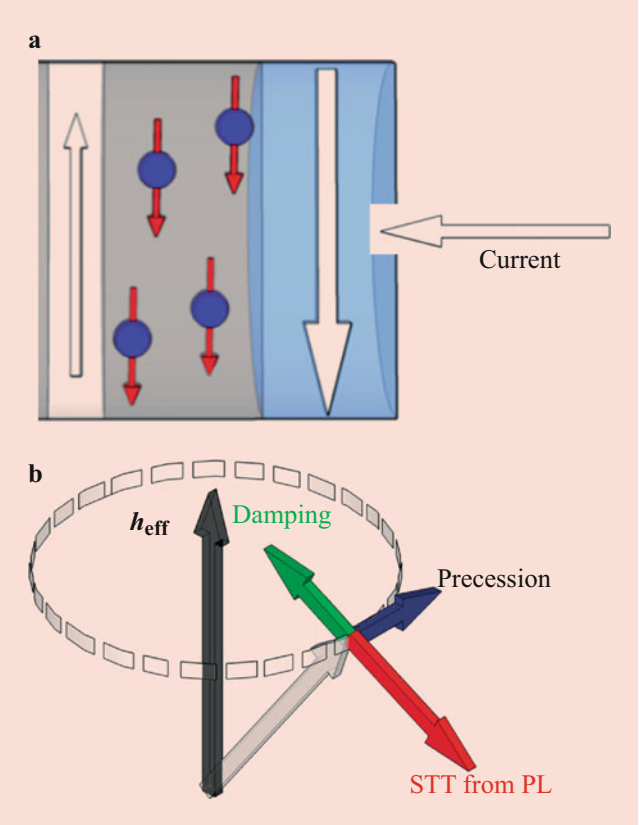

Fig. 31.20 (**a**) Charge current running through a magnetic tunnel junction's pinned layer (PL) creates a spin-transfer torque acting on a free recording magnetic layer. (**b**) torques acting on the magnetization: spin-transfer torque, damping, effective magnetic field torque

and can be straightforwardly embedded in circuits [101]. It is particularly promising to employ nonvolatility in Internet of Things (IoT) and automotive applications, as well as a replacement of conventional volatile CMOS-based DRAM and nonvolatile flash memory. High-density STT-MRAM arrays with 4Gbit capacities have been already demonstrated [106]. For embedded applications, a successful implementation of 8 Mb 1T-1MTJ STT-MRAM on a 28 nm CMOS logic platform [107] was demonstrated. Recently, 128 Mb embedded MRAM with 14 ns write speed was reported [108]. An embedded MRAM solution compatible with 22FFL FinFET Intel's technology is available [109].

With STT-MRAM currently emerging as a commercial product for standalone and embedded applications, it is critically important to introduce STT-MRAM in the main computer memory. This potentially creates a new innovative multibillion dollar industry. Bringing STT-MRAM into the vast computer memory market as standalone and embedded applications for traditional high-performance and low-power mobile platforms will result in an exponential growth of the nonvolatile memory market share in the near future.

Regardless of the first commercial STT-MRAM-based products for standalone applications being available, one critical aspect of the currently used STT-MRAM technology is a relatively high switching current, which is in sharp contrast to the overall demand for reduced energy consumption. This might prevent MRAM from successfully entering the vast computer memory market. The problem of high switching current and large active writing energy jeopardizes the advantages provided by nonvolatility, such as zero standby power, no data refreshment, and no data recovery. At the same time, the minimum energy barrier separating the two stable memory states must be large, at least 60–80 times the thermal energy, to negate the errors due to unwanted thermally agitated magnetization switching in big (1 Gb) memory arrays at long (10 years) retention time. Since the same barrier must be overcome for memory writing, the switching current reduction problem is challenging to address.

Several plausible approaches to address these issues are currently pursued. They include the replacement of the in-plane magnetization orientation in magnetic tunnel junctions (MTJs) with perpendicular magnetization, the use of composite free recording layers, decoupling the write and read current paths, controlling magnetization by voltage, and employing new materials with improved properties and characteristics.

The availability of high-capacity nonvolatile memory close to high-performance CMOS circuits allows exploring conceptually new logic-in-memory [110] and computing-in-memory [111, 112] architectures for future artificial intelligence and cognitive computing [113].

The interest in STT-MRAM has increased significantly after the observation of spin torque-induced switching in AlO_x-based cells [114]. However, the exciting journey of bringing STT-MRAM to the market was ignited by the observation of spin torque-induced switching in MgO-based [115] cells. Depending on the orientation of the layer magnetization, the magnetic pillars can be divided into two categories: (i) perpendicular with out-of-plane magnetization direction and (ii) in-plane with the magnetization lying in the plane of the magnetic layer.

The magnetization dynamics of switching is determined by the Landau-Lifshitz-Gilbert equation [116, 117] complemented by the corresponding torque:

$$\frac{\partial \boldsymbol{m}}{\partial t} = -\gamma\left(\boldsymbol{m} \times \boldsymbol{h}_{\text{eff}}\right) + \boldsymbol{\alpha m} \times \frac{\partial \boldsymbol{m}}{\partial t} - \frac{g\mu_{\text{B}} J}{e\gamma M_{\text{s}} d} \cdot g\left(\theta\right) \left(b\left(\boldsymbol{m} \times \boldsymbol{p}\right) - \left(\boldsymbol{m} \times \left(\boldsymbol{m} \times \boldsymbol{p}\right)\right)\right) \tag{31.56}$$

$\gamma = 2.3245 \cdot 10^5 \text{m/(A·s)}$ is the gyromagnetic ratio, g is the g-factor, α is the Gilbert damping parameter, b is a nonadiabaticity parameter, μ_{B} is Bohr's magneton, J is the current density, e is the electron charge, d is the thickness of the free layer, $\boldsymbol{m} = \mathbf{M}/M_{\text{s}}$ is the position-dependent normalized vector of the magnetization in the free layer, $\boldsymbol{p} = \mathbf{M}_{\text{p}}/M_{\text{sp}}$ is

the normalized magnetization of the first pinned layer, and M_s, M_{sp} are the saturation magnetizations of the free layer and the pinned layer, correspondingly. We use Slonczewski's expressions for the MTJ with a dielectric layer [118]:

$$g(\theta) = 0.5 \cdot p \cdot \left[1 + p^2 \cdot \cos(\theta)\right]^{-1} \tag{31.57}$$

The local effective field is calculated as

$$\boldsymbol{h}_{\text{eff}} = \boldsymbol{h}_{\text{ext}} + \boldsymbol{h}_{\text{ani}} + \boldsymbol{h}_{\text{exch}} + \boldsymbol{h}_{\text{demag}} + \boldsymbol{h}_{\text{th}} + \boldsymbol{h}_{\text{amp}} + \boldsymbol{h}_{\text{ms}} \tag{31.58}$$

$\boldsymbol{h}_{\text{ext}}$ is the external field, $\boldsymbol{h}_{\text{ani}}$ is the magnetic anisotropy field, $\boldsymbol{h}_{\text{exch}}$ is the exchange field, $\boldsymbol{h}_{\text{demag}}$ is the demagnetizing field, $\boldsymbol{h}_{\text{th}}$ is the thermal field, $\boldsymbol{h}_{\text{amp}}$ is the Ampere field, and $\boldsymbol{h}_{\text{ms}}$ is the magnetostatic coupling between the pinned layers and the free layer. Typical values of the parameters characteristic to CoFeB/MgO/CoFeB structure are $M_s = M_{sp} = 8.9{\cdot}10^5$A/m, $A = 1{\cdot}10^{-11}$ J/m, $\alpha = 0.01$, and $p = 0.63$ [119].

Figure 31.20b schematically shows the torques and fields acting on the magnetization during the switching. When the current of the corresponding polarity runs through the structure, it creates the STT which tilts the magnetization away from its equilibrium position. When tilted, the magnetization experiences the effective magnetic field, around which it precesses. The damping term tries to bring the magnetization back to its equilibrium position. The switching occurs, if the STT overcomes the damping term. From this condition the critical current for switching is obtained.

However, the magnetization switching can occur spontaneously due to thermal fluctuations without any current. This is an undesired event, which leads to the loss of the stored information. An important parameter of MRAM is the thermal stability factor which is defined as the ratio of the thermal stability barrier to the operating temperature. For gigabit applications the thermal stability barrier should be at least 80 kT to guarantee the required retention time of 10 years. Achieving large thermal stability and a low switching current for fast switching simultaneously represents one of the main challenges to engineer a good MRAM cell. In in-plane magnetized structures, the shape anisotropy defines the two stable magnetization directions (Fig. 31.21a). In these structures the minimum energy difference separating the two stable magnetization states is determined by the energy difference between the two states with the magnetization in-plane perpendicular and parallel to the easy anisotropy axis. The switching barrier is larger than the thermal barrier defined as the minimum energy barrier separating the two stable magnetization states. This is because at switching the magnetization must get out-of-plane, which results in a large demagnetization energy contribution to be overcome, in addition to the thermal barrier.

For in-plane MTJs, faster switching can also be achieved, when the composite free layer is made of two half-ellipses separated by a narrow gap (Fig. 31.21b). The peculiarities of the magnetization dynamics of the two parts of the composite free layer [111, 120], which occur in opposite senses to each other, lead to the magnetization switching in-plane (Fig. This way the large demagnetization31.21c). This way the large demagnetization penalty of the magnetization getting out-of-plane is avoided, and the switching barrier becomes equal to the thermal barrier. Because the thermal barrier depends on the free layer volume, the required large thermal stability factor of ~80 kT is easily achieved in this structure.

For the perpendicular structures (Fig. 31.22a), the magnetization orientation is already out-of-plane. The large demagnetizing energy penalty one has to pay while writing an in-plane structure does not exist for switching perpendicular structures. Perpendicular MTJs (p-MTJs) with the thermal barrier equal to the switching barrier are thus preferred, because they allow to reduce the switching current. In addition, p-MTJs are better suited for high-density memory [110]. However, it is difficult to find a material with the uniaxial anisotropy so strong that it can overcome the demagnetization field of a thin ferromagnetic layer. A critical technological step allowing to solve this problem was the discovery of an interface-induced perpendicular anisotropy at the CoFeB/MgO interface [121], which makes the very thin CoFeB layer perpendicularly magnetized (Fig. 31.22a).

Both field-induced and STT switching can be complemented with heat-assisted switching [101]. This technology was routinely used in hard disk drives in order to facilitate writing. Methods using thermally assisted switching in MRAM have already been developed. In addition to assisting switching, heat can facilitate new unique functionalities, for instance, using an MRAM cell with a soft reference layer as a magnetic logic unit [122]. This extends the MRAM research and development area toward logic-in-memory architectures and nonvolatile computing.

Regardless of the undeniable success of the first MRAM products appearing on the market, several important challenges still remain. The general requirements for any memory type including MRAM are the ability to write the data with low energy without damaging the device, long data retention, and the ability to read the recorded data without destroying them.

Improving one or two aspects of its functionality usually leads to a degradation of the remaining functionalities [101] in STT-MRAM. Therefore, a careful parameter optimization specific to a particular technology is the main subject which must be addressed in order to facilitate production of high-density memory arrays suitable for replacing SRAM caches and DRAM main computer memory.

As was mentioned already, one of the main problems of STT-MRAM is the relatively high critical current required for

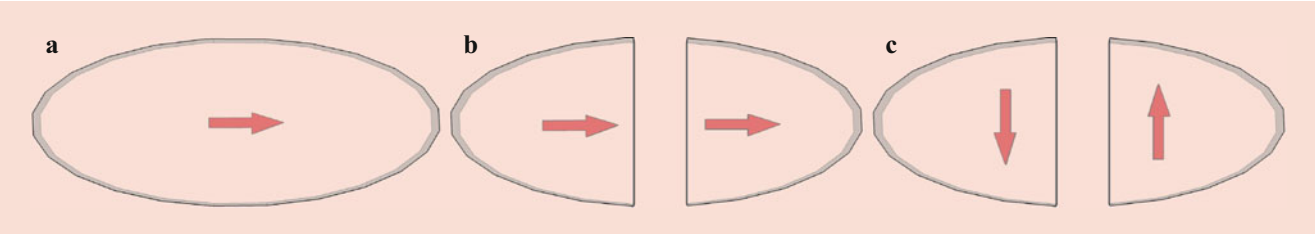

Fig. 31.21 (**a**) Shape anisotropy defined magnetization direction in an elliptic free magnetic layer; (**b**) Stable magnetization direction in a composite free magnetic layer with a narrow splitting between the two parts; (**c**) The magnetic configuration with a maximum energy through which the composite free layer proceeds at STT switching. The composite free magnetic layer switches in-plane, which results in a lower switching barrier and faster switching [111, 120]

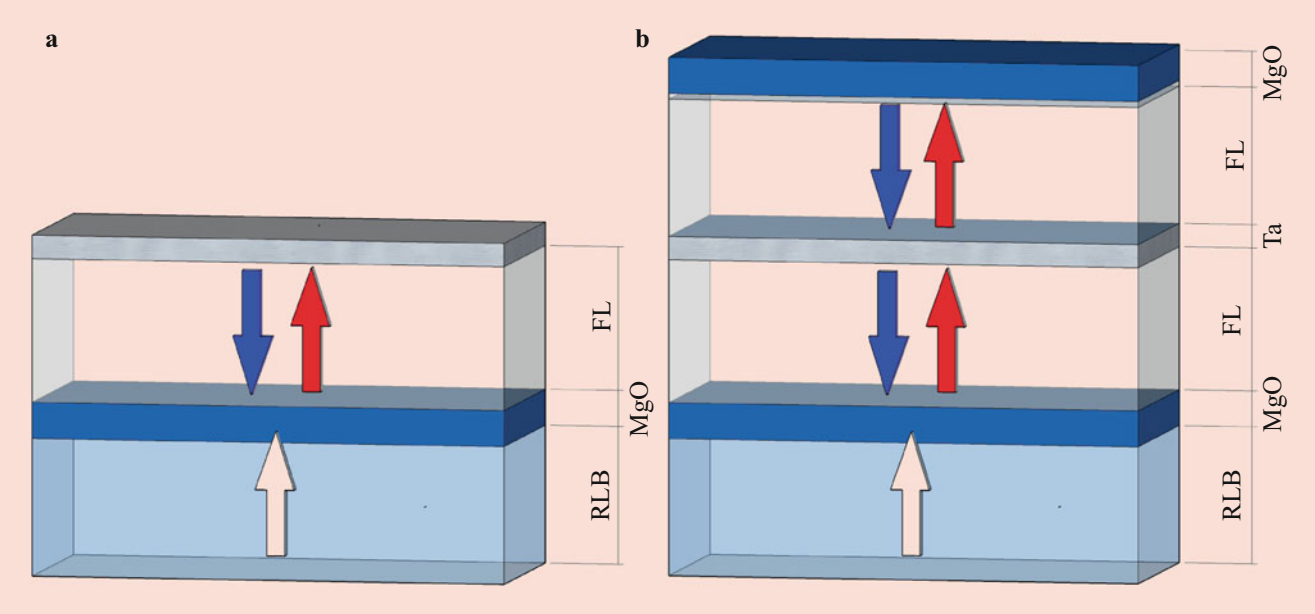

Fig. 31.22 (**a**) Illustration of a perpendicularly magnetized MTJ. The perpendicular uniaxial anisotropy is interface-induced [118]. (**b**) The thermal stability is enhanced by adding a second CoFeB/MgO interface with interface-induced anisotropy [123]. The Gilbert damping is also reduced for the composite free layer made of two thin ferromagnetic CoFeB layers separated by a Ta metallic spacer [123]

STT-induced magnetization switching. This fact has several implications. Firstly, due to the relatively high energy required for writing, memory should not be written frequently as it may negate the benefits of nonvolatility provided by MRAM. Secondly, large switching currents are supplied via an access transistor. This potentially puts scaling limitations on the transistor dimensions of a one-transistor (1T)-1MTJ memory cell.

In order to reduce the switching current density and to preserve the large thermal barrier at the same time, one has to reduce the Gilbert damping and increase the spin current polarization. An interface-induced p-MTJ structure with a composite free layer CoFeB/Ta/CoFeB with two MgO interfaces [123] (Fig. 31.22b) allows boosting the thermal barriers. It turns out that the use of the p-MTJ structure with the two CoFeB/MgO interfaces also reduces the Gilbert damping by half, thus allowing to simultaneously boost the thermal barriers and to reduce the switching current. To scale the diameter of the MTJ beyond 10 nm, the use of shape anisotropy was suggested [124]. It has been shown that the thermal stability can be boosted for small diameters without sacrificing on TMR and without any need of new materials, as FeB for the ferromagnetic free layer and MgO for the tunnel barrier were used.

In order to integrate STT-MRAM with the CMOS fabrication process, MTJs must sustain 400 C temperature typical for the back-end-of-line process. Recently, IMEC reported a process allowing to preserve the high TMR and thermal stability of MTJs [125]. The idea is to invert the free and the fixed layer by putting the fixed layer on top of the MTJ. An additional synthetic ferromagnet instead of an antiferromagnet is employed to pin the magnetization of the fixed layer. This design requires a compensating magnet to be in addition integrated in the structure. Optimization of this magnet can

be used to achieve symmetric switching between the parallel and the antiparallel configuration and back.

A large TMR ratio is needed for reliably reading the information in MRAM. Indeed, the middle reference resistance to which the low and high resistance MTJ states are compared must be well separated from either of them. However, with downscaling it becomes increasingly difficult to control the bit-to-bit resistance variation which results in sacrificing the read margin. As the resistance variation dispersion increases, the TMR must also increase to provide a sufficiently broad window for reliable reading. Obtaining a TMR larger than 350% [126] is an important challenge needed to continue with the devices scaling down.

With growing data services such as Big Data analysis, the need for additional memory capacity and speed as well as in-memory computing has increased dramatically. The last-level cache memory must be increased [127–129] to bridge the memory-bandwidth gap between CPUs and the main memory. The CPU performance can be significantly boosted by using fast nonvolatile memories in cache for data storing without the need to address the main memory.

Advanced STT-MRAM is characterized by high-speed access with 10 ns. It is thus in principle suitable for last-level caches where it guarantees power reduction by a factor of ten [130–132], while other types of nonvolatile memories are much slower and cannot provide the desired high-speed access. Various major foundries including Samsung [133] announce the beginning of production of embedded STT-MRAM based on the 28 nm silicon-on-insulator technology node [134], while GlobalFoundries is planning STT-MRAM production based on the 22 nm fully depleted silicon-on-insulator technology [132]. We are therefore witnessing the beginning of nonvolatile STT-MRAM entering the DRAM and potentially SRAM markets, traditionally dominated by CMOS-based volatile devices. If successful, it will result in an exponential expansion of the STT-MRAM market with a momentous impact on information storage and processing in the near future.

Although the use of STT-MRAM in last-level caches is conceivable [131], the switching current for operating in high-level caches at sub-nanosecond speed is growing rapidly. Increasing critical currents result in large current densities flowing through the magnetic tunnel junctions. This leads to oxide reliability issues, which in turn reduces the MRAM endurance to that of the flash memory. A new technological solution is thus required to use MRAM in L1 and L2 caches.

31.3.2 Spin-Orbit Torque MRAM

The engineering of an electrically addressable nonvolatile memory combining high speed (sub-ns operation) and high endurance suitable for replacing SRAM in higher-level caches of hierarchical multilevel processor memory structures with a nonvolatile memory [110] cannot be based on STT, and the use of new physical principles is required. Among the newly discovered physical phenomena suitable for next-generation MRAM is spin-orbit torque (SOT)-assisted switching at room temperature in heavy metal/ferromagnetic [135–142] or topological insulator/ferromagnetic [143–146] bilayers. In this memory cell, the MTJ's free layer is grown on a material with a large spin Hall angle. The SOT acting on the adjacent magnetic layer is generated by passing the current through this material. The relatively large switching current is injected in-plane along the heavy metal/ferromagnetic bilayer and does not flow through the MTJ, while a much smaller read current is applied through the MTJ. This results in a three-terminal configuration where the read and write current paths are decoupled. Since the large write current does not flow through the oxide in the MTJ, this prevents the tunnel barrier from damage. It improves device reliability by eliminating correlations between the switching current and the retention time. Therefore, three-terminal MRAM cells are promising candidates for future generations of nonvolatile memory for fast sub-ns switching [141]. SOT-MRAM is an electrically addressable nonvolatile memory combining high speed and high endurance and is thus particularly suitable for applications in caches [141]. Although the high switching current is not flowing through a magnetic tunnel junction but rather through a heavy metal wire under it, the current is still high, and its reduction is the pressing issue for SOT-MRAM development.

Topological insulators (TIs) are promising materials for reducing the switching current as they are characterized by a high spin Hall angle and large efficiency Θ_{SH} of charge to spin conversion due to the peculiar perpendicular spin-momentum locking in the interface states [143, 144]. In addition, the strong spin-orbit interfacial Rashba field helps in generating the required spin density in TIs in order to boost the charge to spin conversion efficiency above 100%.

Although a high charge to spin conversion efficiency in TIs has been reported, the electrical conductivity of TIs needed for practical applications to build a high-density, ultra-low power, and ultra-fast nonvolatile memory is not sufficiently high because of the insulating bulk. Recent developments introduce BiSe- [145] and BiSb [146]-based TIs as suitable candidates for emerging SOT-MRAM as they possess a charge to spin conversion efficiency of 18.8 and 52, respectively. This allows to reduce the switching current by two orders of magnitude as compared to W-based SOT-MRAM. In addition, BiSb samples [146] possess very high electrical conductivity making thin BiSb films leading candidates for emerging fast and low-power SOT-MRAM, and the process integration of BiSb into a MTJ stack is currently under scrutiny [146].

The proper integration of the SOT-MRAM fabrication steps with the CMOS process represents a significant challenge as the memory cells must withhold at least the back-end-of-line thermal budget. As IMEC presented recently a technology to integrate a perpendicular beta-phase W/CoFeB/MgO/CoFeB/synthetic antiferromagnetic stack for a SOT-MRAM on a 300 mm CMOS wafer by only CMOS compatible processes [147], there is a cautious confidence that fast low-power nonvolatile magnetoresistive memory suitable for processor caches will be available soon.

Despite the undisputable progress in developing SOT-MRAM, there is one important issue which has not been convincingly resolved so far, namely, a static magnetic field is still required to guarantee deterministic switching [148, 149] or a perpendicularly magnetized free layer. Several paths to achieve the deterministic switching without magnetic fields were suggested. They require solutions to break the mirror symmetry either by means of the shape of the dielectric [150] or the free layer [151] or by controlling the crystal symmetry of the metal line at the microscopic layer [152]. Biasing the free layer by employing an exchange coupling to an antiferromagnet [153–155] and the use of a peculiar tapered sample shape, which controls the switching [156], were recently reported. However, even if in most of these studies field-free switching was reported, these methods either require a local intrusion into the fabrication process or are based on solutions (antiferromagnets, shapes), which complicate large-scale integration of the fabricated memory cells.

To achieve magnetic field-free switching, a scheme based on two sub-nanosecond orthogonal current pulses is promising [111]. This scheme is suitable for integration in a cross-bar architecture. Applied to in-plane structures, the switching scheme has been shown to accelerate the switching of the in-plane structure by a factor of three.

The two-pulse switching scheme can be applied to a free magnetic layer with perpendicular magnetization [157]. Results of simulations described below show that deterministic, fast, and external magnetic field-free switching of the perpendicularly magnetized layers is achieved.

The SOT switching scheme based on the use of two consecutive orthogonal sub-nanosecond current pulses is sketched in Fig. 31.23. The first pulse is applied to the heavy metal line NM1 with a large spin Hall angle. It results in a large spin current in the out-of-plane direction, which impinges the ferromagnetic layer. The spin current creates the SOT acting on the magnetization. The SOT brings the magnetization in-plane in the direction perpendicular to the current direction in MN1. It implies that the current density in the first current pulse is larger than the critical current density [141]. The second consecutive current pulse is applied through the wire NM2 also possessing a large spin Hall angle.

The free layer of dimension $a \times b \times d = 52.5 \times 12.5 \times 2\ \mathrm{nm}^3$ overlaps fully with the heavy metal line NM1 of 3 nm thickness, with the effective Hall angle Θ_{SH} describing the efficiency of the charge-to-spin conversion. Another heavy metal wire NM2 possesses an overlap from the right side lesser than the total free layer width. The magnetization dynamics of the system due to the spin current densities and the spin accumulations is well described by the Landau-Lifshitz-Gilbert equation (31.59):

$$\begin{aligned}\frac{\partial \boldsymbol{m}}{\partial t} &= -\gamma \boldsymbol{m} \times \boldsymbol{h}_{\mathrm{eff}} + \boldsymbol{\alpha} \boldsymbol{m} \times \frac{\partial \boldsymbol{m}}{\partial t} + \\ &+ \gamma \frac{\hbar}{2e} \frac{\Theta_{\mathrm{SH}} J_1}{\mathbf{M}_{\mathrm{S}} d} \left[\boldsymbol{m} \times (\boldsymbol{m} \times \boldsymbol{y})\right] \Theta(t) \Theta\left(t_1 - t\right) - \\ &- \gamma \frac{\hbar}{2e} \frac{\Theta_{\mathrm{SH}} J_2}{M_{\mathrm{S}} d} \left[\boldsymbol{m} \times (\boldsymbol{m} \times \boldsymbol{x})\right] \\ &\Theta\left(t - t_1 - \tau\right) \Theta\left(t_2 + t_1 + \tau - t\right)\end{aligned} \tag{31.59}$$

where $\boldsymbol{m}$ is the position-dependent magnetization $\mathbf{M}$ normalized by the saturation magnetization M_{S}, $\boldsymbol{m} = \mathbf{M}/M_{\mathrm{S}}$, γ is the gyromagnetic ratio, α is the Gilbert damping parameter, e is the electron charge, $\hbar$ is the reduced Plank constant, Θ_{SH} is an effective Hall angle relating the strength of the spin current density to the charge current density J_i ($i = 1,2$) passing through NM1 and NM2, $t_{1,(2)}$ is the duration of the first (second) pulse, and τ is a time delay between the pulses. The spin-orbit torques due to the charge currents through NM1 and NM2 represented by the third and fourth terms on the right hand side of (31.59) are acting on the free layer at the places of the overlaps of the FL with NM1 and NM2 (Fig. 31.23).

We use the parameters (listed in Table 31.1) typical for the perpendicular CoFeB free layer on a MgO tunnel barrier. The thermal stability factor is around 40. Although this thermal stability is not sufficient for standalone applications, this memory cell is suitable for applications in high-level caches, where the requirements for TMR and the stability are relaxed in favor of fast operation.

Table 31.1 Parameters used in the simulations

Name	Value
Saturation magnetization M_{S}	4×10^5 A/m
Exchange constant A	2×10^{-11} J/m
Perpendicular anisotropy K	2×10^5 J/m^3
Gilbert damping α	0.05
Spin Hall angle Θ_{SH}	0.3
Free layer dimensions	$52.5 \times 12.5 \times 2$ nm^3$25 \times 25 \times 2$ nm^3
NM1: $w_1 \times l$	12.5 nm × 3 nm
NM2: $w_2 \times l$	5–52.5 nm × 3 nm

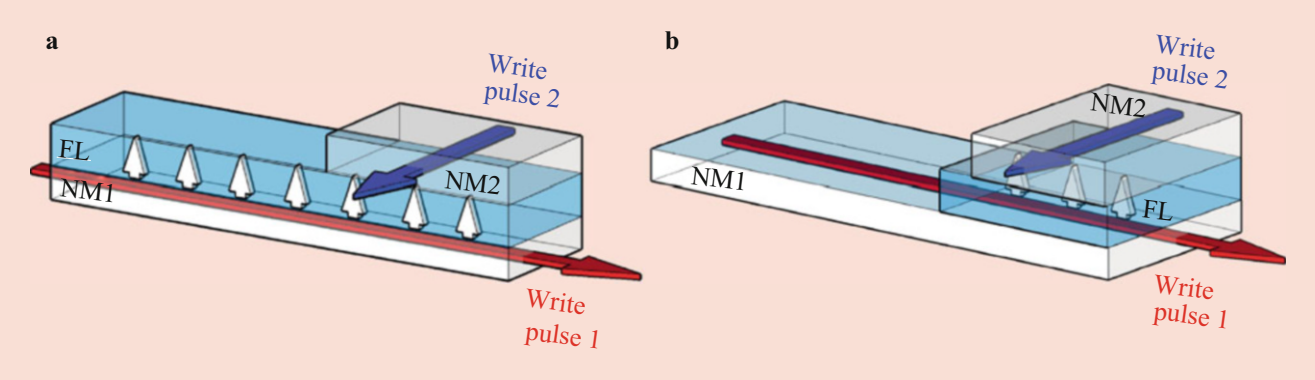

Fig. 31.23 The switching scheme [111] based on two short consecutive orthogonal current pulses provides fast, deterministic, and magnetic field-free magnetization reversal of a perpendicularly magnetized free layer of (**a**) a rectangular shape and (**b**) a symmetric square shape

To realize the switching scheme, a 100 ps short and 100 μA strong current pulse is applied through NM1. The current density equals 2.6×10^{12} A/m^2, which is slightly larger than the critical current density 2×10^{12}A/m^2 reported in [148]. The consecutive perpendicular current pulse is applied through NM2. Thermal effects at 300 K on the magnetization dynamics are described by a fluctuating magnetic field. Different realizations of the field produce diverse realizations of the switching process. Importantly, no external magnetic field is applied.

The time-dependent magnetization dynamics for 20 realizations is shown in Fig. 31.24, where the current density of "Write pulse 2" with 200 ps duration is larger than the critical current applied to NM2 with the width 52.5 nm (equal to the free layer width, complete overlap). Although the current is high (1 mA), it does not provide deterministic switching. It orients the magnetization in-plane against the **x** axis, but there is no torque along the **z** axis. Therefore, after the current is turned off, the magnetization randomly relaxes either in the same or in the opposite direction with equal probability because of the perpendicular magnetic anisotropy.

Unexpectedly, when the current is reduced to 200 μA and the current density to 1.25×10^{12} A/m^2, which is below its critical value, the switching becomes deterministic for all 20 realizations (Fig. 31.25). In this case, the torque due to "Write pulse 2" is not sufficiently strong to align the magnetization along **x** direction, and it only tilts the magnetization away from the **y** direction. In this case, the switching becomes deterministic as the tilted magnetization precesses about the shape effective anisotropy field along the **x** direction, which plays the role of the external field required for making the switching of perpendicular structures deterministic [148]. The polarity of the second pulse therefore defines whether the magnetization relaxes up or down relative to the **z** axis.

If now the current in the second pulse is further decreased to $I_2 = 100$ μA, the switching is robust only, if the second pulse is either short (50–70 ps) or long (>1 ns) (Fig. 31.26).

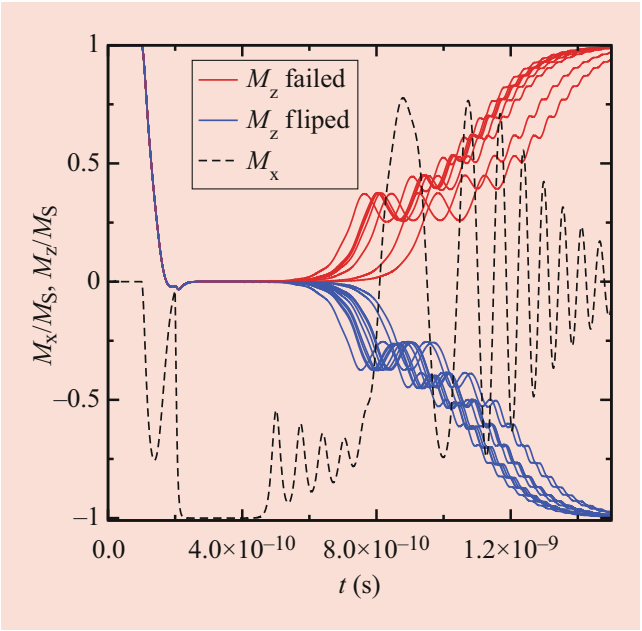

Fig. 31.24 Time evolution of the magnetization in two-pulse switching (second pulse 1 mA/200 ps). Twenty different switching realizations are obtained after 100 ps initial thermalization

The switching becomes fully deterministic for intermediate pulse durations, if the overlap of NM2 with the free layer is reduced to approximately 30%, for the current $I_2 = 100$ μA (Fig. 31.27). As is seen from Fig. 31.27, the "Write pulse 1" puts the magnetization of the free layer in-plane perpendicular to the "Write pulse 1" direction (Fig. 31.27). Depending on the "Write pulse 2" polarity, the corresponding SOT slightly tilts the magnetization in-plane toward the left or right end of the rectangle. Then the magnetization experiences the shape anisotropy field which plays the role of the external field to complete the switching 100% reliably. Figure 31.28 shows that the switching is extremely robust

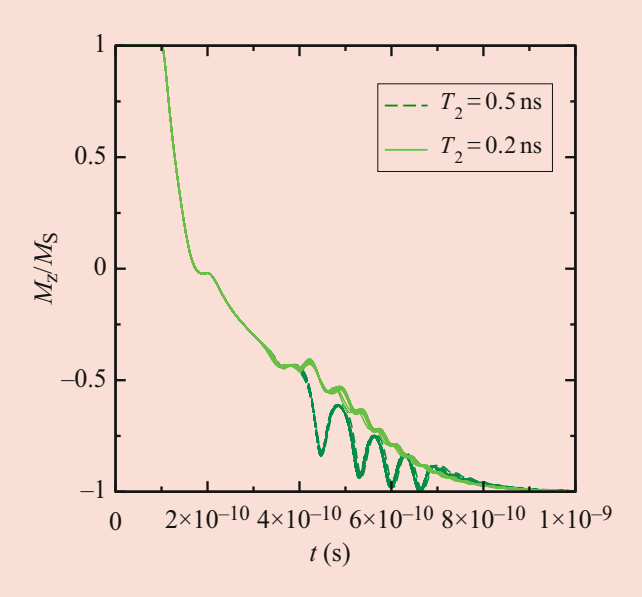

Fig. 31.25 Same as in Fig. 31.24, but with a second pulse current of 200 μA, for two different durations of the second pulse. The 20 realizations switch evenly, almost without dispersion. The switching is deterministic

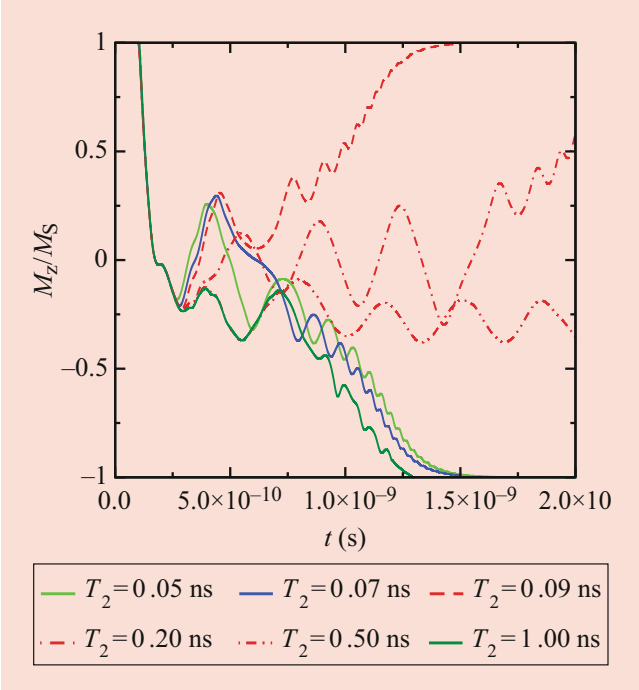

Fig. 31.26 $m_z(t)$ for NM2 fully overlapping with the FL averaged for 20 realizations. $I_1 = I_2 = 100$ μA. For 70 ps $< T_2 <$ 1 ns the switching fails (shown in *red*)

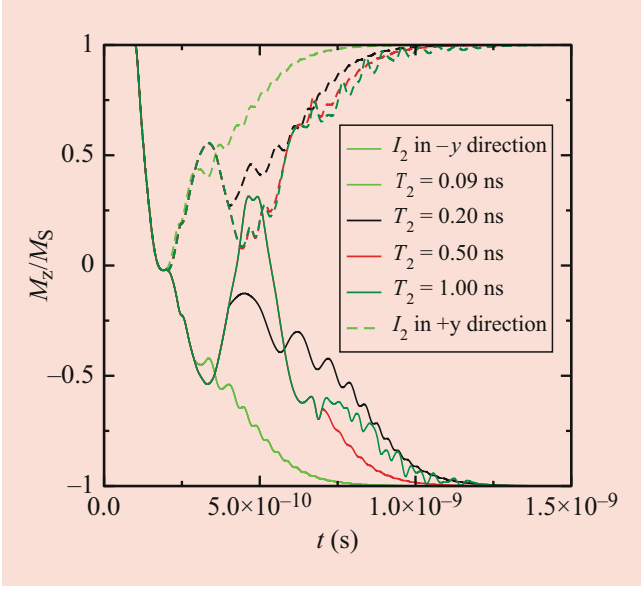

Fig. 31.27 Average of 20 realizations of $m_z(t)$, with $m_z(0) = 1$ for NM2 = 12.5 nm, $I_1 = I_2 = 100$ μA, several T_2, and $\tau = 0$

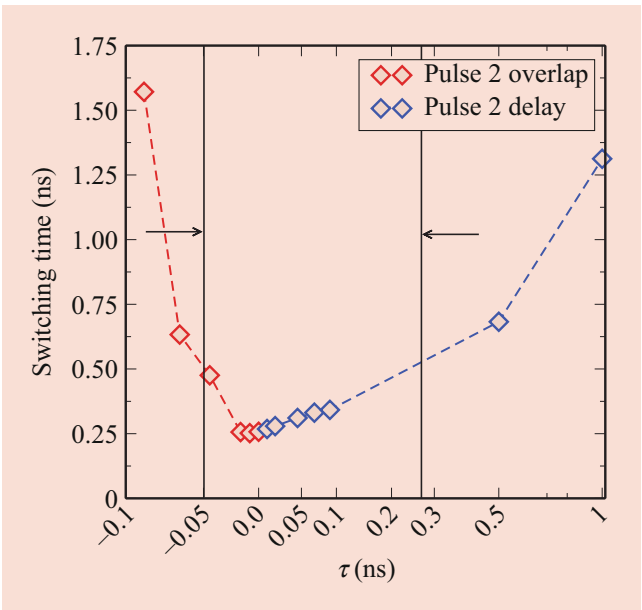

Fig. 31.28 Robust switching at pulse delays between −90 ps $< \tau <$ 1 ns (defined in (31.59)), for $w_1 = w_2 = 12.5$ nm and equal write pulses ($I_1 = I_2 = 100$ μA, $T_1 = T_2 = 100$ ps). Sub-0.5 ns switching is obtained at −50 ps $< \tau <$ 250 ps

with respect to the delay τ, which proves the scheme suitable for practical implementation.

We have demonstrated that the two-pulse switching scheme works for a rectangular sample. However, although footprint size requirements are relaxed in SRAM memory, to grow non-symmetric free layers for benefitting from the extra magnetic shape anisotropy appears superficial as it requires more space and complicates the etching. It is therefore desirable to develop a method for switching a symmetric free layer with perpendicular magnetic anisotropy. Below we demonstrate that the two-pulse SOT switching scheme also

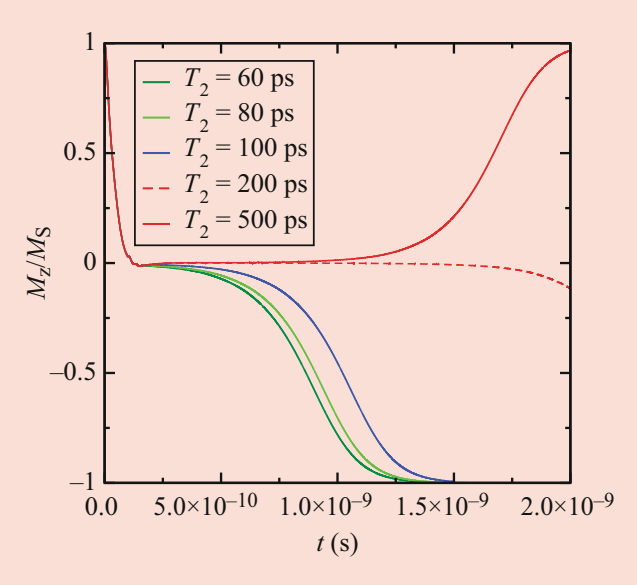

Fig. 31.29 Average of 20 switching realizations. For a partial overlap $w_2 = 17.5$ nm, reliable switching of a square FL at short T_2 pulses appears

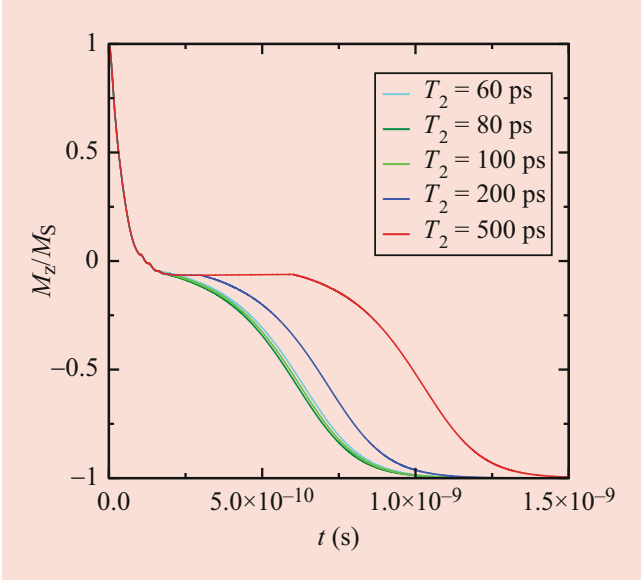

Fig. 31.30 Average of 20 switching realizations for $w_2 = 10$ nm. Reliable switching is observed for all T_2

works for a free layer with the dimensions $25 \times 25 \times 2$ nm^3 of a square form. Again, the free layer overlaps fully with NM1 of $l = 3$ nm thickness. The first pulse of a fixed duration $t_1 = 100$ps and fixed current $I_1 = 200$ μA is applied through NM1. Another heavy metal wire (NM2) of $l = 3$ nm overlaps partly with the FL, $w_2 < a$ and serves to apply the second consecutive perpendicular current pulse $I_2 = (w_2/a)200$ μA of the same current density as in "Write pulse 1," with a variable duration t_2.

If the NM2 overlap with the free layer is reduced to $w_2 = 17.5$ nm, deterministic switching is observed for all 20 realizations, when the duration T_2 of "Write pulse 2" becomes shorter than 200 ps (Fig. 31.29). If the overlap w_2 is further reduced below 15 nm, the switching becomes deterministic for all pulse durations T_2 considered (Fig. 31.30). The magnetization snapshot in Fig. 31.31 demonstrates the position-dependent magnetization just after the "Write pulse 2" was turned on. The magnetization under NM2 rotates due to the SOT of the second pulse. The stray field of the magnetization rotated by the pulse through NM2 creates an effective in-plane magnetic field for the rest of FL. This field makes the magnetization to precess around it away from its in-plane orientation. The whole magnetization of the free layer precesses in the same sense after "Write pulse 2" is turned off. Fig. 31.32 proves the main result of the work that the switching scheme is robust not only with respect to $t_2 = 80 \pm 20$ ps fluctuation but also to fluctuations of $w_2 = 11 \pm 4$ nm as almost the same fast switching time is obtained.

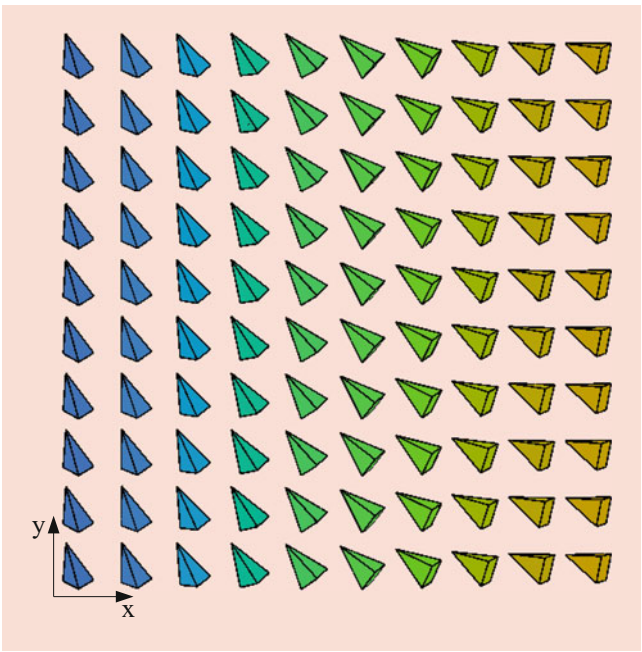

Fig. 31.31 Magnetization in the free layer just after the second pulse is turned off. The magnetization in the left part of the free layer starts precessing about the stray magnetic field created by the right part. This stray field plays the role of the external magnetic field required for deterministic switching of a perpendicular free layer by SOT

We conclude that the two-pulse SOT switching scheme allows fast, robust, and the external field-free switching of a free layer with perpendicular magnetization of arbitrary shape. The spin-orbit torque due to the first pulse tilts the magnetization of the free layer in-plane perpendicular to the "Write pulse 1" direction. In a rectangular sample, the spin-

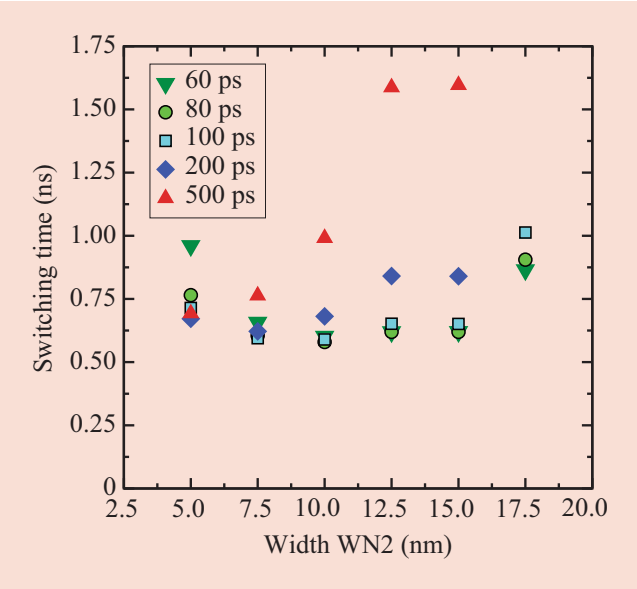

Fig. 31.32 The switching time as a function of the NM2 width. The NM2 width of 12.5 nm is optimal as it guarantees fast, robust, and deterministic switching which is insensitive to small variations of the pulse duration or NM2 width

orbit torque of the second consecutive current "Write pulse 2" pushes the magnetization toward one of the ends of the sample. Then the magnetization starts precessing around the shape anisotropy field. The shape anisotropy field plays the role of the external in-plane magnetic field needed to make the SOT switching of a perpendicularly magnetized free layer deterministic.

If the overlap of NM2 with the rectangular free layer is not complete, the magnetization in the part which overlaps with NM2 is tilted in-plane faster than the rest of the free layer. An additional stray magnetic field due to the faster moving magnetization acts on the rest of the free layer in complement to the shape anisotropy field. The stray magnetic field due to the magnetization of the free layer part overlapping with NM2 is sufficient to make the switching deterministic in a symmetric free layer of a square form. Therefore, the suggested two-pulse SOT switching scheme yields fast and reliable magnetic field-free switching of a symmetric perpendicular free layer, which is suitable for large-scale integration.

31.3.3 Advanced MRAM Developments

The two types of emerging magnetoresistive memory, STT-MRAM and SOT-MRAM, rely on writing the information by means of overcoming the energy barrier between the two memory states with a torque. If the energy barrier is suppressed, for example, by applying a voltage to the structure, the magnetization, which precesses around an effective magnetic field, can be put into the alternative magnetization state, if a barrier is re-introduced at the end of the voltage pulse [158]. An MRAM controlled by voltage [159–162] is a viable option for last-level cache applications.

Because the voltage-induced switching is unipolar, the voltage-controlled MRAM is free from the read disturbance which is characteristic of STT-MRAM. A voltage-controlled MRAM cell is a two-terminal device, where the separation between read and write is performed by alternating the polarities during these two operations.

Voltage-controlled MRAM has a few issues preventing it from being broadly used in applications. One of the problems originates in an undesirable variability due to the thermal noise. As the final state after the switching depends on the initial state after the barrier lowering, the thermally induced magnetization fluctuations can result in write errors.

Another problem is related to data reading. As no current is required to switch the magnetization, the tunnel barrier separating the two ferromagnets in a voltage-controlled memory cell is typically larger than the barrier in an STT-MRAM cell. This leads to a larger resistance of the voltage-controlled memory cell, which results in smaller currents. Small currents lead to a longer delay while reading the state by a sense amplifier. Both problems can be solved [162] by carefully tailoring and optimizing the entire circuit. Extending the ideas of voltage-controlled magnetic anisotropy, the voltage pulse can be applied not only to lower the potential barrier between the two magnetization states. For an opposite voltage polarity, the switching barrier is increased, which additionally prevents the switching while reading [163].

A device operating by using both voltage-controlled magnetic anisotropy and SOT switching was suggested in [164]. The switching is mediated by a spin-orbit and/or spin Hall torque generated by the current flowing through a conductive line made of a heavy metal underneath the MTJ, after the perpendicular magnetic anisotropy is weakened by a voltage applied. For reading a voltage pulse with a polarity opposite to that used for writing is applied to rise the potential barrier, which hardens the cell immunity against read disturb errors.

A conceptually new voltage-controlled magnetic memory device exploring unconventional properties of a heterostructure is composed of a topological insulator and a magnetic insulator [165]. The magnetization is reoriented by means of an electric field which creates the current only through the surface states in the topological insulator interfacing the magnetic insulator. The spin accumulation at the interface with the magnetic insulator is then created by means of the spin Hall effect. The spin accumulation provides a torque acting on the magnetization of the magnetic insulator, which ensures the magnetization switching [166].

From emerging device concepts based on innovative physical principles, antiferromagnetic spintronics [167] possesses numerous potential opportunities for the future of spintronic

applications. Antiferromagnetic materials do not generate any stray field. They are extremely robust against magnetic field perturbations. Importantly for applications, antiferromagnets are characterized by ultrafast dynamics and may be suitable for cache applications. As the antiferromagnetic order parameter can also be inverted by spin-orbit torques [168], memory concepts similar to STT-MRAM were suggested. However, as an antiferromagnet does not possess a net magnetization, the anisotropic magnetoresistance effect [168] is employed in order to read the information. As the anisotropic magnetoresistance of an antiferromagnet at room temperature is still weaker compared to the tunneling magnetoresistance in a magnetic tunnel junction, to benefit from both fast antiferromagnetic dynamics and large TMR, the use of partly compensated antiferromagnets with a nonzero net magnetization is promising [169].

31.3.4 Racetrack Memory

Modern spintronic devices undoubtedly play an increasing role in future microelectronics. Spintronics-based solid-state magnetoresistive memories STT-MRAM and SOT-MRAM discussed in details up to now possess no moving parts to record or to read the information, in contrast to magnetic hard disk drives with magnetic recording and read heads [170]. Magnetic racetrack memory [171–173] combines the two concepts of solid state-memory and hard disk drive-based memory with moving heads. Magnetic data encoded in a series of magnetic domain walls in a magnetic nanowire is shifted back and forth along the nanowire: the magnetic racetracks. Like in a hard disk drive, the information is recorded and read by magnetic heads [172]. As many domain walls can be created on a single racetrack, the memory offers an extremely high-density capacity. In addition, each racetrack can be arranged on U-shaped wires standing vertically over a grid of read/write heads. The memory is promising to store a large amount of data comparable to that on a hard disk drive, but allowing a much better performance at significantly less power.

The important property of racetrack memory is that magnetic domain walls are shifted together synchronously in the same direction when the electric current is run through the racetrack. Domain walls are moved by means of spin-transfer torque generated by a spin-polarized current acting on the nonuniform magnetization within the walls. In the initial demonstration of the first generation of racetrack memory [174], the maximum velocity of the domain walls was about 100 m/s and was limited by the current density when unwanted heating of the nanowire was detected.

In order to increase the storage density on a racetrack, the domain walls must be made more compact. Nanowires composed of magnetic ultra-thin Co and Ni multilayers develop a perpendicular magnetic anisotropy, which allows to reduce the domain walls' dimensions to just a few nanometers. As the domain walls were moved by the spin-transfer torque acting on the volume of domain walls, their velocities in the second generation of racetrack memory were similar to those in the first generation. Thin films of CoFeB on MgO can be used to build perpendicular magnetic anisotropy domain wall racetrack memory [175]. It was demonstrated that its cell area can be reduced down to $\sim$2–3 F^2/bit to achieve Gb storage/die. The data storage speed was reported to achieve 500 MHz at a low power $< \sim$1 pJ. Additionally, MTJs instead of magnetic heads were used in order to write and read information.

Similar to the transition from slower STT-MRAM to faster SOT-MRAM, the use of more efficient interface-induced spin-orbit torques instead of spin-transfer torques allowed to boost the domain wall velocity up to several hundred m/s. Another important magnetic interfacial contribution, the Dzyaloshinskii-Moriya exchange interaction, helps forming compact Neel chiral domain walls [176]. Fast motion of chiral domain walls resulted in the third generation of racetrack memory.

Control of magnetic domain wall pinning and motion is of great importance to develop nonvolatile memory and logic circuits based on materials compatible with CMOS technology. Recently, an efficient pinning was engineered by growing CoFeB/MgO ultra-thin magnetic films with perpendicular anisotropy on a nano-patterned substrate [177]. Steps could be quite easily generated with a pitch scalable to the limits of lithography of less than 10 nm. The process is adopted from a well-known CMOS industrial process guaranteeing low costs at large-scale mass production.

Ferromagnetic domains generate a long-range magnetostatic field acting on the neighboring domains and the unwanted interaction between domain walls within and between racetracks poisoning the performance [170]. The use of a racetrack made of a synthetic antiferromagnet largely eliminates the magnetostatic fields [178]. The domain walls were moving extremely fast with the velocity of 750 m/s, thanks to the so-called giant exchange torque due to the antiferromagnetic coupling within the synthetic antiferromagnet [178]. Such high domain wall velocities indicate the fourth generation of racetrack memory for picosecond applications. It demonstrates that the last generation of racetrack memory is ready for industrial applications, with the research focus shifting toward reliability and reproducibility of domain wall motion and thermal stability.

Domain wall motion can be employed not only for accessing the stored information by bringing the relevant bit to a reading head or an MTJ. Recently current-driven magnetic domain wall logic [179] discussed in the next section was introduced.

To conclude the section, we mention the idea of using skyrmions or anti-skyrmions instead of domain walls as the memory storage element [180]. This will definitely acceler-

ate the progress in racetrack memory in particular and magnetoresistive nonvolatile memories in general. Nevertheless, describing the method here goes well beyond the scope of the chapter.

31.4 Spintronic Logic

Spin-based devices are considered as promising candidates to surpass the limits of state-of-the-art CMOS-based logic circuits by introducing nonvolatility into logic circuits. Although spin switches based on spin-enhanced transistors have been successfully demonstrated, the increase of the on-current ratio between the parallel and antiparallel source/drain magnetization configuration at room temperature and the efficient gate-voltage-induced spin control remain the main challenges preventing these devices from entering the market so far. In addition, as all proposed up-to-date spin switches require the charge current to transfer the spin, it sets limitations for the applicability of such devices in mainstream microelectronics which is already suffering from high power demand, and new ideas to realize spin-based switches for digital applications are urgently needed.

31.4.1 Magnetic Domain Wall Logic

A complete logic architecture which uses magnetic thin wires and domain wall motion along these wires was suggested at the beginning of the new century [181]. In order to perform data processing with this magnetic domain wall architecture, no electronic elements like transistors are required, so all calculations are performed in the magnetic domain. By engineering the magnetic wires and making junctions of a particular shape, all basic CMOS logic elements and gates can be implemented. The information is stored in the two magnetization orientations relative to the magnetic wall propagation direction. The signal fan-out is easily implemented by splitting a magnetic wire into two or more branches. Then, like in a splitter, the domain wall continues propagating through the branches.

A logic AND gate is implemented, if domain walls are coming to a splitter from the direction opposite to that in fan-out. The domain wall propagates further through the wire after the junction, if and only if the walls are arriving through each of the two input branches.

If now the two magnetic wires connected under a very small angle form a cusp, the domain wall changes the propagation direction after passing the cusp. As now the magnetization orientation relative to the propagation direction is opposite to the one before the cusp, the cusp-like structure represents a natural implementation of a NOT logical gate. In [181] the domain wall motion was driven to be an external rotating in-plane magnetic field which played simultaneously the role of a clock and a power supply. The logic gates can be arranged in a magnetic circuit, and a 5-bit magnetic shift register was demonstrated [181]. An advantage of the magnetic domain wall logic is that all the calculations are performed in the magnetic domain. However, an external magnetic field is required to operate magnetic circuits, which limits the technology's scalability.

Recently, the idea of using fully electrical current-induced domain wall motion to generalize domain wall logic was realized [182]. The architecture based on magnetic domain walls takes advantage of their fast motion discussed in the previous section and of the flexible design to store and to process information. The chiral coupling between neighboring magnetic domains due to the interfacial Dzyaloshinskii-Moriya interaction promotes a noncollinear spin alignment and helps realizing a domain wall inverter. Several reconfigurable NAND logic gates were successfully cascaded to perform the operations XOR and full-add by electrical control of the magnetic data. The energy consumption of a single NOT operation in a 10×10 nm^2 racetrack is estimated at 2×10^{17} J. Although comprehensive benchmarking of the proposed concept is pending [183, 184], it is positioned as a scalable platform to all electrically manipulated magnetic logic suitable for low-power, "instant-on" nonvolatile applications.

31.4.2 Logic-in-Memory

Magnetoresistive memories are CMOS compatible and can be embedded directly on top of a CMOS logic chip. This layout allows not only to introduce memory close to logic; it is also practical as it facilitates three-dimensional integration of circuits. The advantage of such an integration is that high-performance CMOS layers are separated by low energy-consuming nonvolatile MRAM containing spacers. At the same time, a combination of fast nonvolatile memory with CMOS circuits is a fertile playground for realizing microprocessors with reduced power consumption working on an entirely new principle. Placing MRAM arrays directly on top of CMOS circuits allows reducing the length of interconnects and the corresponding delay time. The computer architecture, where nonvolatile elements are located on a chip with CMOS devices, is traditionally called logic-in-memory architecture, although as of yet no information is processed in nonvolatile elements. Therefore, these hybrid CMOS/MTJ logic circuits employ MTJs only for storage. The actual logic operations are still carried out by CMOS components. Power-efficient MRAM-based logic-in-memory concepts have already been demonstrated [110]. They include field-programmable gate arrays and ternary content addressable memory, as well as other variants. These CMOS/spintronic hybrid solutions are already competitive

in comparison to the conventional CMOS technology with respect to power consumption and speed. The introduction of nonvolatility in circuits helps cutting the power consumption typically by 50%, with an outstanding 90% reduction in specific circuits [110]. As there is no general recipe for a transition toward large-scale logic systems, thorough and extensive studies to benchmark the different hybrid CMOS/MTJ logic circuits are required [183, 184].

31.4.3 Stateful Logic

Placing the actual computation into the magnetic domain by introducing nonvolatile processing elements reduces the need of converting magnetically stored information into currents and voltages for processing and helps to simplify the circuit layout and to increase the integration density. MTJs could be used as elementary blocks for nonconventional in-memory computing architectures. It was demonstrated in [185–187] that the direct communication between STT-MTJ devices can be exploited to realize conditional resistance switching on a target MTJ. The conditional switching depends on the initial resistance logic state and can be mapped to a specific Boolean operation. The initial resistance states of the MTJs act as the logic inputs and the resistance states after the operation hold the logic output. For these operations a readout of the MTJs' resistance states prior to a subsequent logic operation is not needed. Thus, stateful logic circuits exhibit a simple architecture in comparison to the hybrid CMOS/MTJ logic circuits with a CMOS-based logic implementation. Two types of stateful logic gates [111], reprogrammable logic gates [185, 186] and material implication gates [187, 188], are briefly discussed below.

The reprogrammable gates can realize conventional Boolean logic operations in two steps through a proper preset operation (TRUE or FALSE) in the output MTJ and then apply a certain voltage level to the gate. Depending on the reprogrammable logic states of the input MTJs, the preset state of the output MTJ, and the applied voltage level, a conditional switching behavior is performed on the output MTJ, which corresponds to a particular logic operation. Input MTJs are left unchanged as the current flowing through the output MTJ is divided between several inputs, thus becoming insufficient to alter their initial states.

Any two of the 1T-1MTJ cells in an MRAM array can also perform a conditional switching of a target MTJ depending on the state of the source MTJ [187, 189], an operation called material implication. The material implication operation (IMP) can, in combination with the FALSE operation, cover the whole space of all Boolean operations. A current-controlled implication logic gate proposed in [187] (Fig. 31.33) realizes a conditional switching behavior on the target MTJ (right) depending on the initial logic states of both the source and the target MTJ.

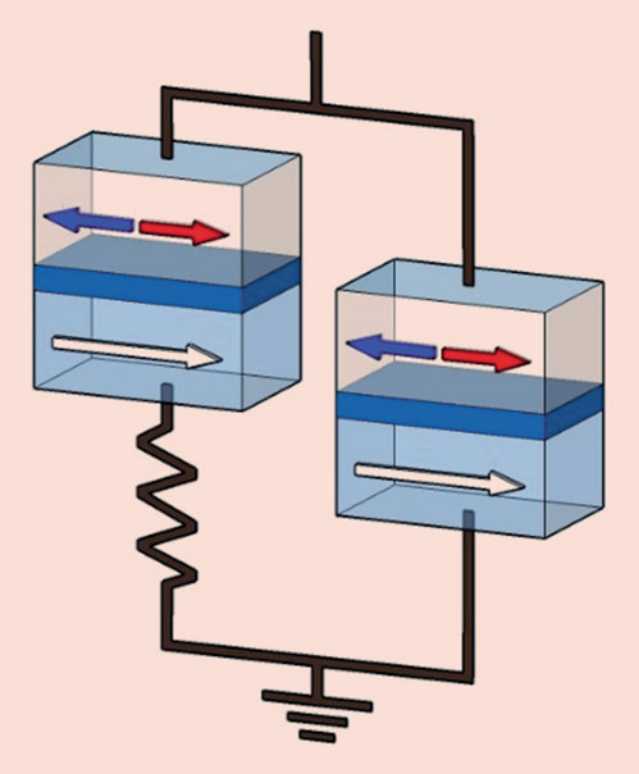

Fig. 31.33 A current-controlled implication logic gate [187] realizes a conditional switching behavior on the target MTJ (right) depending on the initial logic states of both the source (left) and the target MTJ

A comprehensive reliability study and comparison between the reprogrammable and the implication logic gates has been carried out in [190]. It has been shown that in order to reduce the switching errors, the TMR ratio must be increased. It has also been demonstrated that for a given TMR ratio, the implication gate exhibits a more reliable behavior in comparison to the reprogrammable logic gate devices. Due to a superior reliability of the material implication gate, implication-based logics outperforms the reprogrammable gate for complex logic functions like XOR and full-add operations. It makes the implication-based logics an implementation of choice for large-scale circuits.

By integrating MTJs on top of a CMOS circuit, one-transistor/one-MTJ (1T/1MTJ) cells are realized. These 1T/1MTJ cells typical for STT-MRAM structures can be assembled in an array and exploited for logic circuits and the development of novel nonvolatile large-scale logic architectures [191]. The advantages of the MRAM-based stateful logic are highlighted by demonstrating the STT-MRAM-based implementation of the fundamental arithmetic functions and a stateful spintronic full-adder [192]. The latter involves only 6 1T-1MTJ cells and 27 subsequent FALSE and IMP operations [192]. Recently, a massively parallel NOT operation based on IMP implementation by using

the voltage asymmetry of the voltage-controlled magnetic anisotropy effect and the precessional dynamics of the switching process was proposed [112]. By elaborating on design examples, the trade-off for such technologies with respect to the execution time, the energy consumption, and the reliability was investigated; however, a complete benchmarking [183, 184] is still missing.

The logic architectures described above are based on devices acting primarily as memory elements supplemented by computing functionalities. An alternative option is to follow a conventional path with memory and computing units separated, in which both elements are nonvolatile and implemented in the magnetic domain. The motivation for placing the actual computation into the magnetic domain is to eliminate the need of converting magnetically stored information into currents and voltages for processing and to operate only with spin degrees of freedom.

31.4.4 Buffered Magnetic Logic Environment

The use of a composite free layer results in significantly faster switching in STT MRAM cells as discussed in Sect. 31.3.1 The idea of combining several MTJs with a common free layer enables the realization of a nonvolatile magnetic flip-flop [193]. It consists of three antiferromagnetically coupled spin polarizer stacks featuring out-of-plane magnetization (Fig. 31.34). The polarizer stacks are grown on top of a common free layer with a perpendicular magnetic anisotropy. The stacks are separated from the free layer by MgO tunnel layers. The left and right stacks are used as inputs, while the middle stack is for readout. The information is stored in the magnetization orientation of the common free layer. Depending on the *polarity* of the input pulses, the torques acting on the free layer either add up or oppose each other. The resulting magnetization is preserved, if the input currents are opposite. This results in a HOLD operation. The magnetization can be put along the desired direction, if the currents run in the same direction, which results in SET/RESET operation. This behavior corresponds to flip-flop logic [194].

Extending the idea of a free layer common to several input signals applied through magnetic stacks, a majority gate [195] can be realized (Fig. 31.34). Together with the material implication gate, a majority gate-based calculation represents another example of performing logic operations differently as compared to CMOS circuits. In CMOS circuits any Boolean function is typically realized as a sequence of NAND operations. In contrast to NAND which gives an output "false" when all inputs are "true," the majority gate returns "true," when more than 50% of input signals are "true".

As first STT-based majority gate prototypes were recently fabricated [196], a realization of STT majority gate-based logic could already be possible in the near future. Processing with majority gates can be quite efficient. For example, complementing a majority gate with magnetic flip-flops used as buffers to store the output of the majority gate operation at a certain gate leg, a compact implementation of a one-bit full-adder is enabled. By connecting several majority gates through corresponding flip-flop buffers attached to their legs, the information transfer between different gates is ensured resulting in a nonvolatile processing environment [197]. The environment is capable of executing operations in parallel, and it offers the benefit of shared buffers between neighboring majority logic gates. Thus, it allows to reduce the energy and time spent for the information transport while maintaining a very dense layout. The synergetic combination of flip-flops and majority gates into a grid enables the flexible allocation of employed resources and gives generous freedom in reconfiguring its logic as the number of utilized buffers and gates can be adjusted depending on the task.

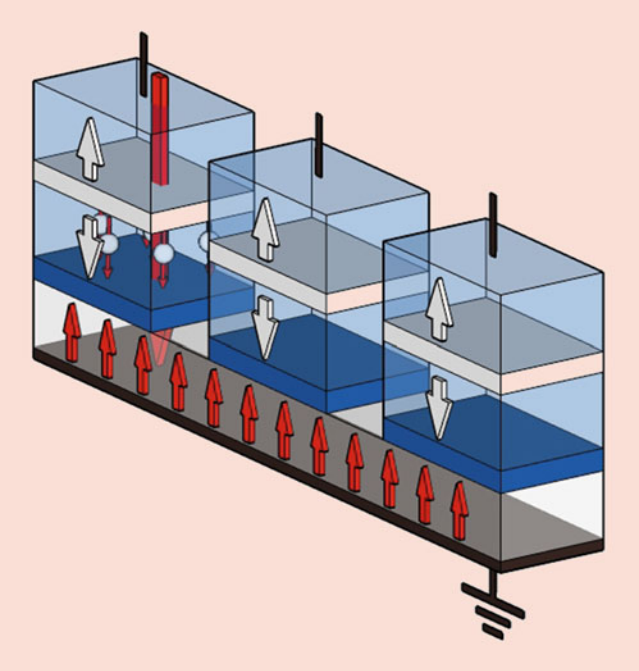

Fig. 31.34 Magnetic flip-flop [194] and a three-terminal majority gate [195, 196]. Three synthetic antiferromagnetic stacks are grown on a common free layer. The stacks provide spin-polarized currents running through the free layer. The spin polarization depends on the pulse polarity applied to a stack. The two stacks are used as inputs, while the stack in the middle is for reading. The magnetization of the free layer flips only if the two inputs are of the same polarity. This way a magnetic flip-flop is built [194]. By using the middle stack as output, a three-terminal majority gate is realized [195, 196]

31.4.5 All-Spin Logic

The fact that a spin signal is in principle independent from charge transport can be exploited for spintronic logic [198–

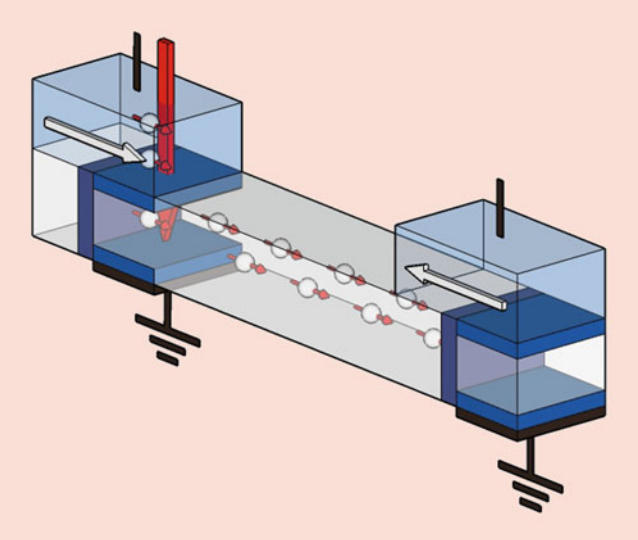

Fig. 31.35 All-spin logic. Non-equilibrium spin accumulation is created under a ferromagnetic layer (left) by passing the charge current through it. The spin accumulation diffuses along an interconnect and creates a spin-transfer torque acting on the right ferromagnetic layer

200]. The idea is to have a spintronic device which employs spin at every stage of its operation. This way a repeated spin-to-charge conversion is not needed. Input and output information are represented by the magnetization of nanomagnets. Physically separated nanomagnets are connected by nonmagnetic interconnects capable of carrying pure spin currents (Fig. 31.35). By inserting a charge current through a magnet, spin-polarized electrons are accumulated below the respective magnet in the interconnect. This spin accumulation diffuses along the interconnect to the next nanomagnet, where it exerts an STT on the magnetization. The generated spin signal is a pure spin current and can be used for sequential as well as combinational logic [198, 201, 202]. The all-spin-logic concept has gained popularity and ignited a wide variety of activities; however, even though the decoupling from the charge transport should reduce the power dissipation drastically, it appears to be not sufficient to outperform state-of-the-art CMOS circuits [183, 184, 203].

31.4.6 Benchmarking and Magnetoelectric Spin-Orbit Logic

Exploring the electron spin as a computational degree of freedom is a necessary step to proceed beyond charged-based CMOS devices in order to overcome CMOS-related limitations, namely, increasing demands to reduce the power consumption and, especially, the standby power with the introduction of new device generation nodes. A technology based on exploiting the magnetization orientation in ferromagnets to store the binary data promises a reduction in the standby power. However, the information is written by means of an STT exerted on a free layer created by spin-polarized currents. In STT-based logics, the spin-polarized currents are produced by the electrical currents running through the structure. As the current densities and the currents needed for the magnetization reversal of free layers with a sufficiently high thermal stability are large, a comparative benchmarking of emerging logic devices with respect to state-of-the-art CMOS logic is necessary. A comprehensive methodology proposed in [183, 184] demonstrates that although the introduction of spintronic devices into circuits is beneficial for specific applications, the overall performance of emerging spin-based circuits is still inferior as compared to CMOS circuits. Results of benchmarking [183, 184] SpinFET logic [73], STT/domain wall-based logic [193, 204], spintronic majority gate logics [195–197], and all-spin logic [198, 200] with respect to high-performance CMOS logic are shown in Table 31.2. One concludes that although circuits based on emerging spintronic devices are characterized by a lower power density and therefore smaller area, they possess a much longer delay and provide a much lower data throughput as compared to high-performance CMOS. One can also observe that SpinFET-based architectures and all-spin logics do not allow to reduce substantially the power density [183]. Although a careful benchmarking of STT material implication-based logic [187, 190] and magnetic domain wall-based logic [179] is pending, their operational principle is still based on torques generated by electric currents. Therefore, with a certain degree of confidence, one could conclude that it is unlikely these concepts will outperform CMOS logic, at least at the current technological level.

Table 31.2 Comparison of several logic circuits based on CMOS and spintronic devices with respect to delay (picoseconds), power density (watts per area), and throughput (number of 32-bit arithmetic logic unit operations per unit time and unit area, in units of tera-integer operations per second, TIOPS)

Name	Delay (ps)	Power density (W/cm^2)	Throughput ($TIOPS/cm^2$)
CMOS high performance	84 [183]	46.5 [183]	90 [205]
SpinFET	282 [183]	18 [183]	30 [183]
STT/domain wall	112,820 [183]	0.2 [205]	1.2 [205]
Spintronic majority gate	38,094 [183]	0.6 [205]	18 [205]
All-spin logic	26,261 [183]	38.2 [183]	7.5 [205]
MESO	2100 [205]	0.6–3.5 [205]	150 [205]

For energy-efficient solutions, it is mandatory to preserve the obvious advantages of spintronic logic devices, namely, nonvolatility and reconfigurability. As STT-based devices are not as fast as CMOS devices and STT-driven magnetization manipulation is energy consuming, a new fully electrical but

much more energy-efficient magnetization switching principle is required. The magnetoelectric effect defined as an ability to manipulate the magnetization by applying an electric field is extremely attractive as no charge current is flowing through or near the information storing magnetic layer. An electric field control of the magnetization direction at *room temperature* has been recently established in Pt/CoFe/Cu/-CoFe/$La_{0.1}Bi_{0.9}FeO_3$ [205]. A switching voltage lower than 1 V has already been demonstrated [205], while the ultimate goal to achieve switching at 0.1 V is currently pursued.

As no current is required for information writing, the efficient reading of the magnetization information and its transfer to the next device remain the critical steps prone to high power dissipation. To achieve the magnetization reading, a supply current flows through a part of the ferromagnetic layer overlapping with a material characterized by large spin-to-charge conversion efficiency. As in all-spin logic, the current becomes spin-polarized after passing the ferromagnetic layer, and the spin current is accompanying the flow of the supply current. The spin current generates a large charge current in the material due to the large spin-to-charge conversion [205]. The conversion is due to an inverse spin Hall effect. The promise of converting the spin current into a large charge current is enabled by the ongoing advances in spin-to-charge conversion using topological or high spin-orbit-coupling materials.

The charge current generated from the spin current due to the inverse spin Hall effect flows along the axis orthogonal to the spin polarization and spin current. An interconnect transfers the information to the next device. The charge current direction in the interconnect is determined by the magnetization direction of the ferromagnetic layer. This current supplied to the next device ensures the accumulation of the charge in its ferroelectric capacitor sufficient to manipulate the ferromagnetic layer. This way a highly energy-efficient logic based on magnetoelectric spin-orbit (MESO) devices is enabled [205].

The use of two physical principles, namely, the magnetoelectric effect for efficient and fast writing and large spin-to-charge conversion efficiency in emerging materials for efficient reading, puts nonvolatile electrically manipulated MESO-based devices as clear winner within the previously used benchmarking [183, 184, 205]. In particular, by simulating a 32bit arithmetic logic unit performance, the MESO logic shows a data throughput similar to high-performance CMOS logic, but at a one order of magnitude lower power density [205]. The logic based on MESO devices also demonstrates the lowest delay as compared to all spintronic logics [205], which makes it a clear favorite for building future fast nonvolatile energy-efficient logic. Examples of logic based on nonvolatile devices do not exhaust the whole variety of conceivable combinations between emerging nonvolatile devices and mature and very well-established CMOS devices. The availability of high-capacity nonvolatile memory close to high-performance processing units enables new computing architectures for future artificial intelligence and cognitive computing [113]. Nonvolatile MTJs are suitable for neural network realizations as they can be considered as a current-driven programmable resistor, a memristor [206]. MTJ-based neural networks featuring nonvolatile synapses [207] allow for high-speed pattern recognition with about a 70% reduction in gate count and a 99% improvement in speed as compared to their CMOS counterparts. All-spin binary neuromorphic computing systems with probabilistic inference and online learning can enable a new generation of state-compressed and low-power computing platforms [208]. Neuromorphic computing is becoming a reality, with self-learning chips already appearing on the market [209].

The successful adoption of nonvolatility in microelectronic systems by developing various logic, logic-in-memory architectures and in-memory processing will inevitably result in increasing dissemination of this technology for other applications such as ultralow-power electronics, high-performance computing, Big Data analysis, automotive electronics, and the Internet of Things and is expected to have an enormous impact on neuromorphic computing and artificial intelligence.

Acknowledgments The financial support by the Austrian Federal Ministry for Digital and Economic Affairs and the National Foundation for Research, Technology and Development and the Christian Doppler Research Association is gratefully acknowledged.

Viktor Sverdlov received his MSc and PhD degrees in physics from the State University of St. Petersburg, Russia, in 1985 and 1989, respectively. From 1989 to 1999, he worked as a staff research scientist at the V.A. Fock Institute of Physics, St. Petersburg State University. During this time, he visited ICTP (Italy, 1993), the University of Geneva (Switzerland, 1993–1994), the University of Oulu (Finland, 1995), the Helsinki University of Technology (Finland, 1996, 1998), the Free University of Berlin (Germany, 1997), and NORDITA (Denmark, 1998). In 1999, he became a staff research scientist at the State University of New York at Stony Brook. He joined the Institute for Microelectronics at the *Technische Universität Wien*, in 2004. In May 2011, he received the *venia docendi* in microelectronics. His scientific interests include device simulations, computational physics, solid-state physics, and nanoelectronics.

Siegfried Selberherr was born in Klosterneuburg, Austria, in 1955. He received the degree of Diplomingenieur in electrical engineering and the doctoral degree in technical sciences from the *Technische Universität Wien* in 1978 and 1981, respectively. Dr. Selberherr has been holding the *venia docendi* on computer-aided design since 1984. Since 1988, he has been the Chair Professor of the Institut für Mikroelektronik. From 1998 to 2005, he served as Dean of the Fakultät für Elektrotechnik und Informationstechnik. Prof. Selberherr published more than 400 papers in journals and books, where more than 100 appeared in Transactions of the IEEE. He and his research teams achieved more than 1200 articles in conference proceedings of which more than 250 have been with an invited talk. Prof. Selberherr authored three books and co-edited more than 45 volumes, and he supervised, so far, more than 100 dissertations. His current research interests are modeling and simulation of problems for microelectronics engineering. Prof. Selberherr is a Life Fellow of the IEEE, a Fellow of the Academia Europaea, a Fellow of the European Academy of Science and Arts, and a Fellow of the Asia-Pacific Artificial Intelligence Association, AAIA.

Abstract

Neuromorphic computing aims at processing information in a way which is similar to the human brain, therefore featuring the ability to learn, adapt, and generalize with high computing parallelism and energy efficiency. To pursue this ambitious goal, neuromorphic computers must adopt brain-inspired architectures, which radically differ from the von Neumann concept of conventional computing. Neuromorphic computing thus typically relies on neural networks, consisting of neurons and synapses which are ideally compact, scalable, and operated at low voltage and current. Several device technologies have been proposed for neuromorphic computing, including both conventional memory devices based on the complementary metal-oxide semiconductor (CMOS) technology, and alternative memory (or memristor) technologies, where the storage concept is not based on charge, rather it relies on the local modification of the active material.

This chapter will review the status of neuromorphic devices including both CMOS-type and memristive devices. First, neuromorphic concepts using floating-gate and static random access memory (SRAM) arrays will be described, followed by memristive synapses and neurons which offer unprecedented density and scalability. The applications and performance of the various neuromorphic computing concepts will be illustrated and discussed.

32.1 Introduction

The complementary metal-oxide semiconductor (CMOS) technology has been the industrial platform for computing since the start of the microelectronics industry in the last century. The main advantage of the CMOS technology is its industrial manufacturability, where the parameters of the transistors and diodes can be controlled via the fabrication

process and, most importantly, the scaling according to the Moore's law [1]. Despite all difficulties in the physical scaling of the transistor size, sub-10 nm technology nodes have been recently announced and soon will be commercially available [2, 3]. Approaches to further scale the technology in the future include multigate transistors [4] and 3D integration [5], which supports CMOS technology as the industrial mainstream technology platform for the future years and decades.

Besides scaling, the computing architecture is also facing significant challenges. Digital computers are all based on the von Neumann architecture, where data are processed in a central processing unit (CPU) and stored in a working memory, such as a dynamic random access memory (DRAM). The von Neumann architecture, however, suffers from significant latency and energy required by the movement of data between the CPU and the memory. This is a key challenge for big data tasks, where the information to be processed mainly consists of unstructured data such as audio, video, and other sensor data. The movement of large amount of input data and processing parameters, such as the synaptic weights in a neural network, constitutes a significant overhead from the point of view of latency and energy consumption. The memory bottleneck of von Neumann computers can be radically solved by in-memory computing (IMC), where data are processed in situ, directly within the memory [6]. In-memory computers do not follow the von Neumann architecture, in that there is no physical distinction between processing and memory units. The memory is constructed such that the computing can be executed physically within the data, for instance employing the concept of physical matrix-vector multiplication (MVM) in a cross-point array of resistive memory elements [7]. In-memory MVM has been fruitfully demonstrated for various applications, including the training of neural networks [8], the processing of image files [9, 10], and the solution of linear systems [11, 12].

Among the various approaches to IMC, the neuromorphic approach is one of the most fundamental and promising. Neuromorphic computing takes inspiration from the brain, to process information via neural networks consisting of neuron and synaptic elements. As in the human brain, there is no distinction between memory and processing units in a neural network, which accounts for the extreme energy efficiency of the brain, consuming only 20 W on average [13]. A generic neural network is the one originally proposed by McCulloch and Pitts in 1943 [14]. As shown in Fig. 32.1, input signals (x_1, x_2, etc.) are transferred to the neuron via synapses, which multiply the input signal by a characteristic weight (w_1, w_2, etc.). The weighted inputs are then summed within the neuron, and transformed by a characteristic non-linear activation function, such as a sigmoidal function, which yields the neuron output. Figure 32.2 shows a generalized neural network including 4 neuron layers, namely, the input layer, the output layer, and 2 intermediate or hidden layers.

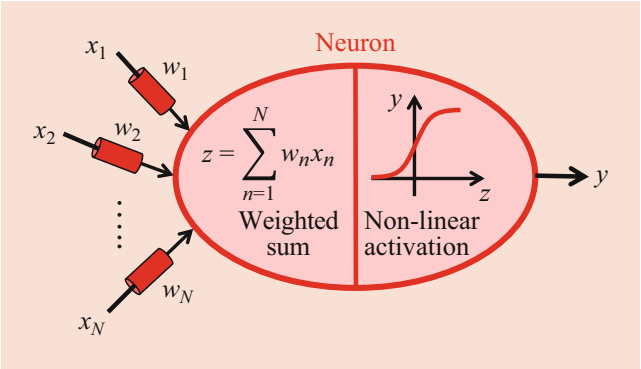

Fig. 32.1 Scheme of mathematical model of McCulloch and Pitts neuron where the sum of input signals x_n weighted by synaptic weights w_n is converted into the output y by application of a nonlinear activation function

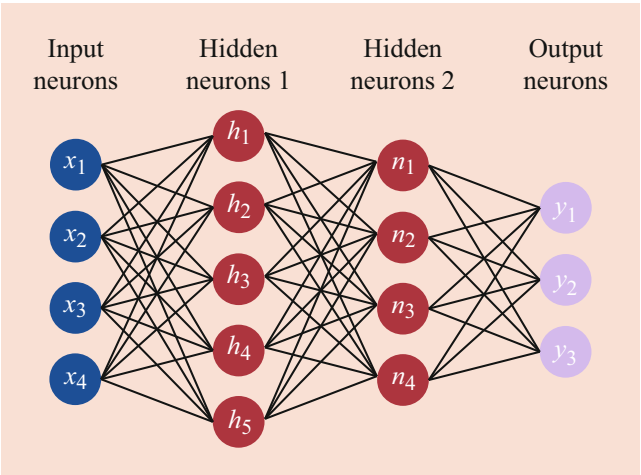

Fig. 32.2 Sketch of a multilayer perceptron (MLP) neural network, where the signal fed to the input layer forward propagates to the output layer passing through two hidden layers. Every neuron within the first three layers is fully connected to the neurons of next layer by individual synaptic connections. (Adapted from D. Ielmini et al. [23])

Originally proposed by Rosenblatt in 1957 [15], this neural network, also known as multilayer perceptron (MLP), is able to recognize, classify, and generalize, similar to our brain. The synaptic weights can be tuned for a certain task, e.g., recognizing between motorcycles and cars, by supervised learning algorithms, which iteratively optimize the value of each weight until the network reaches an acceptable classification accuracy [15, 16]. The MLP provides the fundamental basis for deep learning, where neural networks with many hidden layers are trained for recognition of images, speech, video, and other types of unstructured data [17–19]. A key issue for all deep learning machines is that they rely on conventional hardware based on the von Neumann architecture, such as the graphics processing unit (GPU) [20] and the tensor processing unit (TPU) [21]. To overcome the memory bottleneck issue, neuromorphic hardware must be developed

by adopting more radical, innovative circuit schemes, where non-von Neumann architecture and advanced devices allow for parallel computation and high energy efficiency [22].

From a device viewpoint, the MVM with memory devices can support the neuromorphic training and inference, while also providing schemes for compact representation of synaptic plasticity taking place in the human brain [23, 24]. Therefore, truly brain-inspired concepts of neuromorphic computing can be developed adopting nonvolatile memory devices. CMOS-based memories, such as static random access memory (SRAM) [22, 25] and floating-gate memories [26–30] have been proposed as possible synaptic devices to represent the weight of neuron-to-neuron connection. However, SRAM devices are volatile, thus requiring an initial upload of all synaptic parameters at system boot. On the other hand, floating gate memories, such as Flash, are typically affected by high operation voltages, and relatively slow program/erase. Most recently, emerging devices, broadly referred to as memristors, have been shown to provide a compact, functional, and brain-inspired option for implementing synaptic and neuron elements. A memristor consists of a two-terminal device where the resistance or conductance can change by the application of a relatively large voltage exceeding a threshold voltage. Memristor devices include resistive switching random access memory (RRAM), phase change memory (PCM), and other devices based on ferromagnetic and ferroelectric memory effects at the nanoscale. The size/-voltage scalability of these devices, combined with the nonvolatile nature of the storage, makes memristive approaches extremely promising for implementing brain-inspired, non-von Neumann neuromorphic systems.

Neuromorphic circuits can be organized into two main domains of neural networks, which can be referred to as deep neural network (DNN) and spiking neural network (SNN). Although both these types of network rely on the structure shown in Fig. 32.2, the input processing and learning mechanism are different. In DNN, all input signals are generally applied at the same time, encoding the input information via either amplitude or duration [31]. The input signals then propagate in the forward direction by multiplication with synaptic weights and summation at hidden and output neurons. Learning is generally carried out via supervised training techniques, where input patterns, e.g., images of faces, objects, digits, etc., are presented to the input layer together with a characterizing label. After forward propagation, the resulting output is compared with the ideal output corresponding to the label, thus allowing to calculate an error. This error is used to update the synaptic weights according to the backpropagation technique [32]. The training goes on for several epochs, each consisting of the presentation of the whole dataset of the patterns, until the recognition accuracy reaches a given threshold, generally above 90% [17–19]. In most cases, the supervised training is operated off-line, i.e., in a dedicated supercomputer equipped with high performance GPU or TPU. The synaptic weights are then stored in neural networks to carry out the inference operation, namely, the recognition of real-time images on the field. On the other hand, on-line supervised training has also been proposed, where the learning stage is operated in situ within the neural network, thus allowing for a compensation of nonidealities of the synaptic arrays, such as the cell-to-cell variability of conductance window and update characteristics [8, 33].

Contrary to the DNN, the SNN is more deeply anchored to the human brain model, where the most relevant information is the spike time, with less relevant roles played by amplitude and pulse width [34]. Neurons in an SNN typically have an integrate-and-fire structure, where incoming spikes are integrated until a threshold is reached, at which point a spike is emitted to the next neuron layer. Similar to the human brain, an SNN can implement a number of unsupervised training methods, all relying on the synaptic plasticity concept. In fact, many learning mechanisms in our brain are unsupervised, i.e., without labels, rather they take place by inherent feedback and interaction of sensory information within the biological neural network. Such type of learning can be supported by spike-timing dependent plasticity (STDP) rule described in Fig. 32.3. According to STDP, the weight of a synapse changes depending on the time delay Δt between spikes taking place at the pre-synaptic neuron (PRE) and the post-synaptic neuron (POST). If the POST spike follows, after a relatively short time, the PRE spike ($\Delta t > 0$), then the synaptic weight is potentiated (Fig. 32.3a). On the other hand, if the PRE spike follows the POST spike within a short time window ($\Delta t < 0$), the synaptic weight is depressed (Fig. 32.3b). STDP behavior has been evidenced in biological synapses in the hippocampus [35] and has been proven to lead to unsupervised learning of image patterns in stochastic SNNs [36–41]. Other spike-controlled plasticity processes have been proposed, namely, triplet-based STDP [42, 43] and spike-rate dependent plasticity (SRDP) [44, 45], and demonstrated in hardware [46–48]. In addition to unsupervised learning and the ability to replicate brain-inspired cognitive processes, SNNs benefit from a reduced energy consumption, as computation occurs only when it is needed, i.e., at the arrival of a spike. CMOS and memristive devices may play a leading role in both DNNs and SNNs, to enable scaling, nonvolatile storage of the synaptic weights, physical computation (e.g., by the MVM concept), and real-time adaptation by memory update processes.

This chapter reviews the current status regarding neuromorphic hardware developed with CMOS and memristive devices. Artificial synapses will be described referring to both DNNs for specific datasets (e.g., images, faces, objects, etc.) and SNNs able to learn by local STDP. The chapter is organized as follows: Sect. 32.2 reviews the operation principles of memory transistor and mainstream NAND and

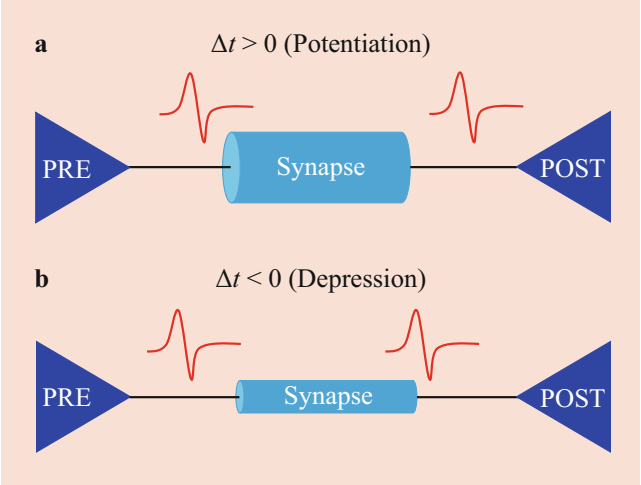

Fig. 32.3 Illustrative sketch of STDP experimental protocol controlling the synaptic plasticity. (**a**) If the spike emitted by PRE at certain time arrives just before the POST spike at synapse ($\Delta t > 0$), the weight of synaptic connection increases. (**b**) On the contrary, if PRE spike arrives just after the POST spike at the synapse ($\Delta t < 0$), the weight of synaptic connection decreases

NOR Flash technologies. Sections 32.3 and 32.4 are devoted to CMOS implementations, specifically focusing on synaptic circuits and neuromorphic networks based on floating-gate and SRAM arrays, respectively. Section 32.5 addresses the memristive devices with 2-terminal and 3-terminal structure. Section 32.6 reviews the synaptic implementations and hardware demonstrators of neuromorphic SNNs and DNNs with memristive devices. Section 32.7 discusses the existing applications and possible challenges of neuromorphic computing with CMOS/memristive devices. Finally, Sect. 32.8 presents the conclusions of the chapter.

32.2 Memory Transistor and Mainstream Flash Technologies

The memory transistor is the basic storage element adopted in mainstream nonvolatile memory technologies. Its working principles can be traced back to the change of threshold-voltage (V_T) of MOS devices arising from fixed charge in their gate insulator [49]. In order to exploit this effect to achieve a reliable memory device, an isolated charge storage layer is introduced in the gate stack of an MOS transistor (typically, an n-channel device). This layer may be either highly-doped polycrystalline silicon (polysilicon) or a dielectric material with a high density of microscopic defects able to capture/release charge carriers, as shown by the elementary structures schematically depicted in Fig. 32.4. In the former case, the charge storage layer is called a floating-gate. In the latter, it is called a charge-trap layer. In either case, the resulting gate stack allows not only to store a large amount of charge at a well-defined vertical distance from the gate of the transistor, i.e., inside the floating-gate or the charge-trap layer, but also to keep the charge stored at that distance over a timescale of months or years, thanks to the dielectric barriers blocking the emission of the stored charge toward the gate and the channel. The charge Q_S in the storage layer can then be considered as the parameter defining the state of the memory transistor and, by suitably discretizing it, digital information can be stored in a nonvolatile way in the device. Sensing of this information can be easily achieved by exploiting the proportionality between Q_S and the resulting shift of V_T (ΔV_T) with respect to the neutral storage layer condition, according to $\Delta V_T = -Q_S/C_{sg}$, where C_{sg} is the capacitance between the storage layer and the gate. In particular, the bits stored in the device can be determined on the basis of the value (high/low) of the drain current (I_D) resulting when, with a fixed drain bias (V_D), suitable gate biases (V_G) in-between the V_T values resulting from the discretization of Q_S and ΔV_T are applied, as shown in Fig. 32.5.

Changing the amount of charge in the storage layer and, in turn, the stored bits can be accomplished by means of different physical mechanisms. Among them, those which are by far the most exploited are Fowler-Nordheim (FN) tunneling and channel hot-electron injection (CHEI) [49, 50] (Fig. 32.6). FN tunneling may be achieved by applying a positive or negative V_G high enough to trigger a large flow of charge carriers between the channel and the storage layer by quantum mechanical tunneling through the energy barrier separating them (a flow of charge carriers between the gate and the storage layer may also take place, but this is typically undesired during device operation and thus minimized by suitable design choices). CHEI requires, instead, heating the carriers in the inversion layer of the transistor by means of a high V_D and redirecting them over the energy barrier separating the channel from the storage layer through a high V_G. While both FN tunneling and CHEI can be used to increase device V_T (program operation), only the former mechanism can be used to reduce V_T (erase operation).

It is worth mentioning, moreover, that FN tunneling typically requires much higher voltages than CHEI to move a similar amount of charge into the storage layer within a comparable time period. However, almost all the net charge flowing through the source and drain contacts of the memory transistor during a FN program operation is injected into the storage layer, while only a small fraction of the net charge flowing from source to drain is injected into the storage layer in the case of CHEI. This means that while the injection efficiency (corresponding to the ratio between the current injected into the storage layer and the current flowing at the source and drain terminals) of FN tunneling may in principle approach 1, that of CHEI is much smaller, typically close to 10^{-5}. Thus, the former mechanism is highly power-efficient and the latter is more power-hungry.

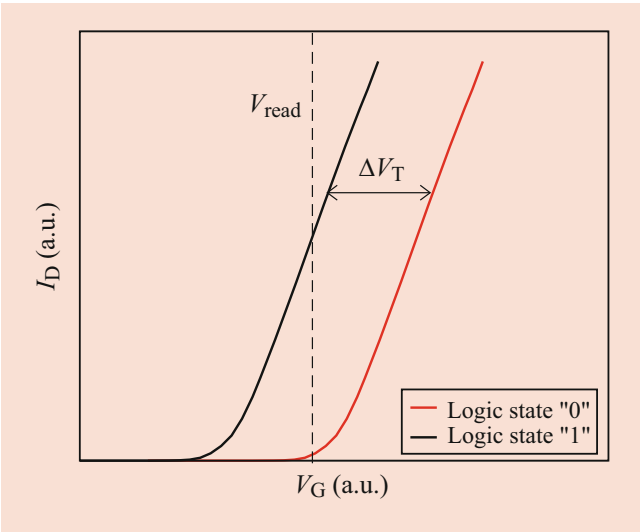

Fig. 32.5 Memory cell I-V curve for two amounts of charge in the storage layer, determining two different logic states

Due to their severe electrical stress on the gate dielectrics of the device, the number of program and erase operations that can be safely performed on a memory transistor for digital data storage is hardly higher than 10^5. The generation of microscopic defects in the bulk of the gate dielectrics and at the channel surface induced by program and erase operations, in fact, compromises the possibility to control device V_T and thus to store data in a reliable way. In particular, these defects may affect the program and erase performance and accuracy and, after V_T placement, may introduce relevant time-dependent instabilities in V_T itself due to their capturing/releasing charge carriers or their acting as stepping stones for the charge exchange between the storage layer and the channel or the gate of the memory transistor. All these effects may be particularly negative when the cells are used for machine learning applications, since they may compromise the accuracy of operations such as the MVM.

Starting from the elementary device structures reported in Fig. 32.4 and the general working principles discussed in the previous paragraphs, the specific design of memory transistors, their operating conditions and their organization into arrays strictly depend on the target applications of a memory technology. To understand this point, it is worth referring to the technologies representing the dominant solid-state solutions for nonvolatile data storage today, i.e., the NOR and NAND Flash technologies. Both these technologies make use of n-channel memory transistors as storage elements. However, their different aims lead to a different design of the memory devices, to the adoption of different working conditions and to a different organization of the memory array. The adoption of FN tunneling for the erase of a large number of cells in parallel (in a flash, hence their name) is, anyway, a common feature of the two solutions.

NAND Flash technologies target the storage of large amounts of data and, therefore, tend to minimize the cost per bit and to maximize the operating data throughputs of the memory chip. Since minimizing the cost per bit of the chip corresponds to maximizing its bit storage density, i.e., the ratio between the chip capacity and area, the reduction of (i) the silicon area per memory transistor, (ii) the number of contacts and service elements needed to address the memory cells in the array, and (iii) the array segmentation, represent some of the most important solutions that allowed to achieve the goals of the technology [51]. In a NAND Flash array, then, memory transistors are connected in series into strings (Fig. 32.7a) and a large number (tens of KBytes) of them belonging to different strings are programmed and read in parallel to maximize the operating throughput of the memory chip during data storage and retrieval (tens and hundreds of MBytes/s are, respectively, typical program

and read throughputs of NAND Flash chips nowadays). The possibility to program a very large number of cells in parallel is one of the benefits coming from the adoption of FN tunneling for both program and erase operations, allowing to limit the total current needed to transfer charge to/from the storage layer of the memory transistors thanks to the high injection efficiency of this mechanism. Drawbacks of the previous solutions are, however, the long times needed to perform single program operations (in the hundreds of μs timescale) and to access randomly selected stored bits (in the tens of μs timescale) in the array. It is worth mentioning, finally, that the improvement of the performance parameters of the technology and, in particular, of its bit storage density has long been pursued by means of a scaling process involving the reduction of the device feature size. This process led to the development of memory transistors with feature size as small as 15 nm in the middle of the 2010's decade and was then replaced by an equivalent scaling approach consisting of stacking many (currently, up to 128) memory cells in the vertical direction [51]. Figure 32.8 shows a schematic for a 3-D vertical NAND Flash array, highlighting the adoption of cylindrical gate-all-around memory transistors with vertical channel.

Differently from the NAND Flash case, NOR Flash technologies are mainly intended for code storage and, therefore, tend to minimize the time needed to store and retrieve small packets of data (a few Bytes). In particular, allowing a random access time to the stored bits shorter than 100 ns is mandatory for the target applications of the NOR Flash technology. To this aim, a strong array segmentation is adopted to reduce the delay times arising from the lines driving each memory transistor and, within each array sector, cells are connected in parallel (Fig. 32.7b). This results in a number of contacts per cell higher than that of NAND Flash arrays. To achieve the goals of the technology, CHEI is used for the program operations, while the use of FN tunneling is limited to the erase operations. The need for a simultaneous gate and drain voltage, in fact, makes CHEI a mechanism allowing to easily achieve fast (in the μs timescale) and single-cell selective program operations within the NOR architecture. As previously discussed, moreover, this mechanism involves moving high-energy electrons above the energy barrier separating the channel from the storage layer of the memory transistors and does not require to reach vertical electric fields as high as those needed to make electrons tunnel through the same energy barrier. This allows to perform the program operations at voltages lower than those required by FN tunneling and to use a dielectric isolating the storage layer from the channel thicker than in the NAND Flash case (the thickness of that dielectric is typically about 10 nm in the NOR Flash case and about 6 nm in the NAND Flash case). However, the relatively high V_D needed for device operation does not allow to minimize the channel length of the memory transistors, which is therefore much longer than in a NAND Flash technology of equal feature size. This contributes, along with the previously discussed features of NOR Flash arrays, to reducing the bit storage density of the technology and, in the end, to increasing the cost per bit of a NOR Flash chip over that of a NAND Flash chip. The cost increase, anyway, allows the NOR Flash technology to offer faster random access operations on the array at the Byte level and to target code storage applications successfully. In this regard, the use of thicker dielectrics isolating the storage layer and of memory transistors with larger dimensions than in the NAND Flash case allows the NOR Flash technology to satisfy another important requirement of code storage applications, i.e., that of an extremely good raw array reliability. It is worth mentioning, finally, that assuring proper array operation and suitable raw array reliability has strongly limited the scaling path of the NOR Flash technology with respect to the NAND Flash technology, with the feature size of the former being about 40 nm at the state-of-the-art.

32.3 Neuromorphic Networks Based on Memory Transistor Synaptic Arrays

Arrays of memory transistors represent a viable alternative to non-volatile memory cross-point arrays to be exploited as synaptic arrays in artificial neural networks (ANNs) and brain-inspired neural networks. Indeed, their main element, often employing a floating-gate as charge-storage layer, can conveniently embed in a single device the wanted synaptic functionalities. In particular, when exploited as synaptic element, a floating-gate transistor is operated in subthreshold regime, where the following well-known exponential relation

$$I_{DS} = I_0 \cdot e^{\frac{q\alpha_G\left(V_{GS}-V_T^{ref}\right)}{mkT}} \cdot e^{-\frac{q\alpha_G\Delta V_T}{mkT}} \tag{32.1}$$

holds between V_{GS} and I_{DS}. Here, I_0 is the current prefactor, q is the elementary charge, m is the subthreshold slope ideality factor, kT is the thermal energy, α_G is the gate-to-floating-gate capacitive coupling ratio, and ΔV_T represents the floating-gate transistor V_T shift from an arbitrary chosen reference $V_T{}^{ref}$. In so doing, I_{DS}, to be considered as the output signal, is the product between a function of V_{GS}, to be considered as the input signal, and a remaining factor $W = e^{-\frac{q\alpha_G\Delta V_T}{mkT}}$ depending on ΔV_T, playing the role of the synaptic weight.

The low currents typical of the subthreshold regime make floating-gate transistors attractive for neuromorphic applications in terms of reduced power consumption. Some other intriguing features are fine weight granularity, coming from the virtually analog and bidirectional tuning of the charge

stored in the floating-gate, and a mature and reliable CMOS compatible fabrication technology, resulting from the continuous effort devoted in the last decades to make non-volatile memory technologies keep pace with Moore's scaling paradigm. Note that while building synaptic arrays using a consolidated technology as floating gate memory transistors is an appealing solution, the issue due to the single cell V_T tunability remains a mandatory requirement to be addressed. For this reason, NOR Flash architecture appears as the most natural candidate for neuromorphic applications, being the memory cells connected in parallel, with all their contacts made available through signal lines. However, the classical NOR Flash program and erase schemes are not suitable for the purpose; in fact, as already pointed out in Sect. 32.2, while the program operation, based on CHEI at the drain side, can be performed on a single cell, the erase operation, relying on FN tunneling, involves a large number of cells at the same time. For this reason, the main approach adopted to enable the necessary single-cell selective erase operation and to build floating-gate transistor-based synaptic arrays consists of making some changes to the memory transistor structure, to the NOR Flash array design or to its working schemes.

The first proposal of exploiting a floating-gate transistor to build an artificial analogue synapse, dating back to the late 1990s [52–54], consisted of modifying its structure to accommodate an additional contact to be exploited for the erase operation. Such device, usually called synaptic transistor, is shown in Fig. 32.9, together with its main features and the adopted program and erase mechanism. A synaptic transistor is essentially equivalent to an n-channel floating-gate transistor, in which its floating-gate is extended

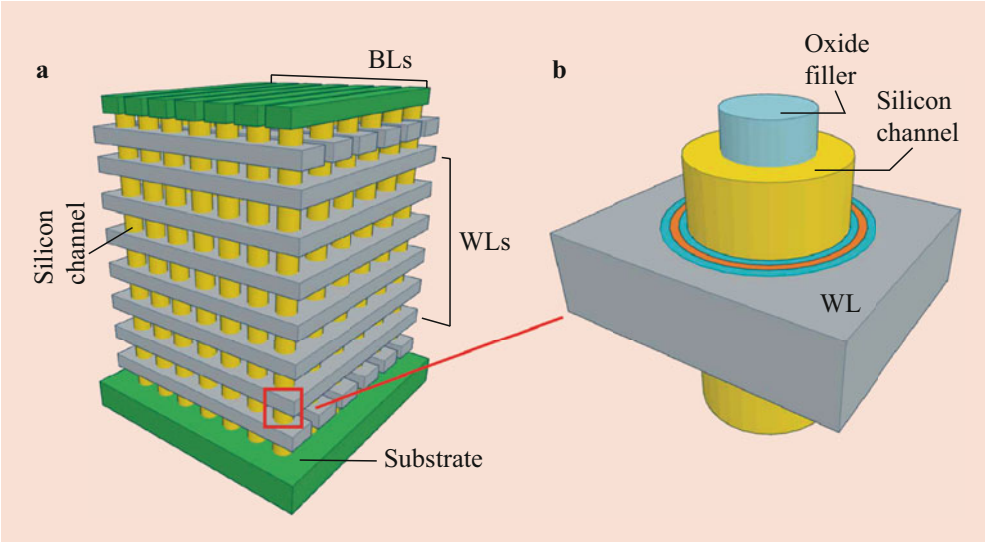

Fig. 32.8 Schematic of a 3D NAND Flash memory array (**a**) and vertical gate-all-around cell structure (**b**). (Adapted with permission from C. Monzio Compagnoni et al. [51], Copyright 2017 IEEE)

as shown in Fig. 32.9 and capacitively coupled to an n^+ contact implantation, referred to as tunneling junction. By applying a positive voltage to the tunneling junction with respect to the gate, electrons stored in the floating-gate can be removed by FN tunneling with single-cell selectivity; in fact, during this operation, the p-substrate, common to all the array cells, is always kept to ground. On the contrary, the program operation is unchanged with respect to its classical scheme, consisting of CHEI at the drain side and achieved by simultaneously applying a positive voltage to gate and drain. A first demonstration of MVM and weight update is reported in [54], while LTP and LTD schemes based on the STDP learning rule are implemented in [29].

More recently, after neuromorphic systems brought renewed attention, other solutions based on custom devices fabrication were proposed [55–57]. In [55] a double-gate floating-body synaptic transistor is introduced, exploiting hot-hole injection in the gate ONO stack to achieve selective erase. In [56], instead, the authors came up with a TFT-transistor with a half-covered floating-gate, with its erase scheme still consisting of stored electrons tunneling out from the floating-gate. Both devices were tested in brain-inspired neural networks in [56] and [57], respectively.

Another approach, alternative to custom device fabrication, consists of slightly modifying commercially available NOR Flash arrays architecture, while keeping the single cell structure unchanged [58–61]. In Fig. 32.10a and b, a schematic cross-section and the equivalent circuit of the 180 nm technology cell by Silicon Storage Technology (SST) [62] chosen for the purpose are depicted, consisting of a floating-gate transistor with a highly asymmetric structure, with its gate overlapping the drain region, while being separated from the source region by a floating-gate. By applying a positive voltage between source and drain, with a positive voltage at the cell gate too, the program operation is performed by CHEI at the source side. On the contrary, the erase scheme requires only a positive voltage drop between gate and source (the drain voltage does not play any relevant role here), allowing trapped electrons to tunnel out from the floating gate. Figure 32.10c shows how such cells are arranged in a NOR Flash array, together with the voltages applied to all the lines during the erase protocol. In this

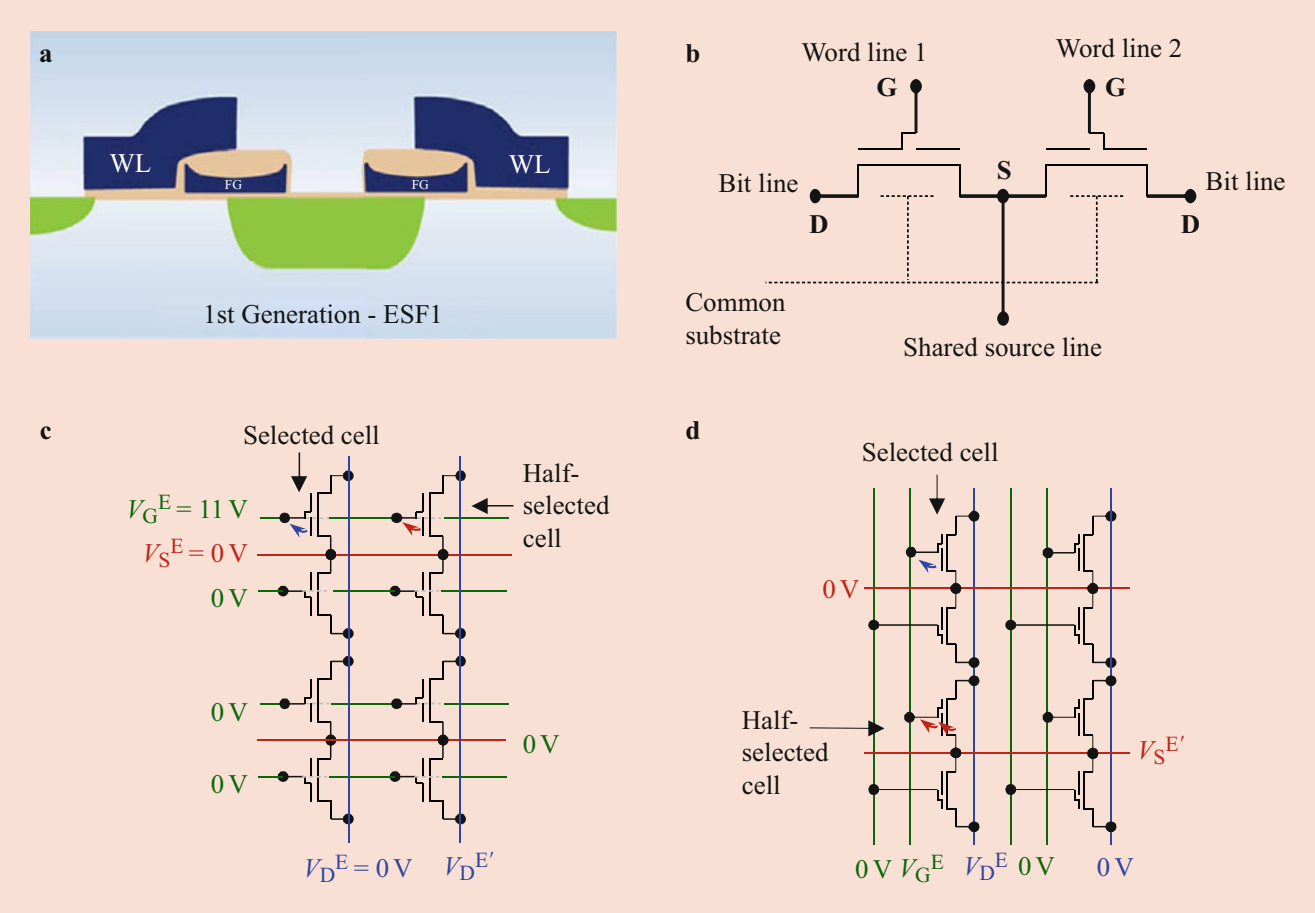

Fig. 32.10 (**a**) Schematic cross-section and (**b**) equivalent circuit of the SST cell structure. NOR array with (**c**) classic and (**d**) modified routing together with the respective erase protocol. (Adapted with permission from F. Merrikh-Bayat et al. [58], Copyright 2015 IEEE)

commercial architecture both WLs and SLs run parallel connecting cells belonging at the same row, hence the erase operation is performed simultaneously on a whole row (this is not true for the program operation since the BL, shorting the drains of all the cells in a column, runs perpendicular to the WL and the SL). To guarantee single-cell selective erase, mandatory for neuromorphic applications, the routing of the array is modified as in Fig. 32.10d, with the WLs now running perpendicular to the SLs. In this way, the voltage scheme depicted in Fig. 32.10d allows to access one single cell at the time, inhibiting any V_T change in the remaining ones. Note that selectivity during program is preserved after this modification.

Two such re-routed NOR Flash arrays have been exploited in [59] and [60] as synaptic arrays to demonstrate a fully integrated three-layer (784 × 64 × 10) ANN, which was trained offline on the Modified National Institute of Standards and Technology (MNIST) handwritten digit database by the backpropagation algorithm.

In order to reduce random drifts and also to implement negative weights, the differential scheme of Fig. 32.11a was adopted. Each synaptic connection is implemented through two adjacent memory cells of each column and each neuron through a differential current operational amplifier summing the resulting BL currents, followed by an activation function block. A schematic for the high level architecture of the whole chip (having a total active area below 1 mm^2) is reported in Fig. 32.11b, where two synaptic arrays (whose dimensions of 785 × 128 and 65 × 20 are determined by the chosen differential implementation), two neuron layers and some additional required circuitry are shown. The resulting network has shown a 94.7% classification accuracy with one-pattern classification time and energy equal to 1 μs and sub-20-nJ, respectively. Moreover, performance is expected to increase considerably when moving from the currently adopted 180 nm to the next 55 nm technology, which was already tested for MVM implementation at array level in [61].

Despite the encouraging results, a drawback associated with the routing in Fig. 32.10d is the increased area per cell, being 2.3 times larger than the original one, due to the additional area needed to accommodate two gate lines for each column [60]. An alternative approach, with the

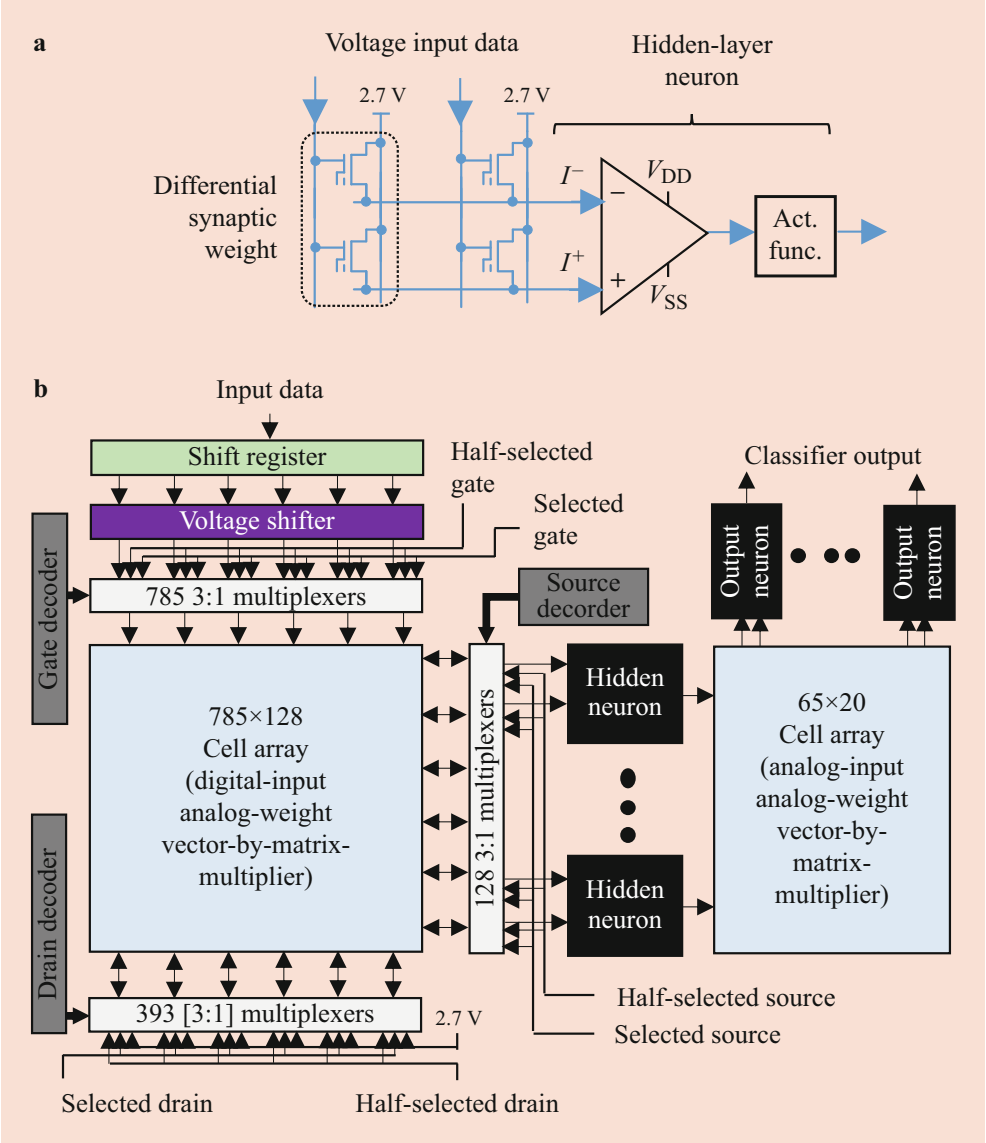

Fig. 32.11 (**a**) Differential implementation of a synaptic connection followed by a hidden-layer neuron, consisting of a differential summing operational amplifier and an activation-function block. advantage of keeping the area per cell unchanged, is reported in [50, 63, 64]. With no change either in the cell or the array design, a simple yet effective single-cell selective erase scheme is suggested and tested on a mainstream common-ground NOR Flash array in 40 nm embedded technology by STMicroelectronics (Fig. 32.12a). As shown in Fig. 32.12b, keeping the CHEI mechanism for cell programming, the parallel cell erase operation, typical of Flash arrays based on FN tunneling, was overcome by exploiting hot-hole injection (HHI) in the floating-gate. In fact, the combined effect of negative WL and positive BL voltages (while grounding the remaining lines) results in holes generated by band-to-band tunneling at the drain side; a fraction of the generated holes, accelerated by the horizontal electric field developed by the drain-to-body voltage drop, are injected in the cell floating-gate reducing the cell V_T. Starting from this program/erase scheme, the STDP learning rule is reproduced through the pre-synaptic and post-synaptic waveforms depicted in Fig. 32.13a. In fact, depending on the time delay Δt between the pre-synaptic and post-synaptic spikes, this scheme makes the rectangular BL pulse occur either during the positive ($\Delta t < 0$) or negative ($\Delta t > 0$) front of the WL waveform. In the former case CHEI takes place, resulting in LTD, while in the latter case HHI is triggered, resulting in LTP. The functionality of this working scheme was proven in a prototype spiking neural network learning according to the STDP rule (Fig. 32.13b) and tested on a pattern recognition task.

A final important aspect that needs to be addressed is the unavoidable uncertainty coming with the tuning procedure of the weights and their stability during the operation of the network. This point is of key importance in DNN inference, for which the weights are transferred to the memory array with closed-loop tuning algorithms to achieve high precision and pre-trained network stability plays a major role. A comprehensive statistical simulation-based investigation of a common-ground NOR Flash-based digit classifier accounting also for V_T placement accuracy and instabilities is reported in [65]. Here the ANN weight distribution resulting from standard network training and testing based on the MNIST database is transferred to the arrays cells. This is done by placing their V_T exploiting the incremental step pulse programming (ISPP) algorithm, widely adopted for program in storage NOR Flash arrays, and, in so doing, evaluating the impact of the statistical nature of electron injection in the floating-gate on the performance of the network (Program Noise, PN). After that, the impact of V_T oscillations due to Random Telegraph Noise (RTN) arising from capture/release of charge carriers in tunnel-oxide defects is also assessed. Starting from a parametric analysis, the authors give some quantitative criteria to determine the accuracy required in the tuning algorithm and the size to which NOR Flash array cells can be scaled when targeting neuromorphic applications.

32.4 Neuromorphic Networks Based on SRAM Arrays

Besides floating-gate memory arrays, another CMOS approach based on SRAM arrays has been extensively investigated for achieving hardware implementation of neuromorphic networks. Despite the limitations due to its volatile storage principle and large footprint, it was demonstrated that a conventional 6T SRAM cell can combine computing and memory functions, thus enabling the implementation of a machine learning classifier based on an SRAM array [66, 67]. Fig. 32.14a shows the architecture of an in-memory machine learning classifier based on a 130 nm CMOS 128×128 SRAM array which, by means of periphery circuits, can be driven in SRAM mode (weight read/write operation) and Classify mode, respectively. In Classify mode, each column of SRAM array operates as a linear classifier making a decision d according to the equation

$$d = \mathrm{sgn}\left(\sum_{i=1}^{N} w_i \cdot x_i\right) \tag{32.2}$$

where w_i is the weight stored in the i-th SRAM column cell and x_i is i-th element of feature vector applied at once to the SRAM array via analog DACs controlling the wordlines WLs.

As shown in Fig. 32.14b, after precharging the bitline pair BL and BLB to the supply voltage, the 5-bit feature vector application to WLs activates a current $I_{BC,i}$ within every cell leading to a proportional BL or BLB discharge depending on the logic value 0/1 stored in the bit cell. Importantly, note that if BL/BLB is treated as a differential voltage signal, one can observe that each element of analog input vector is weighted by −1/+1 and all the column bit currents are summed on BL/BLB, returning a net discharge voltage which is then compared with a threshold by a comparator circuit. As a result, the Classify mode operation of SRAM-based columns provides an energy-efficient and highly parallelized IMC implementation. However, despite these significant benefits, this linear classifier concept, which is a 'weak' classifier since it cannot be trained to fit very complex data distributions, is affected by two critical issues consisting of the non-idealities in MVM due to bit cell variations and BL/BLB discharge non-linearities, and limited weight precision. To overcome these issues, a training procedure based on an error-adaptive classifier boosting algorithm able to compensate fitting errors along with circuit non-idealities by using many weak classifiers [68] combined with the integration of binary weight quantization during error function minimization was developed. Using this training approach, the authors of [66, 67] built a mixed hardware/software image recognition demonstrator employing 45 SRAM column-based classifiers for training and recognition of 9×9 cropped MNIST images, achieving a test accuracy of 90% and a 12× energy saving against an ideal conventional SRAM/digital-adder system with linear classifiers based on binarized weights. In a following work [69], an SRAM-based three-layer binarized DNN capable of a higher test accuracy than the one above discussed was presented. Here, 3 chips were used to implement a three-layer DNN based on a 10×10 input layer, two hidden layers with 96 neurons, and an output layer with 10 neurons. In particular, the hardware demonstration is only limited to training/inference forward propagation while error signal backpropagation and weight updates were computed in software with the data exchange between chip and simulator managed by software-controlled DAQs. This neural network prototype, where any neuron of input and hidden layers is given by an SRAM IMC column, was trained on 50,000 images from MNIST train dataset with cropped size of 10×10 pixels, then quantized to 5-bit inputs, and tested on all 10,000 test images. After a training procedure based on binarized weights and activation functions as theoretically proposed in [70], the three-layer binarized DNN accelerator achieved a maximum on-chip inference accuracy very close to the baseline of 94% after 20 training epochs (<0.4%), with a significant improvement in terms of energy efficiency compared to the same network implemented with standard digital hardware (26×), at a very high efficiency of 700 TOPS/W and 6 TOPS/mm^2 for inference operation.

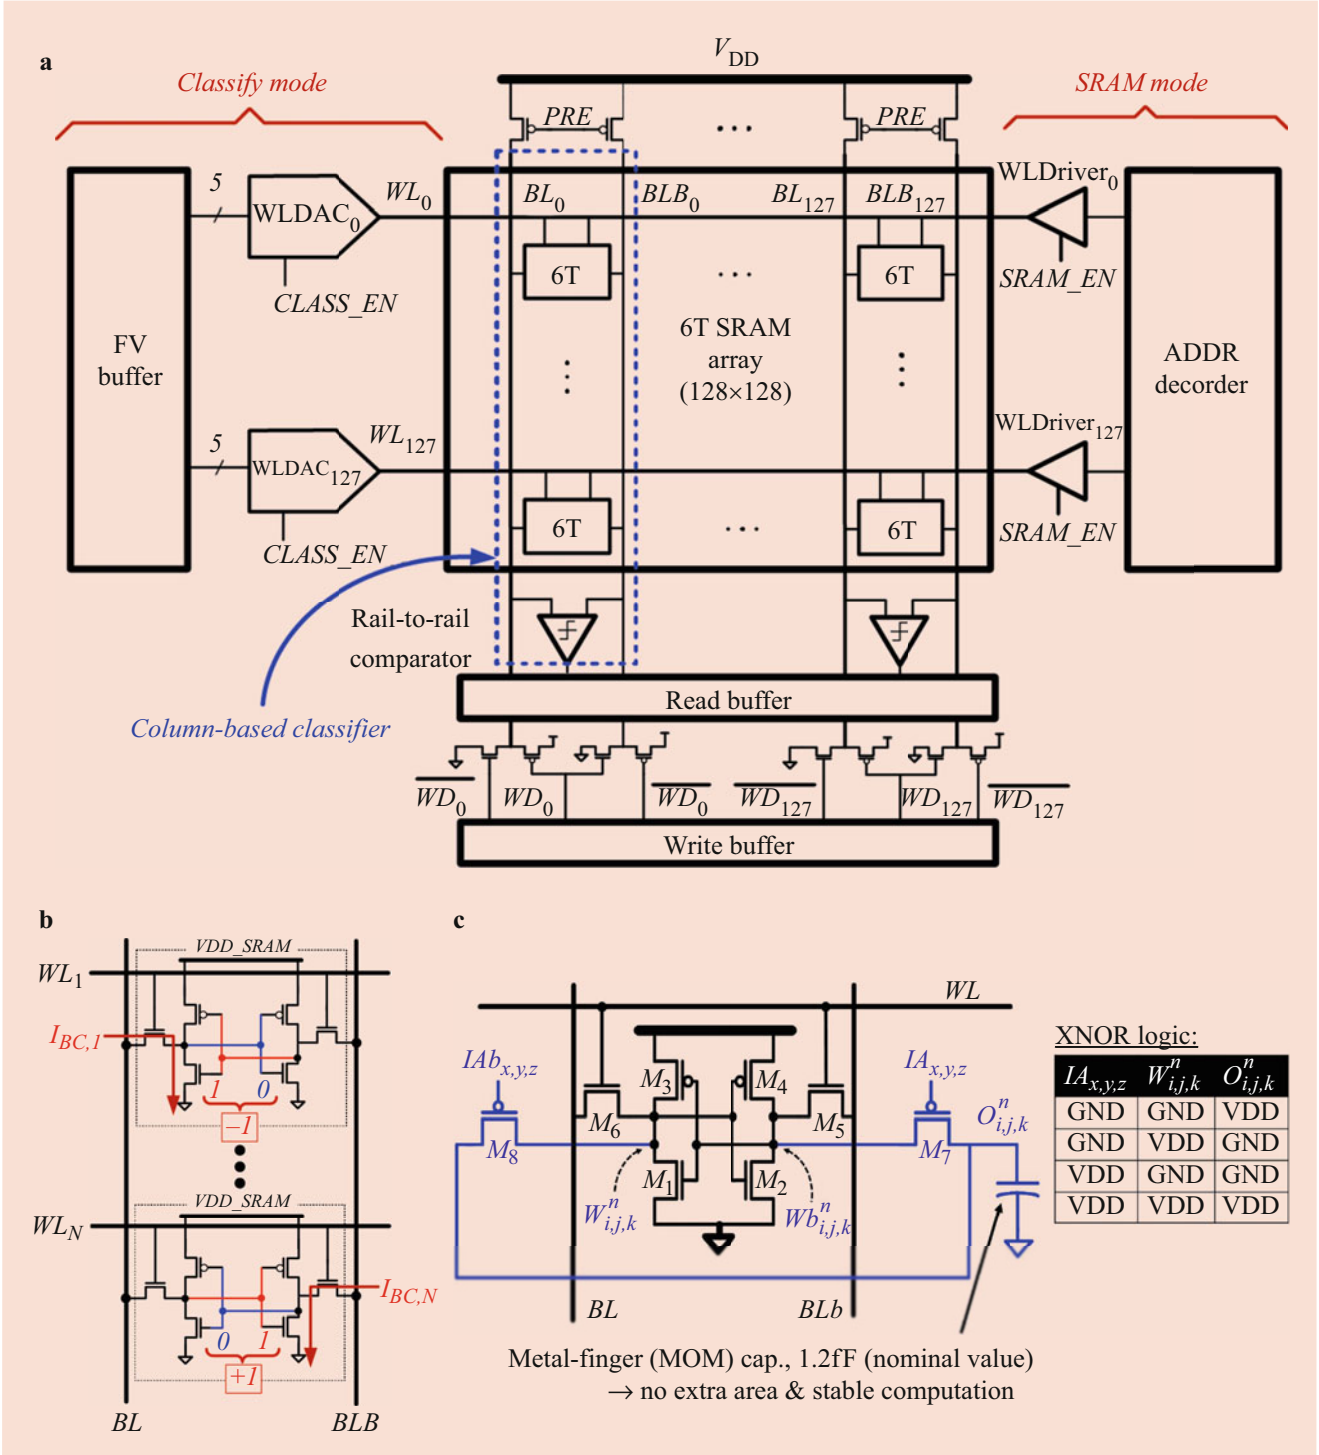

Fig. 32.14 (**a**) Architecture of an in-memory machine learning classifier based on a standard 6T SRAM array that can be operated in SRAM mode (read/write of stored weight) and SRAM classify mode (in-memory multiplication and accumulation along a column). (**b**) SRAM array column implementing a linear weak classifier. Fig. 32.15 (continued)

Besides this implementation, note that other competitive binary DNN accelerators based on 6T SRAM-based IMC have been recently proposed [71].

Fig. 32.14c shows a novel SRAM-based device concept, referred to as 8T SRAM, which combines a standard 6T SRAM with 2 additional PMOS and a finger metal-oxide-metal capacitor [72]. This cell performs the multiplication between a binary 1-bit input signal IA and a 1-bit weight stored in the 6T SRAM, which corresponds to an XNOR function. Compared with standard 6T SRAM cell, the 8T SRAM cell includes a capacitor where the multiplication result is sampled, which allows it to bypass the bit-line variability of standard cell since the cell capacitance can be better controlled in the modern VLSI technology. Thanks to this advantage, the 8T SRAM cell was operated to perform MVM in a binarized convolutional DNN, achieving software-equivalent test accuracy on MNIST dataset (98.6%) and CIFAR-10 dataset (83.3%), and exhibiting an energy efficiency of 866 binary TOPS/W and a throughput of 19 TOPS [73]. Finally, to tackle the binary precision limitation, a novel IMC cell based on two 8T SRAM (T8T SRAM) cells was proposed in [74]. This new cell concept enabled the design and implementation of multibit convolutional DNNs at array level capable of a significant improvement in terms of inference accuracy, in particular for a challenging dataset as CIFAR-10 (from 83.3% to 90.42%).

32.5 Memristive Devices

Achieving brain-inspired functionalities in hardware neural networks requires the identification of technologies suitable to replicate realistic behavior of synapses and neurons. To this end, novel materials-based device concepts referred to as memristors [75, 76] have recently received increasing interest since they offer attractive features such as the opportunity to store information at nanoscale in analogue and nonvolatile states. Moreover, memristive devices can also be operated to execute data processing in situ, thus paving the way to the development of IMC approach [6]. Depending on their structure, memristive devices can belong either to the class of 2-terminal devices or to the class of 3-terminal devices, which results in different functionalities as explained in the following.

32.5.1 2-Terminal Memristive Devices

Figure 32.15 shows the 2-terminal memristive device concepts receiving the greatest interest for neuromorphic hardware. All the devices exhibit a simple structure where two metal electrodes sandwich an insulator and/or active layer. Also, the application of external voltage pulses at the device electrodes called top electrode (TE) and bottom electrode (BE), respectively, leads material properties of these devices to undergo a modification resulting in a change of resistance or magnetic/electric polarization depending on the material.

Figure 32.15a schematically shows an RRAM device, consisting of a metal-insulator-metal (MIM) stack where the resistance of the insulating layer, typically based on transition metal oxides such as HfO_2 [77], TaO_2 [78], TiO_2 [79, 80] and SiO_2 [81], can change from a high resistance state (HRS) to a low resistance state (LRS) and vice versa via the creation and disruption of percolation paths called conductive filaments (CFs), respectively [82–84]. To initiate a CF into an RRAM device, a soft dielectric breakdown called forming is preliminarily performed, leading to a high conductivity enhancement via generation of a high concentration of ionized defects, such as oxygen vacancies and/or metal impurities, in a highly localized region of insulator layer. After forming operation, the application of voltage pulses with the same polarity in case of unipolar RRAM [85–88] or opposite polarities in the case of bipolar RRAM [84] can cause a set transition, which leads the device from HRS to LRS, and a reset transition, which leads the device from LRS to HRS. These resistance transitions are clearly evidenced by the typical current-voltage (I-V) characteristics of bipolar RRAM devices shown in Fig. 32.15b where set process exhibits an abrupt current increase as the applied voltage reaches the set voltage V_{set} whereas the reset process, which starts at negative voltage V_{reset}, shows more gradual dynamics. Specifically, as positive voltage across the RRAM reaches V_{set}, a defect migration driven by drift mechanism is activated from the defect reservoir at TE to the BE causing the formation of CF connecting two electrodes, which results in a resistance decrease. On the other hand, the application of a negative voltage V_{reset} activates a defect migration

Fig. 32.15 Sketch of the main 2-terminal memristive devices recently used for IMC applications such as neuromorphic computing. (**a**) Structure and (**b**) current-voltage characteristics of an RRAM device. RRAM consists of a MIM stack where the creation of a CF within the insulator layer achieved at positive voltages higher than V_{set} leads the device to LRS (set transition) while the dissolution of CF achieved at negative voltages above V_{reset} leads the device to HRS (reset transition). (**c**) Structure and (**d**) resistance-voltage characteristics of a PCM device. In PCM, crystallization of chalcogenide active layer at positive voltage below melting voltage V_m leads the device to LRS, while the melting and amorphization of active layer at voltages above V_m leads the device in HRS. (**e**) Structure and (**f**) resistance-voltage characteristics of an STT-MRAM device. In STT-MRAM, LRS and HRS are achieved depending on whether magnetic polarization in the free layer is parallel (P) or antiparallel (AP) aligned with the magnetic polarization in the pinned layer. (**g**) Structure and (**h**) polarization-voltage characteristics of a FERAM device where a residual positive/negative polarization is exhibited depending on whether the applied voltage is higher than $+V_c$/-V_c, where V_c is a coercive voltage. driven by drift and diffusion mechanisms in the opposite direction, leading to the rupture of CF and the creation of a gap region with low defect concentration, which results in a resistance increase. Resistance in RRAM devices can be tuned in gradual or analogue mode enabling RRAM to exhibit multilevel operation [89–92] which is extremely useful in neuromorphic applications. To this purpose, RRAM also offers high scalability [93] and 3D integration capability [94].

Figure 32.15c shows the structure of a PCM device where the resistance change relies on the phase transformation of an active material [95–98], typically based on a $Ge_2Sb_2Te_5$ (GST) chalcogenide [99] or high-temperature chalcogenide materials such as GeSb [100] and Ge-rich GST [101]. Chalcogenide active material can switch between two different atomic configurations called crystalline phase and amorphous phase, respectively. In PCM, the transition from crystalline to amorphous phase is achieved by a reset operation consisting of the application of an electrical pulse of amplitude higher than the melting voltage V_m, which leads to local melting within the active material, hence a resistance increase to HRS due to the pinning of Fermi level at the midgap [102]. On the other hand, the transition from amorphous to crystalline phase is triggered by a set operation consisting of the application of an electrical pulse of amplitude lower than V_m capable of rapidly inducing active material crystallization via Joule heating [102], thus leading the device to LRS. Resistive switching between two states is also shown by resistance-voltage (R-V) characteristics of PCM in Fig. 32.15d, where positive voltages below V_m cause a gradual resistance change from HRS to LRS due to the crystallization process whereas the application of voltages above V_m leads PCM from LRS to HRS via amorphization process, thus displaying a unipolar switching behavior. Compared to RRAM where the ratio between HRS and LRS is approximately of the order of magnitude of $10–10^2$, PCM exhibits a larger resistance window ranging from 10^2 to 10^4 [103]. This makes PCM very suitable for multilevel operation as demonstrated in [104] where the feasibility of 3 bits/cell PCM is investigated.

Figure 32.15e shows the MIM stack of a spin-transfer torque magnetic random access memory (STT-MRAM), referred to as magnetic tunnel junction (MTJ), where a tunneling insulating layer, typically in MgO, is sandwiched between two ferromagnetic (FM) metal electrodes, typically in CoFeB [105, 106]. STT-MRAM enables to store two resistance states, namely, LRS and HRS, depending on the alignment of magnetic polarization between the free FM layer, where its free polarization can be switched by a spin-transfer torque [107, 108], and the pinned FM layer, where the polarization is fixed [106, 109]. If magnetic polarizations of the two FM layers are parallel (P), a coherent tunneling of spin-polarized electrons is enabled within the MTJ, leading the device to LRS. On the contrary, in case of antiparallel (AP) alignment between free and pinned layer, spin electron tunneling is prohibited, thus leading the device to HRS [106, 109]. Figure 32.15f shows the R-V characteristics of an STT-MRAM device where the set transition from AP to P state takes place at positive voltage whereas the reset transition from P to AP state occurs at negative voltage. It is also noted that abrupt dynamics of set and reset transitions combined with a resistance window of only 200% due to the tunnel magnetoresistance (TMR) effect [110], makes STT-MRAM less suitable for multilevel operation with respect to RRAM and PCM. However, STT-MRAM device exhibits other attractive features including high scalability up to 11 nm [111], very high cycling endurance [112, 113], and fast switching speed [114] as a result of purely electronic nature of polarization switching process in FM free layer.

Figure 32.15g shows a ferroelectric random access memory (FERAM) device exhibiting a MIM structure with an insulating layer based on a ferroelectric (FE) material, such as $PbZrTiO_3$ (PZT) [115], $SrBi_2Ti_2O_9$ (SBT) [116] or doped HfO_2 [117], sandwiched between two metal electrodes [118]. The physical mechanism underlying FERAM operation consists of the switching of orientation of electrical dipoles in FE layer by application of external voltage pulses. Specifically, as shown by polarization-voltage (P-V) characteristics in Fig. 32.15h, the application of a positive voltage higher than a coercive voltage V_c at TE leads the device to display a positive residual polarization $+ P_r$ while a negative residual polarization - P_r is achieved in the FE layer as a negative voltage above V_c in absolute value is applied. Importantly, resistance does not depend on FE polarization in this device, which means that FERAM is not a resistive memory. However, FE state can be measured by probing displacement currents activated by polarization switching, thus enabling a read operation which is unfortunately destructive of previous state. This involves an overhead in terms of energy and time consumption.

32.5.2 3-Terminal Memristive Devices

Memristive concepts can also be implemented with 3-terminal devices, therefore showing more similarities with CMOS-type devices and additional functions with respect to 2-terminal devices. Figure 32.16 shows three examples of 3-terminal memristive synapses, namely, (a) the ferroelectric field-effect transistor (FEFET) [119], (b) the electro-chemical random access memory (ECRAM) [120], and (c) the spin-orbit torque magnetic random access memory (SOT-MRAM) [121].

The FEFET shown in Fig. 32.16a consists of a MOS transistor where the gate dielectric is based on a ferroelectric material, such as a perovskite [118] or doped HfO_2 [122]. In fact, 2-terminal memory devices based on ferroelectric

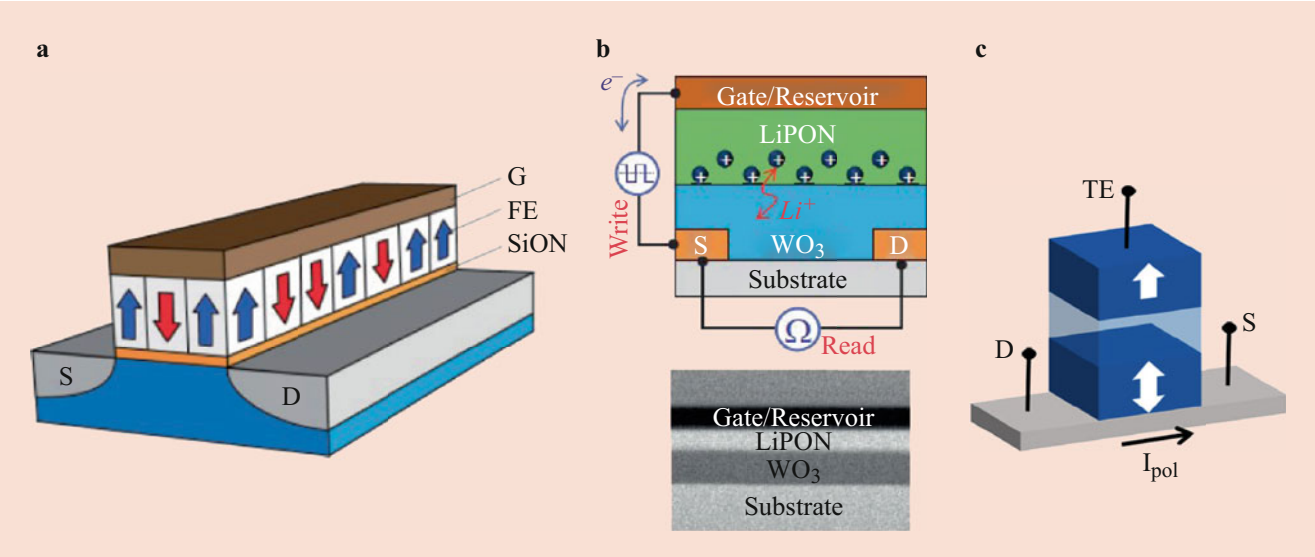

Fig. 32.16 Sketch of three types of three-terminal memristive devices used for synaptic applications. (**a**) Device structure of a ferroelectric field-effect transistor (FEFET), where the channel conductance (weight) modulation is achieved changing the threshold voltage via ferroelectric switching in FE material. (**b**) Device structure of an electro-chemical random access memory (ECRAM), where the channel conductance changes via migration of ionic species such as Li^+ in the electrolyte material due to the application of a voltage at gate terminal. (**c**) Device structure of spin-orbit torque magnetic random access memory (SOT-MRAM), where the MTJ resistance changes because of the magnetic polarization switching induced in the free layer by an in-plane polarization current flowing along the heavy metal write line. capacitors suffer from difficulties due to transient read currents and destructive read [118]. In the FEFET, instead, the permanent polarization of the ferroelectric gate oxide results in a change of the threshold voltage of the transistor, which can be straightforwardly sensed by reading the drain current. The FEFET thus operates similar to a floating-gate memory, except that the ferroelectric material allows for relatively low operation voltage and high speed of polarization switching [123]. FEFET devices can be arranged in high-density arrays with 3D architectures [124], that make FEFET extremely attractive for neuromorphic approaches. FEFET have been employed for neuromorphic synapses [119, 125] and spiking neurons [126, 127]. As the device size is reduced to the 10-nm range, FEFETs increasingly display discrete levels associated with the presence of few individual ferroelectric domains within the small device area [128]. The single-domain effects of V_T might be a challenge toward achieving analogue conductance control of FEFET synapses.

The ECRAM device shown in Fig. 32.16b also relies on the transistor structure where the gate dielectric is replaced by a solid-state electrolyte for Li^+ ion migration [120]. Both inorganic materials, such as lithium phosphorous oxynitride (LiPON) [129] and organic materials as poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) [130], were adopted as electrolyte materials. The migration of Li^+ ions into a $LiCoO_2$ channel causes a decrease in conductivity via Li reduction and intercalation [129]. Alternatively, the Li^+ intercalation in a WO_3 channel induced by an applied positive gate voltage was shown to lead to an increase in conductance (synaptic potentiation), while a negative gate voltage was shown to lead to a decrease in conductance (synaptic depression) [120]. Despite the incomplete physical understanding of the process, ECRAM usually displays very high linearity and symmetry of potentiation/depression processes, which satisfy the constraints for backpropagation training in supervised neural networks [8]. Potentiation/depression in the Li^+ ECRAM with WO_3 channel can be operated at the ns-scale, which makes this synaptic device extremely promising for high speed training of ANNs [120].

Figure 32.16c shows a SOT-MRAM device, which combines an MTJ used to sense the magnetic polarization in an FM layer, similar to the STT-MRAM device, with a heavy metal (HM) line underneath [121, 131, 132]. The HM line is usually made of Pt [133] or Ta [134] and serves for the programming of the MTJ in its parallel or antiparallel states. In fact, a horizontal current flow across the HM line causes a spin accumulation via the spin Hall or the Rashba effects [135], which in turn results in the magnetization switching of the MTJ free layer. The state of the MTJ can be sensed by the vertical current flowing across the MTJ via the TMR effect. Since the programming and reading current paths are decoupled, the device endurance can be significantly extended with respect to STT-MRAM, which is instead affected by MTJ degradation and breakdown due to the high field during the switching process. SOT-MRAM has been adopted to develop

synapses for ANNs [136] and associative memories [137]. SOT-MRAM based neurons were also developed taking advantage of the bistable switching in the MTJ via the HM current [138]. Other 3-terminal devices were also explored for neuromorphic computing, including 2D semiconductor-based mem-transistors [139, 140] and domain-wall-based magnetic memories [141, 142].

32.6 Neuromorphic Networks with Memristive Devices

32.6.1 SNNs with Memristive Devices

To embed learning function in memristive SNNs, STDP demonstration in hardware memristive synapses played a fundamental role. One of the earliest implementations at device level was demonstrated in [143]. In this work, synaptic conductance (weight) modulation was achieved in an Ag/Si-based conductive bridge random access memory (CBRAM), namely, an RRAM device where the CF creation relies on migration of metallic cations from an active Ag/Cu TE to the BE [144, 145], by using a time-division multiplexing scheme with synchronous time frames to convert the relative neuron spike timing Δt into the pulse-width of programming voltage pulses applied across the memristive synapse. To overcome the complexity of this scheme, another approach based on the overlap of voltage spikes with a suitably tailored shape at memristor terminals was developed in [146] and [147], which enabled the STDP functionality in PCM- and RRAM-based synapses, respectively. Based on this approach, brain-inspired SNNs with synapses employing various memristive concepts were simulated and realized in hardware by memristive crossbar arrays [148–152].

However, the implementation of this overlap-based programming scheme typically features some drawbacks. Although the use of a memristor as synapse allows to maximize the synaptic density in a hardware crossbar array, the application of long programming spikes limits network throughput. Also, the use of filamentary-switching RRAM synaptic devices necessarily requires a current compliance mechanism to avoid an uncontrollable CF growth during the potentiation process due to the positive feedback loop between CF size and migration driving forces [153, 154]. To solve these issues, some solutions based on novel materials and/or structures have been investigated. On the one hand, some memristive materials such as SiO_xN_y:Ag [155] and Ta_2O_{5-x}/TaO_2 [156] exhibit a diffusive dynamics enabling non-overlap programming, hence a non-overlap modulation of device conductance suitable for the implementation of a non-overlap STDP protocol. On the other hand, a novel hybrid CMOS/memristive structure where a memristive element is serially connected to a FET, also known as 1T1R structure, received increasing interest thanks to its ability to combine significant advantages for synaptic applications such as current limitation during potentiation, the independent control of communication and plasticity phases thanks to the additional terminal, and the suppression of sneak paths in crossbar arrays.

Figure 32.17a schematically shows a 1T1R structure where a FET is serially connected to an RRAM device with $Ti/HfO_x/TiN$ stack [39]. To achieve an electronic synapse, the 1T1R structure was operated in a neuromorphic circuit as the one depicted in Fig. 32.17b [41]. Here, the application of voltage pulses at gate terminal of FET activates the 1T1R structure enabling the transmission of a current spike proportional to RRAM conductance toward the input of the POST via BE since the TE is generally biased by a low voltage to allow for communication between PRE and POST. After entering the POST, the synaptic current is integrated by an integrate-and-fire circuit inside the POST leading to an increase in its internal potential V_{int}. As this increasing voltage becomes larger than a certain internal threshold, the POST emits a forward voltage spike being delivered to the next neuron layer and a feedback spike, based on a positive pulse followed by a negative pulse, being delivered at TE to implement STDP protocol in 1T1R RRAM synapse. STDP functionality in 1T1R RRAM synapse can be verified as follows. If the PRE spike arrives before the POST spike ($\Delta t > 0$), the PRE spike can overlap only with the positive pulse within the POST spike, thus leading to synaptic potentiation since the amplitude of the POST pulse V_{TE+} was designed to be higher than V_{set} (Fig. 32.17c). Otherwise, if the PRE spike arrives after the POST spike ($\Delta t < 0$), overlapping spikes lead the synapse to undergo depression since a negative voltage V_{TE-} larger than V_{reset} in absolute value is applied at TE (not shown). The application of this overlapping scheme for variable Δt and initial synaptic resistance R_0 resulted in the experimental STDP characteristics shown in Fig. 32.17d. Here, the relative change in conductance $\eta = \log_{10}(R_0/R)$ supports synaptic potentiation for $\Delta t > 0$ and synaptic depression for $\Delta t < 0$. Also, it should be noted that R_0 plays a key role since it dictates the amount of synaptic update. In the case of positive Δt, if R_0 is the HRS, 1T1R synapse undergoes maximum potentiation whereas if R_0 is the LRS, no change occurs since the synapse is already in LRS. In the case of negative Δt, if R_0 is the HRS, 1T1R synapse undergoes no depression because it is already in HRS whereas if R_0 is the LRS, maximum depression takes place. Note that the overlap window ranging from -10 ms to 10 ms makes that no conductance change can be achieved for $|\Delta t| > 10$ ms.

STDP implementation in 1T1R synapse with PCM or RRAM memristive element enabled simulation-based and hardware demonstrations of SNNs capable of fundamental neuromorphic tasks such as unsupervised learning/recogni-

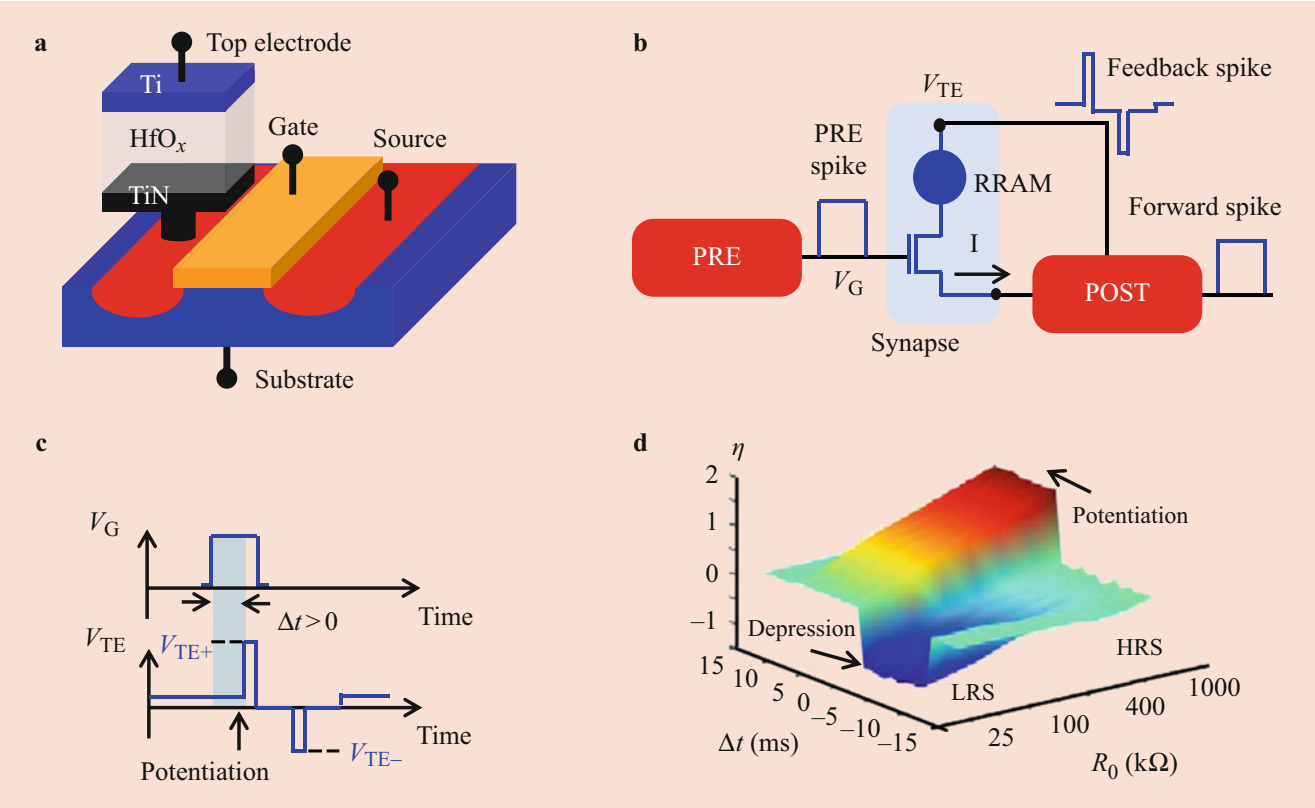

Fig. 32.17 (**a**) Sketch of 1T1R structure displaying a FET and a Ti/HfO$_x$/TiN RRAM used in serial configuration. (**b**) Schematic representation of a 1T1R structure used as synapse connecting a PRE with a POST. The application of the PRE spike at gate terminal activates a current within the 1T1R cell leading the internal potential of POST to increase. As the internal potential crosses an internal threshold, the POST fires a forward spike toward the next neuron layer and a suitably-designed feedback spike at synaptic TE to allow for the update of synaptic weight. (**c**) As the PRE spike anticipates the POST spike ($\Delta t > 0$), the PRE voltage overlaps with the positive pulse of the POST spike, leading the 1T1R synapse to undergo a set transition resulting in the synaptic potentiation. (**d**) 3D color map showing the relative change of synaptic weight $\eta = \log_{10}(R_0/R)$ as a function of the initial resistance state R_0 and the time delay Δt, evidencing that synaptic potentiation is achieved for positive Δt starting from high resistance states whereas synaptic depression is achieved for negative Δt starting from low resistance states. tion of space [37, 39–41, 157, 158] and space/time [159] patterns and pattern classification [160–162].

Figure 32.18a shows the schematic representation of a perceptron neural network [15] where 16 PREs are connected to a single POST via individual synapses implemented by the 1T1R RRAM structure described in Fig. 32.17a. This network was implemented in hardware using an Arduino Due microcontroller (μC) to drive the PRE switches responsible for the generation of voltage pulses at the synaptic gates [41]. These spikes activate synaptic currents whose sum is integrated by μC, leading to the generation of a POST spike as a threshold is hit. At this point, depending on the relative time delay with PRE spikes, the POST spike applied at TE of 1T1R synapses can induce either synaptic potentiation or depression. Based on this network operation, unsupervised learning in hardware SNN was tested by the sequential submission of first three 4 × 4 images from left shown in Fig. 32.18b to the input layer. To achieve unsupervised learning, a stochastic approach consisting of random alternation with equal probability of the submitted input pattern and a random noise image, e.g., the last image in Fig. 32.18b, was implemented. This allowed to achieve depression in synapses outside the pattern, also called background synapses, as a result of the uncorrelation of PRE noise spikes after POST spikes. Figure 32.18c shows the color plot of measured synaptic conductance at the end of each learning phase starting from an initial HRS weight configuration, evidencing the network ability to adapt to submitted input within the end of each training phase, and to forget the previously stored pattern during the following phase. Figure 32.18d shows the sequence of PRE spikes within the submitted pattern and noise applied at input layer during the training experiment, and Fig. 32.18e shows the detailed time evolution of synaptic conductance during the experiment, which displays the convergence of pattern/background conductances to LRS/HRS at the end of each phase. Note that the application of the stochastic approach in this hardware SNN with 1T1R RRAM synapses also allowed to demonstrate both unsupervised

(Adapted from G. Pedretti et al. [41])

learning of competitive patterns thanks to the introduction of software-based lateral inhibitory synapses between two POSTs in the second layer and unsupervised learning of gray-scale images [41].

In addition to SNNs with perceptron architecture, 1T1R synapses were also used in recurrent SNNs to achieve another brain-inspired function as the associative learning [163–165]. Figure 32.19a shows the schematic circuit of the hardware recurrent SNN with Hopfield architecture [166] implemented in [163] where 10 neurons are connected by all-to-all bidirectional PCM synapses with 1T1R structure. To demonstrate associative learning capability, this network was trained submitting in sequence the two non-overlapping patterns shown in Fig. 32.19b, namely, by application of a voltage pulse to neurons within red pixels and no signal to the neurons within blue pixels. As shown in Fig. 32.19c, pattern submission leads the neurons within red pixels to fire causing the application of programming voltage pulses at both input, which controls the TE of column 1T1R cells, and output, which controls the gate of row 1T1R cells. The voltage signal overlap leads the PCM devices of 1T1R synapses shared by externally stimulated neuron pairs to undergo a gradual set transition, hence a synaptic potentiation process. By using this training approach inspired by biological Hebb's postulate [167], the network stores memory states linked with submitted patterns, also known as attractor states [168], which are evidenced by potentiated synaptic weights into the color map shown in Fig. 32.19d.

After the training phase, the Hopfield neural network is operated in the recall mode, namely, its memory states are tested by submitting incomplete versions of original patterns at the input. Fig. 32.19e displays the operation scheme of the neural network during the attractor recall phase, evidencing that an incomplete presentation of the Pattern 1 (no external stimulation at N_6) is able to reactivate N_6 by leading the input current I_6 to overcome $I_{threshold,6}$ thanks to the positive feedback in the attractor state dynamics. Also, Fig. 32.19f shows the spiking response of the Hopfield neural network during the recall of the Pattern 1, thus supporting that the submission of a partial version of original pattern without N_6 on-pixel leads the network to retrieve a sustained output spiking activity within all the attractor neurons after 9 epochs.

32.6.2 DNNs with Memristive Devices

Although the implementation of cognitive computing has recently made great progress thanks to hardware development of memristive SNN prototypes, this kind of neural network emulating brain learning is not yet able to match state-of-art

performance achieved by DNNs in emerging neuromorphic tasks such as pattern classification, recognition of faces and speech, and natural language processing [169]. DNN is a fully-connected neural network where the signal is forward propagated from input to output layer passing through many hidden layers. Differently from SNNs, which are based on unsupervised learning rules such as STDP and SRDP, the weight update in DNNs is generally executed by a supervised learning approach relying on backpropagation. This training method allows to optimize the synaptic weights minimizing a cost function after the iterative presentation of training dataset for many training epochs [17–19]. Implementing this scheme in hardware DNNs however introduces critical issues since the supervised weight update requires synaptic devices exhibiting a bidirectional conductance response with deterministic, linear, analogue, and symmetric behavior [170, 171]. In most cases, memristive devices including RRAM and PCM do not feature such characteristics [8, 170], even if recently investigated three-terminal memristive devices, such as the ECRAM [120] and the ionic floating-gate memory [172], display a conductance response very close to the ideal behavior. Nevertheless, many DNNs have been recently demonstrated in small/medium-scale hardware memristive crossbar arrays by exhibiting increasing performance in terms of processing speed and energy consumption for various applications such as pattern/face classification [173–180], feature extraction [181], and dimensionality reduction [181].

One the earliest experimental demonstrations of DNNs with memristive synapses was carried out in [174]. Figure 32.20a schematically shows the structure of three-layer DNN implemented in [174], consisting of an input layer with 528 neurons, a first hidden layer with 250 neurons, a second hidden layer with 125 neurons and an output layer with 10 neurons. While the synaptic weights were implemented using PCM devices, the neurons were implemented at software level as processing units converting the weighted sum of input signals into an output voltage driving the next layer by a hyperbolic tangent non-linear activation function. This network was designed to classify the handwritten digits of MNIST database which were cropped from 28 × 28 pixel size to 22 × 24 pixel size. As schematically depicted in Fig. 32.20b, network operation relies on the application of backpropagation rule as training scheme. According to backpropagation, the input signal x is forward propagated from input to output via hidden layers resulting in a local gradient δ given by the error signal calculated as the difference of the computed output vector x^D and the desired output vector g. Subsequently, the error term is backward propagated from output to input layer to adjust all the synaptic weights according to the weight update rule $\Delta w_{ij} = \eta \bullet x_i \bullet \delta_j$, where η is the learning rate parameter. To achieve this update rule, synaptic weights were implemented using 2 1T1R PCM cells by encoding the weight into the conductance difference G^+-G^- (Fig. 32.20c). In this way, by applying a complex overlap-based scheme where the weight increase/decrease is achieved by application of identical partial set pulses at G^+/ G^-, the 500 × 661 array including 165,000 PCM-based synapses was programmed. After the weight storage into the array, DNN classification accuracy was tested submitting unseen images from MNIST test dataset. Figure 32.20d shows the result of network operation in classification mode, evidencing a maximum test accuracy of 83% in both experimental test and software-based simulations. To significantly improve this classification performance strongly affected by non-linearity and asymmetry of PCM conductance response, a new synaptic device combining 2 1T1R PCM cells with a 3-transistor/1-capacitor (3T-1C) analogue conductance device was proposed in [179], which allowed to reach a hardware classification accuracy comparable with software performance on MNIST and CIFAR-10/CIFAR-100 datasets [182]. Since then, weight programming has been further optimized in the presence of PCM variability, asymmetry and non-linearity using PCM-only weight storage techniques [183].

The experimental demonstration proposed in [174] was followed by other memristive implementations which were however limited to very small crossbar arrays [175–178]. This limitation has been recently overcome in [180] where a two-layer neural network was implemented into a 1T1R crossbar array with 128 × 64 Ta/HfO_2/Pt RRAM cells. To achieve a classification performance on MNIST test dataset higher than 83%, an on-line in-situ supervised training scheme exploiting the linear and symmetric conductance response exhibited by Ta/HfO_2/Pt RRAM devices was developed (Fig. 32.21a). According to this scheme based on backpropagation, after calculating the desired weight update ΔW for every weight in the software, each weight change was programmed into the 1T1R array cells, increasing the device conductance ($\Delta W > 0$) via coupled application of suitable voltages at TE and gate terminals or decreasing the device conductance ($\Delta W < 0$) by application of a positive reset pulse at BE followed by a gradual set to reach the desired state.

Figure 32.21b shows the circuit schematic of neural network implemented in an 8-kbit RRAM crossbar array, which includes 64 neurons in the input layer, 54 neurons in the hidden layer, and 10 neurons in the output layer. This figure also shows that the weights were encoded by differential pairs of 1T1R RRAM cells while the neurons were implemented partly in software. After the training phase carried out on a MNIST training dataset including 8 × 8 gray-scale handwritten digit images, network inference was evaluated on MNIST test database, leading to a high experimental recognition accuracy of 91.71% (Fig. 32.21c). Also, the au-

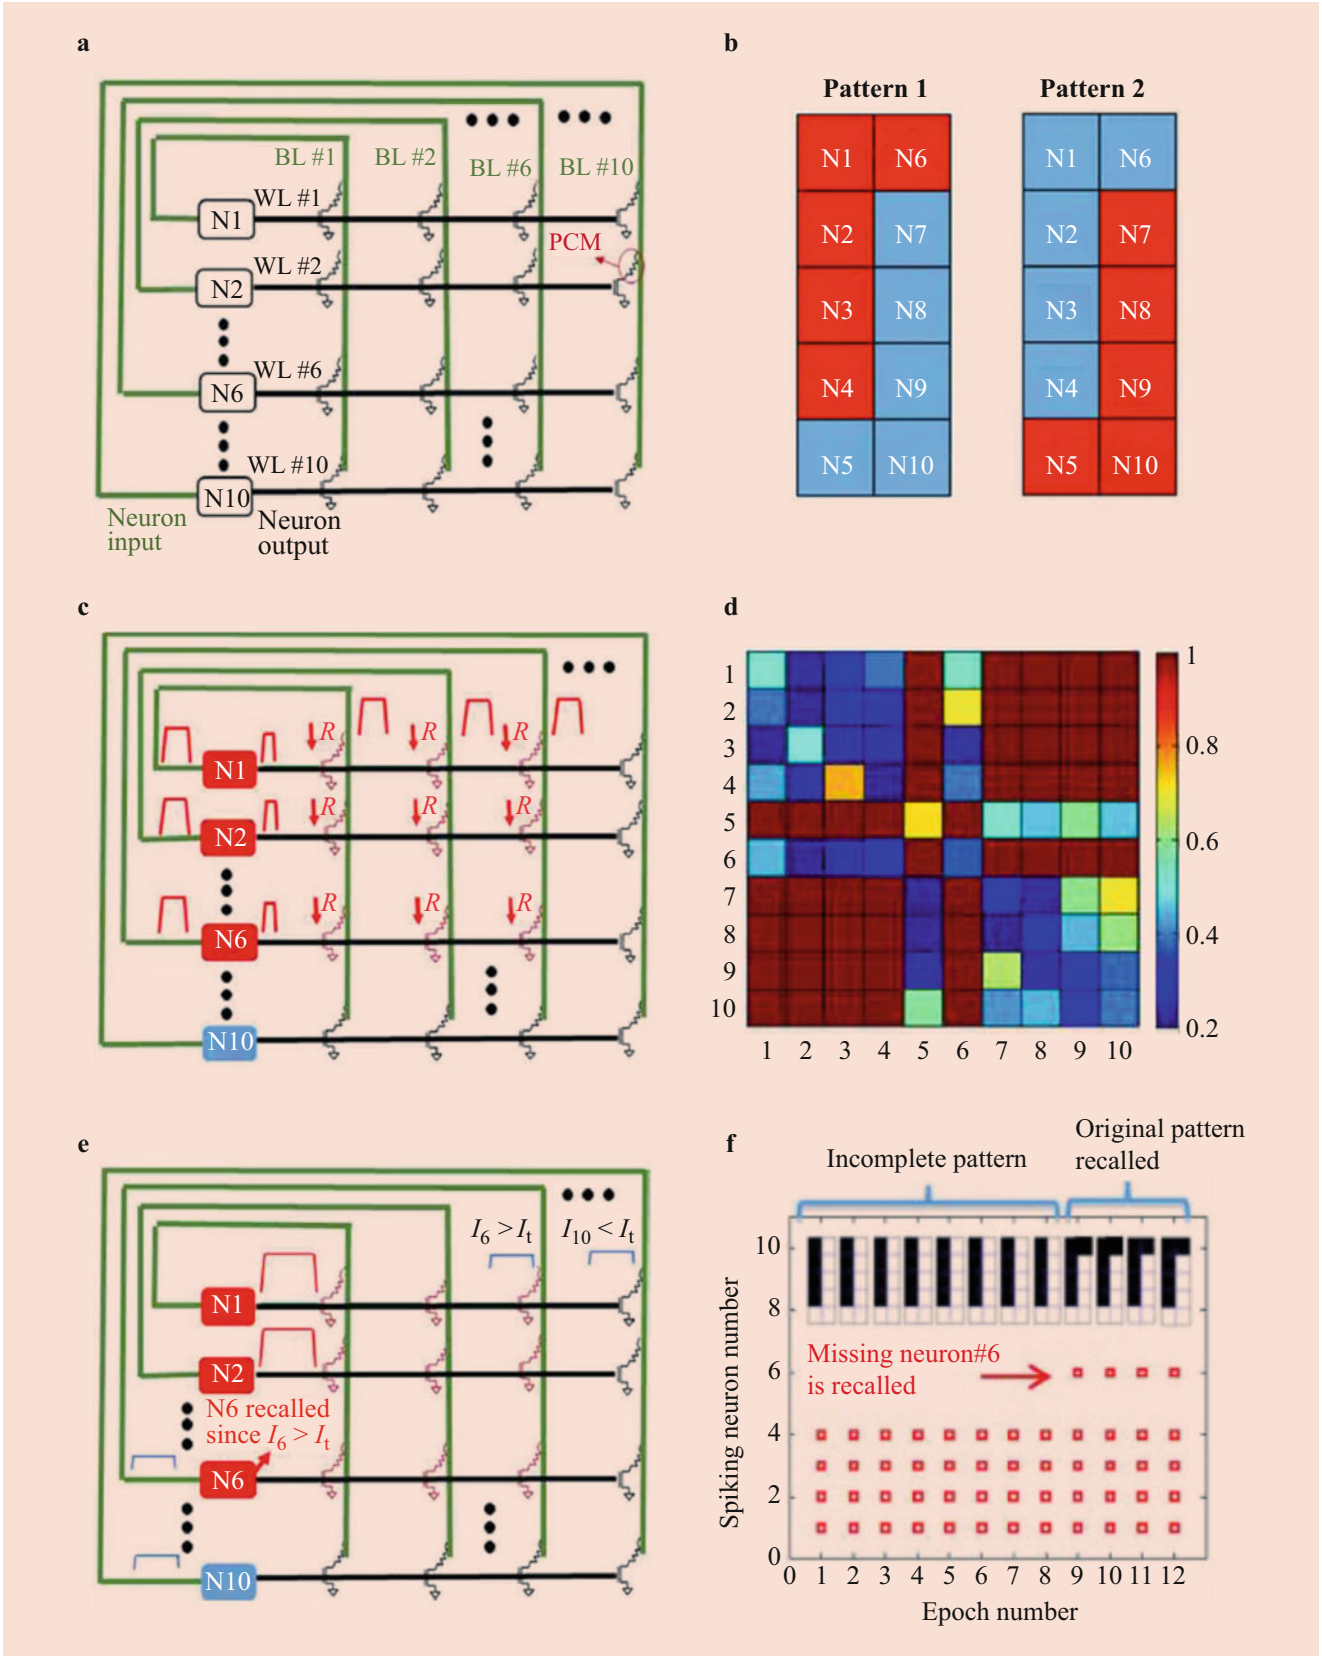

Fig. 32.19 (continued)

thors calculated a larger perceptron network in a 1024 × 512 RRAM-based crossbar array, demonstrating the possibility to achieve inference performance up to 97%. These experimental/simulation implementations thus support the adoption of analogue memristive devices in large memristive arrays as a fundamental step to bring inference performance in hardware closer to software performance.

Although on-line training of neural networks in crossbar arrays is a promising solution to achieve high inference accuracy, another approach aiming at combining high inference accuracy and low power consumption was recently explored in [184]. Here, MNIST classification was addressed by implementation of a two-layer perceptron neural network including 197 input neurons, 20 hidden neurons and 10 output neurons (Fig. 32.22a) in a 4-kbit RRAM array with $HfAlO_x$ 1T1R cells. After performing an off-line network training in software, the precision of synaptic weights was reduced to only 5 levels, thus obtaining a 5-level weight matrix being mapped into the array by application of a novel multilevel incremental step pulse with verify algorithm (M-ISPVA) capable of programming 5 levels in the RRAM devices [185]. Note that the storage of negative synaptic weights given by software simulations was experimentally obtained through the difference of a conductance G and a fixed reference conductance G_r, which provide a positive and negative current term, respectively, as schematically depicted in Fig. 32.22b. Figure 32.22c shows the experimental distributions of synaptic currents read at 0.5 V, evidencing some overlap for 5 programmable levels because of the variability affecting RRAM programming operation [186]. After array programming operation, the inference accuracy of neural network was tested in simulation using the experimental weights. The simulations returned a maximum classification accuracy of about 83%, which is supported by the corresponding confusion matrix collecting inference performance for each digit class (Fig. 32.22d). In addition to the competitive classification accuracy achieved despite the small size of array, this array level network implementation also exhibits low power operation as a result of the storage of synaptic weights into RRAM devices featuring a maximum conductance much lower than the maximum conductance of synaptic devices used in other network implementations such as that discussed in [180].

32.7 Discussion

The combination of good scaling behavior, nonvolatile storage, low-voltage operation, and physical MVM makes CMOS and memristive devices extremely promising for implementation of neural networks such as SNNs and DNNs. Some challenges remain however toward the development of neuromorphic hardware that can be industrialized at large scale. One of the major issues is the limited precision of the synaptic weight stored in the memory device. While digital computers can compute with arbitrary precision, e.g., 16- or 32-bit precision, nanoscale memory devices are affected by physical limitation in determining the conductance. For instance, the precision of the threshold voltage in a Flash memory is limited by the number of electrons stored in the floating gate [187]. Similarly, RRAM conductance is determined by a fixed number of defects that is associated to a certain level of stochastic variation [186]. In addition, some devices such as STT-MRAM can only store binary weights, while others can display drift or fluctuations of the analogue conductance [188, 189]. The limited precision of the synaptic weights results in an approximated MVM and a certain lack of accuracy in recognition, which requires alternative schemes for improved performance [179].

Besides their inherent physical limitations, memory devices could provide additional bio-inspired functionalities thanks to their unique physics. For instance, short-term and long-term memory effects have been evidenced in RRAM, where the retention time can be controlled by either the frequency of the applied spikes [190], or their current [191]. Short-term effects can support STDP [155], short-term memory and spatiotemporal pattern recognition [192]. Stochastic integrate-and-fire neurons have also been proposed based on volatile RRAM [161] and paramagnetic MTJs [193]. These results support the ability to describe relatively complicated functions, such as a stochastic spiking neuron or an STDP synapse, with a single device instead of a circuit with large-area CMOS transistors and capacitors. From this standpoint, the combination of various materials and device concepts is extremely promising, as a wider portfolio of physical properties can be implemented in a single circuit. For instance, the combination of an MTJ neuron and a memristive synapse

Fig. 32.19 (**a**) Circuit implementation of a Hopfield recurrent neural network based on 10 neurons connected with each other by bidirectional 1T1R PCM synapses. (**b**) Input patterns sequentially submitted to the network during the training phase. (**c**) Schematic representation of training phase where externally stimulated neurons fire output spikes overlapping input spikes, leading to potentiation process within 1T1R PCM synapses shared by firing neuron pairs. (**d**) Color plots of synaptic weights after training displaying storage of two memory states linked with submitted patterns. (**e**) Schematic representation of recall phase where the input submission of a partial copy of a training pattern leads the neurons within original patterns with no external stimulation to retrieve their firing activity thanks to the attractor dynamics in the network. (**f**) Recall demonstration at network level using an input pattern without N_6 stimulation. (Adapted from S. B. Eryilmaz et al. [163])

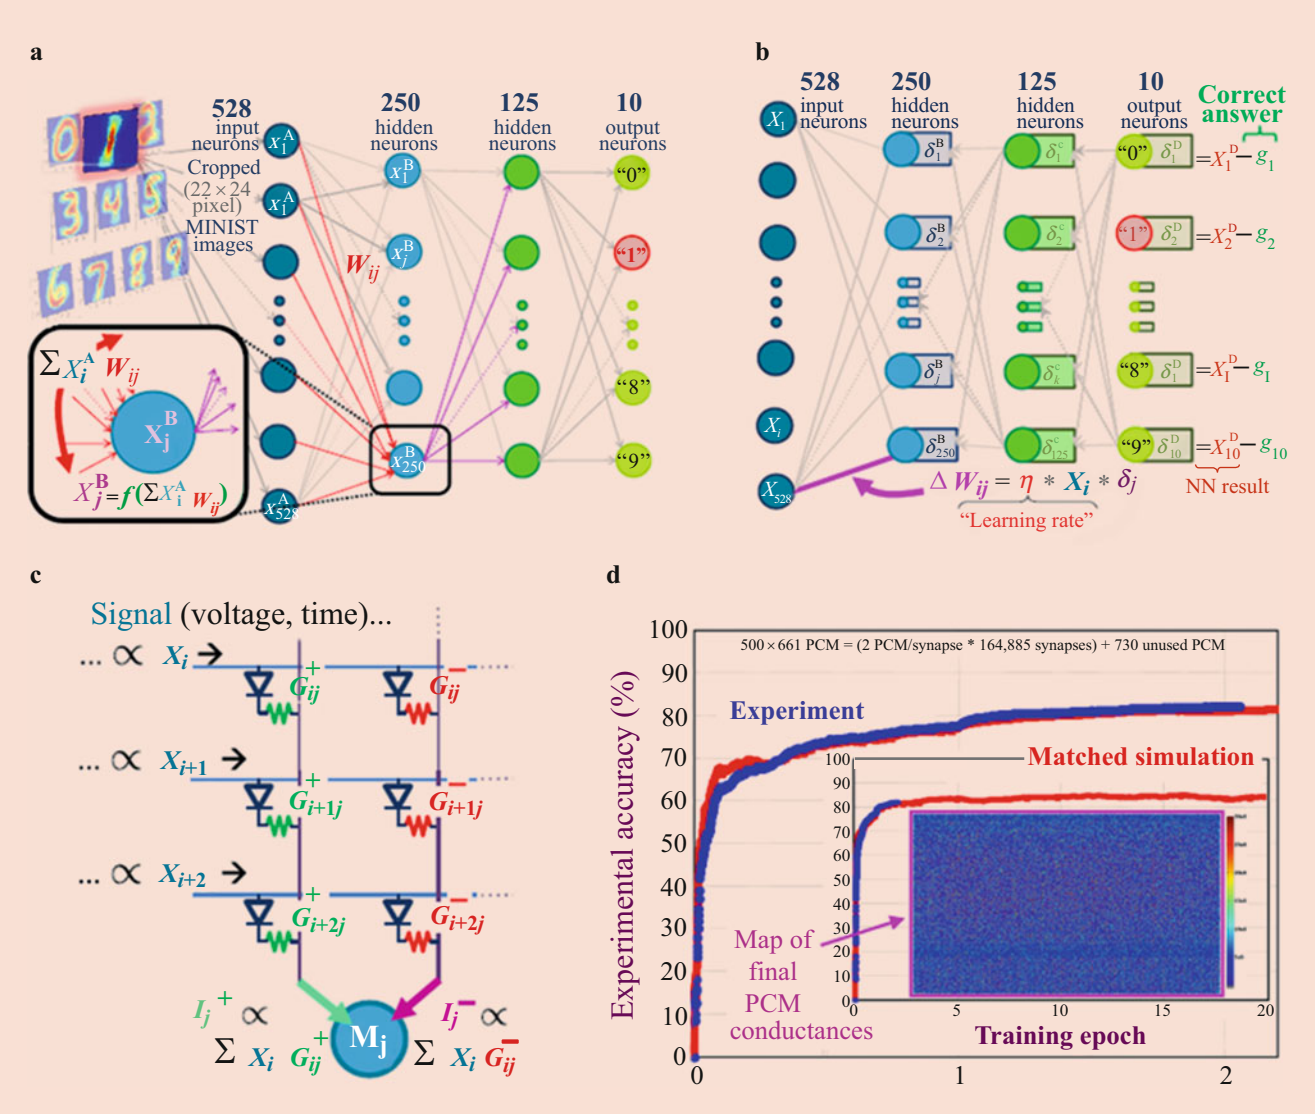

Fig. 32.20 (**a**) Schematic representation of a three-layer DNN for MNIST classification task where every software neuron converts the sum of input currents into a voltage by application of tanh activation function. (**b**) Schematic explanation of backpropagation rule used to train the DNN on MNIST dataset. Input submission leads the output layer to generate an output response which is compared with the correct answer given by input label. The result of this comparison, called error signal, is then backpropagated from output to input layer to calculate the correction term for every weight via the backpropagation weight update rule. (**c**) Schematic representation of the synaptic weight implementation via a differential scheme encoding the weight into the difference of two conductances. (**d**) Experimental and simulated test accuracy achieved in the three-layer DNN with 1T1R PCM synapses. (Adapted with permission from G. W. Burr et al. [174], Copyright 2014 IEEE)

[138] or the combination of a volatile RRAM neuron and nonvolatile RRAM synapses [161], have been proposed for small area, energy-efficient neuromorphic networks.

Finally, it is worth noting that neuromorphic circuits are not limited to applications in cognitive systems to mimic the human brain but can also be applied to a large range of computing problems. It is known, indeed, that recurrent Hopfield networks can support the solution of constraint satisfaction problems (CSPs) such as Sudoku [194], Max-Cut [195], and the Ising spin-glass problem [196]. Hardware accelerators of CSPs have been previously developed by adopting CMOS neuromorphic circuits [197], FPGAs [198], and quantum computing circuits [199]; however, resistive/memristive devices enable the implementation of neural networks in crossbar arrays and provide an intrinsic noise which is essential for the stochastic simulated annealing within the recurrent network [200]. Given the ubiquity of CSPs in many practical fields, such as industrial logistic and scheduling, the neuromorphic computing appears as a valid technology to address real-life problems. Also, very recently it has been

shown that memory arrays with a negative feedback loop, similar to a Hopfield network, can support the solution of general-purpose linear matrix problems, such as linear systems, eigenvector problems, and matrix inversion, in only one computational step [12]. This is a further demonstration that memory devices may have a strong impact on future computing technologies, thanks to physical, analogue, and parallel computing properties.

32.8 Conclusions

This chapter presented the current status of neuromorphic computing based on memory devices, including CMOS and memristive devices. Memory arrays can support the major types of neural networks, namely, DNNs and SNNs, thanks to the unique physics and strong scaling potential of the memory devices. Applications range from typical artificial intelligence tasks, such as recognition of images and speech, to general purpose computing, such as CSPs and linear matrix problems. CMOS/memristive technologies thus appear as a major enabler for the development of scalable, energy-efficient neuromorphic computing systems.

Valerio Milo received the B.S. and M.S. degrees in Electronics Engineering and the Ph.D. degree (cum laude) in Information Technology from the Politecnico di Milano, Milan, Italy, in 2012, 2015 and 2019, respectively. After receiving the Ph.D. degree, he was a Post-Doctoral researcher at the Dipartimento di Elettronica, Informazione e Bioingegneria of Politecnico di Milano, Milan, Italy, until October 2020. He is currently an Application Engineer at Applied Materials Italia Srl, Reggio Emilia, Italy. His research interests include modeling and simulation of resistive switching random access memory (RRAM) devices for neuromorphic and in-memory computing applications.

Gerardo Malavena received the B.Sc and M.Sc degrees (cum laude) in Electronic Engineering from Università degli Studi di Salerno, Salerno, Italy, in 2014, and Politecnico di Milano, Milan, Italy, in 2017, respectively. He received the Ph.D. degree (cum laude) in Information Technology from Politecnico di Milano, Milan, Italy, in 2021 and he is currently a Research Fellow (RTD-A) at the Dipartimento di Elettronica, Informazione e Bioingegneria of Politecnico di Milano, Milan, Italy. His main research interests include the characterization and modelling of 3-D NAND Flash memory arrays and the reliability of power devices for galvanic isolation.

Christian Monzio Compagnoni received the Laurea degree (cum laude) in Electronic Engineering and the Ph.D. degree in Information Technology from the Politecnico di Milano, Milan, Italy, in 2001 and 2005, respectively. He has been with the Dipartimento di Elettronica, Informazione e Bioingegneria, Politecnico di Milano, Milan, Italy, since 2006, where he was an Assistant Professor from 2006 to 2015, and has been a Professor of Electronic Engineering since 2015. He has authored over 120 papers published in international journals and conference proceedings and he holds two U.S. patents. His current research interests include the basic physics involved in the operation and in the reliability of solid-state technologies for data storage, with an emphasis on NOR and NAND Flash memories and on emerging memories. Christian Monzio Compagnoni was a recipient of five awards at the IEEE International Reliability Physics Symposium (IEEE-IRPS), including the Outstanding Paper Award in 2008, the Best Student Paper Award in 2012, 2013, and 2014, and the Best Poster Award in 2015. He served on the Technical Program Committee of the IEEE-IRPS in 2009–2010 (Memory subcommittee), and in 2016 (Memory and Product IC Reliability subcommittee). He has been serving as an Associate Editor of IEEE-Transactions on Electron Devices (IEEE-TED) since November 2015 and he served as a Guest Editor for an IEEE-TED Special Issue on “Reliability” in 2019 and as the Guest Editor-in-Chief for an IEEE-TED Special Issue on “Memory Devices and Technologies for the Next Decade” in 2020.

Daniele Ielmini is a Full Professor of Electronics at the Dipartimento di Elettronica, Informazione, e Bioingegneria of Politecnico di Milano, Milan, Italy. He received the Ph.D. degree from Politecnico di Milano in 2000. He conducts research on emerging nanoelectronics devices, such as phase change memory (PCM) and resistive switching random access memory (RRAM), and on novel computing with memory devices. Prof. Daniele Ielmini was a recipient of the Intel Outstanding Researcher Award in 2013, the ERC Consolidator Grant in 2014, and the IEEE EDS Rappaport Award in 2015. He has been Fellow of IEEE since 2019.

Abstract

Nanoelectronic systems have driven the technology advances for the past half century. But, as we move forward in the twenty-first century, new concepts for computing, notably quantum computing, have appeared that promise dramatic increases in computational efficiency. While these are new systems concepts, they likely will continue to be manufactured using the technology of nanoelectronics. Here, we discuss a variety of approaches which are currently being studied for applicability to quantum computing. But, issues such as scalability, which has facilitated the development of nanoelectronic systems so far, pose important questions for these new and novel approaches.

Keywords

Quantum computing · Entanglement · Superconducting qubits · Spin qubits

33.1 Introduction

The initial idea of constructing a computing machine dates at least to the analytical engine of Charles Babbage at the middle of the nineteenth century. But, it was the theoretical work of Alan Turing in the 1930s that pushed the ideas forward [1]. This led to efforts at many sites to develop computing machines, with commercial development following after World War II. The key driver for nanoelectronics appeared with the invention of the integrated circuit in the 1950s by Jack Kilby [2]. This latter invention enabled the rapid development of integrated circuits with ever smaller critical dimensions and the evolution of what has become known as Moore's law [3]. In this, Moore suggested that the number of transistors on an integrated circuit would continue its trend of doubling every 18 months, leading to the exponential growth that allowed first microelectronics and then nanoelectronics to revolutionize everyday life throughout the world. The physical approach which allowed this was the principles of scaling that applied to the integrated circuits [4]. The scaling approach was based upon the principles that all dimensions

and voltages of a device should be reduced by the exact same factor, so that the electrostatics of the device would be unchanged. As a result, the reduced dimensionality did not, in principle, change device operation as it was downsized. This little overlooked fact meant that integrated circuit was a scalable technology, and this scalability led to the impact of nanoelectronics on the world [5].

33.1.1 Moore's Law

For almost six decades now, evolution in the integrated circuit has continued to follow Moore's dictum on the development of this technology. This steady progress has brought us to the situation today, where the newest leading edge chips are known as the 5 nm generation. While this nomenclature is no longer applied to the most critical dimension, the channel length, it is still an indicator of the progress being made as we move from one generation to the next. While many have predicted the end of Moore's law, we still move on with this scalability of the technology. This has occurred through a number of paradigm shifts, from the planar MOSFET to the tri-gate or FinFET to nanowire FETs. Many, if not most, people have regarded Moore's law as a technology law simply because the most evident appearance is associated with the microprocessor. Many other technologies follow such evolutionary laws. And, the important point is that *Moore's law is, in fact, an economic law*!

In its original version, Moore's law was driven by three technological factors: (1) reducing the transistor size (and therefore the silicon area occupied by it) with the scaling factor, (2) increasing the size of the microchip itself, and (3) circuit cleverness (by which the number of transistors required to perform a given function could be reduced). The key, however, lies in the fact that the cost to manufacture a single integrated microprocessor (i.e., the cost per square centimeter of the chip) has not significantly changed in the last six decades. The reduction in size means that many more transistors, and many more functional units, can be placed on a single chip, resulting in the cost per functional unit decreasing exponentially with time. In the 1970s, the new supercomputers, such as the Cray, cost 10s of millions of dollars. The fact that such a computer can be placed on a single chip (many times over) today suggests that such a computer could be built for less than a single dollar today. In fact, the modern laptop has thousands of times more computing power than that first Cray. Even the modern personal phone has significantly more computing power than that first Cray. It is this economics argument that drives Moore's law, and it is scalability of the technology that enables such an economics driving force. And this leads us to the conclusion that if any new technology is to prove useful, it must be scalable.

33.1.2 Where the Industry Appears to Be Going

Scaling theory involves not just reducing dimensions and voltages, but also the introductions of new technologies along the way. For example, Intel introduced HfO_2 as a new gate insulator with the 45 nm generation, because of its higher dielectric constant. This allowed the use of thicker insulators for the gate dielectric while maintaining the equivalent thinner electrical thickness of SiO_2. Then, they introduced hyper-threading with the 35 nm Xeon processor, which meant that each node could process at least two data threads. Thus, a six-node, hyper-threaded chip could achieve something close to a 12× speedup in processing. Then, they introduced the new tri-gate, or FinFET, technology at the 22 nm node, which turned the transistor on its side. Instead of being planar, it was now vertical with the gate wrapped around the top and two vertical sides. This meant that a much larger gate periphery (width) could be obtained at a smaller net silicon surface area. This was done primarily to reduce the off-state leakage current and resulted in much lower power dissipation on the chip. Today, we are at the 5 nm node, although there have been significant delays in introducing the new chips (as of early 2018) [6]. Even today, the technology for this node is still being developed and discussed. Nevertheless, the device technology for this node is still being discussed. Nevertheless, TMSC has announced production of their this chips [7], and ARM and Cadence are planning to use these chips [8]. Indeed, the new (2021) iPhone 11 uses a 15 nm chip, the ARM A15, which is produced by TSMC using EUV lithography. This chip has eight nodes and utilizes neural net technology for some of the phone's learning processes. On the other hand, Global Foundries have stopped their planned production of 7 nm chips, allegedly for the lack of demand on the part of users [9].

The industry may be at a crossroad for another technological change, and this may involve a move to nanowires fabricated in a gate-all-around technology, where the gate wraps completely around the nanowire. This has been studied in research labs for almost two decades. Nanowires placed parallel to one another on the surface of silicon are not an attractive approach. This is because, if we are to save silicon surface area, the nanowire has to have a large diameter, and this means that it cannot compete with the FinFET in saving Si area and achieving high circuit density [10, 11]. But, another approach is possible, and that is to stack the nanowires vertically [12], an approach which is being developed by many companies [13, 14]. Subsequently, these wires have been made by a variety of techniques, including inductive plasma etching [15], nano-stencil lithography [16], and reactive ion etching [17, 18]. Naturally, there have been studies to see how these devices compared with others such

as SOI MOSFETs [19] and FinFETs [19–21]. At this node, there is also a consideration whether or not to incorporate doping in the channel region, and this has been studied as well for the vertical stacked nanowires [22, 23]. As may be expected, there is certainly a problem with line edge roughness on these nanowires [24–27]. But, perhaps the best sign that this technology is ready for prime time applications is the entry of the major semiconductor producers into the field [28].

33.1.3 New Computational Models: Quantum Computing

The idea of using quantum mechanics to provide more power than classical computers seems to have begun around 1981–1982 [29], but Deutsch put the concept on a sounder footing a few years later [30]. Deutsch reformulated the Turing thesis with the assertion that every finite realizable physical system can be perfectly simulated by a universal model computing machine operating by finite means. However, he pointed out that the output of a quantum machine, although fully determined by the input state, is not an observable itself. Hence, the user must provide some cleverness if this state is to be determined. Benioff in his earlier work pointed out the need for this quantum state to have experienced interference, some indeterminism, and was a non-separable state. Today, we would assign these properties to the presence of entanglement in the quantum state, and Deutsch realized that quantum parallelism was required of such a computer. He also realized that non-dissipative evolution was unphysical, so immediately it became clear that a great deal of effort would be required to minimize the decoherence of the physical states. Deutsch then provided some input as to what type of states or systems might be usable in this process [31]. Jozsa mathematically showed that one could associate a quantum state with each function that one desired to evaluate [32]. This evaluation needed to be a superposition of the various quantum states, with the particular superposition labeled by the desired function. Jozsa and Deutsch were then able to show that this should lead to a rapid solution of problems via the quantum computer [33].

Progress beyond mathematical approaches came shortly after the above when Lloyd suggested that arrays of weakly coupled quantum systems might be able to serve as the quantum computer if they were subjected to a sequence of controlled electromagnetic pulses, which could place the quantum bits into the desired superpositions [34]. This shifted the problem to arranging for the superpositions, and this required algorithms. Perhaps the first such algorithm came from Peter Shor [35, 36] who introduced the idea of the quantum Fourier transform in dealing with numbers generated by the product of prime numbers, a key element in many encryption techniques. Another for fast data base searches was developed by Grover [37]. Sometime, however, the algorithms stimulate rethinking classical approaches by which the new classical approach is just as fast [38].

By the mid-1990s, progress was beginning to speed up in the quest for quantum computers with suggestions for realizable gates and their universality [39–41]. Nevertheless, it was realized that even small amounts of dissipation could upset the computation, and the need for error correction began to be addressed [42, 43], although there are some who assert that general qubit errors are not completely correctable [44]. There has been considerable discussion and debate since the beginning about whether or not error correction will work and even if quantum computing will work [45–49]. Nevertheless, progress has continued and is even accelerating. We will discuss the current (2018) situation with respect to the interests of various companies in the next subsection; it is worth pointing out that much of the discussion has not turned to "if," but to "when." In fact, a recent article has raised the issue of "quantum supremacy," the point at which performing a quantum computation on a quantum computer will prove to be beyond the capabilities of any classical computer [50]. While the processes discussed here are necessarily dated, they can point the way to find the newer, updated results.

33.1.4 State of the Art in Quantum Computing

The quest for quantum computers begins with the qubits. We will describe qubits and their difference from bits in the next section, and the following sections will describe various types of qubits that are in use. Before taking up this task, however, it is worthwhile to examine the approaches which builders of quantum computers have taken, as this particular area has had exponential growth in just the last few years. As a result, it is important to understand that this brief section is the state of the art in late 2018, and it may well change within a few short years. Some more recent developments are also mentioned.

D-Wave Systems delivered the first quantum computer in 2010, but this had an architecture different from a general purpose machine. It was instead focused on an energy minimization structure that is used for what is called artificial annealing. Nevertheless, the machine has been used by several commercial firms. In 2018, D-Wave introduced a 2000 qubit machine using the same architecture. The qubits themselves are made from superconducting circuits with Josephson junctions. More importantly, they launched this same year a real-time application (programming) environment called Leap.

The best known name in the area is IBM, who has become a leader in the field. In fact, they provided web access to their first five-qubit machine so that researchers and

developers could begin software efforts. To aid this, they provided a modular open-source programming environment called Qiskit. More recently, they have developed a 20 qubit machine and later a 50 qubit machine using superconducting Josephson junction technology. In fact, nearly all the companies involved in quantum computers are currently using this approach. One of these is Alibaba, a Chinese company, who has an 11 qubit machine. Google has announced a 72 qubit processor, and Intel has recently announced a 49 qubit chip. Quantum Circuits and Rigetti are also developing qubit systems with the superconducting Josephson technology. Importantly, in 2019, IBM attached their quantum processer to one of their main stream supercomputers, in order to gain information of the usage of the quantum processor. As a result, IBM now claims that about 100 companies have gained experience with quantum computing. In addition, this has changed the focus for future development from the science of the qubit to the algorithmic nature of the circuits themselves.

There are some differences with other manufacturers, however. Intel has developed a 26 qubit processor in which the qubits are built upon the idea of using spin as the logic variable. This chip has qubits which measure only 50 nm across and are quite scalable. IonQ is developing qubits based upon trapped ions, in which an atom is trapped in an electromagnetic confinement environment and the logic state rests in the state of the atom. Then, Microsoft seems to be focusing upon systems composed of topological materials [51], a relatively recently developed, and still not fully understood, class of materials. Here, the interaction between the qubits depends upon what is called braiding [52] approaches which control the phase between the qubits.

For quite some time, there was a belief that quantum supremacy could be achieved if only we could reach 50 qubits in the system. The above discussion shows that while we have reached this number of qubits, the issue of quantum supremacy is still in the air. In late 2019, Google claimed to achieve quantum supremacy with their 53 qubit processor [53]. However, this claim was challenged by several competitors, notably IBM. This is complicated by the fact that IBM has carried out simulations of a 49 qubit system on a classical computer [54], which suggests that we are in fact quite far from reaching the needed supremacy. Similar simulations on 64 qubits have also been performed on normal computers [55]. This should not be viewed negatively, as there is absolutely no doubt that the quest for quantum supremacy will continue with the development of ever larger numbers of qubits, especially as a path has been given [50].

Then, we should ask once again our question about scalability. While the size of the chips discussed above, in terms of the number of qubits, is certainly increasing, mostly, the actual chip size is increasing, and it is not clear whether or not the qubit density is increasing. So, it would seem that the issue of scalability seems to not yet be answered. And, the systems listed above all seem to be of a relatively low number of qubits. This, by itself, is not an issue per se, as modern classical computers are not composed of massive number of bits in their central processing unit (cpu). Indeed, a 64 bit arithmetic computer tends to have a few registers, each of 64 bits, and some control hardware within the cpu. Thus, in the IBM experience, the five qubits were basically the cpu and were used multiple times within the computation. Even so, there are issues that have been raised. Michielsen et al. [56] have pointed out that for a device that maps input data to output data via an algorithm to qualify as a computer, it must achieve two things: (1) for each instance of the input data, the output data should be the correct output data, and (2) for the same input data, the output data should be unchanging when the machine is in the stationary state. These authors have run several algorithms on the IBM Quantum Experience with 5 qubits and find that this machine often fails these tests. In some cases, failure arises for the same algorithm and input data run on different days. These authors offer some explanations as to why this might be the case, but it is nonetheless quite worrying if we are expecting to enjoy the success of quantum computers.

But, there are other problems on the horizon, and these deal with the accuracy, or more precisely the errors, in the quantum computation. It was pointed out above that this leads to erroneous results in some calculations on the current qubit processors. Certainly, error correction can help, but there are doubts among many of the researchers if the required size of the quantum computer can ever be achieved while still maintaining the required accuracy of the calculation using what are basically analog qubits. It is an important issue that is still the subject of intense debate [57].

33.2 Qubits and Entanglement

While it may not appear to be the case, with the similarity of name between bit and qubit, these two quantities are basically quite different. To begin with, the normal bit, the basis of our binary computation in everyday classical computers, has only two values, 0 and 1, which form the binary base. While the qubit also has a 0 and a 1, it is analog in that we may define arbitrary complex values in any manner in which the magnitude of the qubit remains 1. In this section, we want to go through this idea in some detail to understand how we get to qubits with the properties required to make quantum computers.

33.2.1 Bits and Qubits

When the ENIAC was first developed at the University of Pennsylvania, it computed with base-10 circuits [58]. The simplest operation, the addition of two numbers took 0.2 ms.

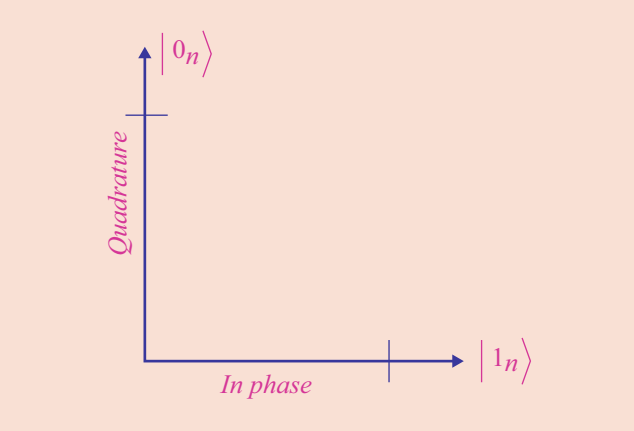

Fig. 33.1 The coordinate set for an arbitrary bit, here the *n*th bit, showing how the axes correspond to the values 0 and 1

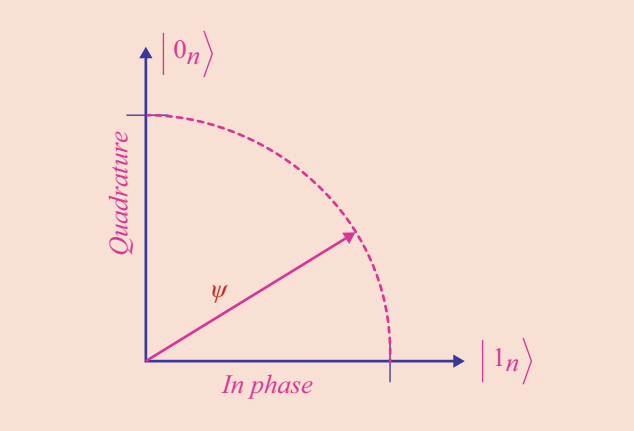

Fig. 33.2 The value of the qubit now is analog and the magnitude of the wave function is now unity

But, calculation in base-10 is somewhat wasteful of computer resources. It was John von Neumann who suggested that the binary system should be used (and he also suggested the stored program approach, which along with binary arithmetic, formed the idea of the von Neumann architecture [59], and both were incorporated in the EDVAC which was the successor to the ENIAC). Essentially, all computers from this time forward have used the binary system, as it is eminently suitable to two-state bits. In Fig. 33.1, the idea of the bit/qubit is presented in as two orthogonal axes in a configuration space (for reasons that will become apparent later). In this space, we define the two unit values on each axis as the states 0 and 1. Then, using quantum notation, we define the state of a classical bit in this space as

$$|\psi\rangle = a\,|0\rangle + b\,|1\rangle\,, \tag{33.1}$$

where

$$a, b \subset (0, 1)\,, a + b = 1. \tag{33.2}$$

Hence, a and b can be either a 0 or a 1, but the two must be different.

In the computer itself, a particular state is defined by the values of the bits used to describe the state. Then, one can define a state transition diagram, in which each possible state is a node, and transitions between these nodes indicate the action taken when a control signal is applied. Various outputs arise from the set of transitions and the state of the machine after the transition. Hence, an algorithm is a set of instructions that guide the system through a set of transitions, changing the various bits under the guidance of the control signals, to a desired result. Good algorithms lead to the machine halting at the end of the algorithm and yield a desired output (and with bad algorithms, the machine sometimes never stops). This same operational model will exist also in the quantum computer. That is, the qubits will define a state; state transitions will depend upon control signals.

33.2.2 Qubits as Two-Level "Atoms"

When we move from the bit to the qubit, the change is rather subtle. We use the same diagram of Fig. 33.2 for the qubit. We still have the two coordinate axes representing the 0 and the 1. But, now the wave function is analog and can take any value on the unit circle. Hence, Eq. (33.1) is still valid, but now the coefficients are related by

$$|a|^2 + |b|^2 = 1. \tag{33.3}$$

Thus, the two coefficients may be complex numbers, and Eq. (33.3) tells us that the net wave function must have a magnitude of 1, the sum over the phase space of the square magnitude of the wave function must be unity, due to its probability interpretation. Now, the problem that arises is that this formulation is overly *restrictive* to the actual wave function for the quantum qubit.

The two states 0 and 1 can be thought of as representing real energy levels of a two-level atom (we will return later to why we use the atom model). Equally well, they can be thought of as the two possible spin states of a fermion – spin up and spin down. Normally, these are aligned along the Z-axis in spherical coordinates. From the latter concept, we then tend to write the Hamiltonian representing this two-level system as

$$H = \frac{\Delta}{2}\sigma_z, \tag{33.4}$$

where Δ is the energy spacing between the two levels and σ_z is a Dirac spinor, given by the 2×2 matrix

$$\sigma_z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}. \tag{33.5}$$

Hence, we have mapped the (0,1) states into the states (−1,1), in terms of $\Delta/2$. Hence, the upper level is taken to be the 1 state and the lower level the −1 state. In terms of these two states, we can then rewrite the wave function as

$$\psi = \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} |a| \, e^{i\phi_1} \\ |b| \, e^{i\phi_2} \end{bmatrix}. \tag{33.6}$$

So, each coefficient has its own phase, which we will deal with shortly.

Now, it is convenient to write the wave function in a slightly different form which characterizes the system, but make the two phases somewhat less arbitrary. Hence, we write the two-level system in terms of the density matrix

$$\rho = \begin{bmatrix} |a|^2 & ab^* \\ a^*b & |b|^2 \end{bmatrix}, \tag{33.7}$$

from which we infer that, from Eq. (33.3), we can write

$$\text{trace}\,(\rho) = 1. \tag{33.8}$$

It is a property of two-level systems that we can define the density matrix slightly differently by using the full set of the Dirac spinors. In this approach, we introduce the polarization **P** and write Eq. (33.7) as

$$\rho = \frac{1}{2}\,(I + \mathbf{P} \cdot \boldsymbol{\sigma})\,, \tag{33.9}$$

where I is the unit matrix and the vector $\boldsymbol{\sigma}$ has the components $\sigma_x, \sigma_y, \sigma_z$. Thus, we are able to write the three component of the polarization as

$$P_x = 2\text{Re}\left(a^*b\right)$$

$$P_y = 2\text{Im}\left(a^*b\right). \tag{33.10}$$

$$P_z = |a|^2 - \lceil b \rceil^2$$

The language in the above description of the density matrix gives the polarization in the real three-dimensional space. But, we can think of the polarization itself as a vector in an abstract three-dimensional Euclidean space. In this space, the state 0 is a unit vector pointing in the $+z$ direction, while the state 1 is a unit vector pointing in the $-z$ direction. The polarization itself resides on the unit sphere in this space; this unit sphere is called the *Bloch sphere*. Such a Bloch sphere is shown in Fig. 33.3, and the two angles are defined as the polar angle and the azimuthal angle, where the former is the angle away from the $+z$ axis, and the latter lies in the (x,y) plane and is measured from the X-axis, as is normal for spherical coordinates. This many qubit operations are easily expressible as rotations around the three axes.

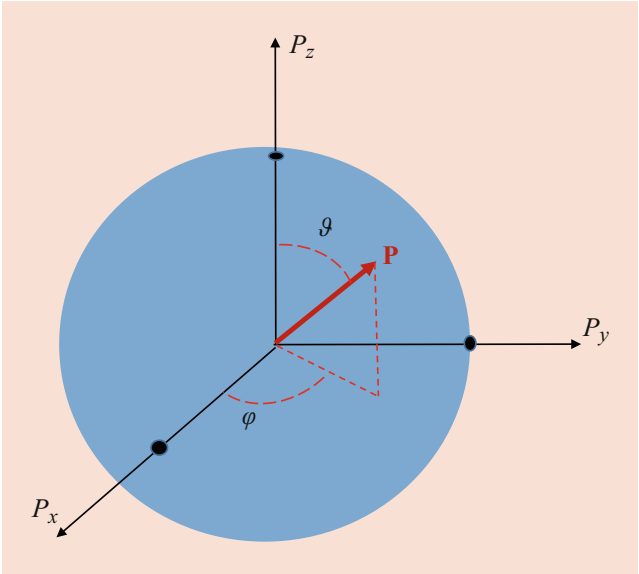

Fig. 33.3 The Bloch sphere allows the polarization to rotate in three directions. Then, many qubit operations are expressible as rotations around one of the three axes

In the above discussion, we talked about the qubit as a two-level system, specifically a two-level atom. This could be two specific levels of a real atom, such as in the ion trap system, or in an artificial atom such as a quantum dot. The important point is that the phrase "two-level atom" is often a "code word" for the qubit system. This is because the energy levels in an atom are nonlinearly spaced; that is, they vary as $1/n^2$. Hence, the two desired levels are separated by an energy that is not the same as the separation of any other two levels. If the levels were linearly spaced, as in a normal harmonic oscillator, one has a problem. For example, if the lower two levels are those of interest, they are separated by exactly the same energy as any other two adjacent levels. This means that excitation of the lower two levels can also be absorbed by any other two levels, and this constitutes a sizable source of decoherence in the qubit. Hence, one desires the energy levels to be nonlinearly spaced, so that the two levels of the qubit do not couple to other unused energy levels. Since, the atom has this property, the phrase "two-level atom" is often applied to any qubit system to indicate it has the desired properties.

33.2.3 Entanglement

Erwin Schrödinger called entanglement the most important aspect of quantum mechanics [60]. This paper was his response to the Einstein-Podolsky-Rosen paradox published earlier in the year. His point was that once the two particles (envisioned by the latter authors) interacted, they were no longer independent from one another. Rather, they must now be described by a single entangled wave function incorporating both particles. And, it was this entanglement that differentiated the quantum system from the classical one. Needless to say, it is entanglement that has become the crucial ingredient in quantum computing that gives rise to the possibility of major speedup in the computation. In the quantum computer, we want qubits to interact with each other under controlled circumstances. When two qubits interact, they become entangled, just as the two particles in EPR. They remain entangled until some mechanism gives rise to decoherence, which breaks up the entanglement. As a result, one needs long decoherence times in the qubits. In this subsection, we want to examine how this entanglement can occur.

In general, the quantum computer works on controlled gates, as these gates provide the interaction between the qubits. As an example, we take the so-called CNOT gate, or controlled NOT. In the classical system, any transistor (or CMOS gate) is naturally a NOT gate. This is because the transistor inverts its input. If we take a high voltage as a logical 1 and a low voltage as a logical 0, then a 1 input to the gate causes the transistor to turn on, which lowers the output voltage, and this gives a 0 output. Similarly, when the input voltage is low, the transistor is in the off state and the output voltage is high. Thus, the input is inverted, which means that the logical output is NOT(input). The CNOT differs from this slightly, in that the action of the transistor gate is controlled in a manner that makes the classical XOR gate. Now, the XOR gate has two inputs, which are called a and b. If either a or b is high (a 1), then the output is also high. But, if both inputs are either high or low, the output of the gate is low. In other words, the output of the XOR gate is 1 if either a or b is high, but not when both are high.

In the quantum CNOT gate, one of the two inputs is taken to be the control signal, which then operates upon the other input, as shown in Fig. 33.4. Here, the control input (e.g., our a) is labeled as c. The input wave function (e.g., our b), from a previous qubit, is denoted by x. The symbol on the bottom line indicates binary arithmetic modulo 2. So, if the control bit is high, the output y is 0 (the carry is ignored). On the other hand, if the control is 0, the current state of the signal x is passed unchanged to the output. This then gives us the XOR function. We can illustrate this further with a "truth table" as

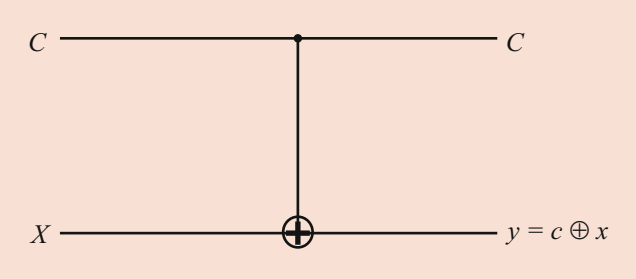

Fig. 33.4 The CNOT gate, where c is the control input and x is the target input. The two are added modulo 2 to produce the output

x	c	y
0	0	0
1	0	1
0	1	1
1	1	0

Here, we can see that the output y is high when either of the two inputs is high, but not when both are the same. We can write the output as a wave function, in which the state of the control bit is the first signal and the state of x is the second variable

$$y \rightarrow |\psi\rangle = \frac{1}{2}\left(|0\rangle\,|1\rangle \pm |1\rangle\,|0\rangle\right) = \frac{1}{2}\left(|01\rangle \pm |10\rangle\right). \tag{33.12}$$

That is, if the control bit is 0, y is 1 only if x is 1, and if the control bit is 1, y is 1 only if x is 0. The wave function (Eq. 33.12) is entangled. That is, if we take the control bit as a two state Hilbert space, and the input bit as a two state Hilbert space, then the entangled output lies in a tensor product Hilbert space, denoted as $H^2 \otimes H^2$. But note that the wave is not a simple product, and it cannot be separated into parts that lie in only one of the individual Hilbert spaces. This is what defines the entanglement. Hence, the wave function in Eq. (33.12) is an entangled wave function. The plus/minus sign gives two possibilities, which both give the same value of 1 for the square magnitude of the wave function (the factor of 1/2 provides proper normalization).

The introduction of the control is really accomplished by the manner in which the interaction between qubits is accomplished and managed. To carry out an algorithm, one has to manipulate the control signals, which actually change the interactions in a specific manner so that entanglement is created, manipulated, or destroyed. This is no different than

the classical computer where bit strings are pushed around, manipulated, and then stored or erased. Here, however, we have the entanglement and the increased power of individual qubits.

33.3 The Silicon Qubit

The idea for a qubit based upon Si effectively dates from the suggestion of Kane to use a ^{31}P dopant in isotopically pure ^{28}Si [61]. In this approach, it was suggested to use the nuclear spin of the P atom, which is 1/2, and the fact that the particular isotope of Si does not have a nuclear spin. Then, the electron wave function for the positively charged donors extends extensively through the conduction band and can mediate the interaction between the nuclear spins on neighboring P atoms. Such a qubit is interesting because it has the promise of a long spin relaxation time and is scalable [62]. Getting the P atoms into the right position thus constitutes a serious problem, but the latter authors have demonstrated that it is possible to create an atomically precise linear array of single P bearing molecules on a Si surface and that these P atoms can act as quantum qubits.

The process of getting a P atom to a precise location turns out not to be so difficult. One method is to hydrogenate the dangling bonds on the Si surface and then to remove particular hydrogen atoms using a scanning tunneling microscope (in ultra-high vacuum) [63]. Removing the hydrogen allows the molecule to be chemically attached to that particular site [64]. In the particular case mentioned above, the molecules from phosphine gas are used to deposit the P atom at the desired position, and then the difficult task is to deposit isotopically pure Si while maintaining the P atom at the desired position [62]. Another approach to locating the P atom is to pursue single atom implantation [65–67]. This latter technology has progressed relatively rapidly, and qubits based upon P atoms have been fabricated with both approaches.

It has also been suggested to use the electron spin rather than the nuclear spin in a semiconductor nanostructure [68]. Use of the electron spin, rather than a nuclear spin, lies in the fact that the electron spin resonance transition for the electron can be rather effectively tuned by electrostatic gates, which are a common part of the single-electron quantum dot structures [69]. In fact, the study of single-electron gate-defined dots in an MOS structure is relatively old [70]. The use of both the single-electron device and electron spin has been reviewed recently [71]. The operation of multiple donor qubits, controlled by surface gates, has been discussed by Witzel et al. [72] and by Mohiyaddin et al. [73]. In particular, the exchange coupling between qubits has been studied further [74]. The operation of a single donor qubit under control of surface gates and measured with a single-electron transistor was evaluated by Dehollian et al. [75]. In Fig. 33.5, we give some information about the operation of this donor qubit formed on the P atom from this latter paper. Here, they use gate set tomography (GST), which is a tool for characterizing logic operations in the qubit. The qubit itself is formed by the spin states of an electron bound to a ^{31}P atom, implanted into the isotopically pure silicon substrate. The spin states are split by an applied magnetic field, and switching is achieved via coupling of the electron spin to the nuclear spin, resulting in a two-spin, four-level system. Qubit preparation is handled by tunneling to/from a single-electron transistor, which is also used for sensing the state. The aluminum gates are placed on top of a SiO_2 layer. In addition, an electron spin resonance signal is used for qubit manipulation.

Sigillito et al. [76] have suggested moving to Ge for better tenability via the bias-induced Stark effect, while Wolfowicz et al. [77] have suggested that surrounding the donor with ^{29}Si nuclear spins may be useful for creating a complete qubit register. Finally, Pakkiam et al. have suggested using quadruple donors together to create a pair of qubits in a singlet-triplet configuration [78].

While much of the effort on single impurity qubits has focused on donors, there has also been some work directed at the use of acceptors as well. There is a feeling that the dopants for this type of qubit need to be near an interface in order to interact well with surface gates. Hence, the use of acceptors near the surface of both Ge an Si has been studied as well [79, 80]. This group has proceeded to demonstrate entanglement and control for the acceptor qubits [81].

The case for nearly all of the above dopant-based qubits is that the dynamic variable is the spin itself. It is possible to consider a hybrid qubit in which the dynamical variable depends upon both spin and charge. The hybrid qubit requires neither nuclear-state preparation nor micromagnets for control and becomes considerably more amenable to systems [82]. This has been studied by these latter authors for the double quantum dot, which is defined lithographically by surface gates (as shown in Fig. 33.6). Here, a more traditional double dot system, similar to those in single-electron transistors, is used for the qubits. Three electrons are used in the system, with the gates tuned so that there are two electrons in the left dot and one in the right dot to define the (2,1) state. Changing the voltage on gate L to raise the energy difference between the dots favors the opposite situation and the state (1,2). The singlet state in the right dot, state (2,1), is taken to be the $|0\rangle$ state. The triplet state in the right dot, the (1,2) state, is taken to be the logical $|1\rangle$. The presence of the extra electron means that the hybrid states of the dots are not pure singlet or triplet and fast electric field techniques can be used to manipulate the qubit in either X or Z rotations on the Bloch sphere.

The coherence can be extended when the hybrid qubit is composed of three electrons in a double quantum dot [83].

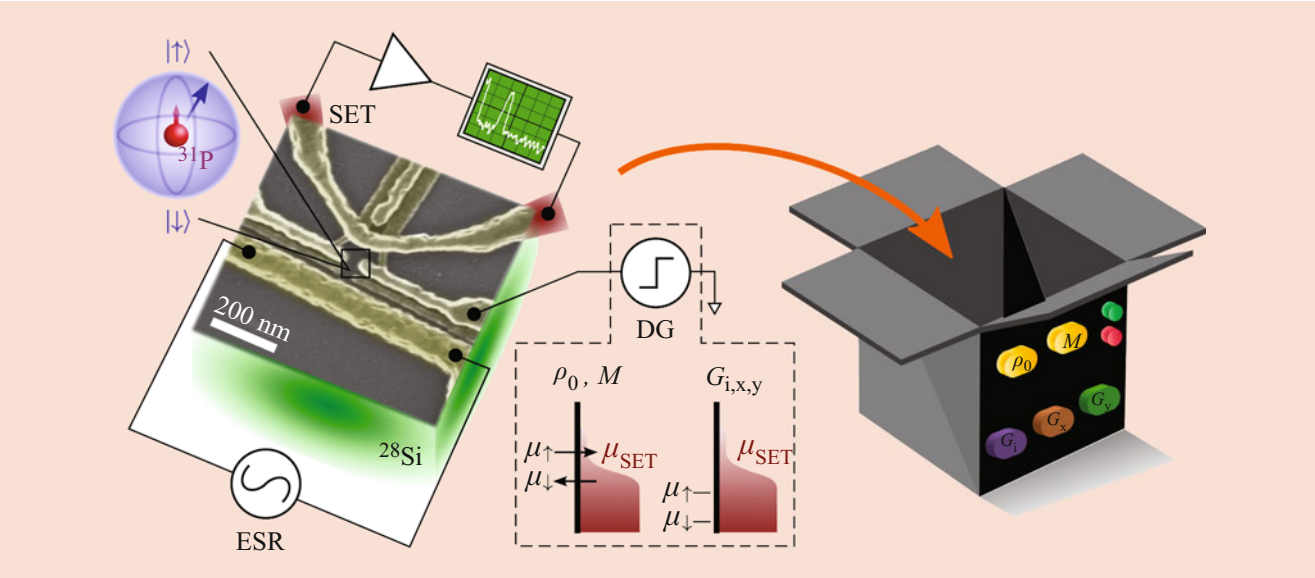

Fig. 33.5 Diagram of qubit device and the gate set tomography (GST) model of a qubit. SEM image of the on-chip gate structure is shown to the left. The aluminum gates have been false colored for clarity. Depicted in red are the source-drain n^+ regions which couple the single-electron transistor to the current measurement electronics. For initialization and measurement, the donor gates are pulsed such that $\mu_\uparrow > \mu_{SET} > \mu_\downarrow$, inducing spin-dependent tunneling between the donor and the SET. When applying a gate sequence, the DG are pulsed to higher voltage to prevent the donor electron from tunneling to the SET. The inset diagram – zoomed from the approximate donor location – represents the Bloch sphere of the qubit, consisting of the spin of an electron confined by an implanted ^{31}P donor, with its nuclear spin frozen in an eigenstate. The GST model treats the qubit as a black box with buttons (right) which allow one to initialize (ρ_0), apply each gate in the gate set ($G_{i,x,y}$), and measure (M) in the observable basis ($|\uparrow\rangle$ *or* $|\downarrow\rangle$). Phys. **18**, 103,018 (2016) DOI: https://doi.org/10.1088/1367-2630/18/10/103018)

Similar surface control gates have been used in the pure spin qubit case as well [84], where multiple dots are used to suppress charge noise. This was studied for a pair of singlet-triplet qubits, each of which was composed of two electrons in a double quantum dot. More recently, the importance of the spin-orbit interaction in these gate-defined dots has been studied [85, 86], and the impact of atomic-scale structure in the energy dispersion on decoherence was investigated [87].

The singlet-triplet qubit is attractive for many reasons, particularly for its high fidelity, at least for single qubit operations. However, for two qubit operations leading to entanglement, it can be problematic in a sense that there are a range of operations over which the interaction can occur, and this leads to a preferred set for good performance [88]. In addition, the interaction between a hybrid qubit (discussed above) and other types of qubits has been studied, since such an interaction can usually be tuned between different operating modes via the gates [89].

Spin qubits formed of quantum dots in the Si/SiO_2 system have been formed in a manner to have from 1 to 3 electrons in the dots [90]. Then, pulsed electron spin resonance is used to exercise coherent control over the qubit. With these structures, these authors then demonstrated the achievement of valley splitting (normally, in the MOS system, the six ellipsoids of the conduction band break into a twofold and a fourfold set due to the inversion potential, and one seeks to further split the lower lying twofold set) [91]. The role of disorder on this valley splitting has also been studied [92]. Another work has suggested that the MOS structure could lead to a maximum density of quantum information when the hybrid qubits are utilized [93].

Quantum dots have also been created in the Si/SiGe heterostructure system. High fidelity gating of a single hybrid qubit has been achieved in this system [94]. The use of a stray magnetic field to switch a spin qubit has also been studied [95]. The optimal geometry for the gates for such a spin qubit in this heterostructure (or in GaAs) has been studied for a single qubit [96] and for a qubit linear array [97]. This theme has been continued with the study of circuit QED for linear arrays of quantum dots [98]. Finally, the coupling of the quantum dot state to that of a photon has been studied in these quantum dots [99, 100].

33.4 The Josephson-Based Qubit

It was clear from the discussion in Sect. 33.1.4 that the dominant current approach lies with superconductivity and the use of Josephson junctions for qubits. The Josephson junction is a tunnel junction in which the materials on either

side of the insulator (or nonsuperconducting material) are superconductors. As it is a tunnel junction, it is natural that the Wigner function comes into play just as for semiconductor tunnel junctions. In one of the earliest uses for this device, a very small junction was used such that single-electron behavior could be observed [101] (in superconductors, for temperatures above absolute zero, the carriers are a mix of Cooper pairs and normal electrons above the gap). Normally, with Josephson junctions, the tunneling is carried out by Cooper pairs, but these authors have generated a master equation that describes both the Cooper pair tunneling and the single-electron tunneling. It is also known that the Josephson junction can be a microwave source, and it has been observed that one can see a so-called Riedel peak in the response of the junction [102, 103]. The Josephson frequency is given by $f_J = 2eV/h$, and the Riedel peak is observed at $f_J = 4\Delta/h$. This peak lies at a bias voltage of $2\Delta/e$ [103]; Δ is the superconducting gap (the factor of 2 appears as the normal energy to raise a Cooper pair above the gap is twice the energy gap due to the $2e$ charge). In the modeling of the single-electron tunneling, it is found that the Riedel peak and the gap for the quasi-particle-pair interference are shifted to $2\Delta/e - e/2C$, while the quasi-particle tunneling gap shifts to $2\Delta/e + e/2C$ [101]. Here, the term $e/2C$ is the Coulomb charging energy for single-electron effects, where *C* is the capacitance of the small junction. Hence, there is a hybridization between the superconducting gap and the Coulomb gap. In this latter paper, the master equation was developed for the Wigner function describing the charging effect on Cooper pairs and quasi-particle pairs, as well as the single electron tunneling in the junction.

The step from a Josephson junction toward a qubit based upon this device was taken in 2005 when the quality factor of a microwave cavity was measured by coupling it to a superconducting qubit device. This approach was used to bring the cavity quantum electrodynamics (cQED) to the table [104]. But, this was not the beginning. Interest in superconducting qubits goes back further. In looking at this, one needs to distinguish two types of qubits: microscopic and macroscopic [105]. The microscopic qubit is based upon

an internal charge or spin, much like the Si qubits of the previous section, or upon two natural levels as in an atom. Macroscopic qubits are based on quantum levels representing collective degrees of freedom like the persistent current in a superconducting ring [106] or excess charge on a superconducting island [107, 108]. Hence, one might think that the macroscopic form will be physically larger, but this is usually only a perception. When superconducting components are used in electrical circuits, then these circuits become quantum objects, which can then be used in either type of qubit. The pursuit of superconducting qubits can be a Cooper pair box charge qubit, the persistent current flux qubit, or a hybrid charge-flux qubit [105]. As a group, this is the pioneering approach adopted by IBM for its initial quantum computers [109].

33.4.1 The Charge Qubit

The charge qubit is composed primarily of the Cooper pair box, where the box is formed by a pair of small Josephson junctions so that single electron tunneling (or Cooper pair tunneling) governs the excitation of the box itself, which is isolated by the two junctions. A single Cooper pair box [110] is a unique artificial solid-state system [107]. Although there are quite a few electrons on the island (box), they all form Cooper pairs in the superconducting state and then condense into a single macroscopic quantum state. This state is separated from the normal electrons by the superconducting gap Δ, discussed above. The only low-energy excitations arise from Cooper pair tunneling when the gap is larger than the charging energy $E_C = e/2C$. On the other hand, if the charging energy is larger than the gap energy, and the thermal fluctuations are suppressed, the system can be considered to be a two-level system in which the lowest two energy states differ by one Cooper pair. The separation of the two levels of interest can be controlled by an additional gate voltage. In Fig. 33.7, we show such a charge qubit from the work of Nakamura et al. [107].

When the island is small, the charging energy dominates the qubit operation, but one can write a simple Hamiltonian as [105]

$$H = 4E_C\left(N - n_g\right)^2 - 2E_J \cos\left(\vartheta\right) \cos\left(\frac{1}{2}\varphi_e\right), \qquad (33.13)$$

where E_J is the Josephson energy ($=\Phi_0 I_c/2\pi$, where $\Phi_0 = h/e$ is the flux quantum and I_c is the critical current in the junction), n_g is indicative of the gate voltage (through the capacitor coupling), φ_e is the external flux, and θ is the difference in the Josephson phases of the two junctions. With the two junctions, the box can be tuned with the external flux passing by the reservoir, much like a SQUID, which is discussed below.

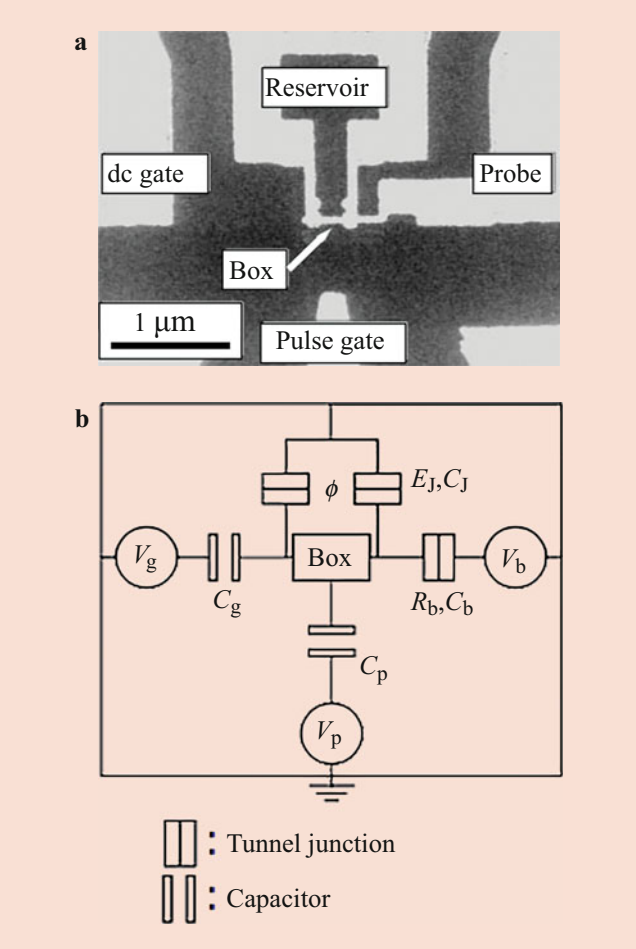

Fig. 33.7 Single Cooper-pair box with a probe junction. (**a**) Micrograph of the sample. The electrodes (light areas) were fabricated by electron-beam lithography and shadow evaporation of Al on a SiN_x insulating layer (400 nm thick) above a gold ground plane (100 nm thick) on an oxidized Si layer. The box electrode is 700 × 50 × 15 nm Al and contains ~10^8 conduction electrons. The reservoir electrode was evaporated after a slight oxidation of the box Al, so that the overlap produces two parallel low-resistance tunnel junctions with Josephson energy E_J. The latter can be tuned by a flux passing through the enclosed void in the reservoir. The box is coupled (through further oxidation) to the probe junction, which is highly resistive. Two other electrodes at left and bottom are capacitively coupled to the box. (**b**) Circuit diagram of the device. Copyright 1998)

When the charge qubit is shunted by a capacitor, as a method of reducing current noise, the device has been called a *transmon* [111]. The shunt capacitor also reduces the charging energy and hence increases the size of the Josephson energy relative to the charging energy. Measurement and control of the box qubit is commonly done by means of microwave resonators with the techniques usual in quantum

electrodynamics, as in other superconductor qubits [112]. As a result, it is possible to couple a pair of transmons to photons and produce nonlinear optical effects such as photon blockade [113].

33.4.2 The Flux Qubit

One of the most interesting aspects of circuits is that a resonant circuit can be a quantum oscillator, much akin to the harmonic oscillator [114]. In the absence of dissipation, the Hamiltonian can be written as

$$H = \frac{q^2}{2C} + \frac{\Phi^2}{2L}, \tag{33.14}$$

where the charge q and flux Φ are the conjugate variables and satisfy a commutator relation with one another. Of course, to reach the quantum limit, we must work at low temperature, which naturally makes a connection with superconducting circuits. In the presence of dissipation, we need to have a good-quality factor $Q\ (= \omega\tau \gg 1)$. Hence, when we couple a Josephson junction to a superconducting ring (the junction is placed in the ring itself), we obtain the persistent current flux qubit, sometimes called an RF superconducting quantum interference device (RF-SQUID). Here, we need to have $E_J \gg E_C$ [106, 115], so the charging energy cannot be too large. The eigenstates of the ring represent two counter-rotating persistent currents, corresponding to a fixed number of flux quanta (h/e) in the loop. The inductance of the ring gives rise to a parabolic potential, like the harmonic oscillator, and adding the Josephson oscillating potential provides the needed nonlinearity to separate off the lowest states from the linear chain, as discussed earlier. For the two levels of the qubit, the Hamiltonian can be written as [105]

$$H = 4E_C n^2 + E_L(\varphi - \varphi_e + \varphi_{int}\sigma_z)^2 - E_J \cos(\varphi), \tag{33.15}$$

where the interaction term arises from the effect of the external bias flux on the two persistent current states. When $\varphi_e = \varphi_0/2$, the lower part of the potential is a symmetric double well creating nearly degenerate $|L\rangle$ and $|R\rangle$ states which lead to bonding and anti-bonding hybrids of these two states. These latter two states are created by the macroscopic tunneling through the Josephson junction which couples the two persistent current states, and these hybrid states provide the two levels of the qubit. The Wigner function in number-phase representation shows that the state of the system evolves into a quantum superposition of two coherent states which clearly demonstrate interference and negative values for the Wigner function description of the system. Yet, when the system is represented in the number-phase coordinates, the Wigner function evolves in a classical manner [115]. This ring-junction system was studied further to investigate the role of dissipation on the evolution of the Wigner function description of the system [116]. In this latter case, the dissipation is incorporated by coupling the system to a reservoir, and this expanded system is then projected back onto the reduced density matrix for the ring-junction system. They conclude that the two coherent states survive even in the presence of dissipation, at least for weak dissipation.

The flux qubit can also be prepared with a three junction ring, much like the hybrid qubit of the next section. This qubit can then be coupled to a transmission line resonator to produce cavity QED interactions. The capacitance between the qubit and the resonator can be controlled by varying the width of the capacitance line, so that the coupling depends upon the number of qubits placed in the overall circuit [117, 118]. We note that this can also be done with single junction qubits [119].

33.4.3 The Hybrid Charge-Flux Qubit

If we add a second Josephson junction in the ring, we can have both the charge box between the two junctions and flux coupled through the ring. If the Coulomb energy E_C dominates the Josephson energy, we have the charge qubit limit. If the Josephson energy dominates the Coulomb energy, we reach the flux qubit limit, but if we have $E_J \geq E_C$, we are in the charge-phase or hybrid charge-flux qubit regime [105]. In many situations, the system acts as a two-level atom, which is called a quantronium [108]. A quite similar version of the quantronium is shown in Fig. 33.8 [120]. The two lower Josephson junctions create the charge box part of the circuit, but the ring from these to the larger third junction creates the supercurrent, flux reservoir. This look is coupled (not shown) to an external flux circuit that is used to vary the flux enclosed in this ring. The box charge is varied through the coupling capacitor and gate voltage. The pair of capacitors are used to reduce the noise, while the current source provides the current drive to the qubit itself. The Hamiltonian for the circuit is given as [120]

$$H = E_C(N - n_g)^2 + E_J\left[1 - \cos\left(\frac{\varphi + \gamma}{2}\right)\cos(\varphi)\right] + \frac{Q^2}{2C} + E_{J0}(1 - \cos\gamma) \tag{33.16}$$

where the different parameters are defined in the figure in terms of the fluxes through the various junctions with $\varphi = (\varphi_1 + \varphi_2)/2$ and n_g has its former meaning. The fluxes are normalized to the flux quantum. The lowest and first

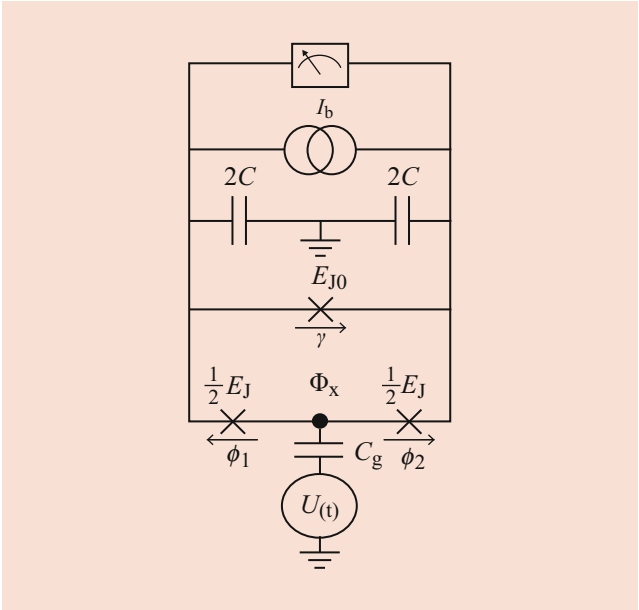

Fig. 33.8 Circuit diagram of the quantronium charge-flux qubit. (Reprinted with permission from G. D. Hutchinson et al., Phys. Rev. A 74, 062302 (2006). Copyright 2006 by the American Physical Society)

excited states of the quantronium are taken to be the $|0\rangle$ and $|1\rangle$ states. In this configuration, the circuit is operated so that the applied flux Φ_x is set to zero and the normalized gate charge is set to 1/2 so that the qubit levels are separated by the Josephson junction coupling energy. Then the Hamiltonian can be written as

$$H' = E_J \left[1 - \cos\left(\frac{\gamma}{2}\right)\right] \sigma_z + E_{C0} N^2 + E_{J0} (1 - \cos\gamma), \tag{33.17}$$

where $E_{C0} = 2e^2/C$ and N is the charge operator for the large Josephson junction. This Hamiltonian describes a two-level system, with the levels separated by an energy given by the first term on the right of Eq. (33.17). The phase in this term provides the coupling between the qubit and the readout junction.

As discussed above, the charge-flux qubit is operated normally at this charge degeneracy point and is controlled and switched via microwave pulses in order to demonstrate the presence of Rabi oscillations between the two qubit states. It often can have a fairly long coherence time and thus can perform hundreds of well-controlled single qubit gate operations. In simulations of the circuit, it is found that during the readout pulse for the circuit of Fig. 33.8, the coherence time of the qubit is of the order of 0.2 ns after the bias current has been applied (the role of the bias current is to dephase the qubit). The simulation results have been compared with the experimental data obtained by Vion et al. [108].

33.4.4 Coupling Qubits

The development of quantum computers now requires one to move from the qubit level to the gate level and the achievement of long coherence times. The development of single qubit gates [121, 122] and two-qubit gates has allowed this process to become real in the recent years. In a major step forward, five qubits have been integrated into a single circuit with the resonators used for readout and the control lines to operate the gates [122]. The qubits used in this chip are variants of the transmon qubit described above. The chip is shown in Fig. 33.9. Each of the qubits is a cross-shaped Xmon variant of the transmon qubits and are placed in a linear array. These qubits are read out by five meandering coplanar waveguide resonators, one used for each qubit. These resonators are coupled to a single readout line, made possible by frequency multiplexing of the resonators. Individual qubits are driven through individual microwave control lines (denoted by *XY* in the figure) as well as inductively coupled d.c. lines (denoted by *Z* in the figure). The operation of the qubits on the Bloch sphere is also indicated in the figure.

Other schemes have been suggested to couple qubits together. The use of capacitors to couple charge qubits via a SQUID circuit is one such scheme [123]. It has also been suggested to couple flux qubits through an *XY*-type of exchange interaction [124]. Nevertheless, the growth of several approaches to the use of superconducting qubits, described in Sect. 33.1.4, clearly points out that quite a few methods similar to that of Fig. 33.9 have appeared in commercial endeavors.

33.5 Integrated Optics

There has been tremendous interest in optical qubits and systems, not the least because of the interest in quantum communications systems. Our connection to nanoelectronics lies in the existence of integrated optics, e.g., putting the optical system on a chip. While we will discuss such chips, it is meaningful to introduce the critical optical processes if we are to understand how such chips work, because they are different from other qubits. One approach has treated qubit-oscillator states. In its most basic form, this is just another variation of the Jaynes-Cummings model in which the two-state atom is replaced by the qubit. This Jaynes-Cummings model is quite old [125] and involves coupling a two-state atom to an electromagnetic resonator. We will discuss it in some detail in the next subsection. The variation of the model involves replacing the two-state atom with a qubit that possesses its own complex nature. Squeezed states have also been used for representing qubits. Measuring these states relies upon the existence of non-demolition detectors that can detect a single photon without destroying it in an

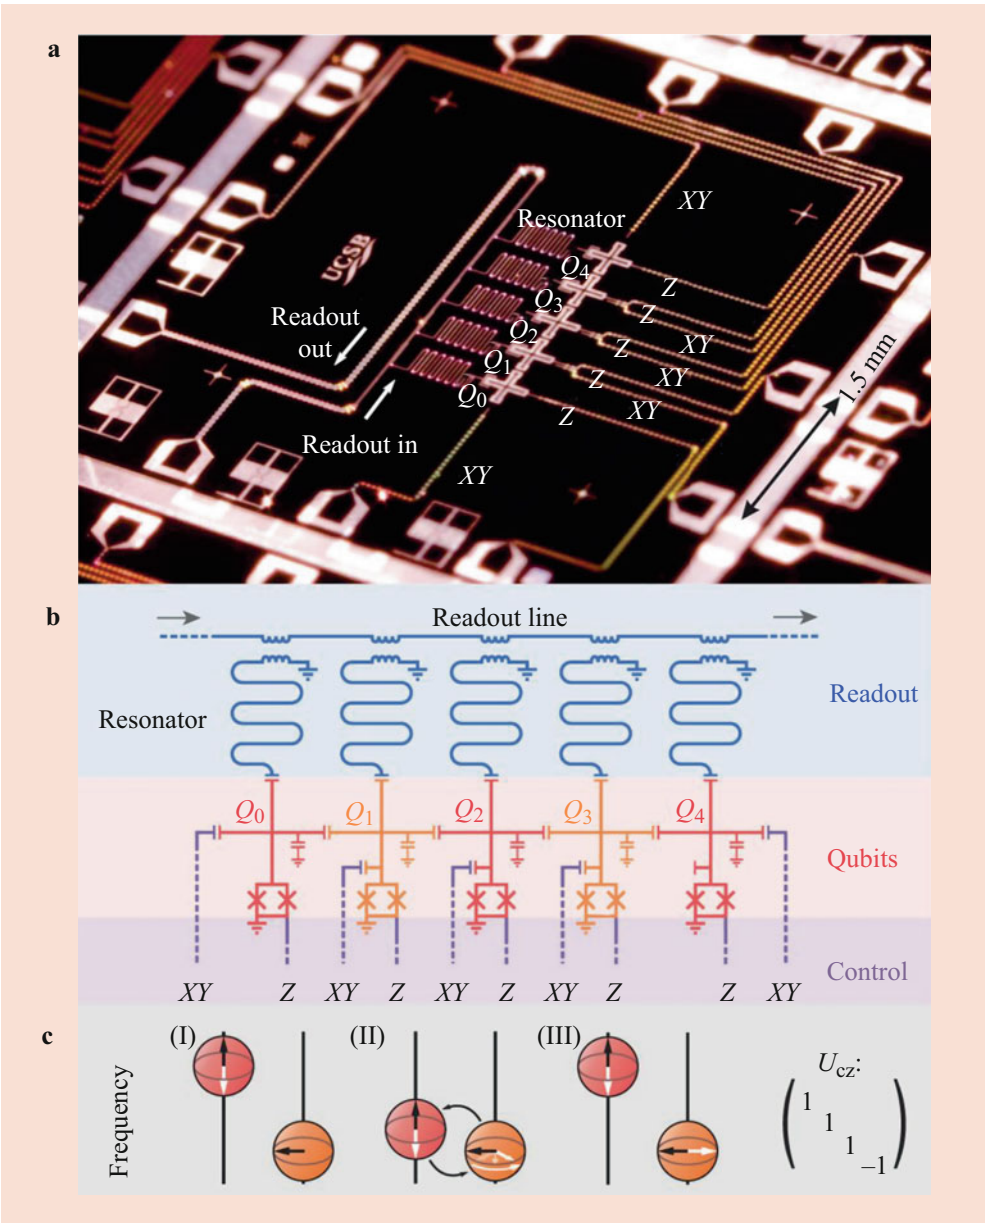

Fig. 33.9 (**a**) Optical image of the integrated Josephson quantum processor consisting of aluminum (light) on sapphire (dark). Copyright 2014)

absorption process. Such detectors often rely upon the phase shift produced by the photon traveling through a nonlinear medium [126]. Recently, two-mode qubit-like entangled squeezed states have been compared with entangled coherent states, through the use of the Wigner functions for the two types of states [127]. The Wigner function and its negative excursion have been used to signify the entanglement of as many as 3000 atoms by a single photon [128]. The role of entanglement for the generation of the negative portions of the Wigner function has also been studied for multi-qubit GHz-squeezed states [129].

The qubit-oscillator system has also been used to create what are called Schrödinger kitten states [130–132], so called because it is a microscopic superposition of two coherent states with opposite phases [133]. By passing these states through a Kerr medium, the gain by such a process can exceed

the normal optical losses and lead to squeezed kitten states. Such kitten states, as well as single-photon states, have been also generated from the steady-state output of a continuously driven optical parametric oscillator [134]. In principle, the kitten state can be generated by subtraction of photons from a squeezed vacuum state [135]. Needless to say, there has been an effort to create chips for these optical circuits; one of the first ones was designed to continuously generate and manipulate entangled states of light [136]. While the goal is to discuss such chips, we begin with understanding the key concepts that differ optics from charge or flux-based systems.

33.5.1 The Jaynes-Cummings Model

The coupling between a two-level atom and a resonant (quantized) electromagnetic cavity is described by a relatively old model, termed the Jaynes-Cummings model [125], that we have already mentioned above. It turns out that the process of coupling a coherent optical beam to such an atom is of great interest in quantum optics, so we want to discuss the model in a little more detail. The model treats the atom as a two-level system and describes the interaction of this atom with a quantized mode of an optical cavity. The principle of the model is analogous to the problem of two coupled classical pendulums that are connected to produce an interaction. This interaction leads to a coupling of the two modes in a way in which all of the energy oscillates between the two pendulums. At a given instant of time, pendulum 1 may be static, while all the energy is in the oscillation of pendulum 2, and at a later time, the process is in the opposite state. In the quantum case, one pendulum is the harmonic oscillator mode of the electromagnetic cavity, while the second is the atom, which is described as an oscillator by its Rabi frequency. Hence, the field can interact with the atomic state and lead to Rabi oscillations of the atomic state population. As with the pendulums, the Rabi oscillation is not static in amplitude. Something different happens, in that the Rabi oscillations collapse and then reappear periodically, just as the energy moves from one pendulum to the other. The temporal time over which this collapse and reappearance occurs has been termed the revival time [137]. When the field in the cavity is in a coherent state, and the atom is prepared in an excited state, it is found that the atomic and field states become rapidly entangled and then subsequently disentangle at one-half the revival time [138]. That is, the maximum entanglement of the atomic states occurs when the Rabi oscillations are strongest and the minimum entanglement occurs when the Rabi oscillations are minimal. More recently, it has been observed that the photon parity operator also shows similar behavior with one important difference. The peaks of the amplitude of the parity operator seem to occur when the Rabi oscillations are at their minimum. So, the amplitude and decay of this parity operator seems to be shifted by half a period from the Rabi oscillations [139]. Because the parity operator is proportional to the number density of the photon field, this latter is also in agreement with the two pendulum concept, as the Rabi oscillation is a minimum when the majority of the energy is in the photon oscillator. The Jaynes-Cummings model was revived in this century [140] and applied explicitly to the problem of a trapped ion interacting with a laser field (which was mentioned in the introduction in connection with one of the commercial approaches to a quantum computer).

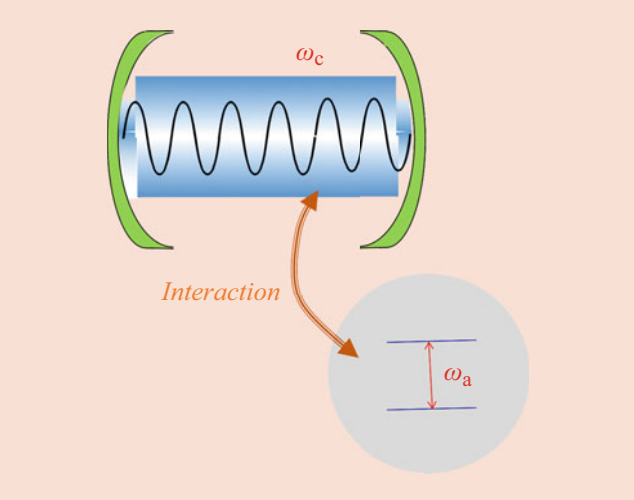

Fig. 33.10 Pictorial representation of the Jaynes-Cummings model in which a two-level atom (lower right) interacts with a mode of a resonant cavity (top)

The Hamiltonian can be described relatively simply in terms of the various components, as discussed above, and shown in Fig. 33.10. First, the electromagnetic field, or the laser field, is quantized as usual in QED in terms of a series of harmonic oscillators that describe each of the modes that can exist in the cavity or wave [141]. Since, we are interested in a single mode, we write the wave energy as

$$H_{\mathrm{EM}} = \hbar\omega_{\mathrm{C}}\hat{a}^{\dagger}\hat{a}, \tag{33.18}$$

where the operators are the normal creation and annihilation operators for the field harmonic oscillator representation of the single mode of the cavity and ω_{C} is the frequency of this mode. The atomic levels are just the two levels of the atom, which we describe with a pseudo-spin index with the spin up state as the upper level and the spin down state as the lower level, so that we can write the Hamiltonian as

$$H_{\mathrm{a}} = \hbar\omega_{\mathrm{a}}\frac{\hat{\sigma}_z}{2}. \tag{33.19}$$

Hence, the atomic frequency describes the separation of the two states. The state of the atom is described by its polarization

$$\hat{S} = \hat{\sigma}_+ + \hat{\sigma}_-, \tag{33.20}$$

where $\hat{\sigma}_+$ and $\hat{\sigma}_-$ are the normal raising and lowering operators of the two-level atom in its own harmonic oscillator notation (See, e.g., [142]). Hence, the polarization is equivalent to the position operator in a normal harmonic oscillator, with the various parameters being folded into a pre-factor discussed shortly. The interaction between the electromagnetic field and the atom occurs through the electric field of the wave. Normally, the potential would be proportional to $eE_z z$, so here we take the position as the polarization and write the interaction energy as

$$H_{\text{int}} = \frac{\hbar\Omega}{2} E_z \hat{z}\hat{S} = \frac{\hbar\Omega}{2} E_z \left(\hat{a}^\dagger + \hat{a}\right)\left(\hat{\sigma}_+ + \hat{\sigma}_-\right). \tag{33.21}$$

The parameter Ω incorporates all the various constants arising from the connection between the operators (from the harmonic oscillators) that appear in Eq. (33.21) and their corresponding position operators. The creation and annihilation operators each have their time variation determined by their respective frequencies, so the four cross terms will have fast variations due to the sum of the frequencies and slow variations due to the difference in the two frequencies. Generally, the fast components are ignored, and only the slow components are retained in what is called the rotating wave approximation. The Hamiltonian is generally separated into two commuting parts, which are described by

$$\begin{aligned} H_1 &= \hbar\omega_C \left(\hat{a}^\dagger\hat{a} + \tfrac{\hat{\sigma}_z}{2}\right), \\ H_2 &= \hbar\delta\tfrac{\hat{\sigma}_z}{2} + \tfrac{\hbar\Omega}{2}\left(\hat{a}\hat{\sigma}_+ + \hat{a}^\dagger\hat{\sigma}_-\right), \end{aligned} \tag{33.22}$$

where $\delta = \omega_a - \omega_C$ is the so-called detuning of the frequency between the field and the atom. This creates a proper 2×2 Hamiltonian, whose eigenvalues are given in terms of the number operator (first term in the parentheses of line one of Eq. (33.22)) for the field as

$$E_\pm = \hbar\omega_C \left(n + \frac{1}{2}\right) \pm \frac{\hbar\Omega_n(\delta)}{2}, \tag{33.23}$$

where

$$\Omega_n = \sqrt{\delta^2 + \Omega^2 n + 1} \tag{33.24}$$

is the Rabi frequency for the specific detuning parameter. If the detuning is small, the atomic state Rabi oscillations occur with an average frequency $\Omega_C = 2\Omega\sqrt{n+1}$. As the mode occupation builds up, the Rabi frequency increases, and the amplitude of these oscillations increases. The photon parity operator is then defined as

$$\Pi_F = (-1)^n = e^{in\pi}. \tag{33.25}$$

The normal expectation value of this operator is found to be [139]

$$\langle \Pi_F(t) \rangle = e^{-n} \sum_{s=0}^{\infty} (-1)^s \frac{n^s}{s!} \cos\left(2\Omega t\sqrt{s+1}\right), \tag{33.26}$$

where the time dependence arises from the time dependence of the effective Rabi frequency. The interesting fact is that for $t = 0$, the cosine is unity, and the expectation value of the parity operator goes asymptotically to zero (the time is scaled with the same coupling factor). Hence, when the density peaks and the Rabi oscillations are strongest, the parity operator vanishes and vice versa.

Many variations on the Jaynes-Cummings model have appeared over time. First, the model has been generalized through the development of a Markovian master equation approach, rather than sticking with the Hamiltonian form [143, 144]. Then, the model has been extended to a double Jaynes-Cummings model by incorporating two two-level atoms within the structure [145–147], as well as to a pair of three-level atoms [148]. An anti-Jaynes-Cummings model used the interchange of the two field operators in the second term of H_2 in Eq. (33.22) [149]. Finally, Miranowicz et al. replaced the electromagnetic field with the phonon field in the study of a nanomechanical resonator [150].

33.5.2 Qubits

The introduction of the quantum process in the previous section on the Jaynes-Cummings model gives us a nice transition into the discussion of optical qubits. Just as the qubit was coupled to a resonator in the superconducting qubit, a similar approach has treated optical qubit-oscillator states. In its most basic form, this is just another variation of the Jaynes-Cummings model in which the two-state atom is replaced by the qubit. In this case, the Hamiltonian becomes [151]

$$H = \hbar\omega_C \hat{a}^\dagger\hat{a} + \frac{\hbar\Omega}{2}\hat{\sigma}_x + \frac{\hbar\Omega}{2} E_z \hat{\sigma}_x \left(\hat{a}^\dagger + \hat{a}\right), \tag{33.27}$$

which differs from Eqs. (33.18–33.21) only in the choice of spinors in the last two terms, e.g., the "atom" and interaction terms. The change introduces the complex nature of the qubit which replaces the two-state atom. This has been studied again, more recently, within the rotating wave approximation [130, 152]. This latter work has used the results to examine the differences among various information-theoretic measures.

Squeezed states have also been used for representing qubits. One of the most ubiquitous objects in quantum mechanics is the Gaussian wave packet, because it can be used to create the minimum uncertainty wave packet, and this Gaussian wave packet is the starting point for squeezed states. Normally, the Gaussian wave packet is a minimum uncertainty wave packet, and, as it is positive definite, it is a classical quantity. The minimum uncertainty packet can be used to make a so-called coherent packet by adding a propagator to it, as

$$\psi(x) = \sqrt{\frac{1}{\sqrt{2\pi}\sigma}} \exp\left[-\frac{x^2}{4\sigma^2} + ik_0 x\right], \tag{33.28}$$

where σ is the standard deviation and k_0 is the wave number for the momentum of the packet. This can be Fourier transformed to an equivalent coherent state in momentum space and the two combined via the Wigner-Weyl transform to provide a Wigner function as

$$f_\psi(x, k) = \frac{1}{h} \exp\left[-\frac{x^2}{4\sigma^2} - 2\sigma^2(k - k_0)^2\right]. \tag{33.29}$$

Hence, the coherent state (Eq. 33.28) gives us a standard Wigner function in phase space that moves with the average momentum of the wave packet. We note that this Wigner function is positive semi-definite (it can take the values of zero at infinite distances from the center in either position or momentum) [153]. So, in quantum optics, the idea of a single photon is represented by a minimum uncertainty wave packet. The idea of the minimum wave packet lies in just this position and momentum spreading of the packet. One problem, of course, is that the photon is supposedly traveling at the speed of light. This gives a great difficulty in describing just what the spread in momentum represents. On the other hand, if the photon represents a particular mode in a resonator, such as in the Jaynes-Cummings experiments of the previous section, then it has a mode momentum that differs from the speed of light. We have to remark that in both cases, there is a difference between the expectation value of the momentum and the speed of light, if for no other reason that that the photon has zero mass. Hence, momentum is described by the propagation constant of the wave, which is linear in the frequency (in free space) as

$$k = \frac{\omega}{c} = \frac{p}{\hbar}. \tag{33.30}$$

In the Wigner function, we note that the spread in position and the spread in momentum are naturally described by the standard deviation σ. The idea of a *squeezed state* is to reduce the uncertainty in the amplitude of the wave [154, 155], by utilizing nonlinear optics. In the first case [154], four-wave mixing was used, while in the latter case [155], parametric down conversion was applied to the optical wave. These nonlinear processes now produce true quantum states, hence the terms quantum optics.

Measuring these squeezed states relies upon the existence of non-demolition detectors that, as mentioned above, can detect a single photon without destroying it in an absorption process. Such detectors often rely upon the phase shift produced by the photon traveling through a nonlinear medium [126]. Recently, a two-mode qubit-like entangled squeezed state has been compared with entangled coherent states, through the use of the Wigner functions for the two types of states [127]. The Wigner function and its negative excursion have been used to signify the entanglement of as many as 3000 atoms by a single photon [128]. The role of entanglement for the generation of the negative portions of the Wigner function has also been studied for multi-qubit GHz-squeezed states [129]. But, it is important to point out that it is the qubit-oscillator system that can be used in the strong coupling limit to produce the nonclassical states necessary for the qubit [156, 157].

The qubit-oscillator system has also been used to create what are called Schrödinger kitten states [130, 132, 152, 158], so called because it is a microscopic superposition of two coherent states with opposite phases [133]. By passing these states through a Kerr medium, the gain by such a process can exceed the normal optical losses and lead to squeezed kitten states. Such kitten states, as well as single-photon states, have been also generated from the steady-state output of a continuously driven optical parametric oscillator [134]. In principle, the kitten state can be generated by subtraction of photons from a squeezed vacuum state [135]. It is these nonclassical states of light that are used in the qubit systems [159].

33.5.3 Qubits and Gates

It is probably not surprising that the idea of a qubit can be extended to multiple qubits and various forms of gates. It is also not surprising that the optical gates are not as far advanced as those for silicon and superconducting technologies. But, the

optical approach has the advantage that it can be foreseen to operate efficiently at room temperature, an advantage that should not be overlooked. Nevertheless, significant progress has been made recently. One approach is to follow the results discussed above and extend the Jaynes-Cummings model to the case of multiple atoms and a resonator which yields the extension of Eqs. (33.18, 33.19, 33.20, and 33.21) to

$$H(t) = \hbar\omega_C \hat{a}^\dagger \hat{a} + \frac{\hbar\omega_a}{2} \sum_{i=1}^{N} \sigma_z^i + \frac{\hbar\Omega}{2} E_z \sum_{i=1}^{N} \left(\hat{a} + \hat{a}^\dagger\right) \hat{\sigma}_x^i, \tag{33.31}$$

where the prefactor of the second term is now interpreted as the qubit/dimer splitting. This has been used to show that a pulsed source can be used to generate many-body correlations in light-matter systems and to determine the time evolution of an N qubit system coupled to the global resonator [160]. A similar approach has been used where the atoms are replaced by exciton levels in charged quantum dots [161] to produce a three-qubit system. In a slightly different approach, two qubits are encoded in the modes of the optical cavity that is coupled to a three-level atom within the cavity [162]. Going a step further, a multi-resonator system has been coupled to a multi-target qubit to produce another type of phase gate [163].

An actual optical system has been integrated on a silicon process to make an effective optical processing chip. In this case, optical ring resonators are coupled to photon-pair sources to produce a path-entangled two qubit state [164]. The schematic of the chip is shown in Fig. 33.11. The laser pump pulse enters from the left and produces a superposition of photon pairs via four-wave mixing with the photon pairs from the resonator. This spontaneous four-wave mixing is a result of the third-order nonlinearity of the silicon waveguide core. Hence, these photon pairs are produced on the chip. The two constituents of the pair are referred to as the signal and idler frequencies, which are equally spaced on either side of the original laser pulse. The two photon source/resonator serves to annihilate two photons from the pump pulse and create the two new photons that are the constituents of the output pair. This pair is then separated into separate paths for the blue and red photons (the high-signal and low-idler frequencies of the pair). This process is done in both the upper path and lower path, and then photons from each of the two paths are entangled in the central section of the chip. The remainder of the chip analyzes the results optically with single-photon counting detectors. These authors have shown that silicon photonics can be used to prepare and manipulate delicate quantum entanglement.

As we have seen in the above discussion, entangled path-encoded qubits can be generated by coherently pumping two photon-pair sources. While the above were generated using four-wave mixing, they can also be created by parametric down conversion [165]. With this in mind, it has been shown how an entire large-scale programmable optical processor can be integrated onto a chip [166]. The photon pair generation can be handled using a photonic hybrid laser based upon silicon [167]. A different chip from Fig. 33.11 has recently been created that also exhibits two-qubit entanglement with integrated optics on a silicon platform [168, 169]. In addition, a chip has been made to entangle higher-dimensional quantum states, called qudits (a qubit is two dimensional, a qutrit is three dimensional, etc.) [170]. Generation of single quantum emitters has been integrated on chip as well [171].

Possible other types of photonics circuits for quantum communications have been reviewed in [172]. Since then, there have been several possible integration approaches for these quantum communications applications [173–175]. Finally, there has been at least one strong argument for the use of photonics for processing, either quantum computing or quantum communications [176].

33.6 Other Qubits

As we pointed out above, quantum computers begin with the qubits. So far, we have described the most common qubits that are in use. But, there are other solid-state qubits that are under consideration, and some of these may prove fruitful. Here, we discuss a few of these. But as before, it is important to understand that this brief section is the state of the art in late 2019, and it may well change within a few short years.

33.6.1 NV Centers

The nitrogen-vacancy (NV) complex centers have been considered for possible qubits for the past few years [177, 178]. The most common material in which this has been created is diamond, a wide band gap semiconductor (5.47 eV). These NV centers are one kind of defect often referred to as a "color center." There are a variety of actual N and V configurations within the crystal structure, each of which produces a different range of defect energy levels [179]. While the center has been found in GaAs [180] and SiC [181–183], diamond remains the most common carrier. The various levels for these centers can be in the infrared or visible for use in these qubit applications. And, the nature of the qubit structure varies, as some approaches use the coupling of the electronic and nuclear spins [184], while others couple the electronic spin to a strain in the crystal [185]. In the latter case, the divacancy has also been used [180].

Normally, the configuration used is with a substitutional nitrogen atom on the diamond lattice with an adjacent vacancy. This NV center is usually discussed in terms of a six-

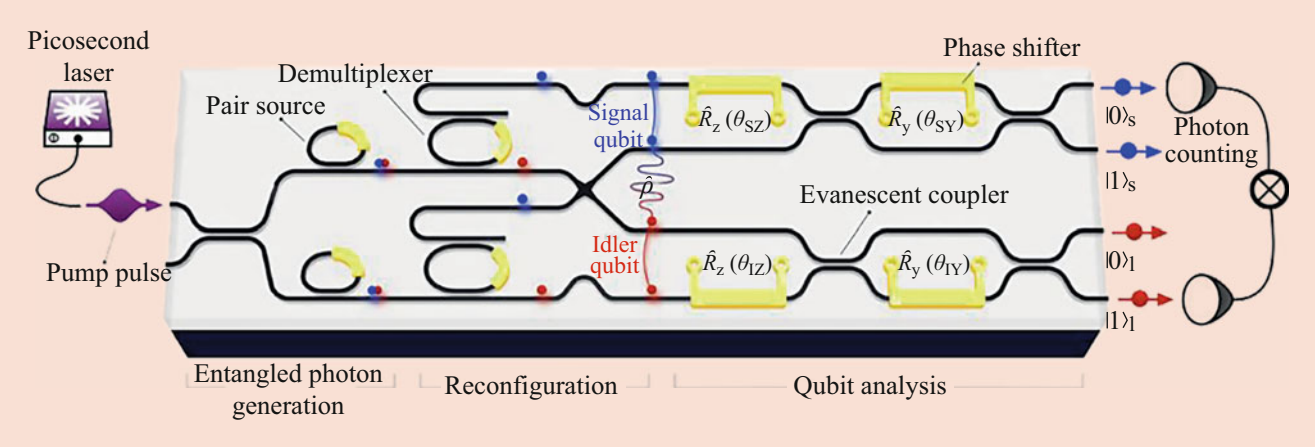

Fig. 33.11 Schematic layout of the silicon photonics chip. A laser pulse is coupled to the chip, where it creates a superposition of photon pairs via spontaneous four-wave mixing. This superposition is separated into blue (high frequency) and red (lower frequency) path qubits, which are analyzed by two interferometers incorporating phase shifters. Photons at the output are separated from the residual pump signal by fiber wavelength-division multiplexers and collected by single-photon detectors. (Reprinted under the Creative Commons 4.0 license from J. W. Silverstone et al., "Qubit entanglement between ring-resonator photon-pair sources on a silicon chip," Nature Commun. **6**, 7948 (2015), copyright 2015 by Nature-Macmillan)

electron model [186]. In this model for the negatively charged center, there is a ground state of an ^{3}A spin triplet, with a zero-field splitting of 11.88 μV between the $m_S = 0$ and the $m_S = \pm 1$ sub levels. The degeneracy of the $m_S = \pm 1$ can be lifted with an external magnetic field, so that either one of these levels, together with the $m_S = 0$ level, form a well-defined two-level system. This two-level system is the physical realization of the qubit [187]. The spin states can be polarized by excitation of an electron to the upper ^{3}E triplet with a green laser and then readout by using the florescence. The quantum state of this spin qubit can be manipulated with the application of a microwave signal [184], especially to affect the interaction between this two-level system and the hyperfine interaction with neighboring ^{13}C atoms. This role of the microwaves can be reversed in that the qubit can be used to sense the presence of the microwaves [188]. Similarly, newer techniques (than above) have been developed to achieve readout of the spin state in a single shot [189].

Now, the problem with using the lower states and their splitting by ∼12 μV is that these states have no chance to push the qubit to room temperature. In SiC, the NV centers appear as nearest neighbor pairs, with the same electronic structure of a ^{3}A triplet ground state and a ^{3}E excited state [190]. In 3C-SiC, a zero phonon line has been predicted at a wavelength of 1.5 μm [191], which could lead to creating a spin qubit with a relatively long lifetime. Experiments have demonstrated three such zero phonon lines in the near infrared, with a line at 1.468 nm being assigned to the transition between the excited and ground states of the NV^- center, showing that this center can be used for quantum communications [183]. Then, it has been shown that one can entangle the qubits formed from two NV centers in diamond via a damped mechanical resonator [192]. Then, the NV center in a nano-diamond crystal was used to show photon bunching and anti-bunching properties and to provide the nonlinearity needed to create four-wave mixing with visible lasers at nitrogen temperatures [193].

The ability to work at higher temperatures may suggest that the NV center will be useful as a quantum memory even if the main qubit computation system is at low temperature. In any case, quantum memories remain a significant problem which can be addressed via these NV centers. A necessary requirement is to protect the qubit of the NV center in a manner to extend the coherence time. The nuclear spin qubit of the neutral NV center has been lengthened through the control by nanometer scale gate electrodes [194]. Another approach used the spin of the NV center and protected it by decoupling the noise environment from the qubit [195]. Then, a so-called loop-gap resonator was shown suitable for applications with spin-based hybrid quantum systems and tested with the NV centers in diamond [196]. Finally, the spin NV center in diamond has been coupled to a superconducting transmon qubit [197] and a superconducting flux qubit mediated by a ferromagnet [198].

Recently a room temperature two-qubit quantum gate has been demonstrated using the electron-nuclear entanglement of the nitrogen-vacancy center in diamond [199]. In this process, the gate functions via microwave control of the geometric phase in a manner that demonstrated nonadiabatic and non-Abelian holonomic control with the polarized microwaves. The operation is demonstrated pictorially in Fig. 33.12. Similar spin entanglement of the nuclear spins has also been achieved with a mechanical resonator [200].

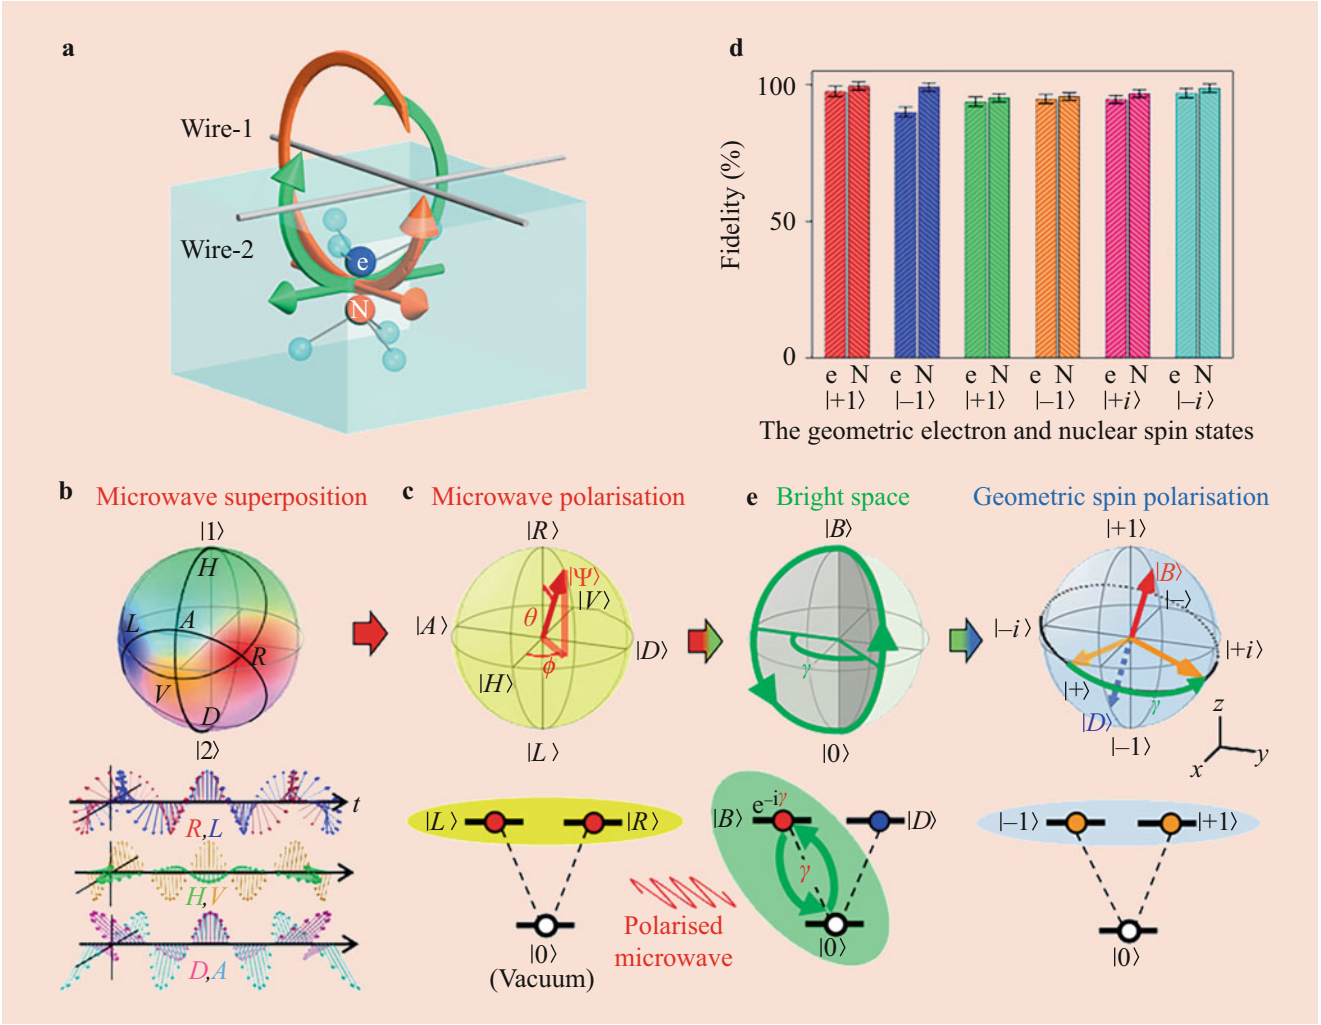

Fig. 33.12 Polarization-based holonomic quantum gates. (**a**) The configuration of the two crossed wires to produce a polarized microwave at the position of an NV center. (**b**) Mapping from the relative amplitude and phase of the microwaves generated by the two crossed wires into the polarizations effective for the electron or nitrogen (^{14}N) nuclear spin in an NV center under a realistic configuration. The $|1\rangle$ and $|2\rangle$ represent microwaves generated from, respectively, wires 1 and 2. (**c**) The mechanism underlying the holonomic quantum gate. The polarized microwaves induce a cyclic evolution of the geometric spin in the bright space based on the bright state $|\beta\rangle$ and the ancillary state $|0\rangle$ with a solid angle 2γ to induce a geometric phase γ on $|\beta\rangle$, resulting in the rotation of the geometric spin around an angle defined by $|\beta\rangle$ and the unchanged dark state $|D\rangle$. (**d**) The fidelities of the state preparation and measurement for the geometric electron (**e**) and nitrogen nuclear (N) spin. Error bars are defined as the s.d. of the photon shot noise. Kosaka: "Universal holonomic quantum gates over geometric spin qubits with polarized microwaves," Nature Comm. **9**, 3227 (2018) under the Creative Commons 4.0 license, copyright 2018 by Nature Communications)

More extensively, it has been shown that radio-frequency pulses can be used to demonstrate initialization, control, and readout of an ensemble of nuclear spins in NV centers [201]. Such a quantum system has also been created by coupling the ensemble of NV centers to surface polaritons [202].

33.6.2 Braiding

Quite generally, the idea of braiding can be connected to the method of which strands of hair are interleaved to form the braids of the hair. In essence, we move strands around other strands, and a mathematical theory for this arises from knot theory [203]. In physics, the importance of knots lies in the interpretation and analysis of graphs, such as the state transition graphs in computer science. For a graph with n vertices, one must evaluate $2n$ possible states of the system in order to compute the partition function. It can easily be imagined that this is a difficult and complex problem. Hence, one has to devise clever means to avoid such a calculation, and one approach is given by the Yang-Baxter equation [204, 205]. Basically, the equation is based upon the idea that particles may preserve their momentum even while scattering

and changing their quantum states. This becomes important to knot theory and the ideas of braid groups through the definition of an R matrix which describes the swapping of two strands (or braids). And, when we apply this idea to quantum computing, we find that such matrix operators provide the operations of quantum gates [206]. As a result, we can use evolution of topologically stabilized states as the basis for the braids, and quantum computing is obtained by the interchanges of these braids. Hence, in the idea of a topological quantum computer, we merely push quasi-particle excitations of some two-dimensional systems around each other. The true significance of the topological approach is the stability provided which means that one likely does not need error correction. The motion of each quasi-particle forms its own braid in $2+1$ dimensions (two spatial dimensions plus time). More importantly, it has subsequently been shown that we only need a single mobile "quasi-particle" in order to do the computation [207]. This has led to a more intense study of braid groups and the discovery of new types [208, 209] as well as approaches to optimizing the choice of braids [210]. A recent review has discussed the character of various braids and their system usage [211].

Braiding was recognized quite early as a method for implementing quantum computing, particularly with anyons. Anyons are generalized quasi-particles in two-dimensional systems, that is, they can be fermions or bosons. In particular, they can be used in quantized systems such as the quantum Hall effect, where the anyon is a quasi-particle moving in one of the edge states. Moreover these states are topologically stabilized, so generally are difficult to create or destroy, which gives some "error correction" to these states in quantum computing [212]. One belief is that appropriate theories to describe the incompressible quantum Hall state are the Chern-Simons gauge theories, in which it is the vortex, or flux tube, that provides the exotic quantum statistics that characterizes the interactions of the quasi-particles in the fractional quantum Hall effect [213]. These interactions move the quasi-holes in a manner that causes the representative wave functions to be multiplied by phase factors and hence furnish a one-dimensional representation of the braid group. Subsequently, experiments were carried out in a unique experiment in which fractional quantum Hall edge states where circulated within an open quantum dot with varying density ([214] see also [215]). Here, the outer edge states were in the 1/3 state, while the inner edge states were in the 2/5 state. The quasi-particles of the 1/3 state circulated around those of the 2/5 state and thus accumulated statistical phase. They found that the phase difference in this process created a shift of $-2\pi/15$, clearly demonstrating the correctness of the braiding assumption. At about the same time, there were theoretical suggestions supporting the idea of using the 2/5 state to generate non-Abelian statistics [216, 217].

At this point, it is probably useful to remind ourselves that Microsoft is pursuing topological quantum computing in its quest to build a quantum computer. More recently, this group has shown that the braiding operation can be done by using an anionic quantum state teleportation, which removes the need to physically transport the anyons around each other [218]. Different fractional Hall state descriptions have appeared, but it seems that it is the state and not its wave function representation that is important [219, 220]. An advantage of the anyon approach is that it should be inherently insensitive to noise in the system, and protocols can be developed to assure this insensitivity [221]. But, it has been pointed out that using the fractional quantum Hall state anyons can implement only a certain set of qubit operations [222] and that new geometric operations are required to realize universal quantum computers. Recently, an approach using lattice models for the anyons has appeared [223]. Finally, an experiment has shown that anyon braiding for qubits created with superconducting circuits composing 7 qubits can obtain a state fidelity of 0.688, for which anyonic excitations and braiding were achieved in single qubit operations [224].

A few years ago, it was realized that one could effectively stabilize the simplest type of non-Abelian anyon in a computing application by using the topological properties. In particular, this state is a defect binding Majorana fermions. Indeed, by combining a "standard" fractional quantum Hall device with a standard superconductor, the resulting structure could support exotic non-Abelian defects with a parafermion, which is a generalized Majorana bound state [225]. Now, the Majorana fermion is itself a rather exotic particle. Ettore Majorana hypothesized the existence of a zero energy particle as a solution to the Dirac equation, which would be its own anti-particle [226]. (Shortly after this, he apparently disappeared in what has become a scientific mystery.) The mention of the Majorana fermion in connection with a topological insulator material and proximity superconductivity seems first to have occurred in 2008 [227], although the possibilities of their use in computing are somewhat earlier. Then experiments using proximity superconductivity in InSb nanowires, which have a large spin-orbit coupling allowing the spins to be separated in a magnetic field, coupled to a topological superconductor, exhibited possible signs of the existence of the Majorana fermion [228]. However, braiding operations are not possible in single nanowires since the exchange operation of two Majorana fermions, located at the edge of a nanowire will cause them to annihilate when they meet. Hence, nanowires need to have an extra leg section to locate one particle, while the other moves around [229]. Yet, there has been progress in using nanowires coupled to superconducting islands to create circuits capable of quantum computing [230].

Then, it has been shown experimentally that a microwave signal can induce Rabi oscillations between adjacent Majo-

rana bound states, and this creates a single qubit gate [231]. In proceeding with the introduction of topological insulators, the desired protected states are surface states. Since they occur on opposite surfaces, this can complicate their use. It has been recently shown that these can be decoupled with "normal" gating operations [51]. Additionally, it has been shown that in the non-Abelian braiding of surface code (surface codes are various error correcting codes that depend upon the nature of the topological surface in use. One form is the toric code, so named because of the two-dimensional surface being wrapped onto the two torus), defects, which can be moved as if they were particles (similar to the Majorana fermions), one can obtain multi-qubit operations [232]. Other novel circuits have also been proposed to achieve quantum computing with Majoranas [233]. While there are many approaches, the nanowire circuits have received the most attention in recent years. Studies of the nanowires themselves have used crossed InSb nanowires. These have shown that ballistic transport is present as indicated by conductance plateaus, which means that the nanowires are not dominated by any disorder [234]. This conductance quantization also occurs with the Majoranas [235]. Then, a structure coupling a 3D Dirac semi-metal (Cd_3As_2) nanowire with superconducting Nb contacts has been studied as well [236].

33.6.3 Surface Bonds

There is a new approach to a silicon qubit, based upon a surface dangling bond. It has long been known that one could saturate the two bonds per atom that were not saturated at the [100] silicon surface by introducing hydrogen (or deuterium). This covers the surface and fully saturates these bonds. By using an STM, one can then remove selected hydrogen atoms to produce a single dangling bond. One can then attach another atom (such as the P atom discussed above [62]) or molecule for the purpose of further study. It has also been demonstrated that the dangling bond itself has two states that can be used for charge transitions that could be adapted to serve as a qubit [237]. The bond acts as a quantum dot, and such dots can be separated by as little as adjacent atoms, and are certainly of sub-nanometer dimension. Moreover, the quantum dot can have several electron trapping states. When pairs are created at adjacent atoms, there can be very high tunneling rates between them [238]. In fact, creating a line of such quantum dots can create an "atomic" wire with appropriate transport properties [239] and which can be gated. More importantly, the carrier capture rates at each quantum dot can be tuned with external gates [240]. Finally, it has been demonstrated that single charges can be controllably moved between two wells, in a chain of paired quantum wells, in such a manner that one can consider how these chains can be used to created qubit gates useful in quantum computing [241]. In general, the charge state can be manipulated in a manner to place its energy level above or below the bulk Fermi level by as much as a few hundred meV, which suggests that this process may be useful at room temperature. Nearly all current embodiments of quantum computers work at extremely low temperatures. The possibility of room temperature operation should open a new approach to creating quantum computers.

33.6.4 Flying Qubits

The idea of flying qubits lies in the use of a single propagating electron as an implementation of a qubit. The idea began in the work of Bertoni et al. [242], where the electron arrives in one quantum wire and either transfers, or not, to a second quantum wire. A more recent implementation has been given by Yamamoto et al. [243], in which an Aharonov-Bohm ring has entrance and exit ports composed of two parallel quantum wires. These parallel wires replace the normal single wire entrance and exit of such a ring, and the purpose is to control tunneling between the two wires in these ports. However, as these authors point out, the study of tunneling between two such quantum wires is much older [244]. Subsequently, the tunneling from one quantum wire to a side wire was studied theoretically [245]. Later, the coupling between two quantum wires, mediated by a quantum dot, through which the coupling occurred, was studied experimentally [246]. This work was later extended by replacing the quantum dot with a simple quantum point contact [247], which is more in keeping with the structures studied by the Modena group [248–250]. Most recently, the flying qubits have been suggested for quantum Hall edge states [251].

While the idea of the flying qubit continues to excite effort on the part of many groups [252], it is not clear that it will make much of an impact on the commercial efforts discussed in Sect. 33.1.4. However, conceptually, this type of qubit may have as much chance as the NV centers discussed in Sect. 33.6.1. But, there are many questions that can arise over the use of quantum-Hall states for the flying qubit. First, of course, is the fact that the stability of the edge states lies to some extent in the presence of charge in them. The separation of the different edge states, and their stability, arises from the many-body interactions between the electrons that result in compressible and incompressible regions [253, 254], a situation which has been imaged by scanning gate microscopy [255]. Will the desired flying qubit reside in an otherwise empty edge state, or will it ride on top of an already present density of electrons? If the former, how sensitive is it to noise in the magnetic field; when it is known that a variation of one flux quantum at the onset of occupation of the next edge state can lead to fractionally charged excitations [256]? Then, of course, there is the fact the quantum Hall edge states are more normally connected with the topological stability and use in

the braiding approach to quantum computing being pursued by Microsoft.

33.7 Summary and Conclusions

If we refer back to Sect. 33.1.4, we know that most prospective quantum computers are focused on using the Josephson technology. And, from the rest of this chapter, it is easy to see that this approach is the most advanced of several possible approaches. In all of these approaches, we are dealing with nanoelectronics. This is expected as this is the industry with the ability to manufacture the needed chips. But, we cannot know which of these technologies will evolve to become the leader in 5 or 15 years. Even optical approaches to quantum computing, which deals more with microelectronics than the nano version, depend upon the ability to produce the chips. And, it is highly likely, with blue lasers, that the optical approach will evolve into nanoelectronics. But, we still must consider that the goal is not to just make quantum computers, but to make quantum computers that operate at room temperature and are general-purpose machines. An important additional consideration is: If these remain special purpose machines operating at very low temperatures, are the results worth the tremendous costs that have been, and will continue to be, expended in the quest to develop these machines.

Another consideration, also mentioned in Sect. 33.1.4, is whether the results obtained in test machines, such as the IBM five-qubit system, can be believed. That is, are they sufficiently accurate? We have to remember that to work on a small system, like the five-qubit machine, the problem has to be parsed into small segments for which the five qubits can process. This means that the control signals, the presence of cache (quantum memory), and transfer systems all must work error-free. Moreover, it is hard to assign where the error occurs. It is well recognized that quantum memory remains a significant problem. The qubits themselves may be functioning in an exact manner, but failure of the other parts provides many possible sources that can contribute to erroneous results. Some of these answers may well come from the studies being carried out on the IBM supercomputer to which the quantum processor has been attached.

Then there is the question of how many qubits are needed to create a general purpose quantum computer. For sure, the five-qubit IBM chip may not be the answer. Predictions that we need millions or billions of qubits are pushing a little too far. The answer needs to be closer to the design of the machine which may not be that different from a classical machine. Numbers like 10^{300} which are bandied about (along with statements that this is more than the sum of all the particles in the universe) are somewhat off-base. Numbers of this size have been used in computers for more than half a century. They are handled with floating point numbers, which have a mantissa and an exponent. And, at least in today's laptops, they are handled with processing registers that are typically only 64–128 bits long. The point is that, it is not the size of the number that is important; it is the accuracy with which you want to know the number. That means that if I want to factor a very large integer, do I need hundreds of qubits, or can I get by with parsing the procedure into smaller segments. Hence, the question is whether or not Shor's algorithm for factoring can be parsed into smaller segments while still controlling the quantum coherence through the entire set of numbers. And, then the question becomes one of determining just how long we can extend the coherence time. In this regard, the technical inquiry shifts from the science of the qubit to that of the quantum system in its entirety, which is the subject of another field.

Abstract

The microelectronics and nano-electronics industry strongly relies on compact models to reduce a new microelectronic product development costs. The goals of this review are to highlight critical issues for the development of compact models for microelectronics and nano-electronics. In this chapter, we've covered the main principles of the compact device modeling. Also discussed are the possibilities of integrating compact models into circuit simulation and design tools, with an emphasis on the Verilog-A standardization, which simplify model implementation into EDA tool.

Keywords

Compact models · SPICE · Verilog-A standardization · Equivalent circuits · IC design · Semiconductors · Modeling · Simulation

34.1 Introduction

The accuracy of the circuit-level simulation results in computer-aided design (CAD) is always proportional to the accuracy of the models. Having "ideal" mathematical descriptions for all components, the computer circuit

simulation program (e.g., SPICE [60]) produces "ideal" results, within the machine's capability. It is unfortunate that the models of some devices are sometimes quite difficult to obtain and many specific cases must be approximated. Selected SPICE models which are reasonably accurate for a wide variety of IC applications are available and are presented in this chapter. There are two basic steps in device modeling. The first step is to develop the mathematical equations or the equivalent circuit which is to represent the particular semiconductor device. The second step, which goes beyond the scope of this chapter, is to determine how to obtain the parameters, which are necessary for the equivalent device representation. Many equivalent circuits have been presented in the literature for various devices.

In this chapter, equivalent circuits are presented for the six most common semiconductor devices. The models presented are not, in all cases, the most sophisticated possible. In fact, some of the models may always need further improvements. These SPICE models do, however, give excellent results in most applications. The measurement procedures are purposely developed using the minimum of complex equipment, in order to make the process available to the widest variety of users.

In addition to illustrating the model and showing the measurement procedures, each device is used in a SPICE application, which verifies to some extent the model obtained. Obviously, for complete verification, many additional tests must be made; however, those shown illustrate the procedure. The device models presented in each section are not derived or developed in this text. References are given for the interested reader; however, the measurement techniques which are not generally available are described in great detail.

A set of programs have been developed for the characterization of the DC and transient behavior of MOS integrated circuits. The DC analysis program calculates and plots the voltage transfer and power dissipation characteristic of an MOS inverter approached from a new point of view. The algorithm enables the characterization of basic MOS IC cells on desktop calculators. The program for the transient characterization calculates and plots the output waveform of three simple MOS cells most often occurring in MOS ICs. The MOS transistor is simulated in terms of a four-terminal large-signal model described by device processing parameters. Complex MOS ICs can be also characterized by appropriately combining earlier SPICE programs [100,101]. Compact device modeling is a very critical issue in microelectronics and nano-electronics because compact models are the type of device models used in circuit simulation and design tools. 2D and 3D numerical simulators are too cumbersome and too much time-consuming to be used in circuits with hundreds or thousands of devices. Compact models, with an analytical or semi-analytical formulation, are therefore of crucial importance for the microelectronics and nano-electronics and sensor industry. Circuit design is not possible without accurate compact models for the devices which are components of the targeted circuits. The application of new device technologies is only feasible when compact models for those new devices are available. Compact model implementation and its simulator validation are also discussed at such open forums like MOS-AK [69] and NEEDS of NanoHub [70], IEEE EDS Compact Modeling Technical Committee [68], series of the compact modeling workshops [61,71], as well as industrial Si2 Compact Modeling Coalition (CMC) [64].

34.2 Passive SPICE Models

This section reviews basic passive SPICE models for circuit simulations and IC design.

34.2.1 Resistor

The resistor model values depend on the process-related device data that allow resistance calculations from its geometric layout information and also include temperature dependence.

General SPICE R instance is:

```
Rname N1 N2 VALUE
```

where N1 and N1 are the positive and negative element nodes, respectively, and VALUE is the resistance in Ohms (Ω), which should not be equal to zero (0). The nominal resistance is calculated knowing the sheet resistance RSH, the geometrical parameter NARROW, and L and W geometries of the resistor device:

$$R = \mathrm{RSH}\frac{L - \mathrm{NARROW}}{W - \mathrm{NARROW}} \tag{34.1}$$

and its temperature dependence follows a simple quadratic scaling rule:

$$R(T) = R\,(T_0)\left[1 + \mathrm{TC1}\,(T - T_0) + \mathrm{TC2}\,(T - T_0)^2\right] \tag{34.2}$$

where TC1 and TC1 the temperature scaling coefficients is in Ω/°C and Ω/°C^2, respectively (Fig. 34.1).

Fig. 34.1 R SPICE symbol

34.2.2 Resistor R3_CMC

R3_CMC 3-terminal resistor model is a three-terminal nonlinear (diffused and polysilicon) resistor element and JFET model [56]. R3_CMC is Verilog-A-based and implemented accordingly [64]. The R3_CMC-*type* parameter controls the p or n type of the substrate. The extraction and simulation of the temperature parameters are controlled using the *tnom* and *trise* parameters, respectively. Parameter default and truncation values are identical to those found in the standard Verilog-A model code. In addition to modeling the depletion pinching effect, accurate modeling of highly linear resistors involves modeling correct velocity saturation. Modeling short devices is considered important only for velocity saturation. However, its effect on nonlinearity is important even for the resistors with "long" L resistor dimension. An interesting and useful way to analyze this phenomenon is in a reciprocal sense, as an effect on mobility:

$$\mu_{\text{red}}(E) = \mu_0/\mu(E) \tag{34.3}$$

There are two common models for μ_{red}; they are:

$$\begin{aligned} \mu_{\text{red}}(V) &= 1 + \frac{\mu_0}{v_{\text{sat}}}\frac{|V|}{L} \\ \mu_{\text{red}}(V) &= \sqrt{1 + \left(\frac{\mu_0}{v_{\text{sat}}}\frac{|V|}{L}\right)^2} \end{aligned} \tag{34.4}$$

where the symbols have their conventional meaning. The first form is often used for analytic simplicity, the second for improved accuracy and lack of singularity at $V = 0$ bias point. For a general velocity saturation model, the total resistor current can be rewritten as $I_{\text{ds}} = I_{\text{depl}}/\mu_{\text{red}}$.

34.2.3 Thin Film Resistor

Thin film resistors are mainly used for MMIC, coplanar waveguide ICs, and related applications. These elements, the CPW TF resistors, are treated as a lossy CPW line with a complex characteristic impedance. The sheet resistance R_{S} of a CPW TF resistor may be scaled with frequency in accordance with the formula:

$$R_S(f) = R_S(F)\sqrt{\frac{f}{F}} \tag{34.5}$$

The scaling can be activated and estimated in advance:

$$F_{\text{GHz}} = \frac{25.33}{(\sigma 10^{-7})\, t^2} \tag{34.6}$$

where σ is the bulk conductivity of the resistive film in S/m and t the thickness of the resistive film in microns. At this frequency, the thickness of the resistive film is the skin depth. If F is set in accordance with this formula, scaling of R_{s} is implemented only for $F > f$; otherwise, for $f < F$, R_{s} stays constant. Typically, frequency F is very large due to small bulk conductance of the resistive material (e.g., hundreds of gigahertz), and setting $F = 0$ is recommended.

34.2.4 Capacitor

General `SPICE` capacitor C instance:

```
Cname N1 N2 VALUE <IC=INCOND>
```

where: N+ and N- are the positive and negative element nodes, respectively, VALUE is the capacitance in Farads (F), and IC can be used to define initial simulation conditions (Fig. 34.2).

34.2.5 Moscap

Standard MOS varactor `SPICE` modeling is based on the simplified expressions for the capacitance, which has limited application in transient simulation compared to charge-based modeling [99]. Applying analytical charge modeling of MOSFETs can be done using surface-potential analysis [76]. To obtain the value of the gate capacitance C_{GB} of an MOS capacitor, the total charge gate charge $Q_{\text{G}} = -Q_{\text{s}} - Q_{\text{o}}$ (where Q_{s} and Q_{o} are the silicon and fixed interface charges) has to be calculated accordingly:

$$\begin{aligned} V_{\text{GB}} &= V_{\text{FB}} + \psi \\ &\quad + \gamma\,\text{sgn}(\psi)[\phi_{\text{t}}(\text{e}^{-(\psi/\phi_{\text{t}})} - 1) + \psi \\ &\quad + \phi_{\text{t}}\text{e}^{(\psi - 2\phi_{\text{F}})/\phi_{\text{t}}} - \text{e}^{-2\phi_{\text{F}}/\phi_{\text{t}}}(\phi_{\text{t}} + \psi)]^{1/2} \end{aligned} \tag{34.7}$$

$$\frac{Q_{\text{G}}}{LWC_{\text{OX}}} = V_{\text{GB}} - V_{\text{FB}} - \psi \tag{34.8}$$

Equations (34.7) and (34.8) have no time dependence. To integrate the frequency-dependent effects of the inversion carriers, a rate equation can be used:

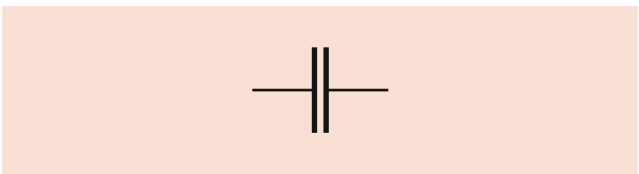

Fig. 34.2 Capacitor C `SPICE` symbol

$$\frac{dQ_I}{dt} = \frac{Q_{I,static} - Q_I}{\tau} \tag{34.9}$$

The time-dependent surface potential in (34.7) can yield convergence in 1–2 Newton iterations for MOSFET modeling above flatband [12]. The AC simulated MOSCAP gate capacitances C_{GB} over a range of frequency ranging from 0.01 to 100 Hz are in Fig. 34.3.

34.2.6 Capacitor with Frequency-Dependent Capacitance

The capacitor with user-specified frequency dependence of capacitance and loss can be modeled too. These models are implemented as a series connection of lossy capacitor and frequency-dependent resistor. Parasitic inductance is in series with a lossy capacitor with L, Q, and R parameters specified as frequency-dependent:

$$R_q(f) = Q(f)/[2\pi f C(f)] \tag{34.10}$$

34.2.7 Chip Capacitor

The chip capacitors are implemented with frequency-dependent Q:

$$Q(f) = Q\left(\frac{f}{FQ}\right)^{\text{ALPH}} \tag{34.11}$$

$$L = \frac{1}{(2\pi FR)^2 C}. \tag{34.12}$$

The impedance Z of the capacitor is given by:

$$Z = \frac{1}{2\pi f C\left(\frac{1}{Q(f)} + j\right)} + j2\pi f L \tag{34.13}$$

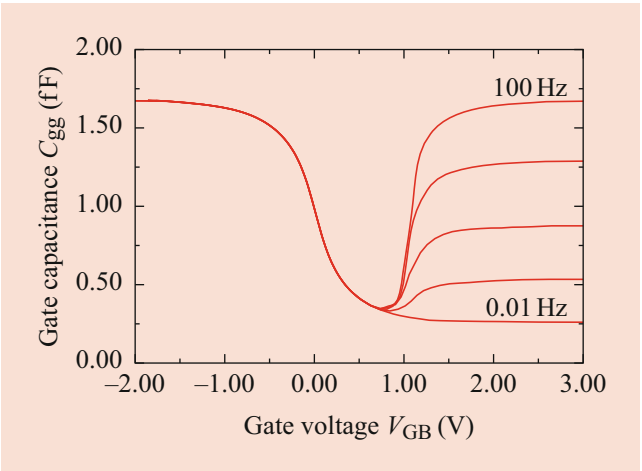

Fig. 34.3 Simulated MOSCAP CV for AC frequency ranging from 0.01 to 100Hz

More advanced chip capacitor models include several important RF phenomena:

- Finite, frequency-dependent Q
- Series and parallel resonance
- Dielectric losses

34.2.8 CPW Capacitor

The models of coplanar waveguide interdigital capacitors represent a transverse metallic strip connecting fingers at both input ports, two lateral grounded conductors, and optional backing ground. To consider interactions between fingers, EM quasi-static coupled lines are used in these models. A coplanar waveguide interdigital capacitor can be modeled using the EM quasi-static technique with a wide range of conductor thicknesses [6]. A quasi-static model can be used for modeling by applying the method of moments by creating a 1D mesh covering the contours of each conductor.

34.2.9 Inductor

The general `SPICE` instance of the inductor model is:

```
Lname N1 N2 VALUE <IC=INCOND>
```

where N+ and N− are the positive and negative element nodes, respectively, and VALUE is the inductance in Henry (H) (Fig. 34.4).

`SPICE` offers several elements and models to analyze inductors in switching regulators, transformers, mutual inductive circuits and other applications. These elements include magnetic winding elements, mutual cores, and magnetic core models, among which are saturable chokes, linear transformers, and transformers. Every inductor model has the effective inductance as a function of temperature with TC1 and TC2 temperature scaling coefficients:

$$L(T) = L\left(1 + TC1(T - T_0) + TC2(T - T_0^2)\right. \tag{34.14}$$

For two inductors L_1 and L_2, the mutual inductance is defined as the coupling coefficient:

$$K = \frac{M}{(L_1 L_2)^{1/2}} \tag{34.15}$$

Fig. 34.4 Inductor L `SPICE` symbol

SPICE transient analysis of the inductors solves the following equations:

$$v_1 = L_1 \frac{di_1}{dt} + M \frac{di_2}{dt}$$
$$v_2 = L_2 \frac{di_2}{dt} + M \frac{di_1}{dt} \tag{34.16}$$

In AC simulations, the linear branch relations are:

$$V_1 = (j\omega L_1)\, I_1 + (j\omega M) I_2$$
$$V_2 = (j\omega L_2)\, I_2 + (j\omega M) I_1 \tag{34.17}$$

Nonideal inductors are modeled as SPICE subcircuits with additional elements to define parasitic effects: the DC resistance of the wire R_{DC} and its self-capacitance C_p. These two additional parameter values are easily extracted from the inductor specifications or specific RF measurement. The following example is a SPICE subcircuit inductor model with its simulations results in Fig. 34.5:

```
.SUBCKT IND4EL 1 2
LO  3 2 POLY 1E-3 0 -6.25E-6
RDC 1 3 0.173
CP  1 2 39.6E-12
RP  1 2 250K
.ENDS
```

In a three-element RLC inductor model, given R_p the relation between the quality factor Q, the inductance L, and the self-resonance frequency f_o (see the Fig. 34.5 plot) is given by:

$$Q = \frac{R_p}{2\pi f_o L_o} \tag{34.18}$$

34.2.10 Inductor Coupling Coefficient

Parameter K provides the mutual coupling between inductors. This element is for use between two inductor elements and should be connected to the "K" ports of those elements. The mutual inductance is calculated as:

$$M = K\sqrt{L1L2} \tag{34.19}$$

where M is the mutual inductance, K is the coupling coefficient, $L1$ is the inductance connected at port 1, and $L2$ is the inductance connected at port 2 (see Eq. 34.15).

34.2.11 Linear Controlled Sources

The controlled sources (CC) are standard features of SPICEThe transformation allowed between input and output of a CC is a multidimensional polynomial. With two types (voltage and current) of input and CC output yield four combinations of input/output and are given SPICE device types of E, F, G, and H, respectively:
The E voltage-controlled voltage source (VCVS)
The F current-controlled current source (CCCS)

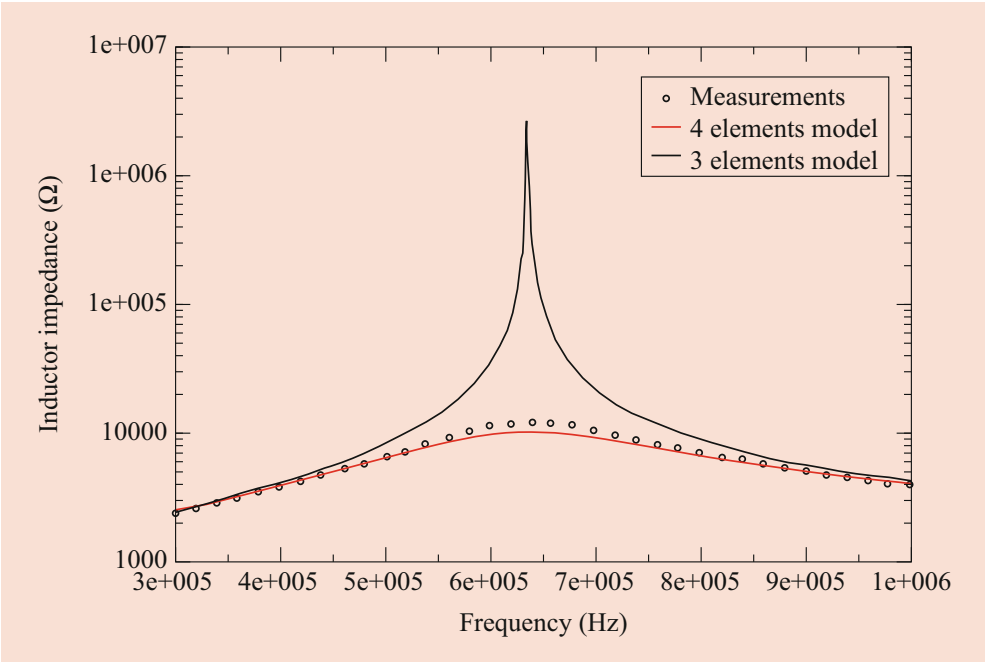

Fig. 34.5 Simulation of two L subcircuit models

The G voltage-controlled current source (VCCS)
The H current-controlled voltage source (CCVS)

These devices act as mathematical functions:
VCVS is the function $v_0 = E(v_1, v_2, v_3, ...)$
CCCS is the function $i_0 = F(i_1, i_2, i_3, \ldots,)$
VCCS is the function $i_0 = G(v_1, v_2, v_3, \ldots)$
CCVS is the function $v_0 = H(i_1, i_2, i_3, ...)$

34.2.12 Dynamic Nonlinear Sources

The behavior of the nonlinear voltage-controlled current (VCCS) or voltage source (VCVS) depends on a given analytical equation EQN. In a simple case, EQN can be defined as:

$$\text{EQN} = A0 + A1V0 + B0V1 \tag{34.20}$$

The voltage variables $V0$ and $V1$ create a four-node source. Three dynamic parameters are created: $A0$, $A1$, and $B0$, accordingly.

34.2.13 Transmission Lines

The SPICE circuit simulator provides three types of models for coupled transmission lines:

- Lumped models
- Distributed models with mutual capacitance C_m and inductance L_m
- Distributed models with decoupled transmission lines

The ideal line is available as a passive network element in SPICE. The corresponding element statement begins with a T and is of the form:

```
T (name) A1 A2 B1 B2
+ Z0 = characteristic impedance
+ (TD = runtime) (IC = .....)
```

where A1 and A2 denote the node names at the beginning of the line and B1 and B2 the node names at the end of the line.

Microstrip lines are formed as planar, conductive strips on a dielectric substrate over a conductive baseplate. Figure 34.6 shows the microstrip line, which is essentially an integrated microwave circuit. Because of the high dielectric of the substrate materials used (e.g., Al_2O_3 with $\epsilon_r = 9.8$), the field lines run predominantly in the substrate between the stripline and the back on ground potential ("ground plane"). The characteristic impedance of the stripline can be used for thin conductor tracks, whose layer thickness is less than a tenth of the web width, and usually can be determined approximately.

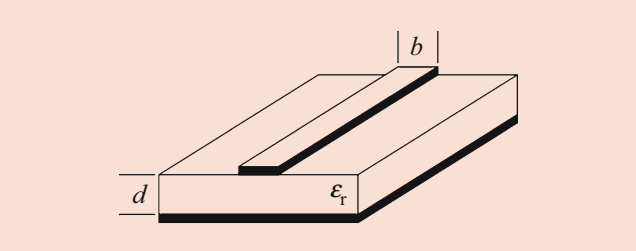

Fig. 34.6 Microstrip line

Thereafter, the following applies to wide lines ($b/d > 1$):

$$Z_0 \approx \frac{120\pi}{\sqrt{\epsilon_r}} \frac{1}{1.393 + b/d + 0.667\ln(1.444 + b/d)} \tag{34.21}$$

The capacitance C' of the microstrip line follows from (34.22) and, for $b/d < 1$ and $b \lesssim \lambda/4$, leads to the approximation formula:

$$Z_0 = \frac{\sqrt{\epsilon_r}}{c_0 C'} \tag{34.22}$$

with ϵ_r the permittivity of selected material and c_0 speed of light in vacuum. By curve fitting to the numerical solutions, it can be shown that for forward stripline design yields Z_0 as:

$$Z_0 \approx \frac{30\pi}{\sqrt{\varepsilon_r}} \frac{b}{d + 0.441b} v\,(\Omega) \tag{34.23}$$

$$C' = 0.556 \frac{\epsilon_{r,\text{eff}}}{\ln[8d/b + b/(4d)]} \quad \left(\frac{\text{pF}}{\text{cm}}\right) \tag{34.24}$$

The corresponding microstrip inductance L' can be calculated using C' and Z_0. In the case of $b/d < 1$, it is

$$L' = 2\ln\left(\frac{8d}{b} + \frac{b}{4d}\right) \quad \left(\frac{\text{nH}}{\text{cm}}\right) \tag{34.25}$$

34.2.14 Linear Models for Transmission Line Systems

Linear models of a distributed transmission line system fit into one of the following categories [89] and can be simulated using free and online CAD tools:

1. Discontinuity Models: These models are meant to predict electrical effects of the connections between transmission line sections. These models include bends, dimensional changes, and the union of up to four transmission lines at a single junction.
2. Transmission Line Models: These models are meant to model the lengths of lines between connections. These models include single lines and coupled lines.

34.3 Active SPICE Models

This section reviews basic active SPICE models for circuit simulations and IC design.

34.3.1 Diode

Standard SPICE diode model implementation allows simulations of the silicon diffused diodes, Zener diodes/pn junctions, Schottky barrier diodes, and nonvolatile memory diodes (with the Fowler-Nordheim tunneling current through gate insulators to model and simulate nonvolatile EEPROM memory effects). The general SPICE instance of the diode model is:

```
Dname N1 N2 MODname <area><OFF><IC=VD0>
```

and SPICE diode model call statement is (Fig. 34.7)

```
.MODEL MODname D <IS=Is N=n ...>>
```

The pn diode model in SPICE is implemented as a voltage-controlled current source which follows the Shockley equation:

$$I_{\mathrm{d}} = I_{\mathrm{s}} \left(\mathrm{e}^{V_{\mathrm{d}}/(N v_{\mathrm{t}})} - 1 \right) \tag{34.26}$$

where:

I_{s} is the saturation current.
V_{d} is the voltage across the pn junction.
N is the nonideality coefficient
v_{t} is the thermal voltage (kT/q).
k Boltzmann constant.
q elementary charge.

to model the IV characteristics of the ideal pn junction diode. Both I_{s} and N model parameters can be easily extracted as the slope and intercept of the semilogarithmic plot of the forward IV diode characteristic. For a reverse-biased diode, the current breakdown occurs at a specific voltage defined as BV; the corresponding breakdown current is set by the IBV parameter value. The diode depletion charge at its pn junction is stored in a voltage-dependent junction capacitance, C_{j} (Fig. 34.8):

$$C_{\mathrm{j}} = C_{\mathrm{j0}} / (1 - V_{\mathrm{j}}/\phi)^{M} \tag{34.27}$$

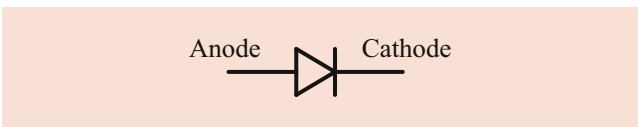

Fig. 34.7 D SPICE symbol

where:

C_{j0} is the zero bias capacitance value.
V_{j} is the junction barrier potential.
M is the grading coefficient ($\frac{1}{2}$ for step and $\frac{1}{3}$ for linearly graded junctions).

Noise diode model is implemented as an independent current sources in parallel with the resistor $\mathrm{RS}_{\mathrm{eff}}$, modeling both noise components: the thermal noise i_{nrs} (34.28) and the shot/flicker noise i_{nd} (34.29) that a resistor generates, using the following equations:

$$i_{\mathrm{nrs}} = \left(\frac{4kT}{\mathrm{RS}_{\mathrm{eff}}} \right)^{1/2} \tag{34.28}$$

$$i_{\mathrm{nd}} = \left(2qi_{\mathrm{d}} + \frac{\mathrm{KF}\,(i_{\mathrm{d}})^{\mathrm{AF}}}{f} \right)^{1/2} \tag{34.29}$$

where KF and AF are SPICE noise model coefficients.

JUNCAP Model

JUNCAP is an advanced model developed by Philips (now NXP). It includes 3D effects from geometrical differences in the sidewall, bottom, and gate-edge-junction profiles; these three contributions are calculated separately. JUNCAP (level=200) model [62] describes all the physical effects: depletion capacitance, ideal diode current, Shockley-Read-Hall recombination and generation currents (in forward and reverse regimes), trap-assisted tunneling (in forward and reverse regimes), band-to-band tunneling, avalanche breakdown, and advanced shot noise. The JUNCAP model uses quasi-static approximations (similar to the MOS modeling of the charge equations) to define current equations and to model corresponding AC effects. The geometrical layout effects are differences in the sidewall, bottom, and

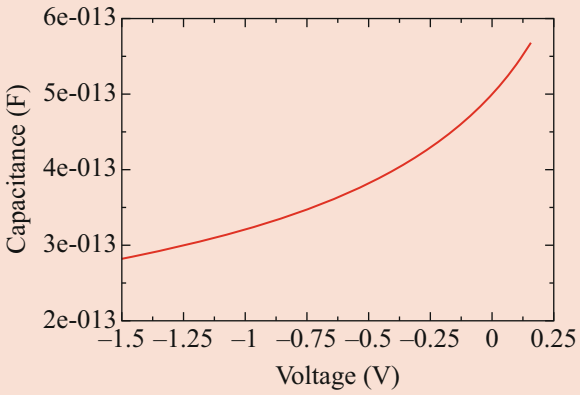

Fig. 34.8 PN diode CV simulations

gate-edge (at a device surface) junction profile contributions to the total current (34.30); the latter includes the diffusion J_d and the generation J_g currents, and the IV characteristic reads:

$$I = J_d \left[n_i^2 + \left(J_g \left(n_i, V \right) \right] \left[\exp\left(\frac{qV}{kT} \right) - 1 \right] \right. \tag{34.30}$$

where n_i is intrinsic carrier concentration with its temperature dependence. The JUNCAP charge of the junction capacitance, with corresponding model parameters P and V_D, reads:

$$Q = Q_j \left[1 - \left(1 - \frac{V}{V_D} \right)^{1-P} \right] \tag{34.31}$$

Finally, total JUNCAP current equations sum all contributions:

$$I = (I_{DB} + I_{GB}) + (I_{DS} + I_{GS}) + (I_{DG} + I_{GG}). \tag{34.32}$$

34.3.2 Photo Diode

The general SPICE instance of the photo diode symbol is (Fig. 34.9) and its simplified model is (Fig. 34.10):

For a photo diode operating in the visible light range, its static characteristic is obtained by solving the continuity equations describing the carrier-transport features of the device. A mathematical model of the photogenerated current density on a pn junction PD was presented [78]. Photodiode stationary 1D continuity equations are solved in the quasi-neutral region along y axis assuming the minority carriers mainly move by diffusion:

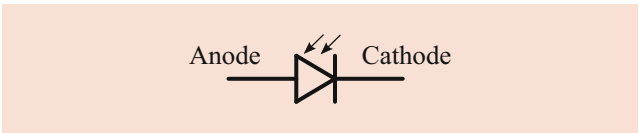

Fig. 34.9 Photodiode SPICE symbol

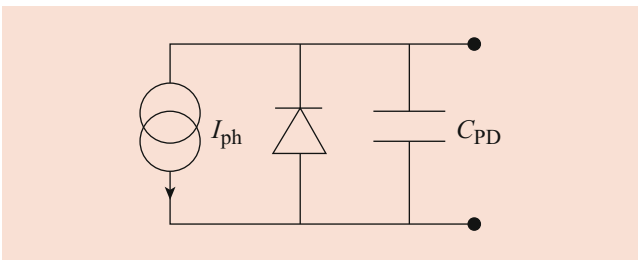

Fig. 34.10 Simplified electrical Verilog-A photodiode model

$$D_n \frac{\partial^2 \left(n_p - n_{p0} \right)}{\partial y^2} - \frac{n_p - n_{p0}}{\tau_n} + G(y) = 0 \tag{34.33}$$

$G(y) = -\partial\Phi/\partial y$ is the optical generation rate, i.e., the number of photogenerated electron-hole pairs per unit volume and time (where Φ is the photon flux). The procedure is similar for holes in the n+ region (Fig. 34.10). The total lateral current component is found by integrating the current density at the boundary of the depletion region over the lateral junction area [10]:

$$I_{ph} = qD_n \frac{8x_{ph}}{y_w} \sum_{n=1}^{\infty} I_1 \left(y_w \right) I_2 \left(x_s \right) I_3 \left(y_j \right) \tag{34.34}$$

Such electrical model has been implemented in Verilog-A [11].

34.3.3 Fowler-Nordheim Diode

Fowler-Nordheim (FN) diode models can be either an MIS or an SIS layer device, assuming its insulator layer is sufficiently thin (100 Å) to permit tunneling of carriers. It models electrically alterable memory cells, air gap switches, and other insulation breakdown devices. Both forward (F) and reverse (R) nonlinear current source DC equations with corresponding $(R \mid F)$ sign of the FN diode are:

$$I_{NFR|F} = \pm A_{eff} J_{R|F} \left(\frac{V_d}{T_{ox}} \right)^2 e^{\frac{E_{R|F} T_{ox}}{V_d}} \tag{34.35}$$

A constant FN diode capacitance is assumed and then defined as:

$$C_{NF} = A_{eff} \frac{\varepsilon_{ox}}{T_{ox}} \tag{34.36}$$

34.3.4 BJT

The general SPICE instance of the bipolar junction transistor (BJT) model is (Fig. 34.11):

```
Qname Nc Nb Ne <Ne> MODname <area><OFF>
+ <IC=Vbeo ...>
```

and the SPICE BJT model call statement is (Fig. 34.12):

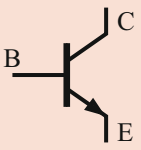

Fig. 34.11 BJT SPICE symbol

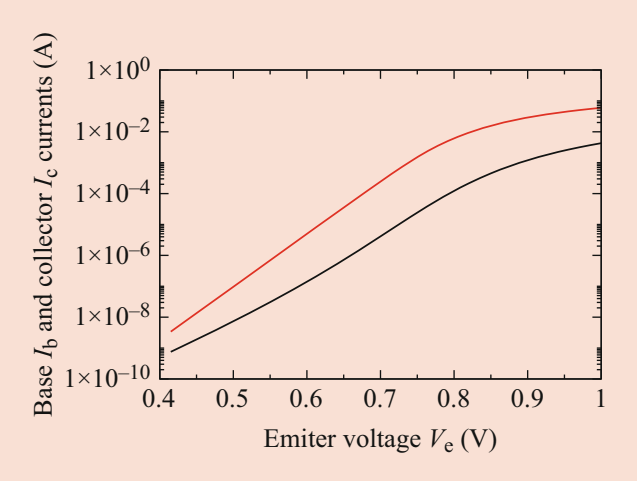

Fig. 34.12 BJT Gummel plot

```
.MODEL MODname NPN/PNP <IS=Is BF=bf
 ...>>
```

Ebers and Moll BJT Model

The Ebers and Moll (EM) BJT model is one of the very first (in 1954), simple nonlinear BJT models; it was proposed by Ebers and Moll [26]. The EM model is valid in all BJT operational regions: saturation, inverse, normal, and off. It is a DC model implementation without any characterization of the charge storage in the device. Basically, all latter BJT DC and large-signal, nonlinear models are referring to the EM model implementation. The injection EM version refers to two current components I_F and I_R, the currents thru the BJT diodes. The EM BJT terminal currents can be mathematically defined following [38], in case of a common base (CB) connected BJT:

$$I_C = \alpha_F I_F - I_R \tag{34.37}$$

$$I_B = (1-\alpha_F)\, I_F + (1-\alpha_R)\, I_R \tag{34.38}$$

$$I_E = -I_F + \alpha_R I_R \tag{34.39}$$

The transport EM model version refers to two current components I_{CC} and I_{EC}, which are flowing thru the BJT diodes; both I_{CC} and I_{EC} represent currents collected or transported across the base:

$$I_C = I_{CC} + \left[-\frac{1}{\alpha_R}\right] I_{EC} \tag{34.40}$$

$$I_B = \left[\frac{1}{\alpha_F} - 1\right] I_{CC} + \left[\frac{1}{\alpha_R} - 1\right] I_{EC} \tag{34.41}$$

$$I_E = \left[-\frac{1}{\alpha_F}\right] I_{CC} + I_{EC}. \tag{34.42}$$

An alternative form of the EM model is its nonlinear hybrid π model as defined in [57], which makes computer linearization to the small-signal model easier.

The EM model has a rather simple temperature dependency and assumes only temperature changes of I_S of the following form:

$$I_S(T) = I_S(T_{nom}) \left[\frac{T}{T_{nom}}\right]^3 \exp\left(\frac{-E_g}{k}\left[\frac{1}{T} - \frac{1}{T_{nom}}\right]\right) \tag{34.43}$$

There are further improvements to the EM model known as EM2 and EM3. The EM2 model allows for a first-order modeling of the charge storage effects to estimate device time responses. It has also a more accurate DC implementation with three ohmic bulk resistances, as well as additional diffusion capacitances C_{DE} and C_{DE} and three junction capacitances C_{jE}, C_{jC}, and C_{SUB}.

Gummel-Poon (GP) BJT Model

The Gummel-Poon (GP) BJT model has been formulated in 1970 [39] and has been implemented into SPICE2 [9, 60]. The element instance for a transistor in the SPICE netlist is:

```
Q(name) CBE <S> Mname <AREA>
```

C denotes the name of the collector node, B the name of the base node, E the name of the emitter node, and S the name of the substrate node, the specification of which is optional. Mname indicates the used transistor model, the parameters of which are shown in a separate .MODEL instruction to be listed. To describe the elements of the wholesale signal model, more than 50 parameters are provided. For NPN, PNP, and lateral PNP transistors, different model instructions are used:

```
.MODEL Mname NPN  (Model parameters)
.MODEL Mname PNP  (Model parameters)
.MODEL Mname LPNP (Model parameters)
```

More complex BJT models for integrated ICs are schematically shown in Fig. 34.13.

The Gummel-Poon model has been well-tested and broadly used model for decades. It delivers sufficient accuracy of the simulation results for many IC design applications. Nevertheless, there are some points in which an improved description is desirable:

- Working point dependency of the standardized base charge q_B for a precise description of the Early effect, of high-injection effects in the base area, and for an HBT with graded base characteristic effects:
- Transit time with high injection
- Base and collector path resistance

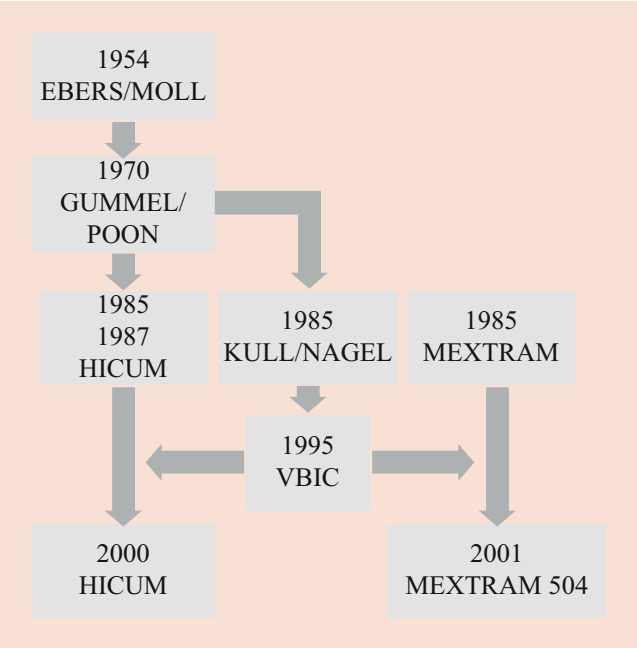

Fig. 34.13 Evolution of advanced BJT models

- Reverse currents and breakthrough
- Temperature dependency, self-heating
- Non-quasi-static effects
- Effects of the pn junction between the collector and the substrate
- Geometry dependencies

VBIC Vertical BJT Model

The VBIC vertical BJT model was developed by representatives of the IC and CAD industries to improve existing, generally used Gummel-Poon `SPICE` model. VBIC includes improved modeling of the Early effect (output conductance), substrate current, quasi-saturation, and behavior over temperature which are necessary for accurate modeling of current state-of-the-art devices. However, it has additionally been defined so that, with default parameters, the model will simplify to be as similar as possible to the Gummel-Poon model [55]. Advantages of VBIC over the Gummel-Poon model include: An Early effect model based on the junction depletion charges A modified Kull model for quasi-saturation valid into the Kirk regime (the high-injection effect at the collector) Inclusion of the parasitic substrate transistor An improved single-piece junction capacitance model for all three junction capacitances Improved static temperature scaling First-order modeling of distributed base and emitter AC and DC crowding Overall improved high-level diffusion capacitance modeling (including quasi-saturation charge) Inclusion of parasitic overlap capacitances Inclusion of the onset of weak avalanche current for the base-collector junction High-order continuity current equations A noise model similar to that of the Gummel-Poon model, with improved shot, thermal, and $1/f$ components

MEXTRAM Model

MEXTRAM bipolar transistor model developed by Philips [24] deploys equations that are explicit functions of the internal branch voltages; therefore, no internal quantities are solved iteratively. Transistor parameters are discussed where relevant; most parameters can be extracted from capacitance, DC, and f_T measurements and are process- and transistor-layout (geometry)-dependent. Initial/predictive parameter sets can be computed from process and layout data. This model does not contain extensive geometrical or process scaling rules (only multiplication factors to put transistors in parallel). The extended modeling of reverse behavior, the increase of the avalanche current when the current density in the epilayer exceeds the doping level, and the distributed high-frequency effect are optional and can be switched on by setting flags. Besides the NPN transistor, a PNP model description is available, both with and without substrate (discrete transistors) modeling. Advantages of MEXTRAM model include: Temperature effects Charge storage effects Substrate effects and parasitic PNP High-injection effects Built-in electric field in base region Bias-dependent Early effect Low-level nonideal base currents Hard- and quasi-saturation conditions Weak avalanche Hot-carrier effects in the collector epilayer Explicit modeling of inactive regions Split base-collector depletion capacitance Current crowding and conductivity modulation for base resistance First-order approximation of distributed high-frequency effects in the intrinsic base (high-frequency current crowding and excess phase shift) In the MEXTRAM model, the Moll-Ross relation is used to take into account the depletion and diffusion charges (Q):

$$I_n = \frac{(I_f - I_r)}{1 + (Qt_e + Qt_c + Qb_e + Qb_c)/Qb_0} \tag{34.44}$$

The computation of the diffusion charges Qb_e and Qb_c is based directly on the solution of the differential equation for the majority carriers in the neutral base region and relates the charges to the injected minority carrier concentrations at the emitter and collector edges. The substrate current of the PNP transistor takes into account high injection. The parameters are substrate saturation current and knee in the substrate current. When the substrate current value is low, the reverse current gain increases at medium reverse current levels.

HiCUM

HiCUM is a scalable physics-based compact bipolar transistor model [83]. Its name derives from **hi**gh-**cu**rrent **m**odel. Generally, bipolar processes span a variety of device struc-

tures and types. The compact BJT models are split into two categories: (1) vertical devices with high-speed NPN transistors and (2) lateral devices with PNP transistors. HICUM is targeted toward the first category. However, it may be necessary to divide the first category into "low-power" ($BV_{CEO} < 10\,V$) and "high-power" ($BV_{CEO} > 10\,V$) transistors if the difference in device design and the electrical application range turns out to be too large for a single model. From an industrial point of view, these requirements can be drawn for a compact model: high accuracy over a wide electrical (and temperature) range; laterally scalable parameter calculation, including variable-contact configurations, in order to allow circuit optimization; numerical stability and fast execution time, although this is somewhat dependent on the application; physics-based derivation, allowing for predictive and statistical modeling; reliable and well-defined extraction procedures, which should be available together with test structures; also, the use of standard equipment and setups only which is important for, e.g., fast throughput; and modular formulation of the model equations, minimizing interrelations between different electrical regions and facilitating simple implementation into circuit simulators. The important physical and electrical effects taken into account by HICUM can be briefly listed: high-current effects (including quasi-saturation); distributed high-frequency model for the external base-collector region; emitter periphery injection and associated charge storage; emitter current crowding (through a bias-dependent internal base resistance); two- and three-dimensional collector current spreading; parasitic (bias-independent) capacitances between base-emitter and base-collector terminal; vertical non-quasi-static (NQS) effects for transfer current and minority charge; temperature dependence and self-heating; weak avalanche breakdown at the base-collector junction; tunneling in the base-emitter junction; parasitic substrate transistor; bandgap differences (occurring in HBTs); and lateral scalability. In contrast to MOS transistor models, the geometry-dependent calculations have been implemented in a separate program (TRADICA [84]) for various reasons. The experimental results indicate that HICUM has been proven to be highly accurate and it has been already applicable for a variety of different technologies, from a relatively low-speed and high-voltage process to commercial SiGe technologies.

IGBT

Isolated gate bipolar transistor (IGBTs) have become widely accepted among circuit designers as an alternative to power BJTs or Darlington transistors in a broad range of power converter and motor drive applications [4]. To design power electronic circuits containing IGBTs, circuit simulations are needed to examine the behavior of the power element within the circuit. A simple SPICE IGBT model was proposed [43] and [42], and it is one of the very first physics-based models

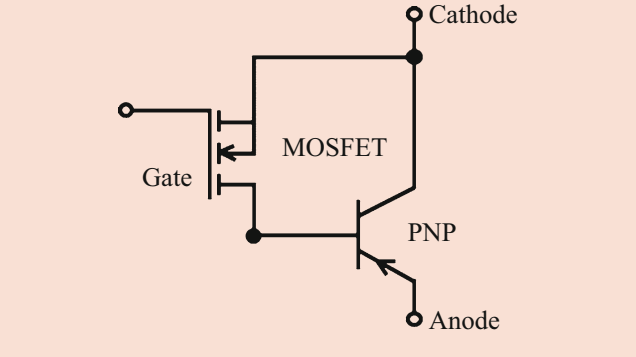

Fig. 34.14 IGBT SPICE subcircuit symbol

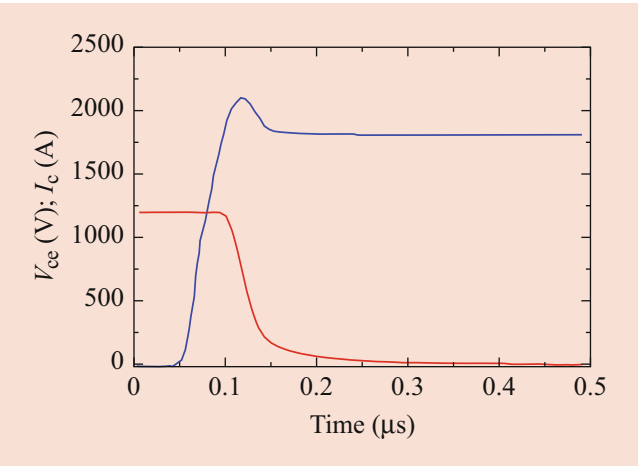

Fig. 34.15 Transient IGBT SPICE simulations

for the low-gain, high-level injection bipolar transistor of the IGBT power device type. To describe the high-level injection operation of the wide base bipolar transistor of the IGBT type (Fig. 34.14) and of other conductivity-modulated power devices, the ambipolar transport theory of the IGBT model describes the transport of electrons and holes in the base and the transient behavior, not available in earlier, conventional quasi-static modeling approaches. Figure 34.15 shows results of transient IGBT SPICE simulations.

34.3.5 MOSFETs

The essential difference among compact models is the choice of the main variables in terms of which the physical processes in the transistor are described. Known-to-date compact models use three different approaches. First developed and most widely used (from the 1960s to the present times) are the models based on the concept of threshold voltage (Vth-based approach) [50,103]. These include LEVEL1-LEVEL3, MM9, BSIM2, BSIM3, and most others [3,35,36,51]. How-

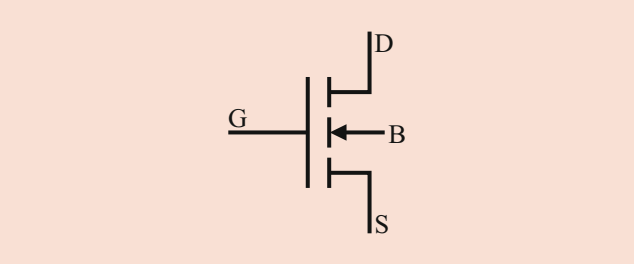

Fig. 34.16 M SPICE symbol

ever, this approach causes too many intractable problems when modeling transistors manufactured by technology with design standards less than 100 nm, with low supply voltage, and intended for analog- and radio-frequency circuits.

Six MOSFET models are implemented in standard SPICE: MOS1 is described by a square-law I–V characteristic [87], MOS2 is an analytical model, while MOS3 [100] is a semiempirical model; MOS6 [80] is a simple analytic model accurate in the short-channel region; MOS4 [77, 86] and MOS5 [46] are the BSIM (Berkeley short-channel IGFET model [85]) and BSIM2. MOS2, MOS3, and MOS4 include second-order effects such as channel length modulation, subthreshold conduction, scattering-limited velocity saturation, small-size effects, and charge-controlled capacitances. Standard SPICE provides six MOSFET device models, (Fig. 34.16) which differ in the formulation of the I–V characteristic. The variable LEVEL specifies the model to be used:

LEVEL=1 - Shichman-Hodges (as described in [87])
LEVEL=2 - MOS2 (as described in [101])
LEVEL=3 - MOS3, a semiempirical model (as described in [101]; Fig. 34.17 shows its IV plot)
LEVEL=4 - BSIM (as described in [86])
LEVEL=5 - BSIM2 (as described in [46])
LEVEL=6 - MOS6 (as described in [80])

$$v_{\mathrm{T}} = v_{\mathrm{TO}} + K_2\left[(-v_{\mathrm{SD}} + \psi)^{1/2} - \psi^{1/2}\right] \qquad V_{\mathrm{SD}} > V_{\mathrm{SS}} \tag{34.45}$$

Berkeley Short-Channel IGFET Model

BSIM1 is the first model that has properties typical of second-generation models [85]. Instead of accurately describing the subtle submicron effects using complex equations, this model uses empirical fit parameters determined with optimization procedures. A large number of parameters simplify the model equations and allow one to more accurately fit equations to experimental data. However, this is achieved at the cost of weakening the connection between the parameters of the technological process and those of the model, i.e., at the

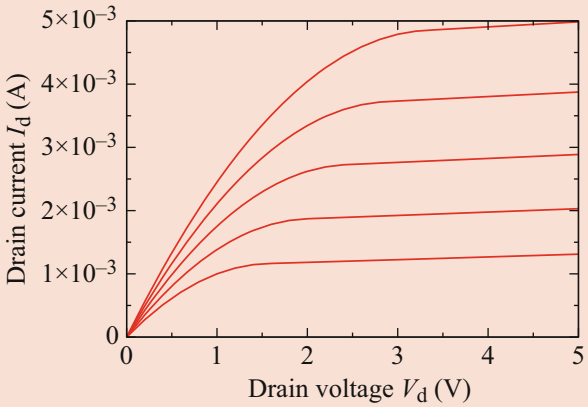

Fig. 34.17 MOSFET Level3 $I_d(V_d)$ plot

cost of deteriorating the predictive ability of the model. BSIM1 takes advantage of earlier Level3 model definition and a number of improvements. This includes the expression for the dependence of the mobility on the vertical electric field that introduces the substrate bias. The equation for the threshold voltage includes an additional term that takes into account inhomogeneous doping of the substrate. The model introduced a more accurate expression for the subthreshold current, which is smoothly connected with the above-threshold characteristic, ensuring continuity of the first derivative. To simulate the saturation of the carrier velocity and its dependence on the longitudinal component of the electric field, completely new dependencies are introduced, essentially simplifying the equation for the drain current, including the equation for saturation current. With a decrease in the effective channel length to 0.8 μm and of the oxide thickness to 15 nm, the BSIM1 model becomes inapplicable [32, 46].

HSPICE Level28

The decrease in geometric dimensions of the transistors has made the shortcomings of the BSIM1 model to appear more and more noticeably. To overcome them, HSPICE Level28 model was proposed [31]. The Level28 has a very wide distribution, thanks to the fact that it was built into the HSPICE program, which was used by the vast majority of CMOS VLSI developers. The HSPICE Level28 model is based on BSIM1 but removes many of its flaws, including that related to discontinuity of the second derivative of the drain current with respect to the gate voltage. For this, the current equations in the subthreshold region were smoothly connected with the equation for the strong inversion mode. Moving from the linear to the saturation region in earlier models was performed as follows: first, the saturation voltage was determined, and then the drain current in the active

region at saturation was made equal to the saturation current at the same point; this did not guarantee the continuity of the derivatives at the connection point. In the HSPICE Level28 model, this problem is solved by applying smoothing functions that have two fitting parameters. The model is a proprietary product and is supplied as an integral part of the HSPICE program, which is a significant drawback.

BSIM3

The previous version (model BSIM2) had gaps, negative conductance, and spurious outliers in the transfer conductance versus gate voltage dependence. To eliminate these problems, the BSIM3v3 model uses smoothing functions, ensuring the continuity and smoothness of the expressions for the drain current and terminal charges. BSIM3 takes into account a more detailed description of the inhomogeneous doping of the channel region in both vertical and horizontal directions and takes into account many new effects associated with small sizes. The model is valid only for transistors with a channel length larger than 0.15 μm [21]. BSIM3v3 was the first compact MOSFET model to successfully pass the standardization procedure at the Compact Model Coalition (CMC) [64].

BSIM4

BSIM4 is a further development of the BSIM3 model for application to MOS transistors made using the 100 μm technology or less. These models, unlike PSP and HiSIM, use the threshold voltage, not the surface potential, as a state change indicator. BSIM4, unlike BSIM3, includes the following: an accurate new model of input impedance for internal nodes; improved model of the substrate for modeling radio-frequency circuits; a new accurate channel thermal noise model and the model noise extension for induced shutter noise; a model that takes into account non-quasi-static effects for both transfer conductance and capacitance; an accurate model of current tunneling through the gate; a flexible, geometry-dependent model of parasitic elements; an improved model for transistors with steep retrograde distribution of impurities in the substrate; an improved model of threshold voltage for devices with implantation into pockets, taking into account the asymmetry of the resistances of the source and drain and their dependence from voltage and accounting (at the user's choice) for electrical, physical, or equivalent thickness of the gate dielectric; a quantum mechanical model of the inversion layer thickness and effective oxide thickness; a refined mobility model; improved models of the effects of GIDL/GISL leaks; an improved model of thermal and flicker noise; the ability to set various volt-ampere and volt-farad characteristics for the source and drain junctions; models of pn junctions with and without current limitation, taking into account the effects of strained silicon; a unified model of the drain-current saturation effect, which takes into account the mechanisms of saturation of the drift velocity of carriers and of the abnormal increase in mobility; the possibility of choosing other materials besides polysilicon, silicon, and SiO_2; a new definition of the threshold voltage to improve the fitting of subthreshold characteristics; and empirical consideration of the well proximity effect (WPE).

The disadvantages of the BSIM4 model include a quite large number of parameters, the appearance of negative resistances and capacitances in some modes, the discontinuity of the derivatives of the drain current and terminal charges in the Gummel symmetry test [54] at $V_{ds} = 0$, the lack of symmetry of some IV and CV characteristics.

BSIM6

BSIM6 is a new generation of the charge-based BSIM Bulk MOSFET model [17]. Its charge-based core is derived from Poisson's solution and has the following features: physical effects (SCE, CLM, etc.) taken from BSIM4; parameter names matched to BSIM4 parameters for compatibility; Gummel symmetry is fulfilled (the model is symmetric for DC/AC modes at $V_{DS} = 0$); Capacitances and corresponding derivatives are also symmetric at $V_{DS} = 0$. The BSIM6 implementation is continuous in all regions of operation with no glitches, this resulting in smooth IV current and CV capacitance behavior; it features physically sound capacitance modeling with short-channel velocity saturation for CV modeling and related effects; physical implementation of BSIM6 model is using global extraction procedure. BSIM6 solves the charge equation using first- and second-order Newton-Raphson technique to obtain analytical expression of q_i without any approximation to calculate the charge equation. Defining the BSIM6 drain current:

$$I_D = I_{drift} + I_{diff} = \mu W \left(-Q_i \frac{d\Psi_S}{dx} + V_T \frac{dQ_i}{dx} \right) \quad (34.46)$$

its mobility model second with the order effects has been adopted from BSIM4:

$$I_D = \frac{\mu_v}{\sqrt{1 + \left(\frac{\mu_v}{v_{sat}} \left| \frac{d\Psi_S}{dx} \right| \right)^2}} W \left(-Q_i \frac{d\Psi_S}{dx} + V_T \frac{dQ_i}{dx} \right) \quad (34.47)$$

and using charge linearization and parameter normalization [27]:

$$\begin{aligned} &2q_i + \ln(q_i) \\ &\quad + \ln\left[\frac{2n_q}{\gamma} \left(\frac{2n_q}{\gamma} q_i \right) + 2\sqrt{-2q_i + \psi_p} \right] \\ &\quad = \psi_p - 2\phi_f - v_{ch} \end{aligned} \quad (34.48)$$

yields the BSIM6 total current expression [81]

$$i_{\mathrm{d}} = \frac{\left(q_{\mathrm{s}}^2 + q_{\mathrm{s}}\right) - \left(q_{\mathrm{d}}^2 + q_{\mathrm{d}}\right)}{\frac{1}{2}\left(1 + \sqrt{1 + \left[\lambda_{\mathrm{c}}\left(q_{\mathrm{s}} - q_{\mathrm{d}}\right)\right]^2}\right)} \tag{34.49}$$

Global BSIM6 parameter extraction [75] produces a single set of parameters for the entire range of MOSFET device lengths, and allows for an accurate evaluation of the next nanoscaled technology nodes [65].

Philips MOS Model 9

MOS Model 9 (version 902) [98] is a compact MOS transistor model intended for the simulation of circuit behavior with emphasis on analog applications. The model gives a complete description of all quantities related to the transistor actions: nodal currents and charges, noise power spectral densities, and weak avalanche currents. The equations describing these quantities are based on the gradual channel approximation with a number of first-order corrections for small-size effects. The consistency is maintained by using the same carrier density and electric field expressions in the calculation of all model quantities. Model 9 provides a model for the intrinsic transistor only; junction charges and leakage currents are not included.

Philips MOS Model 11

MOS Model 11 (MM11), the successor to MOS Model 9, has been developed by Philips [96]. MM11 gives an accurate description not only of charges and currents and their first-order derivatives (transconductance, conductance, capacitances) but also of their higher-order derivatives. In other words, it gives an accurate description of the MOSFET distortion behavior, and as such, MM11 is suitable for digital, analog, as well as RF circuit design. MOS Model 11 is a symmetrical, surface-potential-based model. It includes an accurate description of all physical effects important for modern and future CMOS technologies, such as gate tunneling current, gate-induced drain leakage, influence of pocket implants, poly-depletion, quantum-mechanical effects, and bias-dependent overlap capacitances. Including all of the above, MOS Model 11 achieves superior accuracy as compared to MOS Model 9 without an increase in the number of parameters and with only a slight increase in simulation time.

PSP MOSFET Model

PSP MOSFET model [33] was developed by merging the best features of the two surface-potential-based compact models: SP (developed at the Pennsylvania State University) [18], [33], and MM11 (developed by Philips) [96]. The major features of PSP include the following: physical surface-potential-based formulation in both intrinsic and extrinsic model modules; physical and accurate description of the accumulation region; inclusion of all relevant small geometry effects; modeling of the halo implant effects, including the output conductance degradation in long devices; Coulomb scattering and non-universality in the mobility model; non-singular velocity-field relation enabling the modeling of RF distortions including intermodulation effects (IM3); complete Gummel symmetry; midpoint bias linearization enabling accurate modeling of the ratio-based circuits (e.g., R2R circuits, such as as defined in [34]); quantum mechanical corrections; correction for the polysilicon depletion effects; GIDL/GISL model; surface-potential-based noise model including channel thermal noise, flicker noise, and channel-induced gate noise; advanced junction model including trap-assisted tunneling, band-to-band tunneling, and avalanche breakdown; spline collocation-based NQS model including all terminal currents; and stress model.

The normalized drain charge along the channel length x given in the Ward-Dutton partition [102] by the integral:

$$Q_{\mathrm{D}} = \frac{1}{L}\int_0^L \frac{x}{L} q_{\mathrm{i}} \mathrm{d}x \tag{34.50}$$

becomes in the PSP model:

$$Q_{\mathrm{D}} = \frac{q_{\mathrm{im}}}{2} + \frac{\alpha\Delta\psi}{12}\left(1 - \frac{\Delta\psi}{2H_{\mathrm{PSP}}} - \frac{\Delta\psi^2}{20H_{\mathrm{PSP}}^2}\right) \tag{34.51}$$

The expressions for the current and terminal charges obtained in this manner are continuous and smooth in all regions of operation from accumulation to deep inversion. Another unique feature of PSP is the adequate intermodulation (IM3) modeling of a simple passive mixer. Modeling and simulation of this type of IC are a rather difficult problem. The issue is that (unlike the case for active mixers) passive mixer modeling is sensitive to any singularity at zero drain bias. The non-singular nature of PSP allows proper IC mixer simulations and yields a correct slope (3 dB/dB) for the third harmonic [8].

Since 2016, the PSP model is supported by the CEA-Leti modeling group [63].

EKV2.6

The EKV model version 2.0 appeared in 1994 [27] and has continuously being developed up to the present time. Details of the model and simulation examples can be obtained from the website [66]. The model is built by analyzing physical processes in deep submicron MOS transistors and is designed to simulate analog and analog-digital circuits, operating at low currents and voltages (1.2–1.5 V and below). The model is based on the charge of the inversion layer and

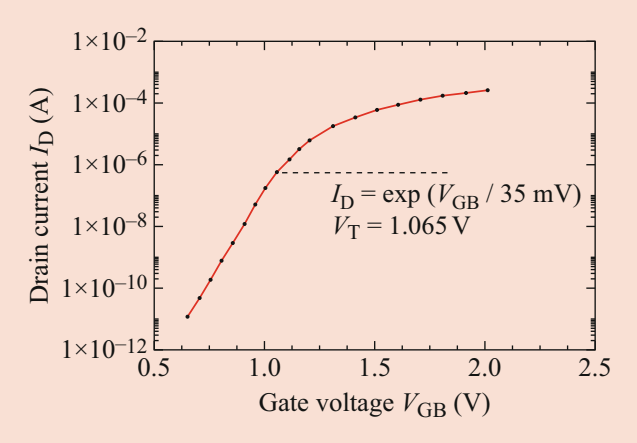

Fig. 34.18 EKV $I_d(V_g)$ plot

is the only widespread model built on this principle. Initial publications on weak inversion (or subthreshold) MOSFET operation date back to the early 1970s [5, 29, 73, 92, 95]. EKV compact model developments are focused on MOSFET operation in the weak inversion. The model uses the bulk substrate terminal as the reference to preserve source-drain symmetry. In the EKV definition has similarities with the Ebers-Moll bipolar transistor model. An internal feature of EKV model is the slope factor n:

$$I_D = \frac{W}{L} I_{DO} e^{\frac{V_G}{nU_T}} \left[e^{\frac{-V_S}{U_T}} - e^{\frac{-V_D}{U_T}} \right] \tag{34.52}$$

$$\frac{W}{L} I_{DO} = I_S e^{\frac{-V_{TO}}{nU_T}} \tag{34.53}$$

Unlike previous generations, the EKV model has the following properties that are important in modeling ultralow-power analog ICs: it provides an accurate modeling of the g_m, g_{ds} conductances at all internal nodes; it takes into account the non-quasi-static effects; it features an accurate model of white and flicker noises; it has a small number of parameters (the model kernel uses only ten parameters) and a simplified procedure for parameter extraction (Fig. 34.18 shows its transfer plot).

EKV3

The EKV3 model [13] is based on the ideas of EKV2.6. Additionally, it takes into account a number of effects necessary for modeling deep submicron MOS transistors, mainly in the area of weak and moderate inversion [15]. The model is designed for the ultralow-power analog device modeling and IC simulations. Work [14] compares the simulation results with experimental 100-nm CMOS data for frequencies up to 20 GHz, with a channel length from 110 nm to 2 μm; it shows that the Y-parameters of the model are in good agreement with the experimental data over the entire frequency range and at all bias voltages and also shows that non-quasi-static effects. Non-quasi-static effects have been investigated for long-channel transistors at frequencies up to 20 GHz. Importantly, in the short-channel transistors it takes into account extrinsic parasitic elements. Based on the results, it can be concluded that the model can be used for analog circuits as well as for RF CMOS circuits.

HiSIM MOSFET Model

All transistor characteristics are described by the HiSIM (Hiroshima-University STARC IGFET Model) model as a function of surface potential, which is calculated iteratively at each applied voltage under the charge-sheet approximation [58]. The concept of surface potential allows one to obtain the general expression for the sum of the diffusion and drift currents, which eliminates the need for smoothing functions. The basic HiSIM equations for the inversion layer charge Q_i and the depletion layer charge Q_b are written at position y along the channel with the effective gate voltage V'_G:

$$\begin{aligned} Q_i(y) &= -C_{ox}\left(V'_G - \phi_S(y)\right) - Q_b(y) \\ Q_b(y) &= -qN_{sub}L_D\sqrt{2\beta\left(\phi_S(y) - V_{bs}\right) - 1} \end{aligned} \tag{34.54}$$

HiSIM takes into account all significant short-channel effects, known by now. Particularly accurate and without applying binning, this model takes into account the gate-induced drain leakage (GIDl) effect.

Other MOSFET Compact Models

The academic and industrial R&D groups continue developments of other MOSFET compact models:

34.3.6 SOI MOSFET Models

The MOS transistors fabricated on the silicon-on-insulator (SOI) substrate are different from conventional MOSFETs. The device layer, in which the conducting channel is located, is on a buried oxide (BOX) insulating it from the silicon substrate. A number of categories of SOI MOSFETs can be distinguished. They can be realized as devices with Schottky barrier junctions, pn junctions, or as devices with l-h junc-

tions, which in the extreme are junctionless transistors. In the extremely downscaled SOI MOSFETs, the architecture of source/drain regions and of their contacts is of great importance. The transistors with pn junctions work in the inversion mode, whereas the transistors with l-h junctions work typically in the accumulation mode. According to the device layer thickness and doping concentration, two types of the SOI MOSFETs can be distinguished: partially depleted (PD) SOI MOSFETs and fully depleted (FD) SOI MOSFETs. The PD SOI MOSFETs appeared at the beginning of the SOI technology de and are still in use. However, the state-of-the art SOI MOSFETs have channels with very low doping to minimize the random doping fluctuation (RDF) effect, to minimize the carrier mobility degradation, and to enhance the gate control over the channel conductance. Due to this, their mode of operation changes between full depletion in the OFF state to the full inversion or accumulation in the ON state. According to a shape of SOI MOSFETs, different geometries may be distinguished, e.g., planar and fin-type ones. There are also devices with pi- and omega-type channels. However, they were developed in the past rather for research purpose. Finally, according to a number of gates, among practical solutions of the SOI MOSFETs, there are single-gate, double-gate, and gate-all-around (GAA) devices. Standard PD, FD SOI MOSFETs are single-gate devices. FinFETs and ultrathin body and buried oxide FD SOI (UTBB FD SOI) MOSFETs are double-gate devices (in the FinFETs, both the gates are shortened). In the state-of-the-art nanosheet and nanoribbon transistors, the channels are wrapped with the gates. Other solutions, though theoretically possible, do not have a practical meaning. A large variety of the SOI MOSFET architectures, modes of operation, and gate control need compact modeling for the process/device/circuit development. In this section, only a few implemented and most often used ones will be briefly presented and discussed.

PD SOI MOSFET

The physical model of the n-channel PD SOI MOSFETs is presented in [93, 94] with available Verilog-A description [37]. It takes into account the basic phenomena in such devices including diffusion/drift transport in the front and bottom (if exists) channels, avalanche ionization in the drain-body junction depletion area, thermal recombination in the source-body space charge area and nearby, thermal generation in the drain-body space charge area and nearby. Taking these effects into account allows to determine the floating-body potential and next all the internal and terminal DC current components. Obviously, the "kink" effect both in the subthreshold and strong inversion ranges is clearly visible on the output characteristics. Having the DC model characteristics, it is possible to determine the non-quasi-static (NQS) small-signal (AC) characteristics of the SOI MOSFET. The NQS AC model was developed based on the Hauser approach [41]. This approach is physically more sound than the quasi-static (QS) approach, in which the capacitances are calculated as the derivatives of the charges assigned to the terminals with respect to the terminal potentials. Moreover, it does not use a channel charge sharing between the source and drain terminals [102], which in fact results only from mathematical transformation.

Figure 34.19 shows general current flow in the PD SOI MOSFETs, which can be described in two modes assuming small-signal analysis:

$$i_{\mathrm{S}}(t) + i_{\mathrm{Gf}}(t) + i_{\mathrm{D}}(t) + i_{\mathrm{Gb}}(t) = 0 \tag{34.55}$$

$$u(t) = U + u^{*}\mathrm{e}^{j\omega t} \tag{34.56}$$

in DC mode:

$$I_{\mathrm{S}} + I_{\mathrm{Gf}} + I_{\mathrm{D}} + I_{\mathrm{Gb}} = I_{\mathrm{S}} + I_{\mathrm{D}} = 0 \quad \Rightarrow V_{\mathrm{BS}} \tag{34.57}$$

in AC mode:

$$i_{\mathrm{s}}^{*} + i_{\mathrm{gf}}^{*} + i_{\mathrm{d}}^{*} + i_{\mathrm{gb}}^{*} = 0 \quad \Rightarrow v_{\mathrm{bs}}^{*} \tag{34.58}$$

This yields the expressions for the drain current in both sides, source and drain, respectively:

$$\begin{aligned}
i_{\mathrm{cf}}^{*}(0) &= \left\{\lambda_{\mathrm{f0}}\left[v_{\mathrm{s}}^{*} - \left(v_{\mathrm{gf}}^{*} - v_{\mathrm{tf}}^{*}\right)\right]\right. \\
&\quad \left. + \mu_{\mathrm{f0}}\left[v_{\mathrm{d}}^{*} - \left(v_{\mathrm{gf}}^{*} - v_{\mathrm{tf}}^{*}\right)\right]\right\}/\Theta_{\mathrm{f}} \\
i_{\mathrm{cf}}^{*}(L) &= \left\{\lambda_{\mathrm{fL}}\left[v_{\mathrm{s}}^{*} - \left(v_{\mathrm{gf}}^{*} - v_{\mathrm{thf}}^{*}\right)\right]\right. \\
&\quad \left. + \mu_{\mathrm{fL}}\left[v_{\mathrm{d}}^{*} - \left(v_{\mathrm{gf}}^{*} - v_{\mathrm{thf}}^{*}\right)\right]\right\}/\Theta_{\mathrm{f}} \\
Y_{xy} &= \delta_{xy} i_{x}^{*}/v_{y}^{*}; \\
C_{xy} &= \mathrm{Im}\left(Y_{xy}\right)/\omega; \\
&\text{where}: \quad x, y \in \{s, gf, d, gb\}
\end{aligned} \tag{34.59}$$

BSIM SOI

BSIM-SOI is a compact model for SOI devices. BSIM-SOI model variants are BSIM-IMG, a model for independent multi-gate (usually front and back gate) MOSFETs, and BSIM-CMG, a model for common multi-gate MOSFETs [65]. The whole BSIN-SOI family represents different approaches to the SOI MOSFET modeling: threshold voltage-, charge-, and surface-potential-based. The basic BSIM-SOI v.4.6.1 model is a threshold voltage-based model constructed similarly to the BSIM4 model of the conventional MOSFETs. It enables simulation of operation of a variety of planar devices. The model parameter SoiMod serves as a selector for the PD device model (SoiMod=0), for the unified PD&FD model (SoiMod=1), for the ideal FD device model (SoiMod=2), and for the model selection by BSIMSOI itself.

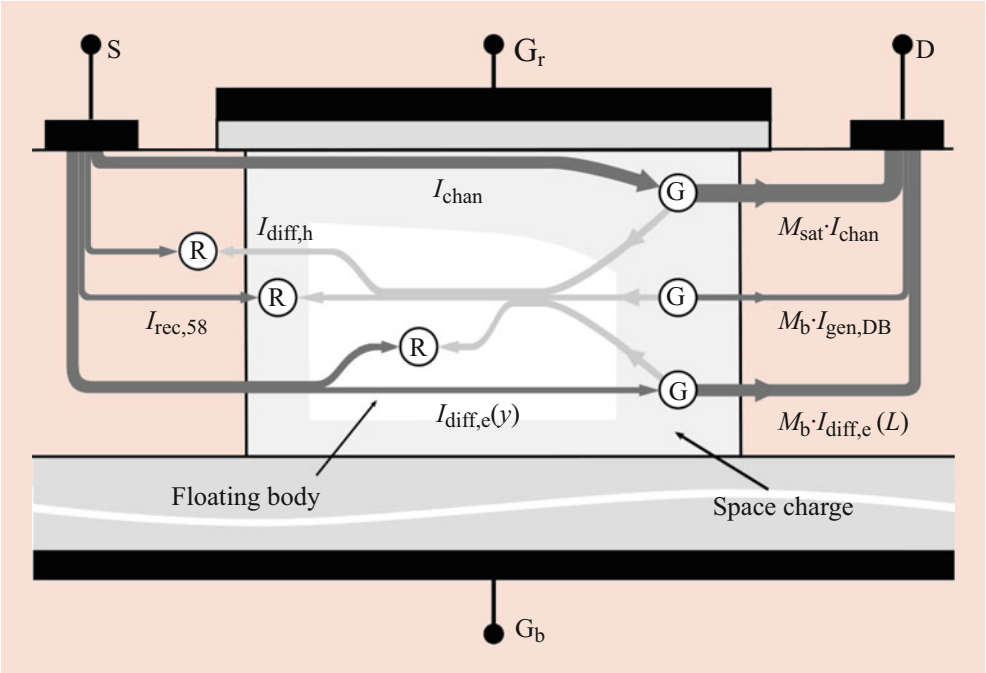

Fig. 34.19 Approximation of the distribution of current components in the non-fully depleted SOI MOSFET

The BSIM-CMG model accounts for different transistor architectures, which are declared by a parameter GEOMOD, namely, double-gate (GEOMOD=0), e.g., FinFET, triple-gate (GEOMOD=1), quadruple-gate (GEOMOD=2), cylindrical (GEOMOD=3), and unified (GEOMOD=4). In all these cases, the gate effective width is modified according to the declared architecture. The model accounts also for two types of FinFET substrate selected by a parameter BULKMOD. FinFETs on SOI substrate or on Si substrate are selected by setting BULKMOD=0, 1 accordingly. As opposed to BSIM-SOI, the BSIM-CMG model is constructed based on the charge-based approach, i.e., the primary variables of the model are the channel charge densities at the source and drain ends of the channel q_{is} and q_{id} derived from the electrostatics.

The surface-potential-based BSIM-IMG model serves for simulation of the double-gate (DG) SOI MOSFETs with both gates independently biased. The gate stacks at the gates may be different, i.e., different work functions, fixed charge densities, and gate insulator thicknesses can be specified. To determine the surface potentials for both gates, the Poisson's equation is solved iteratively taking into account a coupling between both gates.

HiSIM SOI

Developed at the Hiroshima University [67], HiSIM SOI is fully depleted. SOI-MOSFET is developed based on the surface-potential description, considering the potential distribution vertical to the channel and parallel to the surface explicitly. Besides the comparison to measured I–V data, the model is verified with 1/*f* noise analysis, sensitive to the carrier concentration and distribution along the channel. And furthermore, for the accurate modeling of the short-channel effects, the parasitic electric field induced through the buried oxide is considered.

The SOI MOSFET device has thee Si-SiO_2 interfaces as schematically shown in Fig. 34.20, and corresponding charges are induced at all these surfaces. The following three basic equations are derived from the Poisson equation and the Gauss law, by considering boundary conditions assuming an approximation of a linearly decreasing current distribution into the bulk of SOI MOSFET device:

$$V_{gs} - V_{fb} = \phi_{s,SOI} - \frac{Q_i + Q_{dep} + Q_{b,SOI} + Q_{s,bulk} + Q_G}{C_{OX}} \tag{34.60}$$

$$\phi_{s,SOI} = \phi_{b,SOI} - \frac{Q_{s,bulk} + \frac{1}{2}Q_{dep}}{C_{SOI}} \tag{34.61}$$

$$\phi_{b,SOI} = \phi_{s,bulk} - \frac{Q_{s,bulk}}{C_{BOX}} \tag{34.62}$$

Corresponding capacitances C_{OX}, C_{SOI}, and C_{BOX} are functions of the SOI device layer thicknesses; V_{gs} and V_{fb} are the gate-source bias voltage and the flat-band voltage, respectively. ll charges appearing in the above equations are

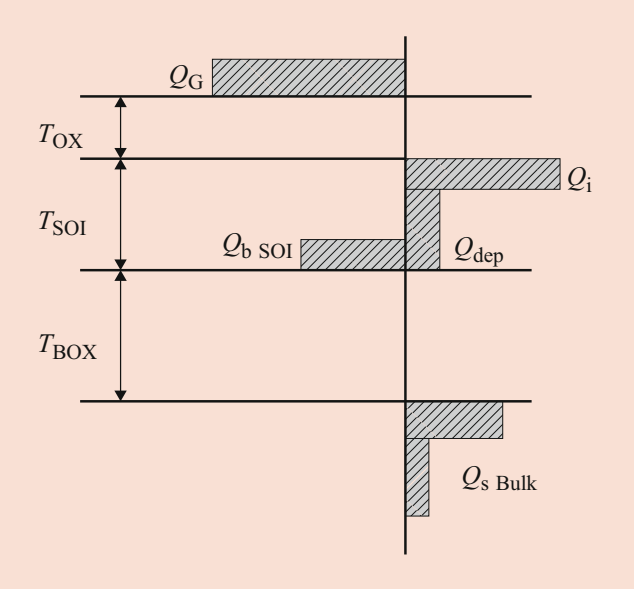

Fig. 34.20 Charges in HiSIM SOI model

functions of the three surface potentials in the SOI devices. To guarantee accurate and flexible circuit simulation for a device with the various SOI layer and BOX layer thicknesses at any operating conditions, the above three equations are solved iteratively in the HiSIM SOI model. Modeled physical phenomena in the HiSIM SOI can be summarized as follows: physical dependence on device parameters, short-channel effects, narrow-channel effects, impact ionization effect, poly-depletion effect, quantum mechanical effect, pocket implantation effects, low- and high-field mobility model, leakage current models, noise models for all conduction mechanisms, floating-body effect, history effect, body-tie effect, self-heating effect, both DC and AC Gummel symmetries, and diode model for S/D junctions.

Leti L-UTSOI

L-UTSOI is a surface-potential-based compact model dedicated to FD-SOI technologies with thin lightly doped device layers, in particular for UTBB devices accounting for back interface inversion. It was developed by CEA-Leti [72], and it has been selected in 2020 by the CMC as a standard compact model for FD SOI devices. An FD SOI transistor is a four-pin transistor with a back gate that allows tuning the device in a low-leakage and low-power operating regime or higher-performance operating regime. The L-UTSOI symmetry between front and back interface has been respected in all equations of the core model. Its core is also valid for all independent double-gate MOSFETs. The L-UTSOI accounts for numerous physical effects, namely, interface coupling, back interface inversion/dual-channel operation; ground-plane depletion; quantum confinement; velocity saturation; short-channel effects; channel length modulation; series resistance with gate voltage-dependence; parasitic currents (gate current, GIDL/GISL); parasitic capacitances (overlap, fringe); self-heating effect; stress model; noise models (flicker, thermal, induced gate, shot); and source/drain junction asymmetry. The model accuracy was verified against DC/AC characteristics for the 28-nm FD SOI process, measured for nFETs with 7-nm device layer thickness, 25-nm BOX thickness, and n-type backplane. This unique capability offered by FD-SOI technology allows the fabrication of smaller, faster, and denser chips than standard complementary metal oxide semiconductor (CMOS) technology.

UFSOI/UFPDB/UFDG

The UFSOI models (UFPDB and FD/SOI) are developed by the University of Florida and implemented into `SPICE` [30], [22]. The original bases of the models are described under "SOISPICE/ UFSOI." The UFPDB model (evolved from the NFD model) is unified for application to PD/SOI and bulk-Si MOSFETs with just one small set of model parameters. Recently, the models have been upgraded to include gate-body direct tunneling current and an option for a strained Si/SiGe channel. The FD/SOI model has been evolved into a separate model (UFDG) for generic double-gate MOSFETs, which is also applicable to UTB FD/SOI devices

34.3.7 JFETs

The JFET device (Fig. 34.21) is formed by diffusing a pn junction as a gate diode between the source and drain. Similarly, in MESFETs, the gate is created as a metal layer over the gate-control region, which provides a Schottky-contact diode. To control the current flow, both technologies modulate the depletion region of the gate diode.

Modeling basic JFET and MESFET effects include:

- Charge-conserving gate capacitors
- Back-gating the substrate node
- Mobility degradation due to gate field
- Computationally efficient DC model [23, 90]
- Subthreshold equation
- Physically correct width and length

The ideal current equation accounts for all DC currents of the JFET device, and its two pn junctions are modeled by these ideal diode equations:

$$I_{gd} = I_{Seff}\left(e^{\frac{V_{gd}}{Nv_t}} - 1\right) \quad \text{for } V_{gd} > -10Nv_t \tag{34.63}$$

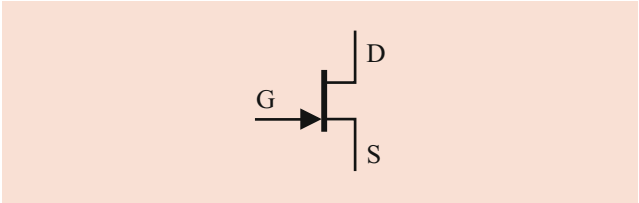

Fig. 34.21 JFET SPICE symbol

$$I_{gd} = -I_{Seff} \text{ for } V_{gd} \leq -10Nv_t \tag{34.64}$$

$$I_{gs} = I_{Seff}\left(e^{\frac{V_{gd}}{Nv_t}} - 1\right) \quad \text{for } V_{gs} > -10Nv_t \tag{34.65}$$

$$I_{gs} = -I_{Seff} \text{ for } V_{gs} \leq -10Nv_t \tag{34.66}$$

The SPICE .MODEL statement selects a JFET or MESFET model to simulate a netlist

```
.MODEL mname NJF <Level = val>
<pname1 = val1> ...
```

The variable LEVEL specifies the model to be used for SPICE simulations:

- Level=1 JFET model
- Level=2 JFET model
- Level=3 MESFET model
- Level=4 TOM3 MESFET model
- Level=5 Materka model

Basic JFET or MESFET IV characteristics are defined by the model parameters VTO and BETA, which also determine the variation of drain current with gate voltage. LAMBDA determines the output conductance, IS the saturation current of the two gate junctions. Two ohmic resistances, RD and RS, are included. The charge storage is modeled by nonlinear, depletion layer capacitances for both gate junctions, which vary as the $-M$th power of the junction voltage and are defined by the parameters CGS, CGD, and PB. Noise model parameters KF and AF are also a function of the JFET source and drain series resistances (RS and RD), as well as a function of temperature. Parameters ALPHA and A model noise in MESFETs. SPICE JFETs models are mostly used regional approaches [16, 25, 82]. The most complete treatment until now [105] includes empirical subthreshold definition in above-threshold JFET operation.

Recently, a unified charge-based model for double-gate and cylindrical architectures of junction field-effect transistors (JFETs) has been developed [45]. JFETs were mainly used in analog low-noise ICs; with the recent advances in SiC technology, there are an increasing number of JFET applications in power electronics. Advanced JFET models can be implemented as junctionless FETs with an infinite gate capacitance, as proposed in [45]. The model was derived without the need to develop a new physical set of analytical relations. Assuming that the whole JFET channel operates in depletion, the gate-channel pn junction should be reversely biased ($V_{GS} < 0$) in order to avoid the gate leakage current. The JFET channel charge density and its potentials in depletion mode are expressed as follows:

$$V_{GS} - V_{ch} - \Delta\phi_{ms} - U_T \ln\left(\frac{N_D}{n_i}\right) \overset{dep}{\approx} -\frac{Q_{sc}^2}{8qN_D\varepsilon_{si}} - \frac{Q_{sc}}{2C_{ox}} + U_T \ln\left[1 - \left(\frac{Q_{sc}}{Q_{fix}}\right)^2\right] \tag{34.67}$$

As anticipated above, a JFET can be described as a JLFET with an infinite gate capacitance:

$$V_{GS} - V_{ch} - V_{bi} \overset{dep}{\approx} \frac{-Q_{sc}^2}{8qN_D\varepsilon_{si}} + U_T \ln\left[1 - \left(\frac{Q_{sc}}{Q_{fix}}\right)^2\right] \tag{34.68}$$

JFET threshold voltage is the gate voltage where Q_m tends to zero (at $V_{DS} = 0$) with the JFET pinchoff voltage V_P defines as:

$$V_{TH} = V_{bi} + V_P \tag{34.69}$$

The JFET drain current in depletion mode can be obtained using:

$$I_{DS} = \frac{W\mu}{L_G} f(Q_m)\Big|_S^D = \frac{W\mu}{L_G}[f(Q_{m,d}) - f(Q_{m,s})] \tag{34.70}$$

where $f(Q_m)$ is a function of the mobile charge densities fulfilling $Q_{sc} = Q_{fix} + Q_m$.

A symmetric double-gate junction FET (three-terminal DG JFET) proposed in [52] models drain current and total charges of corresponding nodes, as well as their derivatives, accordingly. The total node charges at source and drain are calculated by integrating the charge density along the channel, applying the well-known Ward-Dutton partitioning. The gate charge is obtained from charge balance as:

$$Q_G = -(Q_D + Q_S) = -W_{ch}\int_0^{L_{ch}} Q_m dx \tag{34.71}$$

and this allows to analytically estimate the transcapacitances as the partial derivatives of the node charges versus terminal voltages:

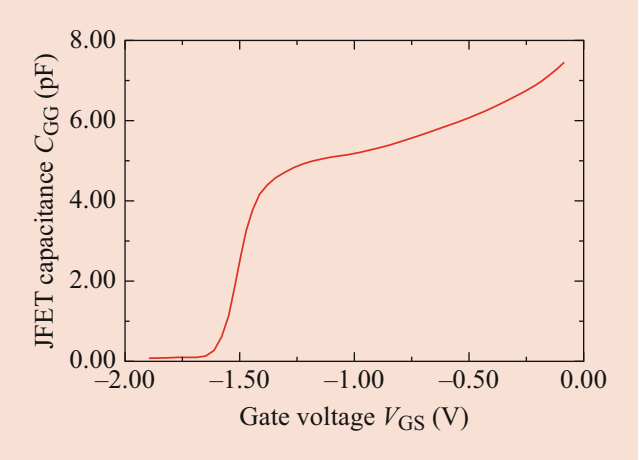

Fig. 34.22 JFET gate capacitance plot

$$C_{ij} = \pm \frac{\partial Q_i}{\partial V_j} \tag{34.72}$$

where i and j correspond to G, D, or S nodes of the JEFT device. The analytical definition of all JFET transcapacitances simplifies the model validation and Verilog-A implementation. Figure 34.22 shows the CV plot of a JFET gate capacitance.

34.4 HV/Power Compact Models

In this section, selected HV/power compact models are presented.

34.4.1 LDMOS

High-voltage MOSFETs are those that can support a higher V_{DS} voltages and currents I_D than regular MOSFETs. Because of this versatility, they are used to switching loads ON/OFF, to up- or down-convert between different voltage levels or, more generally, for power management and RF backend to provide high-power amplification (Fig. 34.23).

34.4.2 MM20 LDMOS Model

MOS Model 20 (MM20) is a compact MOSFET model intended for analog circuit simulation in high-voltage MOS technologies. It describes the electrical characteristics of double-diffused MOS devices including a lateral MOS device under a thin gate oxide layer [1]. MOS Model 20 gives a self-consistent description of all quantities related to transistor action: nodal currents, nodal charges, and noise power spectral densities. The equations describing these quantities are

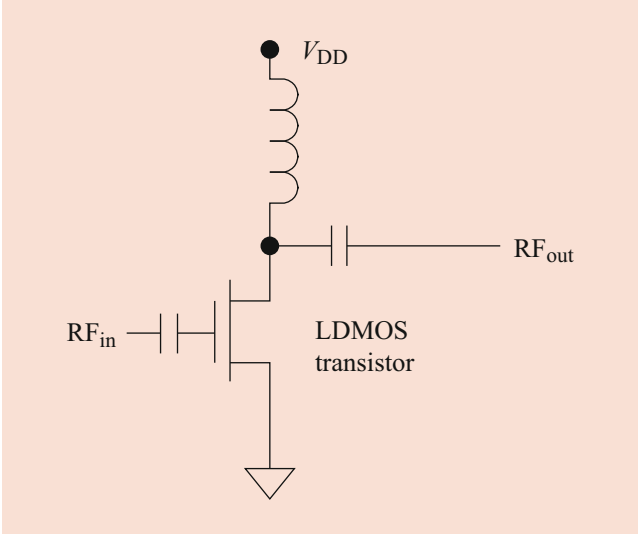

Fig. 34.23 Basic LD MOSFET RF subcircuits

based on surface-potential formulations, resulting in equations valid over all operation regimes (i.e., accumulation, depletion, and inversion in both the channel region and drift region). The surface potential as a function of the terminal voltages is obtained by the explicit expression derived earlier [97]. The currents through MM20 device consist of the DC current I_{DS} from drain to source and the charging currents at the drain, gate, source, and bulk terminal. Therefore, the total current into corresponding terminal is given by:

$$\begin{aligned} I_D &= I_{DS} + I_{DB} + (\mathrm{d}Q_D/\mathrm{d}t) \\ I_G &= \mathrm{d}Q_G/\mathrm{d}t \\ I_S &= -I_{DS} + (\mathrm{d}Q_S/dt) \\ I_B &= -I_{DB} + (\mathrm{d}Q_B/dt) \end{aligned} \tag{34.73}$$

34.4.3 HiSIM-HV: A Compact Model

The HiSIM-HV [53] is high-voltage MOSFET model based on the HiSIM (Hiroshima-University STARC IGFET Model) model for conventional bulk MOSFETs [58] and features a consistent potential description across MOSFET channel and drift region. Symmetric and asymmetric device types are covered for up to several 100 V switching capability. HiSIM-HV has accurately implemented scaling channel and drift region lengths as well as channel width properties. The model is based on the charges controlled by voltages.

34.5 Organic TFT

Selected organic TFT compact models are presented in this section.

34.5.1 RPI a-Si TFT Model

RPI a-Si TFT model (Fig. 34.24) is an amorphous silicon (a-Si), thin film transistor (TFT) model [88]. The field-dependent mobility of RPI a-Si TFT is determined by the gate voltage overdrive, the same as in other TFT models [20]. However, it is superior to earlier models, since it considers effects resulting from localized energy states in the thin-film bandgap, especially for downscaled TFT devices. This allows for more accurate prediction of threshold voltages, field-dependent mobility, leakage currents, kink effects, and drain currents above threshold.

34.5.2 AIM-SPICE MOS15

MOS15 amorphous silicon (a-Si) thin film transistor (TFT) model is implemented in AIM-SPICE [44]. The models have been compared with experimental data to validate its implementation with device gate lengths down to 2 μm (for poly-Si) and 4 μm (for a-Si) in a temperature range of 25–150 °C at the frequencies up to 10 MHz. Its main features include modified charge control model and induced charge trapped in localized states. Above threshold includes field-effect mobility becoming a function of gate bias and band mobility dominated by lattice scattering. Below threshold includes Fermi level located in deep localized states and related position of Fermi level, including the deep DOS back to the gate bias, as well as empirical expression for current at large negative gate biases for hole-induced leakage current; interpolation techniques are applied to the equations to unify the model.

Features of the MOS15 a-Si TFT model include:

- Modified charge control model and induced charge trapped in localized states
- Above-threshold operation includes:
  - Field-effect mobility becoming a function of gate bias
  - Band mobility dominated by lattice scattering
- Below-threshold operation includes:
  - Fermi level located in deep localized states
  - Relate position of Fermi level, including the deep DOS back to the gate bias
  - Empirical expression for the current at large negative gate biases for hole-induced leakage current
- Interpolation techniques applied to the equations to unify the model.
- AIM-Spice includes an automatic.

34.6 Progressive Modeling Directions

Future compact models, which set new development challenges, are discussed in this section.

34.6.1 Single-Electron Transistors (SET)

A constant interaction (CI) SET model (Fig. 34.25) describes the energetics most straightforwardly [49] and inexpertly assumes that the Coulomb interaction between the electrons is independent of the doping concentration [48].

34.6.2 Quantum Dot

Quantum dot devices with semiconductor optical amplifier have already shown excellent characteristics (Fig. 34.26). Studies have demonstrated the usefulness of QDs for optical amplification, all-optical switching, and signal processing [91]. The different parts of the equivalent circuits interact together to represent the gain recovery process, saturation properties, and chirp behavior in both linear and nonlinear operation regimes of QD-SOA. The equivalent circuits are then used for `SPICE` simulation. It has been shown that `SPICE` simulation results agree well with the full, numerically calculated results [79].

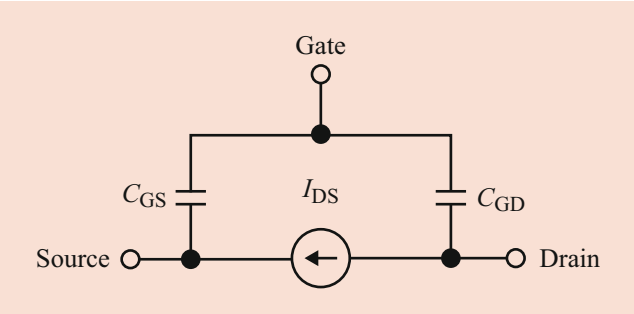

Fig. 34.24 Organic RPI a-Si TFT model

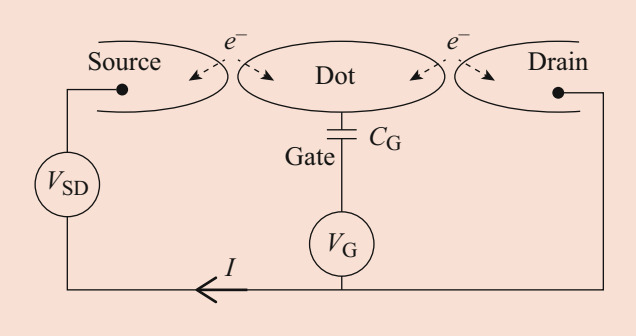

Fig. 34.25 Coulomb interaction in single-electron transistors

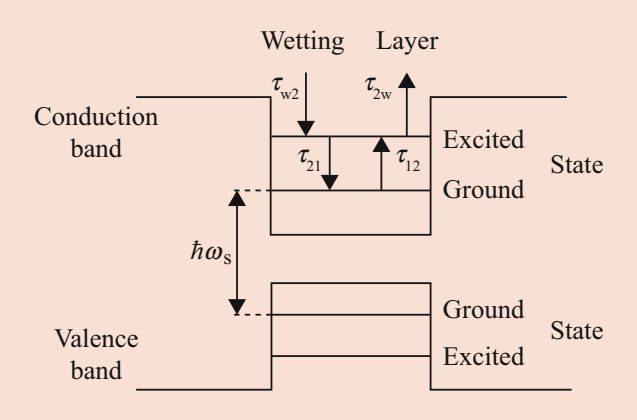

Fig. 34.26 Quantum dot

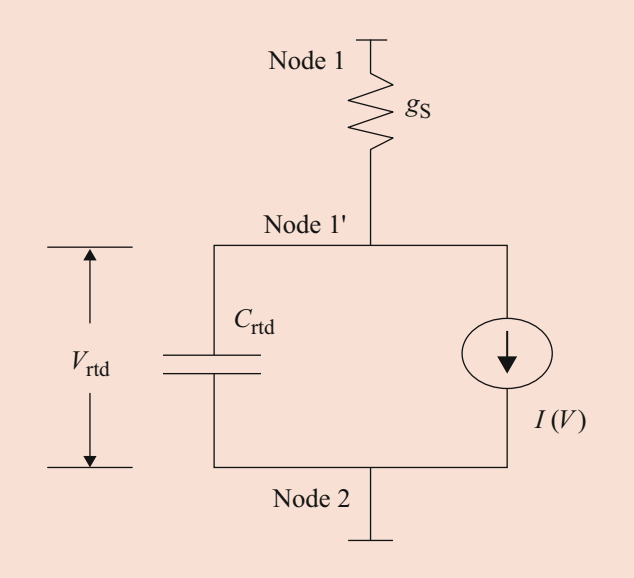

Fig. 34.27 Resonant tunneling diode model

34.6.3 Resonant Tunneling Diode

Figure 34.27 shows a general equivalent circuit model for resonant tunneling diode (RTD). The component g series is used to represent contact resistance and some other losses which appear during the manufacturing process. The voltage-controlled current source I(V) represents the DC IV characteristic of the RTD. The capacitance CRTD represents the CV characteristic of the RTD [59].

34.6.4 Rapid Single-Flux Quantum (RSFQ) Device

Recent developments concerning the rapid single-flux-quantum (RSFQ) circuit family are reviewed (Fig. 34.28).

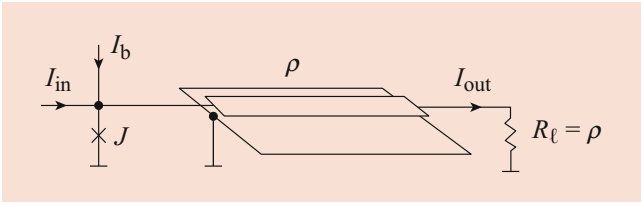

Fig. 34.28 Rapid single-flux quantum (RSFQ) device

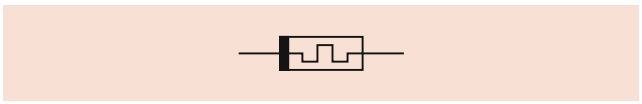

Fig. 34.29 Memristor SPICE symbol

Elementary cells in this circuit family can generate, pass, memorize, and reproduce picosecond voltage pulses with a nominally quantized area corresponding to the transfer of a single magnetic flux quantum across a Josephson junction [19].

34.6.5 Memristor

In the paper published by Dr. Williams [104] manufacturability of a memristor, the so-called fourth elementary passive element, has been reported. Theoretical symmetry between the nonlinear resistor (voltage vs. current), nonlinear capacitor (voltage vs. charge), and nonlinear inductor (magnetic flux linkage vs. current) has been reviewed by Chua in his 1971 paper [25]. Several models for memristors have been developed with their Verilog-A implementations, e.g., the linear ion drift model, the nonlinear ion drift model, the Simmons tunnel barrier model, and the threshold adaptive memristor (TEAM) model (Fig. 34.29).

34.6.6 Negative Capacitance Model

A recent paper has proposed a negative capacitance model [2]. The negative capacitance (NC) effect, observed in various semiconductor devices, physical mechanisms, and their effects are discussed in detail with the theoretical interpretation of experimental data [28]. Quantum transport properties of negative capacitance transistors (NC-FETs) with monolayer black phosphorus (ML-BP) are theoretically studied (Fig. 34.30).

34.6.7 Magnetic Tunnel Junction

The magnetic tunnel junction (MTJ) is defined in [74] and [7,40]. A new spin-transfer torque (STT) model allows circuit designers to simulate key aspects of spin-transfer torque

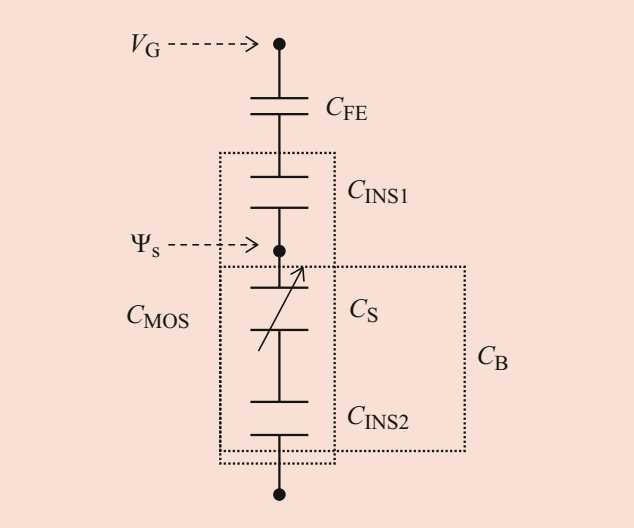

Fig. 34.30 Negative capacitance model

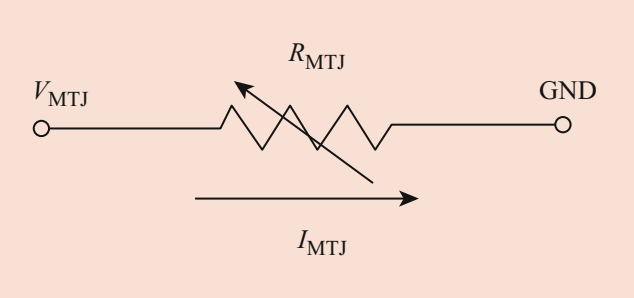

Fig. 34.31 Magnetic tunnel junction

MRAM (STT-MRAM), such as read and write delays. It is a self-contained, physics-based magnetic-tunnel junction (MTJ) `SPICE` model that can reproduce realistic MTJ characteristics based on user-defined input parameters, such as the free layer's length, width, and thickness parameters [47]. Using the MTJ `SPICE` model, scalability studies of both in-plane and perpendicular MTJs can be performed across different technology nodes with minimal effort (Fig. 34.31).

34.7 Conclusions

Developing compact models for the microelectronics /nanoelectronics industry is crucial for reducing product development costs and gaining access to new technologies. In this chapter, we have addressed critical issues for developing compact models for microelectronic and nano-electronic devices. We have analyzed the main fundamentals of compact device modeling, the typical assumptions made, and the main principles that circuit simulation and design tools use in conducting analyses based on device models. Moreover, we have discussed the possibilities of integrating compact models into circuit simulation and design tools, with particular emphasis on Verilog-A standardization, which makes the implementation of the compact models into EDA tools easy. The key parameter extraction strategies are beyond the scope of this chapter. We have also discussed the main challenges of developing compact models for emerging devices, many of them utilizing new materials, that are enabling new applications such as quantum computing, cryogenics, flexible and wearable electronics, and bioelectronics.

Wladek Grabinski received the Ph.D from the ITE, Warsaw, in 1991. He was with IIS, ETHZ and subsequently with LEG, EPFL. Later, worked at Motorola/Freescale Geneva. Wladek is IEEE EDS Compact Modeling TC Member. Since 1999, Wladek coordinates the MOS-AK Association. He is now consulting for MOST modeling and parameterization for RF CMOS ICs designs.

Daniel Tomaszewski received the M.Sc. degree in electronics from Warsaw University of Technology, Warsaw, in 1980, the Ph.D. degree in electronics from Institute of Electron Technology, Warsaw in 1998, and the D.Sc. degree from Lodz University of Technology, Lodz, Poland in 2018. Since 1980 he has been with Institute of Electron Technology transformed later into Lukasiewicz-Institute of Microelectronics and Photonics, Warsaw. His research concerns simulation of semiconductor processes and MOS devices, compact modeling and characterization of semiconductor devices: MOSFETs, BJTs, and sensors.

Abstract

In this chapter an outline of the very diverse topic of process simulation is given. This includes the process steps of ion implantation and thermal annealing, which introduce, activate, and modify dopant distributions, and the process steps lithography, deposition, and etching, which are used to structure the semiconductor wafer. The section on oxidation deals with the simulation of the oxide growth, whereas the aspect of dopant segregation is included in the section on diffusion. Finally, the impact of process variations is outlined. Overall, the process simulation chapter primarily deals with the physics and the related models for the various process steps, whereas the discussion of generic algorithms, e.g., for the solution of partial differential equations, is left for another dedicated chapter of this book. However, some algorithms which are specific for process simulation are also briefly described in this chapter.

Due to the diversity of the area of process simulation, this chapter could not strive for completeness in the presentation of the physical models. We largely refer to silicon technology, whereas most models can also be applied for or adapted to other top-down semiconductor technologies where, in contrast to bottom-up technologies based on self-assembling, patterning steps, ion implantation and high-temperature process steps are used to generate three-dimensional geometries and dopant distributions.

35.1 Scope and History of Process Simulation

This chapter deals with the physical and chemical processes employed to fabricate semiconductor devices based on semiconducting material such as silicon, namely, to generate their geometries and the spatial distributions of dopants, mechanical stress, and potentially further quantities which determine and influence the electrical behavior and the reliability of the devices. The processes to be studied may be grouped into those which primarily influence the geometry, namely, lithography, etching, and deposition, and those which primarily introduce and modify dopant distributions and their activation, namely, ion implantation and thermal annealing. Oxidation primarily changes the local geometry but also affects dopant distributions. Epitaxy is used both to deposit semiconducting layers with desired properties and to introduce dopants, and silicidation is a combination of metal deposition and annealing to form metal-silicon alloys to act as contacts.

Process simulation is an integral part of technology computer-aided design (TCAD). The overall industrial benefit of TCAD in terms of the reduction of development times and costs was already in the 2011 International Technology Roadmap for Semiconductors (ITRS) [1] estimated at about 40%. Although no serious assessment is available on how much process simulation contributes to this benefit, its impact is in any case very significant. Especially, there were also statements from industry that the impact of TCAD cannot be given in percent, because several technological developments would even not be possible at all without the use of TCAD.

Historically and long ago, these processes could be described with macroscopic process parameters, such as the temperature to which wafers were exposed in a furnace reactor, used for annealing or oxidation. During the last decades and in parallel with device scaling, it got increasingly important and difficult to reliably and accurately control such parameters in both space and time. In turn, it has got more and more important to characterize, simulate, and control how such parameters depend on the process equipment used. One of the first effects considered already decades ago was the temperature profiles which occur when a wafer is introduced into a furnace reactor for annealing or oxidation: Whereas the wafer is initially at room temperature, it is gradually heated while being pushed into the furnace reactor. The temperature to which a dopant is then exposed depends on the temperature distribution in the furnace, the movement of the wafer into its target position, and the thermal conduction within the wafer. This is one of the first examples for the need to simulate not only geometries and dopants at transistor scale but also the development of spatial and temporal distributions in the process equipment. This so-called equipment simulation is therefore also considered in this chapter. Especially it is also highly relevant for the advanced fabrication steps used for current nanoscale transistors, such as millisecond annealing, and lithography steps employed to generate patterns far smaller than the wavelength of the light used (e.g., 40 nm structures with 193 nm wavelength double patterning immersion lithography, according to the 2013 International Technology Roadmap for Semiconductors (ITRS) [2]).

With both physical processes and device architectures being driven to their limits, systematic and stochastic variations of the processes used can no more be neglected. The most famous and obvious effect is random dopant fluctuations (RDF) [3]: For example, for threshold voltage implants of 10^{12} cm^{-2}, at mean 4 ions are implanted into a 20-nm-long and 20-nm-wide transistor channel. Because ion implantation is a statistical process, this means that the real number of ions implanted into the channel fluctuates around the mean value of 4. In turn, also the threshold voltage is distributed around its nominal value. Such variations are critical for the overall yield in semiconductor fabrication. A short overview of this aspect is given at the end of this chapter.

The scope of process (including equipment) simulation outlined above is very wide and diverse. In turn, the detailed discussion of the large set of processes and models needed to simulate them would require a dedicated and rather thick book: One of the first reviews of the at that time emerging area of process simulation was published in 1984 as one chapter of a book on the simulation of semiconductor devices in general [4]. Twenty years later, the book on just one (very important) area within process simulation, the modeling of dopant diffusion and activation, published by one of the authors [5] extended to more than 500 pages. Since then, the diversity and complexity of process and equipment models has further grown, due to shrinking features and new processes, materials, and physical effects having come into play. Therefore, this chapter cannot give a comprehensive review of all details. Rather, it intends to give the reader an overview how the input data needed for device simulation, in terms of geometries, active dopants, and strain, can be generated by simulation and which merits and limitations the approaches employed have. In view of this and of the limited space available, we do not include epitaxy, silicidation, and chemical-mechanical polishing CMP. Whereas the chapter

generally refers to silicon as the semiconductor material used, most models can also be applied or adapted to other semiconducting materials. Generally, we refer to specific literature for further details.

Another important aspect to consider is that the level and effort of simulation has historically changed and will continue to do so: Whereas for the simulation of a transistor with one micron channel length, the use of (kinetic) Monte Carlo methods was neither necessary nor possible, a completely different situation applies for sub-decananometer transistors, where shrinking feature sizes both necessitate and partly enable more sophisticated simulation methods. Compared with device simulation, ab initio approaches are hardly used for process simulation, but nevertheless can support the development of computationally more efficient models. During the last decades, simulation has developed from one-dimensional process simulation with academic tools around 1980 [6–8] through two-dimensional process simulation in the 80th and 90th [9, 10] to the current situation where three-dimensional process simulation with commercial tools [11, 12] is the industrial standard. Moreover, in the early days of technology computer-aided design, the individual process steps were mostly treated in isolation, in order to optimize the process step in question, e.g., the annealing steps employed to create high dopant activation while maintaining a shallow junction. In the course of device scaling and more physical models being developed, the interactions between the individual process steps became ever more important. A common example is that dopant diffusion and activation critically depend on the distribution of point defects, which is influenced not only by the annealing step itself but also by other preceding process steps, such as ion implantation or thermal oxidation. In turn, integrated simulation of whole process flows, or the most important part of them, became mandatory. Concerning the transfer of process results into device simulation, in some cases simplistic assumption on device geometry and dopant distributions were made to simplify device studies, e.g., using Gaussian dopant profiles or abrupt junctions. However, such assumptions are sometimes physically not sound and are especially for current nanoscale devices misleading and likely invalidate the results of subsequent device simulations. In turn, the result of the simulation of the whole process flow must be transferred into the device simulator to be used, in most cases necessitating major remeshing. Currently even the gap between the device community and the lithography community is closing, because transistors no more depend on the footprint of the resist structures patterned in lithography steps, but also on the impact of in general non-vertical edges of the resist lines on subsequent etching and deposition processes. This adds to the impact non-vertical nitride, poly, or oxide masks on implanted profiles, which has been included in state-of-the-art process simulation since long.

35.2 Simulation of Ion Implantation

For decades, analytical models have been the workhorse for the simulation of ion implantation. Therefore this chapter starts with this approach and describes it in some detail.

35.2.1 Analytical Models

Some fundamentals of the analytical description of ion implantation can still be taken from the very early book mentioned above [4]. In general, analytical models use distribution functions $f(x)$ which are normalized to unity and vanish for very large (positive and negative) x:

$$f(-\infty) = f(\infty) = 0; \int_{-\infty}^{\infty} f(x)\,\mathrm{d}x = 1 \tag{35.1}$$

The dopant distribution $C(x)$ is then obtained by multiplying the distribution function $f(x)$ with the implanted dose N_D. The part of the vertical distribution for x smaller than zero does not stand for a dopant profile. Rather, it is assumed that the integral across the negative axis corresponds to the amount of particles which are backscattered from the wafer surface during implantation [13].

The analytical models use range moments of the distribution $f(x,y)$, both in vertical (x) and in lateral direction (y), and also partly mixed moments in both directions. Here, x refers to the direction parallel to the incident ion beam and y to the direction perpendicular to this. The first moment in vertical direction is the mean value of the depth in which the ion is stopped, the so-called projected range:

$$R_\mathrm{p} = \int_{-\infty}^{\infty} x \cdot f(x)\,\mathrm{d}x \tag{35.2}$$

whereas the further moments in vertical direction, the range straggling ΔR_p, the skewness γ, and the kurtosis β are centered around R_p:

$$\Delta R_\mathrm{p} = \sqrt{\int_{-\infty}^{\infty} \left(x - R_\mathrm{p}\right)^2 f(x)\,\mathrm{d}x} \tag{35.3}$$

$$\gamma = \frac{1}{\Delta R_\mathrm{p}^3} \int_{-\infty}^{\infty} \left(x - R_\mathrm{p}\right)^3 f(x)\,\mathrm{d}x \tag{35.4}$$

$$\beta = \frac{1}{\Delta R_\mathrm{p}^4} \int_{-\infty}^{\infty} \left(x - R_\mathrm{p}\right)^4 f(x)\,\mathrm{d}x \tag{35.5}$$

In case of two-dimensional distributions in x and y, $f(x)$ must be replaced by $f(x,y)$, and the integration runs across x and y.

Due to symmetry, the odd moments in lateral direction are equal to zero. Important lateral moments are the lateral range straggling $\Delta R_{\mathrm{p,l}}$ and the lateral kurtosis β_{l}:

$$\Delta R_{\mathrm{p,l}} = \iint_{-\infty}^{\infty} y^2 f\,(x, y)\ \mathrm{d}x\,\mathrm{d}y \tag{35.6}$$

$$_{\mathrm{l}} = \frac{1}{\Delta R_{\mathrm{p,l}}^4} \iint_{-\infty}^{\infty} y^4\, f\,(x, y)\ \mathrm{d}x\,\mathrm{d}y \tag{35.7}$$

Because the lateral shape of the implanted doping profile generally depends on the depth x, it is also useful to introduce mixed moments $X^i\,Y^j$ [14]:

$$X^i Y^j = \frac{1}{\Delta {R_{\mathrm{p}}}^i \cdot \Delta {R_{\mathrm{pl}}}^j} \iint_{-\infty}^{\infty} \left(x - R_{\mathrm{p}}\right)^i y^j\, f\,(x, y)\,\mathrm{d}x\,\mathrm{d}y \tag{35.8}$$

Whereas again odd moments in y vanish, moments X^iY^2 describe the change of the profile width with depths. Moments X^iY^4 describe the change of the lateral kurtosis with depth.

One-Dimensional Analytical Models

The analytical description of ion implantation is based on distribution functions from statistics, which in the context have no physical background except that ion implantation is a statistical process and that dopant profiles have certain shapes.

Simplest but sometimes still used is the Gaussian distribution, which approximates the vertical distribution as

$$C(x) = \frac{N_{\mathrm{D}}}{\sqrt{2\pi}\,\Delta R_{\mathrm{p}}}\ \exp\left(-\frac{\left(x - R_{\mathrm{p}}\right)^2}{2\Delta R_{\mathrm{p}}^2}\right) \tag{35.9}$$

It is apparent that due to the non-negligible implantation energy, the depth distribution of implanted ions is not symmetric, and not Gaussian. Generally, Pearson distributions have been shown [15] to best describe vertical profiles of implanted ions. These are defined as solutions of the differential equation:

$$\frac{\mathrm{d}f(x)}{\mathrm{d}x} = \frac{x - a}{b_0 + b_1 \cdot x + b_2 \cdot x^2} \tag{35.10}$$

Here, the parameters a, b_0, b_1, and b_2 depend on the vertical range moments; see Eqs. (35.2), (35.3), (35.4), and (35.5) [4]. Depending on the values of b_0, b_1, and b_2, the denominator of Eq. (35.10) may have singularities. In turn, different types of Pearson distributions result, depending on the values of skewness and kurtosis, from which b_0, b_1, and b_2 are calculated; see Fig. 35.1 [4].

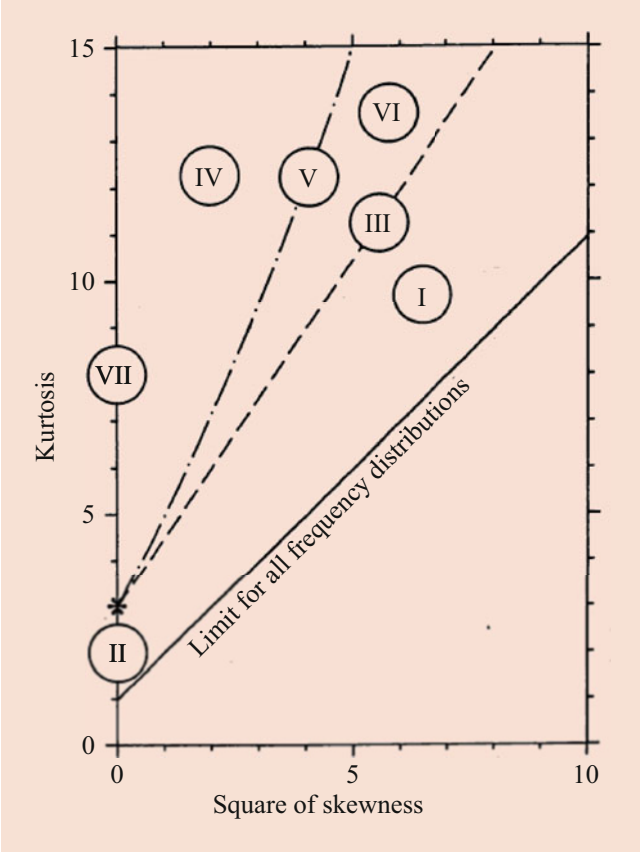

Fig. 35.1 Domains of validity of type (Roman number) of Pearson functions [4] depending on skewness and kurtosis

For vertical distributions, mostly Pearson IV distributions are suited best:

$$f(x) = K\left[-\left\{b_0 + b_1\left(x - R_{\mathrm{p}}\right) + b_2\left(x - R_{\mathrm{p}}\right)^2\right]^{1/2b_2}\right. \cdot \exp\left[-\left(\frac{b_1 / {b_2}^{+2\cdot a}}{\sqrt{4\cdot b_2\cdot b_0 - b_1^2}}\right) \cdot \arctan\frac{2b_2\left(x - R_{\mathrm{p}}\right) + b_1}{\sqrt{4\ b_2 b_0 - b_1^2}}\right] \tag{35.11}$$

For vanishing skewness, symmetric Pearson II, Pearson VII, and also Gaussian distributions (for a kurtosis of three) result. Depending on the parameter values, these are used for the lateral dopant distributions.

A very essential aspect in ion implantation is channeling: A larger amount of the ions penetrate deeper into the target if they are implanted along a low indexed crystalline direction.

Generally, implantation is performed with a tilt angle of about 7° to 10° [16], in order to minimize channeling. This situation is described by the Pearson distributions of type IV discussed above. For other (non-standard) tilt angles, range parameters may need to be adapted, depending on the amount of channeling occurring, or Monte Carlo methods should be used, as outlined in Sect. 35.2.2. For implantation into amorphous targets, where no channeling occurs, generally the asymmetric Pearson I and Pearson VI distributions are applicable, with Pearson III and Pearson V as limiting cases. In case of high-dose implantation into crystalline targets, amorphization occurs during the process. This situation can be described by the weighted addition of a Pearson distribution with parameters for a crystalline target and another Person distribution with parameters for an amorphous target [17].

Analytical One-Dimensional Multilayer Models

Ion implantation is not restricted to the ideal cases where the wafer can be divided into areas of bare silicon and areas which are masked by a layer which is not penetrated by the ions. Rather, ions are partly implanted through layers, and mask edges have a finite height and are in general not parallel to the implantation direction. In view of this, models are needed to describe the implantation into multilayer targets. In principle, such models would need to take the differences in the electronic stopping and in the nuclear scattering of the layers into account. Whereas the projected range of the implanted ions is strongly influenced by both electronic stopping and nuclear scattering, the range straggling is primarily influenced by the nuclear scattering as the dominating statistical process in ion implantation. In view of this, some models were published which approximate the change of the doping profile in silicon due to the influence of masking layers by taking the differences of the projected ranges and/or in the projected range straggling in the materials in question into account. The first and well-known model [18] assumed Gaussian profiles for both the mask (layer 1, with thickness t) and the silicon (layer 2) below, using for both layers the projected range and the projected range straggling in question. In addition, the profile in the silicon layer was shifted by

$$d = t \cdot \left(1 - \frac{\Delta R_{p2}}{\Delta R_{p1}}\right) \tag{35.12}$$

The weaknesses of this model were its limitation to Gaussian functions and that the ratio of the projected range stragglings did not sufficiently describe the changes in the stopping powers and, in turn, the profile shift. A generalization of this model [19] removed the restriction to Gaussian profiles:

$$C(x) = C_1(x), x \le t \tag{35.13}$$

$$C(x) = \frac{\Delta R_{p1}}{\Delta R_{p2}} \cdot C_1\left(\frac{\Delta R_{p1}}{\Delta R_{p2}}\, x - t\left(\frac{\Delta R_{p1}}{\Delta R_{p2}} - 1\right)\right), x > t \tag{35.14}$$

However, it still used the modified profile of the first layer also for the second layer and yields wrong results for the limiting case of $t \to 0$, where the profile in the second layer should be C_2 (x) and not ΔR_{p1} $/\Delta R_{p2} \cdot C_1$ $(\Delta R_{p1}$ $/\Delta R_{p2} \cdot x)$.

A model which well considers the original profile shape in the material in question and the changes in projected range due to masking layers is the Numerical Range Scaling model (NRS) [19, 20]. Here, for all layers in the stack, Pearson distributions are used with the range parameters for the material in question. Then, for all but the first layer, the layers on top are considered by shifting the profile based on the thicknesses of the layers on top and the ratios of the projected ranges.

For the implantation through a mask of thickness t (layer 1) into layer 2, this reads

$$C(x) = C_1(x) \text{ for } 0 \le x \le t \tag{35.15}$$

$$C(x) = \alpha \cdot C_2\left(x - t\left(1 - \frac{R_{p2}}{R_{p1}}\right)\right) \text{ for } x > t \tag{35.16}$$

Here, α is a scaling factor after which the model is named: Because no simplifications are made for the profile shapes $C_1(x)$ and $C_2(x)$ (unlike, e.g., in the Ishiwara-Furukawa model [18] where Gaussian distributions are assumed), α cannot be given in analytical form but results from numerical integration, to ensure that $C(x)$ is normalized to the total implanted dose.

A similar scaling of the ranges was also suggested in the LAYER model [21], however restricted to Gaussian profiles, for which dose conservation could be achieved by an analytical scaling factor. In the LAYER model, for the distribution in the second layer, a joint half Gaussian distribution was used, which assumes different range stragglings before and after its maximum, both depending on the projected range in the material of the first layer and projected range stragglings in the materials of the first and the second layer. By comparison with Monte Carlo simulations, it was shown that the range straggling in the second layer does not match especially for very thin or very thick masks [22].

As an extension of the NRS model, in the Improved Numerical Range Scaling model (NRS') [20], the projected range stragglings are corrected based on the layer thickness and the ratios of the projected range stragglings and the projected ranges:

$$\Delta R'_{p2} = \Delta R_{p2} + t \left(\frac{\Delta R_{p1}}{R_{p1}} - \frac{\Delta R_{p2}}{R_{p2}} \right) \tag{35.17}$$

Figure 35.2 shows the comparison between the Numerical Range Scaling model (NRS) and the Improved Numerical Range Scaling model (NRS') and measurements using secondary-ion mass spectroscopy (SIMS) for the implantation of boron with an energy of 100 keV and a dose of 10^{15} cm^{-2} through a silicon nitride layer into silicon. Whereas the NRS model already well describes the shift of the dopant profile in the silicon due to the different stopping power of the nitride layer, NRS' also yields a good description of the profile width in the silicon. However, it still fails to predict the change of the width in case of strange material combinations, such as the implantation of lithium into a stack of cadmium on gold. These are better described by a further refinement of the NRS' model, which was motivated by some aspects of the LAYER model and resulted in a further modified range straggling in the second layer [22]:

$$\Delta R'_{p2} = \Delta R_{p2} + t \left(\frac{\Delta R_{p1}}{R_{p1}} \cdot \frac{R_{p2} + \Delta R_{p2}}{R_{p1} + \Delta R_{p1}} - \frac{\Delta R_{p2}}{R_{p2}} \right) \tag{35.18}$$

The multilayer models outlined above in some way approximate the shift of the doping profile in the buried layers due to the different stopping power of the masking layer or layers and partly also the changes of the profile width. However, during ion implantation backscattering plays an important role. In result, the doping profile in a masking layer may also be influenced by a layer situated below. This holds especially in case of a light masking layer on top of a heavy substrate, and if the maximum of the doping profile is in the second layer, and compared with the projected range not too far from the interface. Based on considerations for the reflection of implanted ions at interfaces and in thin films, a simple model for the reflection at the interface between layers was developed, which is in the following outlined for a masking layer on top of a substrate. Here, the backscattered particles are described by half of a Gaussian distribution, located in the masking layer with its maximum at the interface. The reflected dose equals to a reflection coefficient times the amount of dopants passing the interface, and the projected range straggling of the reflected particles depends on an approximation of the maximum depth of the implantation profile in the masking material, the mask thickness, the implantation energy, and the mean particle energy at the interface. Good agreement with Monte Carlo simulations has been reported even for extreme combinations of implanted ions such as implantation of Li into a stack of silicon on gold [23].

Another effect which is at the edge of the possibilities of an analytical multilayer model is the treatment of channeling. As mentioned above, for implantation into a single semi-infinite layer, the double Pearson approach outlined above yields a good description. In principle, this can be extended by simply applying one of the multilayer models outlined

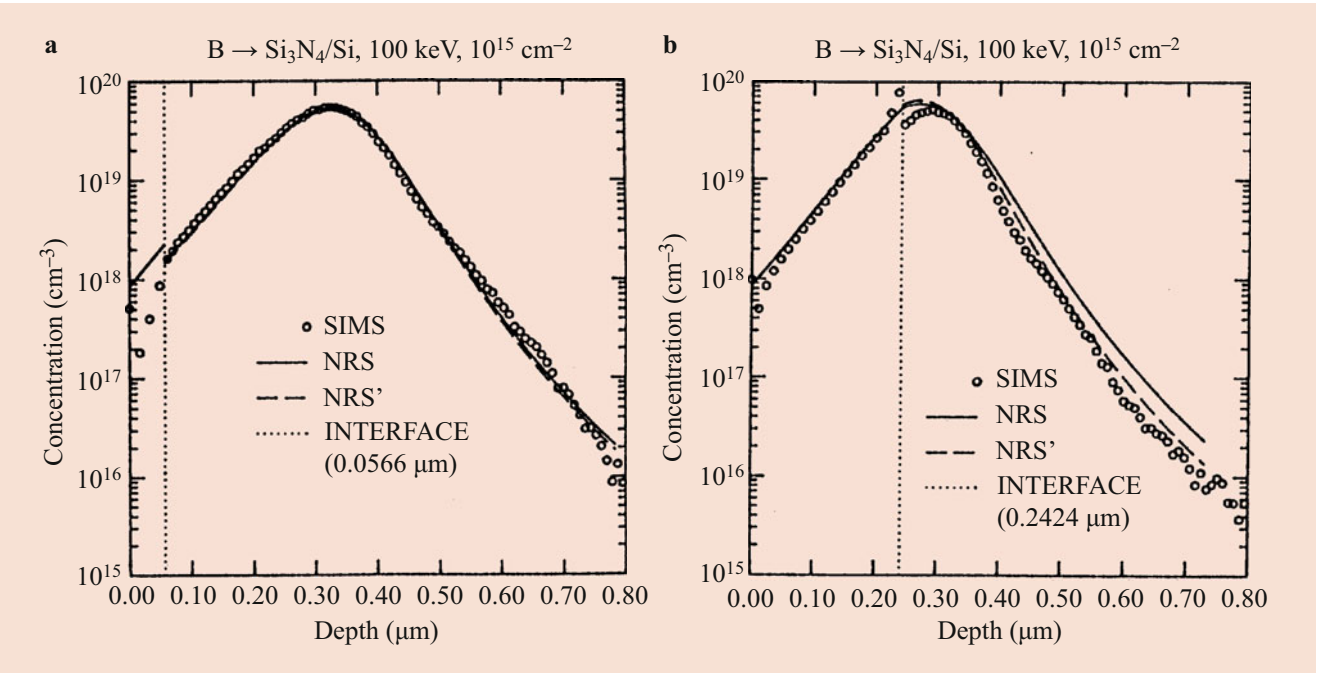

Fig. 35.2 Comparison of the analytical multilayer models NRS and NRS' with SIMS measurements for the implantation of boron at an energy of 100 keV and a dose of 10^{15} cm^{-2} through a Si_3N_4 layer of (**a**) 0.0566 μm; (**b**) 0.2424 μm thickness into silicon [20]

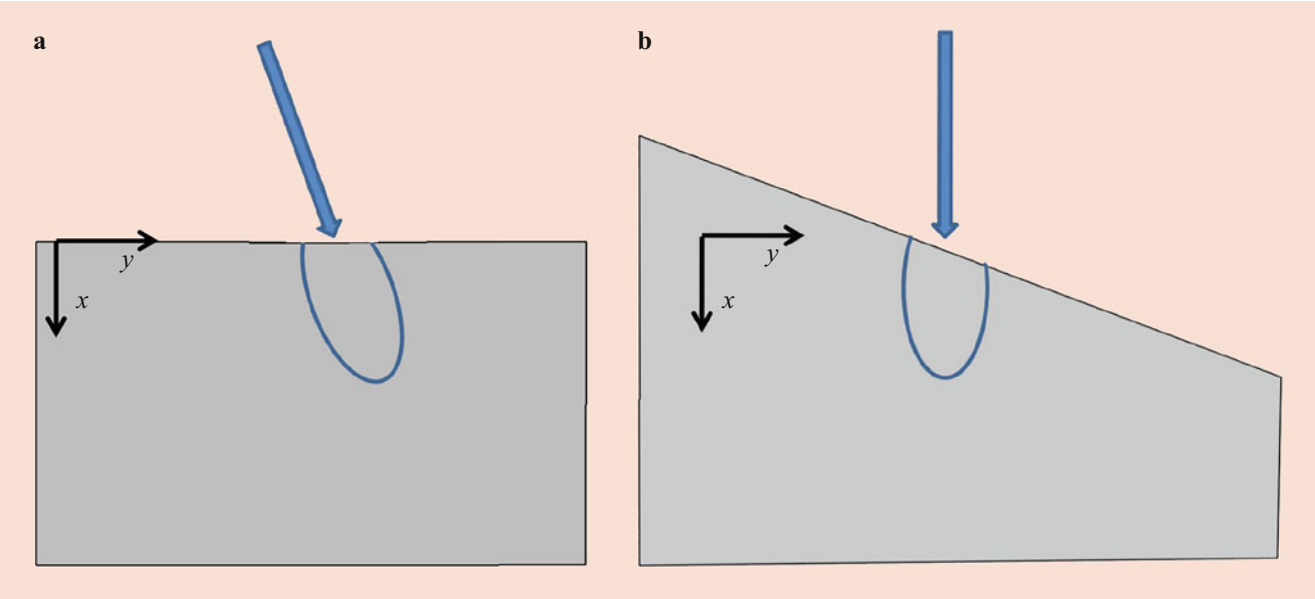

Fig. 35.3 Basic two-dimensional sketch for point response function for titled ion implantation. (**a**) Tilted implantation in standard coordinate system; (**b**) equivalent situation of vertical implantation into tilted wafer

above to both the crystalline and the amorphous Pearson distribution. However, already for the Numerical Range Scaling model explained above, a reasonable agreement with SIMS measurements was reported, and the benefit of applying the double Pearson approach together with NRS was rather limited [22].

In conclusion, in many cases Pearson distributions combined with the Numerical Range Scaling model (NRS) or better the Improved Numerical Range Scaling model (NRS') yield good approximations for one-dimensional dopant profiles. This depends of course on the quality of the range parameters, which must be provided upfront from other sources, as outlined below. The NRS model is also partly being used in commercial process simulation programs [11], however without the modification of the projected range straggling included in the NRS' model. The importance of the use of appropriate model parameters (range moments) is among others highlighted by the availability of different data sets, linking to earlier simulation programs, in current tools. Further refinements of one-dimensional analytical models for ion implantation appeared not to be very useful, due to the growing complexity of description and the need to provide additional parameters which would be difficult to obtain. This would diminish the advantages of analytical implantation models and can be considered as reason why the state-of-the-art in one-dimensional implantation models is about stable since many years.

Multidimensional Implantation Models

The basic approach in all multidimensional implantation models is that first a point response function $g(\boldsymbol{\eta}, \boldsymbol{\zeta})$ is calculated which describes for each point $\boldsymbol{\eta}$ in two or three dimensions the normalized distribution of the ions implanted just at one point $\boldsymbol{\zeta}$ of the wafer surface. Here, it is necessary to take into considerations that the implantation is usually tilted (by about 7°) compared with the wafer normal and rotated out of a two-dimensional simulation plain. This is equivalent to tilting and rotating the wafer geometry by the opposite angles and then considering vertical implantation into this modified structure; see Fig. 35.3. Therefore, in the following "vertical" means in direction of the implantation beam, and "lateral" means perpendicular to the implantation beam.

The two- or three-dimensional dopant distribution then results from the integration across all incident ions beams and multiplication with the implanted dose N_D:

$$C(\boldsymbol{\eta}) = N_\mathrm{D} \cdot \int g(\boldsymbol{\eta}, \boldsymbol{\zeta}) \, \mathrm{d}\boldsymbol{\zeta} \tag{35.19}$$

The main topic for multidimensional implantation models is then how to get the point response functions g. The methods range from simplistic analytical assumptions to extracting the point response functions from Monte Carlo simulations; see the corresponding subsection below. Similar to the one-dimensional (vertical) distribution described above, also g must be normalized to unity when integrating across the full two- or three-dimensional space.

The first model published dealt with the implantation through an ideal mask window, where vertical mask edges are situated at $-a$ and a. Strictly speaking the mask should

be infinitely thin (to avoid scattering of ions out of the mask into the mask window), but nevertheless the mask should completely stop ions implanted into the mask. Gaussian shapes of the point response function both in vertical and lateral direction (x and y) were assumed. For implantation at a point (0,y'), this reads

$$g(x,y) = \frac{N_\mathrm{D}}{\sqrt{2\pi}\,\Delta R_\mathrm{p}} \exp\left(-\frac{(x-R_\mathrm{p})^2}{2\Delta R_\mathrm{p}^2}\right) \cdot \frac{1}{\sqrt{2\pi}\,\Delta R_\mathrm{pl}} \exp\left(-\frac{(y-y')^2}{2\Delta R_\mathrm{pl}^2}\right) \tag{35.20}$$

and the convolution in Eq. (35.19) results in the two-dimensional dopant distribution [24].

$$\begin{aligned} C(x,y) &= \int g\left(x, y-y'\right) \mathrm{d}y' \\ &= \frac{N_\mathrm{D}}{\sqrt{2\pi}\,\Delta R_\mathrm{p}} \exp\left(-\frac{(x-R_\mathrm{p})^2}{2\,\Delta R_\mathrm{p}^2}\right) \cdot \\ &\quad \frac{1}{2}\left[\mathrm{erfc}\left(\frac{y-a}{\sqrt{2}\Delta R_\mathrm{pl}}\right) - \mathrm{erfc}\left(\frac{y+a}{\sqrt{2}\Delta R_\mathrm{pl}}\right)\right] \end{aligned} \tag{35.21}$$

where erfc is the complementary error function. Approaches like Eq. (35.21) are appropriate in case of device simulation studies which start from analytical dopant profiles. For different mask windows, simply the integration limits need to be changed accordingly. The simplest assumption for implanted and then annealed dopant profiles is to replace the standard deviations ΔR_p and ΔR_pl by

$$\sqrt{\Delta R_\mathrm{p}^2 + 2Dt} \text{ and } \sqrt{\Delta R_\mathrm{pl}^2 + 2Dt} \tag{35.22}$$

respectively, because after this replacement, both the point response function of Eq. (35.20) and in turn the dopant profile in Eq. (35.21) satisfy the linear diffusion equation valid for intrinsic diffusion:

$$\frac{\partial C}{\partial t} = D\Delta C \tag{35.23}$$

It should be kept in mind that both Gaussian point response functions for ion implantation and linear diffusion are very crude assumptions. However, assuming Gaussian implantation profiles also in lateral direction, without carrying out the convolution which leads to the complementary error functions erfc in Eq. (35.21), would lead to unphysical results and must be strictly avoided also as input for device simulation.

Two aspects are essential for the generalization of the point response function approach given in Eq. (35.19): First, $g(\boldsymbol{\eta}, \boldsymbol{\zeta})$ depends for each entry point $\boldsymbol{\zeta}$ on the local material and on the masking layers on top. Second, it is unphysical to assume that the lateral profile shape, e.g., for the implantation at just one point of the wafer surface, stays constant, independent of the depth: Heavy ions like arsenic are scattered less than light ions such as boron. In result the doping profile somewhat broadens with depth for heavy ions like arsenic, whereas it gets narrower for boron which has a higher likelihood to be backscattered toward the wafer surface. For easier presentation, in the following the two-dimensional case is discussed, whereas the extension to three dimensions is obvious. These effects can be considered by assuming a convolution between a vertical multilayer profile $f(x,y')$ as discussed in the preceding subsection and a lateral profile $g(x',y–y')$ which depends on the depth x':

$$C(x,y) = \int f\left(x,y'\right) g\left(x', y-y'\right) \mathrm{d}y' \tag{35.24}$$

Since the vertical distribution $f(x,y')$ is calculated at the lateral coordinate y', the masking effects of the layers through which the ion has passed is taken into consideration. For the lateral distribution $g(x',y–y')$, depending on the range parameters in question, a symmetric Pearson distribution should be used [25]. The vertical coordinate x' can either be equal to x, as in the original publication, or be equal to the entry point into the target for the lateral coordinate y', which is more complicated to implement. The usage of mixed models $X^i\,Y^j$ according to Eq. (35.8) allows to well describe the depth dependence of the lateral projected range [26] and the lateral kurtosis [27]. In the latter paper, a mix of a parabolic and an exponential approach was given for the depth dependence of the square of the lateral range straggling, whereas an exponential approach was presented for the depth dependence of the lateral kurtosis, in both cases depending on the vertical, the lateral, and the mixed range moments introduced in Eqs. (35.2), (35.3), (35.4), (35.5), (35.6), (35.7), and (35.8). Figure 35.4 shows as an example the comparison of the analytical model with Monte Carlo simulations, assuming depth-independent lateral profiles, depth-dependent lateral straggling, and depth-dependent lateral straggling and lateral kurtosis, respectively. In this latter case, the analytical model and the Monte Carlo simulations agree within the statistical error of the Monte Carlo results.

Model Parameters for Analytical Models

As mentioned above, analytical models need suitable vertical, lateral, and partly also mixed range moments. These must be provided upfront as tables depending on the combination of ion and target material, implantation energy, and potentially dose. For the latter two, a suitable number of

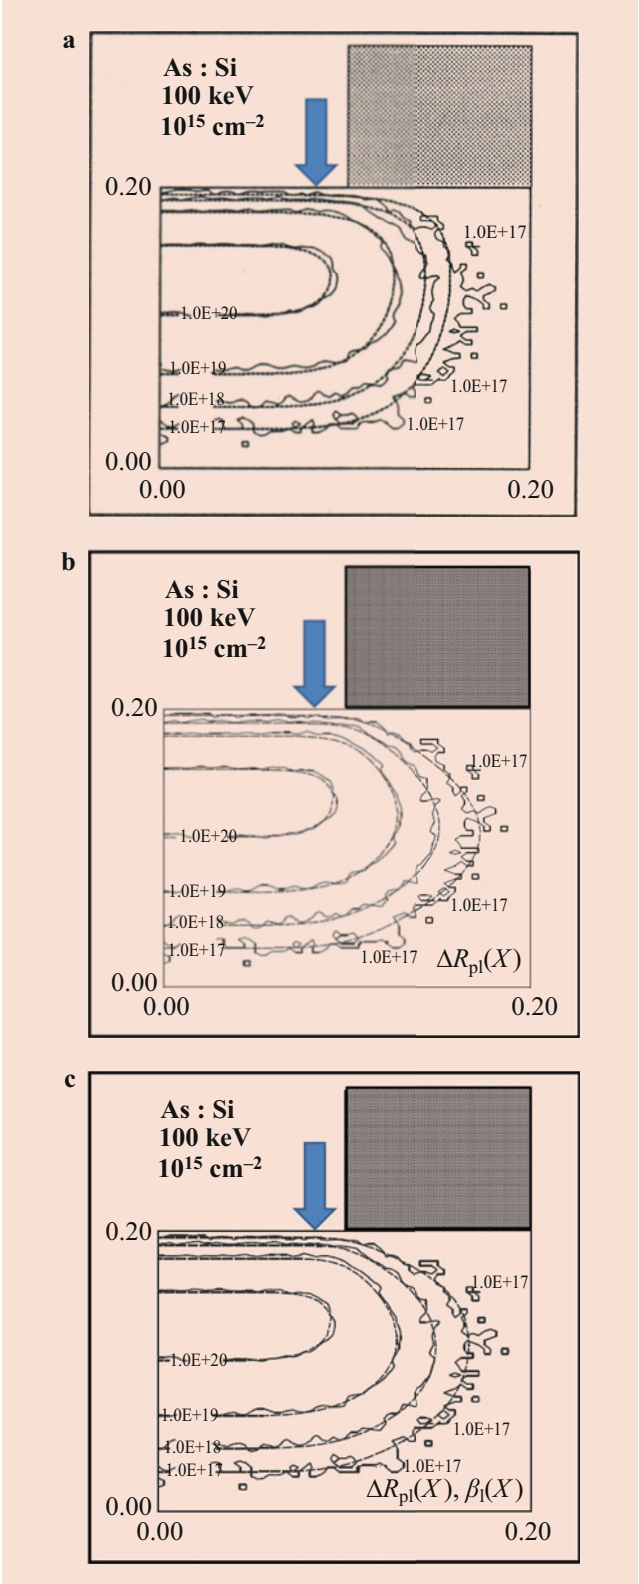

Fig. 35.4 Comparison between analytical model (broken lines) and Monte Carlo simulation of implantation of arsenic at an energy of 100 keV and a dose of 10^{15} cm^{-2} near an ideal mask edge. Equiconcentration lines of 10^{20} cm^{-3}, 10^{19} cm^{-3}, 10^{18} cm^{-3}, and 10^{17} cm^{-3} shown. (**a**) Standard model with ΔR_{pl} and β_{l} independent of depth x; (**b**) ΔR_{pl} depending on x; (**c**) ΔR_{pl} and β_{l} depending on x, leading to better agreement for low concentrations

discrete values is used. Whereas state-of-the-art characterization techniques such as SIMS enable the accurate measurement of vertical range profiles and, in turn, the extraction of appropriate vertical range moments, the possibilities for extraction of lateral and especially of mixed range moments from experiment are limited, and the experimental effort becomes excessive. Alternatively, for amorphous targets, all these range moments may be efficiently and accurately extracted from Boltzmann transport calculations, where this equation is not solved directly but its moments are calculated including their dependence on the implantation energy, starting from an infinitesimally small value. This approach was used in the RAMM code [14]. The range moments both for amorphous and for crystalline targets can also be extracted from two-dimensional Monte Carlo simulations, as described below. Here, a sufficient number of particle trajectories must be traced to yield sufficient accuracy of the moments while keeping computation time per implantation energy acceptable for the extraction of tables with various ion/target combinations and implantation energies. Both for the use of Boltzmann transport and Monte Carlo simulations, the use of appropriate physical models for electronic stopping and nuclear scattering, as outlined below, is mandatory. It was demonstrated in the literature [28] that for amorphous targets (vertical), range moments extracted from Boltzmann transport calculations with RAMM and from Monte Carlo simulations using the well-known TRIM code [29] agree well with experimental values obtained by SIMS measurements.

Analytical Models for Intrinsic Point Defects

Because subsequent annealing steps are critically influenced by the distribution of intrinsic point defects (especially vacancies and interstitials of crystal atoms), including those generated during ion implantation, there is a need to also include them in the analytical models for ion implantation. The problem is, however, that the capabilities to measure the distributions of intrinsic point defects are by far not sufficient to extract range moments. In turn, either very simple models are used for point defects or the required parameters have to be extracted from Monte Carlo simulations, as described below. It is also essential to take into account that point defects diffuse very fast and neighboring vacancies and interstitial atoms may partly recombine already during the implantation itself. In turn, in the "+1 model" as the simplest approach, it is assumed that one interstitial and no vacancies are generated per (and at the same position as the) ion implanted.

An established model which is also used in commercial simulators [11] was published already in 1988 [30]. Here, no difference is made between vacancies and interstitials. For the implantation of light ions such as boron and phosphorus, an exponential and a Gaussian function are joined at a position x_0 (naming of variables adapted from [30]), with the

parameters adjusted to assure continuity of the distribution and of its derivative at x_0:

$$(x) = \begin{cases} C_1 \cdot \exp\left(\frac{x}{a_1}\right), x \le x_0 \\ C_2 \cdot \exp\left[-\frac{(x-a_2)^2}{2 \cdot a_3{}^2}\right], x > x_0 \end{cases} \tag{35.25}$$

For heavy ions such as arsenic or antimony, the exponential and the Gaussian distribution are interchanged. The parameters C_1 and C_2 depend on a_1, a_2, a_3, the implantation dose, and the number of point defects generated per ion. In the literature the parameters a_1, a_2, and a_3 were extracted from Monte Carlo simulations, resulting in good agreement between the analytical defect profile and Monte Carlo simulations for the examples presented there. In addition, the lateral defect profile from Monte Carlo simulation could be fitted well with a Gaussian distribution.

For a further brief description of the assumptions used as initial condition for the simulation of post-implantation annealing, see Sect. 35.3.6.

35.2.2 Monte Carlo Simulation

For the Monte Carlo simulation of ion implantation, a large number of ion trajectories is traced until the implanted ions have been stopped, which means that their energy has been reduced to a negligible value. In case of relatively high doses and large structures (e.g., 100 nm scale, as shown in Fig. 35.4), the number of ion trajectories calculated is orders of magnitude smaller that the number of the particles implanted in reality. In consequence, in the simulations pseudo-particles are considered, which have the same properties as the real particles but each represent a large number of them.

The ion trajectories are governed by the energy transfer to the electron gas in the target, which is modeled by the so-called electronic stopping S_e and by the scattering at the (shielded) charges of the crystal lattice, the so-called nuclear scattering S_n:

$$S_{n,e} = -\frac{1}{N}\left(\frac{dE}{dx}\right)_{n,e} \tag{35.26}$$

The first general assumption made is the so-called binary collision approximation, in which only two-body problems are considered, where the impinging ion is at a time only scattered by the potential of one target atom. Because the masses of the implanted ions and of the target atoms are comparable (none of these can be neglected compared with the other), the scattering process is usually calculated not in the laboratory system but in the center-of-mass system. The relationship between implantation energy, masses, and scattering angles in both the laboratory system and the center-of-mass system is given in standard textbooks on mechanics or in standard literature on implantation [31]. First, the reduced mass m_c and the energy E_c of the projectile in the center-of-mass system have to be calculated from its mass m_1, energy E_0, and velocity v_0 in the laboratory system and the mass m_2 of the target atom:

$$m_c = \frac{m_1 \cdot m_2}{m_1 + m_2}; E_c = \frac{1}{2} m_c \cdot {v_0}^2 \tag{35.27}$$

The final results for the scattering angle in the center-of-mass system, Θ, the scattering angle in the laboratory system, ϑ; and energy transfer from the implanted ion to the target ion in the laboratory system are given by

$$\theta = \pi - 2\int_{r_{min}}^{\infty} \frac{p\,dr}{r^2 \cdot \sqrt{1 - \frac{V(r)}{E_c} - \frac{p^2}{r^2}}} \tag{35.28}$$

$$\tan\vartheta = \frac{m_2 \sin\Theta}{m_1 + m_2 \cos\Theta} \tag{35.29}$$

$$T = \frac{4\, m_1 m_2}{(m_1 + m_2)^2} E_0 \sin^2\left(\frac{\Theta}{2}\right) \tag{35.30}$$

Here, r is the distance between implanted ion and target atom during scattering, r_{min} its minimum value, for which the denominator in Eq. (35.28) equals zero. p is the impact parameter: the minimum distance between the implanted ion and the target in case the ion would not be scattered.

Physical Models

Besides the mechanical problem summarized above, physical models are needed for both the electronic stopping S_e and the nuclear scattering S_n. Because these should be applicable for arbitrary combinations of ions and targets, it is advisable to develop universal models which hold for all combinations. This is generally done by introducing an interatomic screening function $\phi(r)$ [31]:

$$\phi(r) = \frac{V(r)}{Z_1 Z_2 e^2 / r} \tag{35.31}$$

where the numerator is the actual shielded coulomb potential of the target ion and the denominator is the unshielded potential of the implanted ion with charge $Z_1\, e$ and the target atom with charge $Z_2\, e$. As discussed in literature [31], the so-called universal screening potential ϕ_U yields good interatomic potentials, with the Bohr radius a_0 of about 0.529 Å as the length scale:

$$\phi_U = 0.1818\, e^{-3.2x} + 0.5099\, e^{-0.9423x} + 0.2802\, e^{-0.4029x} + 0.02817\, e^{-0.2016x} \tag{35.32}$$

$$x = \frac{r}{a_u} \quad a_u = \frac{0.8854\, a_0}{Z_1^{2/3} + Z_2^{2/3}} \tag{35.33}$$

For the electronic stopping S_e, no universal equation is available. Calculation starts from a fit of the stopping power for protons and includes several scaling and correction steps [31].

Implementation

Current Monte Carlo (MC) simulation programs for ion implantation can be categorized according to the way the target is treated, either as amorphous or crystalline, and whether modifications of the target during implantation are considered or not. Furthermore, several approaches are available to speed up Monte Carlo simulations. Well-known historical examples for MC codes are the amorphous Monte Carlo code TRIM [29] and the crystalline Monte Carlo code MARLOWE [32]. Current MC codes are numerous, including implementations provided by software houses.

Amorphous Monte Carlo simulation: In the simplest case, the target is treated as amorphous, and the effect of modifications during the implantation process on the particle trajectories is neglected. In this case, the true positions of the target atoms are not considered. Employing the binary collision approximation mentioned above, a straight ion trajectory is assumed between the individual scattering effects, which are separated by an assumed mean free path length L. Because most scattering processes occur at impact parameters p which are that large that the scattering angles ϑ (and the transferred energy T) can be neglected, for L a value significantly larger than the interatomic spacing of the (neglected) crystal lattice can be chosen. In parallel, the maximum impact parameter p_{max} to be considered is limited. For consistent simulation, the cylinder with p_{max} as radius and L as length must contain one target atom:

$$\pi \cdot p_{max}^2 \cdot L = \frac{1}{N} \tag{35.34}$$

where N is the density of target atoms. Besides that Eq. (35.34) must be fulfilled, the choice of L and p_{max} depends on the Monte Carlo simulator in question. The actual value of p^2 is then selected at random between 0 (head-on collision with scattering angle 180°) and ${p_{max}}^2$. The scattering angle ϑ and the energy loss T of the ion in the laboratory system are calculated according to Eqs. (35.27), (35.28), (35.29), (35.30), (35.31), (35.32), and (35.33). Between the individual scattering events, the ion energy is reduced by integration of the electronic stopping S_e along the straight path between the scattering events. An approximation for the number of point defects generated is frequently made based on the Kinchin-Pease formula [33, 30], according to which this number is proportional to the ratio of the transferred energy T (or a fraction of this) and the energy needed to generate a Frenkel pair (crystal atom leaving its site and generating a pair of vacancy and interstitial).

Whereas the analytical simulation of ion implantation is in general computationally less expensive, the use of amorphous Monte Carlo simulations is advisable if no suitable range parameters are available, or especially if implanted ions cross interfaces between different layers (including free space) beyond the limitations of the multilayer or multidimensional analytical models summarized above. A common situation where this applies is ion implantation into the neighborhood of a trench. In this case, a significant fraction of the implanted ions is scattered out of the material and into the trench, causing doping of the opposite sidewall of the trench. An example is given in Fig. 35.5.

Crystalline Monte Carlo simulation: The inclusion of the crystal structure increases the program complexity and the computational effort. In essence, based on the current position and direction of flight of the ion, the next neighboring crystal atom is located, or the next few neighboring crystal atoms are identified. In the first case, the binary collision approximation can be used directly, calculating the impact parameter p and subsequently the transferred energy T and the scattering angle ϑ. In the second case in principle, the scattering of an ion in the superposition of two or more screened potentials ϕ_i would need to be calculated, for which in general no analytical formula is available. In turn, this problem is approximated by applying the binary collision approximation separately to each of the scattering processes identified. The details how to extract the final energy transfer T and the scattering angle ϑ for these individual scattering events depend on the simulation code in question. Random parameters are mainly the impact parameter of the first collision of the incident ion with a crystal atom and partly thermal vibrations of the target atoms.

The benefit of the crystalline Monte Carlo simulation, beyond the amorphous Monte Carlo simulation outlined above, is its capability to simulate channeling. For standard implantation into crystalline silicon, where tilt and rotation angles are selected to minimize residual channeling, also analytical models can provide appropriate distributions of implanted ions, provided the models summarized at the beginning of this section are used with suitable range parameters for the combination of implanted ion and crystalline target in question. Such range parameters can be extracted from point response functions obtained from crystalline Monte Carlo

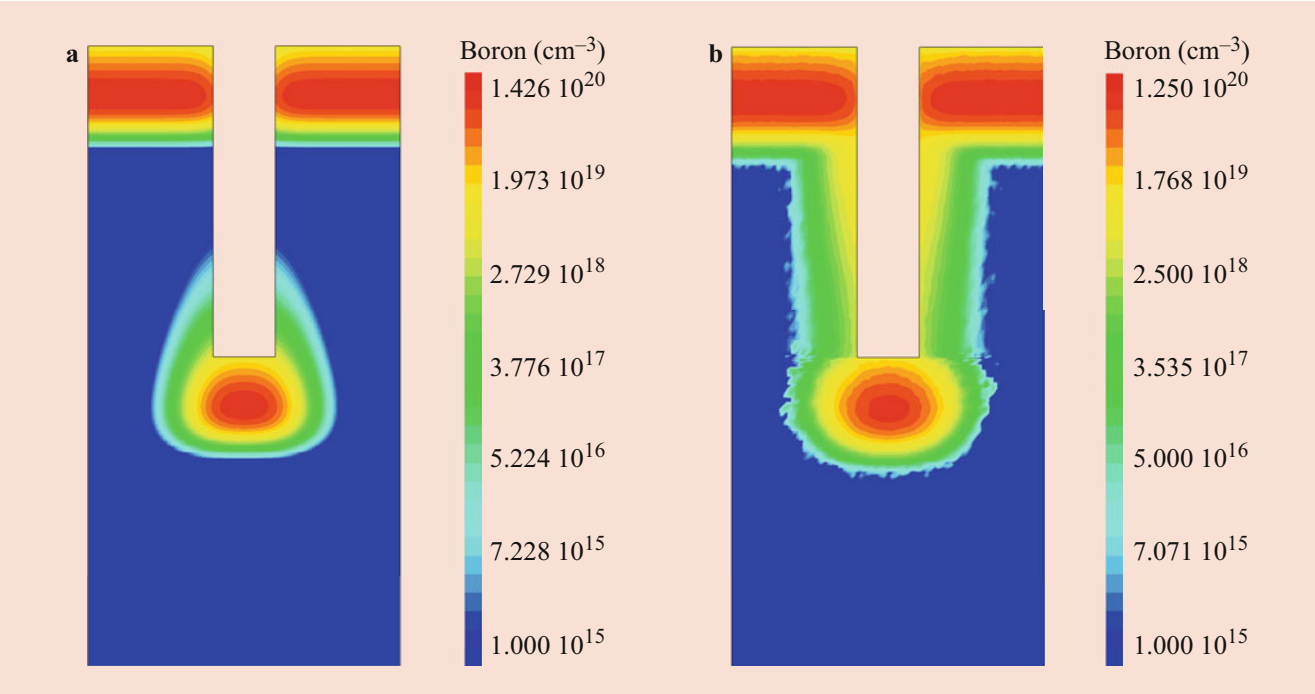

Fig. 35.5 Simulation of implantation of boron at an energy of 20 keV and a dose of 10^{15} cm^{-2} into amorphous silicon with a trench. (**a**) Analytical simulation; (**b**) amorphous Monte Carlo simulation. The doping of the sidewall for the trench cannot be described with analytical methods

simulations or partly from measurements of dopant profiles. On the other hand, advanced materials such as SiC partly show pronounced channeling effects which moreover depend on covering layers of oxide, as illustrated in Fig. 35.6 [34]. The doping spikes occurring here cannot be reasonably described by analytical models.

Dynamic Monte Carlo simulation: The next extension is the inclusion of target modifications which occur when the implanted ion kicks a crystal atom (or an ion implanted before) from its current position. This may even generate cascades of secondary particles. Here, an atom leaves its position in case the energy T transferred to it exceeds a critical value. In consequence, the trajectory of this knock-on particle must be simulated with the same approach as the trajectory of the implanted ion. This increases both the amount of data to be stored and the computational effort. The benefit is that dynamic effects like target modification (e.g., sputtering and amorphization) and the dose dependence of channeling are as well included in the simulations as the extraction of the distributions of the vacancies and interstitials generated.

Statistics: Generally, Monte Carlo simulations require the calculation of a large number of ion trajectories, depending on the dimensionality of the problem and on the size of the simulation domain. For example, for the three-dimensional simulation of source-drain implantation about 100,000 ion trajectories should be calculated to achieve a "smooth" doping profile without artificial fluctuations, resulting in computation times of minutes to hours on a standard PC, depending on ion mass and energy. This situation changes if the simulation domain and the implantation dose are small enough to allow the simulation of the trajectory of each implanted ion: Here, the fluctuations are physically meaningful and part of the results required.

The statistics of Monte Carlo simulations can easily be improved in either of two ways: The first approach is to just calculate a point response function for one surface point and then to copy this on a suitable mesh of surface points, rather similar to the calculation and use of analytical point response functions [35]. Second, in the trajectory split approach [36], the pseudo-particles are split into two or more particles as soon as they enter areas with low concentration of implanted species. The pseudo-particles resulting from these split then represent an accordingly smaller number of real particles and are in turn considered with a lower statistical weight. Their further trajectories are then calculated using random numbers which are independent between these trajectories. This splitting procedure may be repeated several times for decreasing concentrations of the implanted ions. In consequence, additional calculations are only carried out for the relatively rare parts of the trajectories which are situated in low-concentration areas.

Monte Carlo simulation can also be applied to describe novel processes such as plasma doping (PLAD) (also named plasma immersion ion implantation), where charged ions are extracted from a plasma, in order to generate shallow doping profiles with high ion currents. Besides source-drain profiles,

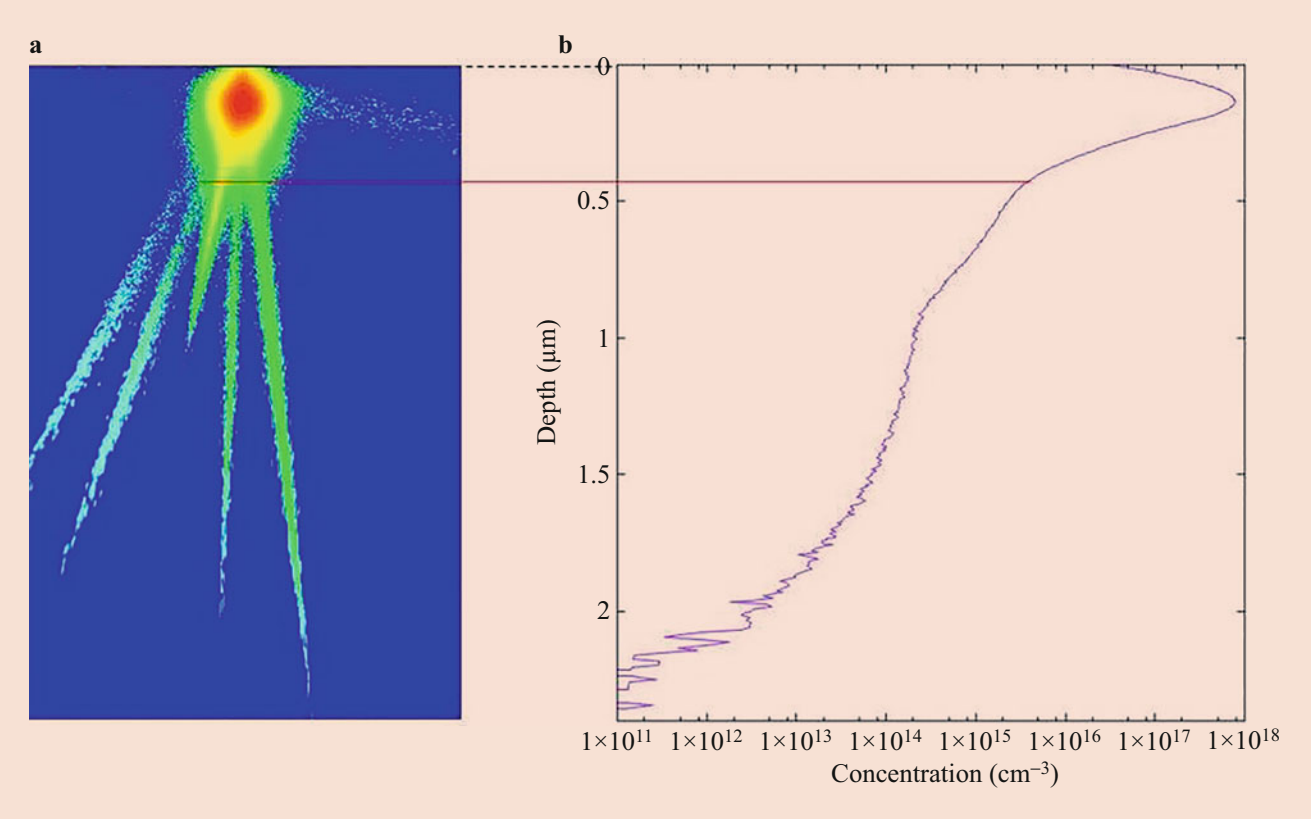

Fig. 35.6 Monte-Carlo simulation of implantation of aluminum at an energy of 140 keV and a dose of 10^{13} cm^{-2} into 4H SiC covered with a 30 nm thick oxide layer: (**a**) 2D point response function and (**b**) 1D vertical profile [34]

PLAD can also be used to generate surface-conformal doping of trenches or FinFETs. For the simulation of PLAD, the energetic distribution of ions can be extracted from physical considerations on the plasma sheath [37] and finally be approximated by analytical expressions, as, e.g., in [38]. This distribution can then be fed into Monte Carlo simulators as described above, which are then used to calculate the spatial distribution of the implanted ions.

35.3 Simulation of Diffusion and Activation

During any process steps at elevated temperatures, the thermally induced movement of dopant atoms and other impurities may lead to a noticeable broadening of their distribution as well as to quasi-chemical reactions with other atoms of the same or other impurity species or with intrinsic point defects. For dopants, the latter typically manifests itself in an electrical activation which is lower than the respective total concentration. Annealing processes at elevated temperatures are used intentionally, e.g., to drive-in dopants deeply into power semiconductors or to electrically activate implanted dopants and to anneal the damage created by the ion implantation processes. However, as indicated already, diffusion and reduced electrical activation may originate from any technological process at high-enough temperatures whether during front-end or back-end processing. In the following, the most important concepts associated with diffusion phenomena in semiconductors are outlined with an emphasis on silicon. For a more comprehensive presentation, the interested reader is referred to reviews such as [5, 39, 40, 41].

35.3.1 Intrinsic Point Defects and Impurities

In crystalline semiconductor materials like silicon, germanium, or SiGe alloys, most of the atoms of which the semiconductor consists are arranged in the form of a diamond structure. In other semiconductors like SiC, the atoms may be arranged in cubic or hexagonal structures. Only few atoms may be missing from their lattice sites or can be found elsewhere. Since such defective atomic arrangements affect only their nearest neighbors, they are referred to as "point defects." Point defects comprising only atoms of which the semiconductor consists of are called "intrinsic point defects." Empty lattice sites, as shown schematically in Fig. 35.7a, are referred to as vacancies. For silicon, even close to the

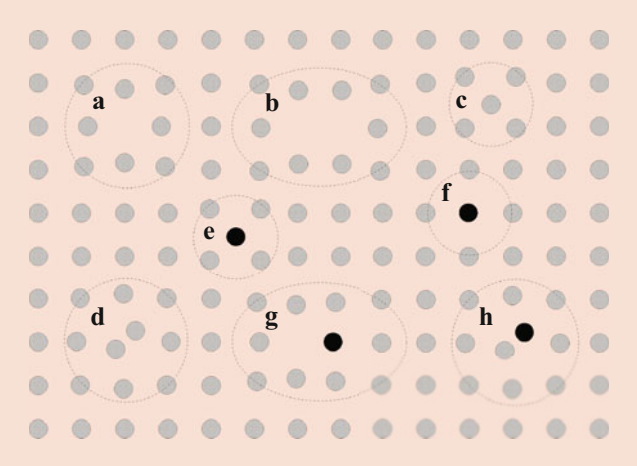

Fig. 35.7 Schematic representation of point defects in elemental semiconductors: (a) Vacancy, (b) divacancy, (c) self-interstitial, (d) interstitialcy, (e) interstitial impurity, (f) substitutional impurity, (g) impurity-vacancy pair, (h) impurity-self-interstitial pair. (after [5])

melting point, less than one out of 10^7 silicon atoms are expected to be missing. Vacancies on neighboring sites (see Fig. 35.7b) are called divacancies. The counterpart of vacancies are semiconductor atoms which either occupy as self-interstitials sites between the lattice atoms as in Fig. 35.7c or share with another semiconductor atom a lattice site as in Fig. 35.7d. Such an atomic configuration is usually referred to as interstitialcy, split-interstitial, or dumb-bell interstitial. Similar to vacancies, less than one out of 10^7 silicon atoms are expected to occupy such interstitial positions even close to the melting point.

Atoms differing from the semiconductor atoms are called impurities. Some of them like oxygen or hydrogen occupy preferentially interstitial sites as indicated in Fig. 35.7e. By far the most important impurities for the Group-IV semiconductors (Si, Ge, SiGe, SiC, etc.) are dopant atoms from the Groups III and V of the periodic system. They preferentially substitute the lattice atoms as shown schematically in Fig. 35.7f. Dopants from Group III require an additional electron to satisfy the four valence bonds to the neighboring silicon atoms which leads to the formation of a hole in the valence band. Based on their ability to "accept" an electron, the Group III atoms are referred to as "acceptors." Substitutional Group V atoms, on the other hand, have one electron too many and can donate it to the conduction band. Accordingly, they are referred to as "donors." In addition to occupying interstitial and substitutional sites, impurities may be found in pairs with vacancies as in Fig. 35.7f or with silicon atoms sharing a regular lattice site as in Fig. 35.7h.

Vacancies can be thought to result from taking one of the lattice atoms from its site and dragging it to a kink at the surface of the semiconductor. Similarly, the intrinsic interstitial defects can be thought to result from dragging semiconductor atoms from a kink at the surface to the respective site. In addition, both can be created as pairs by dragging a lattice atom to an interstitial position and vice versa annihilated by dragging an interstitial atom to a vacancy. The latter processes are usually referred to as bulk generation and recombination of intrinsic point defects.

The probability to find intrinsic point defects in a specific metastable atomic configuration reflects the respective free energy of formation $G^{\mathrm{f}}_{\mathrm{X}}$. Accordingly, it is not "either-or" but rather "as well as" to find intrinsic point defects in the one or the other configuration. Because of that, it makes hardly sense to discern self-interstitials and interstitialcies, and all such configurations will be referred to as self-interstitials in the following. Besides the point-like configurations, vacancies and self-interstitials were assumed to exist in an extended state, i.e., that one atom in an overall tetrahedrally coordinated region comprising some 10–20 silicon atoms is missing or too much. In the most recent work of Voronkov and Falster [42], as an example, vacancies in three different configurations are postulated to coexist to explain a multitude of seemingly contradictory phenomena.

For the impurity complexes, the situation depends on how the impurities are introduced. For impurities in a closed system, the relative concentrations of the particular atomic configurations need to sum up to the total concentration. For systems in which dopants can enter from a reservoir, their formation energy in the semiconductor will determine the solubility concentration of the impurity in the semiconductor; see Sect. 35.3.8.

Given the concentration of possible sites C_{XS} at which a specific defect can be realized and the number Θ_{X} of internal degrees of freedom of the defect at a specific site, the concentration of a defect X in steady state is given by

$$C^{\mathrm{eq}}_{\mathrm{X}} = \Theta_{\mathrm{X}}\, C_{\mathrm{XS}} \exp\left(-\frac{G^{\mathrm{f}}_{\mathrm{X}}}{kT}\right) \tag{35.35}$$

with k standing for Boltzmann's constant and T for the absolute temperature. For charged defects, G^{f} will depend on the Fermi level. Deviations of the Fermi level can be expected for dopant concentrations which exceed significantly the charge carrier concentration n_{i} which would be found under intrinsic conditions, i.e., without dopants. Assuming Boltzmann statistics to be a valid approximation at elevated temperatures, the concentration of a defect in a particular charge state can be expressed in terms of the concentration C_{X^0} of the neutral charge state and the electron concentration n as.

$$\begin{aligned} C_{\mathrm{X}^-} &= C_{\mathrm{X}^0}\delta_{\mathrm{X}^-}\left(\frac{n}{n_{\mathrm{i}}}\right) & C_{\mathrm{X}^=} &= C_{\mathrm{X}^0}\delta_{\mathrm{X}^=}\left(\frac{n}{n_{\mathrm{i}}}\right)^2 \\ C_{\mathrm{X}^+} &= C_{\mathrm{X}^0}\delta_{\mathrm{X}^+}\left(\frac{n_{\mathrm{i}}}{n}\right) & C_{\mathrm{X}^{++}} &= C_{\mathrm{X}^0}\delta_{\mathrm{X}^{++}}\left(\frac{n_{\mathrm{i}}}{n}\right)^2 \end{aligned} \tag{35.36}$$

Therein, the charge states have been indicated by $-$, $=$, 0, $+$, and $++$ for singly negative, double negative, neutral,

positive, and doubly positive. The respective δ_X denote the relative concentration under intrinsic conditions.

35.3.2 Basic Diffusion and Reaction Mechanisms

Simple point defects diffuse by jumping from one energetically favorable site to a neighboring one. In case of simple interstitial impurities as depicted schematically in Fig. 35.7e or h, it is the migrating atom itself which performs the jumps. For the self-interstitial configurations in Fig. 35.7c, d, it could also be always the same silicon atom that moves from site to site. However, it could also be that a self-interstitial assumes the site of a neighboring lattice atom and displaces it to the interstitial site. Finally, the vacancies shown in Fig. 35.7a move when a neighboring semiconductor atom jumps into the vacant lattice site. As long as such point defects do not interact and as long as no forces like electric fields have to be considered, the evolution of their concentration can be described by Fick's laws. Fick's first law

$$J_X = -D_X \operatorname{grad} C_X \tag{35.37}$$

establishes a purely phenomenological definition of the diffusion coefficient D_X of a defect X as a proportionality constant between the net number of defects passing a unit area per time, the diffusion flux J_X, and the gradient of the defect concentration C_X. Fick's second law

$$\frac{\partial C_X}{\partial t} = \operatorname{div}(-J_X) = \operatorname{div}(D_X \operatorname{grad} C_X) \tag{35.38}$$

is a combination of Fick's first law with a continuity equation and constitutes a diffusion equation that can be used to calculate the change in concentration due to diffusion as a function of time t. The concept of a concentration and a gradient obviously requires a certain number of defects per unit volume considered. A complementary view can be obtained by observing the movement of a single defect through the crystal. Given the projection of the mean jump distance L between two stable configurations on one of the axes of the coordinate system, the mean square displacement of the defect from its origin

$$\langle D_N{}^2 \rangle = NL^2 \tag{35.39}$$

increases linearly with the number N of its jumps. As shown by Einstein more than a century ago, the mean square displacement can be used as an atomistic definition of the diffusion coefficient D in (35.37) and (35.38) in the form

$$D = \frac{\langle D_N{}^2 \rangle}{2t} = \Gamma \frac{L^2}{2} \tag{35.40}$$

with $\Gamma = N/t$ standing for the number of jumps per time. In general, the diffusion coefficient is a tensor. However, for diamond structures like silicon or germanium, it reduces to a scalar. Transitions between energetically favorable positions require that an energetically less favorable saddle point is assumed and overcome. Diffusive jumps usually require the motion of more atoms than just the moving one. Accordingly, not only the increase in enthalpy H^m at the saddle point has to be considered but also the different entropy S^m of the system. Altogether, the jump frequency is usually expressed as

$$\Gamma = \Gamma_0 \exp\left(\frac{S^m}{k}\right) \exp\left(-\frac{H^m}{kT}\right) \tag{35.41}$$

with the attempt frequency Γ_0. Combining (35.40) and (35.41), diffusion coefficients can be written in the form of an Arrhenius law

$$D = D_0 \exp\left(-\frac{H^m}{kT}\right) \tag{35.42}$$

where the prefactor D_0 comprises all temperature-independent terms. The diffusion coefficient of interstitial oxygen in silicon, as an example, follows this relationship from cryogenic temperatures to the melting point for more than 13 decades [43]. Depending on the species, usual values for the activation energy H^m range from 0 to 5 eV for silicon. To include the effects of mechanical stress on the diffusion coefficient, its temperature dependence (35.42) is completed for hydrostatic pressures P in the form

$$D = D_{P=0} \exp\left(-\frac{P\Delta V}{kT}\right) \tag{35.43}$$

introducing the activation volume ΔV. Positive numbers for the activation volume mean retarded diffusion for compressive stress and enhanced diffusion for tensile stress and vice versa for negative activation volumes. In magnitude, activation volumes are expected to range up to the volume associated with a lattice atom. For non-hydrostatic pressures, a tensor form has to be adopted in which the hydrostatic pressure is replaced by the strain tensor and the activation volume by a strain-activation tensor.

As indicated already above, defects are expected to coexist in a variety of charge states. In case of dopant concentrations exceeding the intrinsic concentration of charge carriers n_i, an electric field will be established in the semiconductor which exerts a force on the charged defects. Accordingly, the diffusive jumps will be biased since the defects gain or lose energy when they move in the field from their energetically favored site to the saddle point. To include such effects, Fick's first law is adapted in the form

$$J_X = -D_X \operatorname{grad} C_X - z_X \mu_X C_X E \tag{35.44}$$

where the charge state z has been defined here as the number of negative charges associated with the charge state (i.e., $+1$ for a singly negatively charged defect or -2 for a doubly positively charged defect). It should be noted, however, that an association of the charge state with the number of positive charges is just as common in the literature. The mobility μ was already shown by Einstein to be related to the diffusion coefficient by

$$D/\mu = kT/q \tag{35.45}$$

with q standing for the elementary charge. Expressing the electric field as the negative gradient of the electrostatic potential ψ, (35.44) takes the familiar form

$$J_\mathrm{X} = -D_\mathrm{X} \operatorname{grad} C_\mathrm{X} + z_\mathrm{X} D_\mathrm{X} C_\mathrm{X} \operatorname{grad}\left(\frac{\psi}{U_\mathrm{T}}\right) \tag{35.46}$$

with the thermal voltage U_T introduced for kT/q.

With defects co-existing in a number of charge states, any charge state contributes to the diffusion process with a different diffusion coefficient. Adding the contributions of the individual charge states to total concentrations and fluxes, one arrives again at the diffusion Eqs. (35.38) and (35.46). The diffusion coefficients and charge states in these equations are Fermi-level-dependent mean values weighted with the relative concentration of the respective charge state. However, particularly for vacancies and self-interstitials, the experimental knowledge is far from allowing to establish such dependences, and one pragmatically uses Fermi-level-independent values.

The situation becomes more complicated in case of dopants and other impurities which preferentially reside on substitutional sites as indicated in Fig. 35.7f. In such a configuration, the respective atoms are assumed to be immobile. To diffuse, they need to come into an interstitial configuration as depicted schematically in Fig. 35.7e, h or in a configuration with a vacancy as indicated in Fig. 35.7g. Diffusion as interstitials as in Fig. 35.7e is expected particularly for transition metals like gold and platinum. For boron in silicon, as another example, diffusion as pair with self-interstitials in analogy to Fig. 35.7h was suggested by Windl et al. [44] on the basis of ab initio calculations. Other elements like antimony in silicon and most dopants in germanium are assumed to diffuse via bound pairs with vacancies as shown schematically in Fig. 35.7g. Since even multiple exchanges of sites between vacancy and dopant would not lead to an effective movement, this mechanism requires that the vacancy partially dissociates from the dopant and returns to another nearest neighboring site of the impurity. In general, dopants will diffuse via both, self-interstitials and vacancies, although one of these mechanisms may dominate. Despite the atomistically completely different mechanisms, migrating interstitial atoms and pairs with intrinsic point defects are assumed to diffuse macroscopically as entities. As such, diffusion coefficients and charge states can be assigned to them, and their movement can be described in analogy to the concepts discussed above.

With substitutional impurity atoms being assumed immobile, the mobile dopant complexes must form dynamically. For boron and self-interstitials, De Salvador et al. [45] were able to clarify experimentally the complex reaction paths to mobile pairs. However, this is a rare case and for most other pair-formation reactions, such a detailed knowledge is not available. Accordingly, pair formation is usually described in a more generic way. Such pair-diffusion models were pioneered by Yoshida et al. [46] who proposed that substitutional impurities M_s form mobile MV pairs, depicted schematically in Fig. 35.7g, with vacancies V by the quasi-chemical reaction:

$$M_\mathrm{s} + V \underset{k_{\mathrm{MV}\leftarrow}}{\overset{k_{\mathrm{MV}\rightarrow}}{\rightleftharpoons}} \mathrm{MV}. \tag{35.47}$$

The analogy for self-interstitials I is the formation of mobile MI pairs, shown schematically Fig. 35.7h, via

$$M_\mathrm{s} + I \underset{k_{\mathrm{MI}\leftarrow}}{\overset{k_{\mathrm{MI}\rightarrow}}{\rightleftharpoons}} \mathrm{MI}. \tag{35.48}$$

Within the level of description of process simulation, it is not important whether MI is a bound impurity-self-interstitial pair or an interstitial impurity M_i. Interactions of self-interstitials with dopants were probably first considered by Seeger and Chik [47] in the form of their interstitialcy mechanism. For metal interstitials, one usually refers to the kick-out mechanism suggested by Gösele et al. [48]. In addition to the pairing reactions, one needs to include the bulk-recombination reaction

$$I + V \underset{k_{\mathrm{IV}\leftarrow}}{\overset{k_{\mathrm{IV}\rightarrow}}{\rightleftharpoons}} 0 \tag{35.49}$$

of self-interstitials and vacancies to an undisturbed lattice site symbolized by the "0." For metal diffusion, instead of the formation of vacancy pairs, one needs to consider the reaction of metal impurities with vacancies

$$M_\mathrm{i} + V \rightleftharpoons M_\mathrm{s} \tag{35.50}$$

proposed first by Frank and Turnbull [49] for copper in germanium. For the diffusion of dopants in semiconductors, such a reaction, just as the counterpart of a dopant-vacancy

pair reacting with a self-interstitial

$$\mathrm{MV} + I \rightleftharpoons M_s, \tag{35.51}$$

constitutes a dopant-concentration-dependent parallel path to the recombination of self-interstitials and vacancies which also influences the concentrations of the pairs in steady state.

A quantitative description of the full system requires that the interactions between intrinsic point defects, substitutional impurities, mobile impurities and mobile complexes of impurities with intrinsic point defects, etc., are taken into account. This is usually done via the methodology of diffusion-reaction equations by writing, e.g., the interaction of species A with species B to species C in the form of the binary quasi-chemical reaction

$$A + B \underset{k_{\leftarrow}}{\overset{k_{\rightarrow}}{\rightleftharpoons}} C \tag{35.52}$$

with $k_{\rightarrow}$ and $k_{\leftarrow}$ being the forward and backward reaction constants. The reaction term

$$R = k_{\rightarrow} C_\mathrm{A} C_\mathrm{B} - k_{\leftarrow} C_\mathrm{C} \tag{35.53}$$

is common to the continuity equations of the species A to C

$$\begin{aligned} &\frac{\partial C_\mathrm{A}}{\partial t} = \operatorname{div}(-J_\mathrm{A}) - R; \quad \frac{\partial C_\mathrm{B}}{\partial t} = \operatorname{div}(-J_\mathrm{B}) - R; \\ &\frac{\partial C_\mathrm{C}}{\partial t} = \operatorname{div}(-J_\mathrm{C}) + R \end{aligned} \tag{35.54}$$

and couples them. The different signs of the reaction term in the continuity equations mean that the concentrations of A and B are reduced when A and B react, while the concentration of species C increases. In the common case of several parallel reactions, the respective reaction terms are added or subtracted in the continuity equations of the species. For immobile species like substitutional dopants, the diffusion term is simply omitted in the continuity equation. In equilibrium or stead state, the concentration of the product can be expressed as

$$\begin{aligned} C_\mathrm{C}^\mathrm{eq} &= C_\mathrm{A}^\mathrm{eq} C_\mathrm{B}^\mathrm{eq} \frac{\theta_\mathrm{C}}{\theta_\mathrm{A}\theta_\mathrm{B}} \exp\left(\frac{G_\mathrm{A}^\mathrm{f} + G_\mathrm{B}^\mathrm{f} - G_\mathrm{C}^\mathrm{f}}{kT}\right) \\ &= \frac{\theta_\mathrm{C}}{\theta_\mathrm{A}\theta_\mathrm{B}} \exp\left(\frac{G^\mathrm{B}}{kT}\right) \end{aligned} \tag{35.55}$$

in terms of the respective concentrations of the reactants, the numbers of internal degree of freedom of the defects at specific sites θ_X, and their formation energies G_X^f. As long as charge is conserved in the reaction, the binding energy G^B will be independent of the Fermi level. A particular advantage of binary reactions is that the forward reaction rates can be estimated on the basis of Waite's theory of diffusion-limited reactions [50] in the form

$$k_{\rightarrow} = 4\pi a_\mathrm{R} (D_\mathrm{A} + D_\mathrm{B}) \tag{35.56}$$

as a function of the diffusion coefficients of the reacting species and the recombination radius a_R which is usually assumed to be on the order of the bond length between two lattice atoms. For the cases that both particles are electrically charged and that reaction barriers have to be overcome, extensions are available from Debye [51] and Waite [52], respectively. To determine the backward rate, two procedures have been used in literature. The first one is based on the concept that the backward reaction constant $k_{\leftarrow}$ is basically the break-up frequency of the defect. This is very similar to (35.43) with S^m and H^m replaced by the dissociation entropy and enthalpy of the defect C. The second method uses the fact that the forward and backward reaction rates of all reactions need to cancel out in equilibrium. Accordingly, the ratio of forward and backward reaction rate can be written in terms of the equilibrium concentrations of the species

$$\frac{k_{\rightarrow}}{k_{\leftarrow}} = \frac{C_\mathrm{C}^\mathrm{eq}}{C_\mathrm{A}^\mathrm{eq} C_\mathrm{B}^\mathrm{eq}} \tag{35.57}$$

which in turn can be written via (35.55) in terms of the binding energy of the reaction.

35.3.3 Macroscopic Diffusion Behavior of Dopants

Within the methodology of diffusion-reaction equations outlined in the previous subsection, mobile complexes are postulated to form via the reactions (35.47) and (35.48). In addition, the complementary reactions of the mobile complexes with intrinsic point defects via the reactions (35.50) and (35.51) need to be taken into account. To calculate the generation rate of the mobile complexes, concurrent reactions between substitutional dopants and intrinsic point defects in all charge states have to be included. For the mobile complexes, the single negative, neutral, and single positive charge states are usually considered, and steady state between them is assumed to be established rapidly. The resulting system of coupled partial differential equations then consists of the continuity equations for the self-interstitials and vacancies as well as for each dopant in continuity equations for the substitutional dopants and the pairs with self-interstitials and vacancies. Accordingly, this type of diffusion model is commonly referred to as "five-stream model." Although already a simplification, five-stream models are able to capture fairly complex diffusion phenomena. To illustrate some of

them, useful simplifications and their areas of application are discussed below.

As indicated first by Cowern et al. [53], a dynamic description of the formation of mobile dopant species is important to understand the macroscopic diffusion behavior for short annealing times. To illustrate this, we consider a simple system in which a substitutional impurity M_s changes with a frequency $1/\tau$ into the mobile state MI. Denoting the steady-state ratio of the concentrations in the substitutional and the mobile state by α and assuming that the diffusion flux follows Fick's first law (35.37), one arrives at a coupled system of equations in the form

$$\begin{aligned} \tfrac{\partial C_{M_s}}{\partial t} &= -\tfrac{1}{\tau} C_{M_s} + \tfrac{\alpha}{\tau} C_{\mathrm{MI}}, \\ \tfrac{\partial C_{\mathrm{MI}}}{\partial t} &= \operatorname{div}\left(D_{\mathrm{MI}} \operatorname{grad} C_{\mathrm{MI}}\right) + \tfrac{1}{\tau} C_{M_s} - \tfrac{\alpha}{\tau} C_{\mathrm{MI}}. \end{aligned} \tag{35.58}$$

Assuming that all atoms are initially in a narrow layer in a depth of 0.5 µm, the total concentration $C_{\mathrm{M}} = C_{M_s} + C_{\mathrm{MI}}$ for $\alpha = 1000$ and D_{MI} chosen so that the macroscopic projected diffusion length for the time τ equals $\sqrt{2 D_{\mathrm{MI}} \tau / \alpha} = 10$ nm is shown in Fig. 35.8 (coupled system) together with a simulation in which steady state between the substitutional and interstitial species is assumed (one equation). For the latter case, the diffusion equation results for all times in the Gaussian profiles shown. The same profiles are obtained for the coupled system for long diffusion times for which substitutional and mobile impurities are in steady state. In contrast, for the shortest time, the delta-doped layer is still clearly visible, and the profile has a characteristic shape with exponentially decreasing flanks.

For sufficiently long diffusion times, the substitutional impurities will be in steady state with the respective mobile species. To calculate concentrations of the mobile complexes, as emphasized by Cowern [54], one needs to consider the pairing reactions (35.47) and (35.48) as well as the reactions of the pairs with the opposite intrinsic point defects via the reactions (35.50) and (35.51). This leads in non-equilibrium situations to a nonlinear dependence of the pair concentration on both the self-interstitial and vacancy concentrations. However, for the important case that bulk recombination maintains local equilibrium between the intrinsic point defects ($C_{\mathrm{I}} C_{\mathrm{V}} \sim C_{\mathrm{I}}^{\mathrm{eq}} C_{\mathrm{V}}^{\mathrm{eq}}$), the same pair concentrations are predicted as in the case that the reactions (35.50) and (35.51) are ignored and the pair concentrations can be calculated from (35.55). Considering the diffusion of dopants, one has to keep in mind that acceptors on substitutional sites are negatively charged and donors positively. Accordingly, the concentrations of single negative, neutral, and single positive pairs C_{MX}, with X standing either for self-interstitials I or vacancies V, will be

$$\begin{aligned} C_{\mathrm{MX}^-} &= \eta_{\mathrm{MX}^-} C_{M_s^-} \frac{C_{\mathrm{X}}}{C_X^{\mathrm{eq}}}; \; C_{M\mathrm{X}^0} = \eta_{\mathrm{MX}^0} C_{M_s^-} \frac{C_{\mathrm{X}}}{C_{\mathrm{X}}^{\mathrm{eq}}} \frac{p}{n_{\mathrm{i}}}; \\ C_{\mathrm{MX}^+} &= \eta_{\mathrm{MX}^+} C_{M_s^-} \frac{C_{\mathrm{X}}}{C_{\mathrm{X}}^{\mathrm{eq}}} \left(\frac{p}{n_{\mathrm{i}}}\right)^2 \end{aligned} \tag{35.59}$$

for acceptors and

$$\begin{aligned} C_{\mathrm{MX}^-} &= \eta_{\mathrm{MX}^-} C_{M_s^+} \frac{C_{\mathrm{X}}}{C_{\mathrm{X}}^{\mathrm{eq}}} \left(\frac{n}{n_{\mathrm{i}}}\right)^2; \; C_{\mathrm{MX}^0} = \eta_{\mathrm{MX}^0} C_{M_s^+} \frac{C_{\mathrm{X}}}{C_{\mathrm{X}}^{\mathrm{eq}}} \frac{n}{n_{\mathrm{i}}}; \\ C_{\mathrm{MX}^+} &= \eta_{\mathrm{MX}^+} C_{M_s^+} \frac{C_{\mathrm{X}}}{C_{\mathrm{X}}^{\mathrm{eq}}} \end{aligned} \tag{35.60}$$

for donors. Therein, the $\eta_{\mathrm{MX}^{-/0/+}}$ stand for the temperature-dependent relative concentrations of pairs under intrinsic conditions ($n = p = n_{\mathrm{i}}$) with the respective point defects being in equilibrium ($C_X = C_{\mathrm{X}}^{\mathrm{eq}}$).

It should be noted that all the pair concentrations are proportional to the concentration of the substitutional atoms. In systems not too far from equilibrium, the concentrations of the pairs are expected to make up only a small fraction of the total concentration. As long as the concentrations of pairs remain small in comparison to the total dopant concentration, they will increase linearly with the respective point-defect concentration. In situations far from equilibrium, the formation of pairs will lead to a reduction of the substitutional concentration and consequently to a sublinear increase of the concentration of the dominating pair with the respective point defect concentration. In the limiting case, the redistribution of the dopants atoms takes place in the form of the dominating pairs with the respective diffusion coefficient.

In many important cases, the concentrations of pairs can be safely ignored. Then, the concentration of substitutional dopant atoms C_{M_s} in (35.59) and (35.60) can be replaced by the total dopant concentration C_M. Adding the continuity equations leads to the diffusion equation

$$\begin{aligned} \tfrac{\partial C_{\mathrm{M}}}{\partial t} = \operatorname{div}\Big(& D_{\mathrm{MI}} \operatorname{grad}\left(C_{\mathrm{M}} \tfrac{C_{\mathrm{I}}}{C_{\mathrm{I}}^{\mathrm{eq}}}\right) + D_{\mathrm{MV}} \operatorname{grad}\left(C_{\mathrm{M}} \tfrac{C_{\mathrm{V}}}{C_{\mathrm{V}}^{\mathrm{eq}}}\right) \\ & - z_{\mathrm{M}} \left(D_{\mathrm{MI}} \tfrac{C_{\mathrm{I}}}{C_{\mathrm{I}}^{\mathrm{eq}}} + D_{\mathrm{MV}} \tfrac{C_{\mathrm{V}}}{C_{\mathrm{V}}^{\mathrm{eq}}}\right) C_{\mathrm{M}} \operatorname{grad}\left(\tfrac{\psi}{U_{\mathrm{T}}}\right)\Big) \end{aligned} \tag{35.61}$$

with the diffusion coefficients D_{MX} given by

$$D_{\mathrm{MX}} = \eta_{\mathrm{MX}^-} D_{\mathrm{MX}^-} + \frac{\eta_{\mathrm{MX}^0} D_{\mathrm{MX}^0} p}{n_{\mathrm{i}}} + \eta_{\mathrm{MX}^+} D_{\mathrm{MX}^+} \left(\frac{p}{n_{\mathrm{i}}}\right)^2 \tag{35.62}$$

for pairs with acceptors and

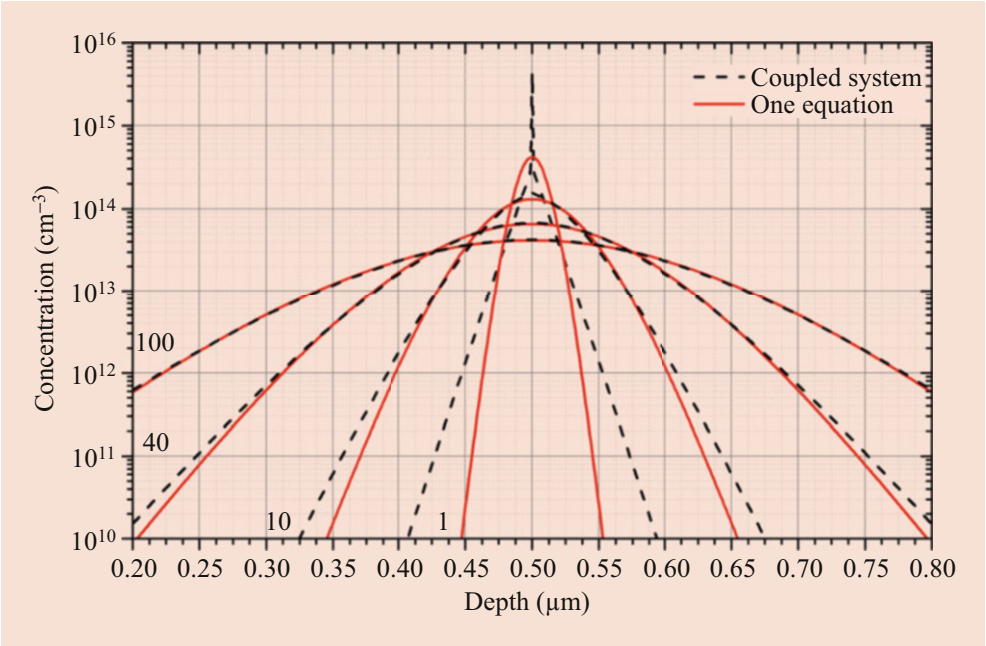

Fig. 35.8 Diffusion of impurities from an initially delta-doped layer, simulated by diffusion equations for mobile species and substitutional species and under the assumption of local equilibrium between these species. The running index is the diffusion time in multiples of the time constant τ. (After [5])

$$D_{\mathrm{MX}} = \eta_{\mathrm{MX}^-} D_{\mathrm{MX}^-} \left(\frac{n}{n_\mathrm{i}}\right)^2 + \eta_{\mathrm{MX}^0} D_{\mathrm{MX}^0} \frac{n}{n_\mathrm{i}} + \eta_{\mathrm{MX}^+} D_{\mathrm{MX}^+} \tag{35.63}$$

for pairs with donors. For both, the dependence of the diffusion coefficient on the Fermi level reflects the increase of the concentration of pairs in extrinsically doped semiconductors.

As long as the semiconductor is intrinsically doped, with vacancy and self-interstitial concentrations at equilibrium, and negligible strain effects, the respective diffusion coefficients of the dopants depend just on temperature. This "intrinsic diffusion coefficient" $D_0 = D_{\mathrm{MI}} + D_{\mathrm{MV}}$ shown in Fig. 35.9 for the main dopants in silicon and germanium is probably the best-studied property of dopants in semiconductors. An exception is boron in germanium for which only three experimental determinations are available which resulted in values which are orders of magnitude apart [55]. Comparing the other dopants for silicon and germanium, it is also noticeable that the fastest and slowest diffusers exchange places.

A further important property of dopants is the degree to which they diffuse via self-interstitials and vacancies. This is typically expressed in terms of the fractional diffusivity via self-interstitials:

$$f_\mathrm{I} = \frac{D_{\mathrm{MI}}}{D_{\mathrm{MI}} + D_{\mathrm{MV}}}. \tag{35.64}$$

The degree to which dopant atoms diffuse via vacancies and interstitial atoms was a subject of sharp discussions after Seeger and Chik [47] introduced the interstitialcy mechanism which lasted well after the review of Fahey et al. The current understanding of dopant diffusion in silicon was developed on the basis of diffusion studies in which some dopant atoms show enhanced diffusion, while the diffusion of others is retarded. Such studies, discussed in more detail in Sect. 35.3.5, in combination with information about the growth of extrinsic stacking faults led to the conclusion that boron and aluminum diffuse in silicon nearly exclusively via self-interstitials, while antimony has been found to diffuse nearly exclusively via vacancies. Arsenic in silicon diffuses via both, and phosphorus diffuses at low concentrations nearly exclusively via self-interstitials while at high concentrations a dominant diffusion via vacancies has been found. In germanium, all elements except boron were suggested to diffuse via a vacancy mechanism. For boron, the considerably lower diffusion coefficient in comparison to the other dopants is sometimes associated with an interstitial diffusion although no unambiguous experimental evidence is available.

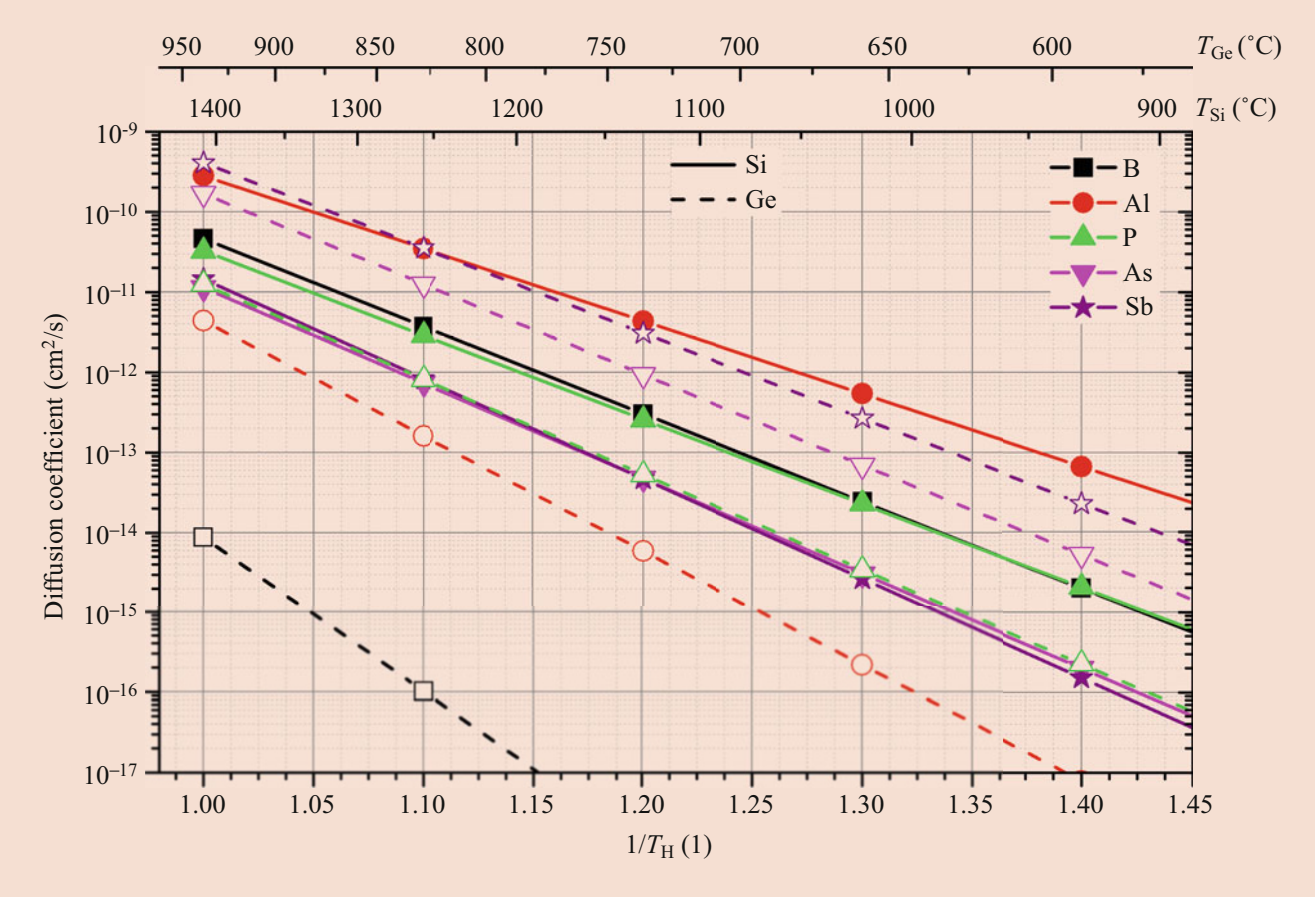

Fig. 35.9 Intrinsic diffusion coefficients of dopants in germanium and silicon as a function of the inverse homologous temperature. (The data are from [5] and [41] for silicon and germanium, respectively)

35.3.4 Dopant Diffusion at High Concentrations

Particularly for contact areas, the active doping concentration cannot be high enough. For such conditions, the charge carrier concentrations exceed the concentration n_i by far. The effects of such high doping levels on dopant diffusion will be discussed briefly in this subsection on the basis of an experiment reported by Orr Arienzo et al. [56] in which a highly doped polysilicon layer maintained a constant concentration of boron during the diffusion at 950 °C for 1 h.

The first simulation result shown in Fig. 35.10, denoted "Intrinsic diffusion," was obtained under the assumption of intrinsic diffusion with a constant diffusion coefficient. The resulting error function profile apparently underestimates the dopant penetration by far.

The second simulation result, denoted "+ Field effect," takes into account that the extrinsic doping concentration results in an electric field E which acts via (35.44) as an additional driving force for dopant redistribution. This manifests itself, as shown, e.g., by Smits [57], in an effective diffusion coefficient which depends via

$$D = D_0 \left(1 + \frac{C}{\sqrt{C^2 + 4n_i^2}} \right) \tag{35.65}$$

on the dopant concentration. However, the enhancement by a factor of two for $C \gg n_i$ remains too small to explain the experimental profile.

Considering also that boron diffuses predominantly via neutral pairs with self-interstitials, i.e., with an effective diffusion coefficient (35.62) which increases linearly with the hole concentration, one obtains the profile denoted "$D(p)$" in Fig. 35.10 under the assumption that the intrinsic point defects remain in equilibrium. In comparison to the previous simulations, the concentration-dependent diffusion coefficient results in pronounced platykurtic profiles which are flatter at the top but steeper at the flanks. Assuming an effective diffusion coefficient which increases quadratically with the respective charge carrier concentration would lead to a deeper penetration of the dopants but also to even steeper flanks.

To reproduce the gentler slope of the experimental profile as in the profile denoted "Full model," one has to take the

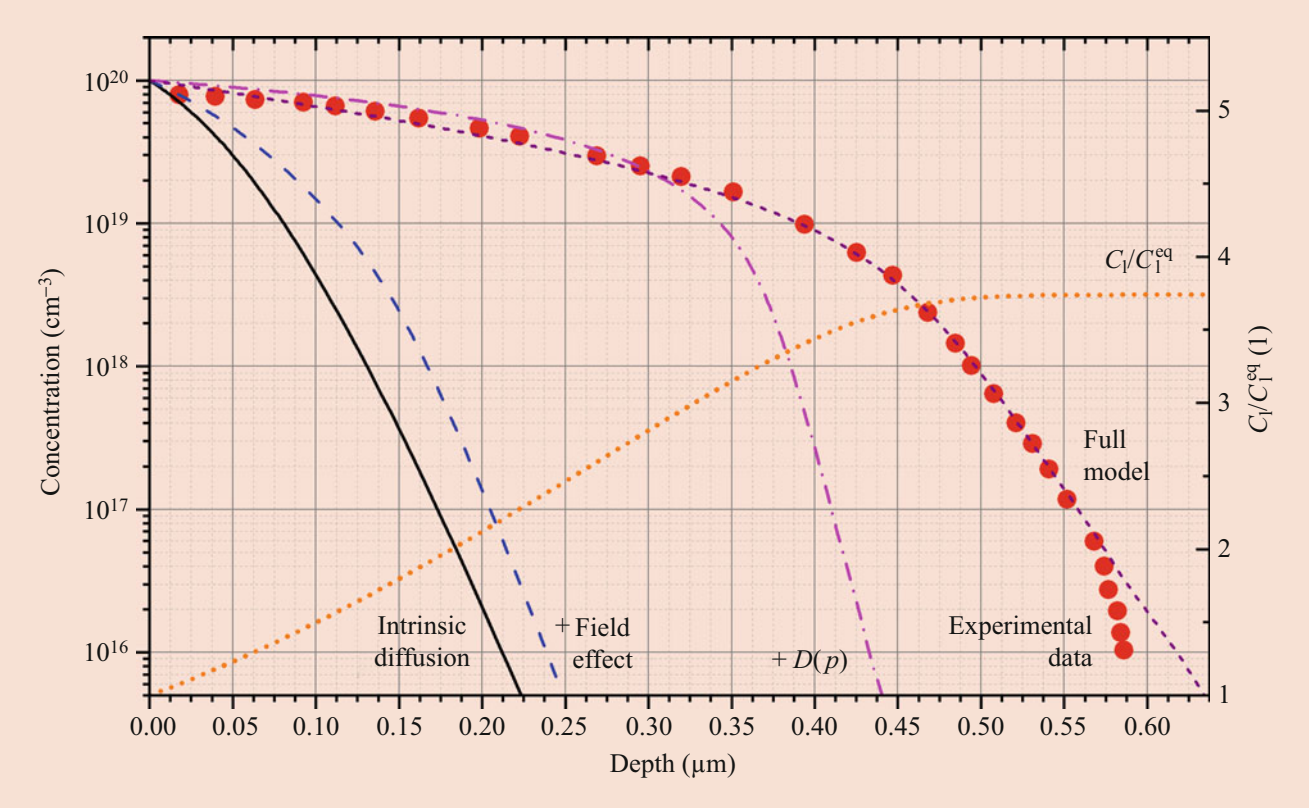

Fig. 35.10 Simulation of the diffusion of boron at high concentrations. (Courtesy C. Ortiz, Fraunhofer IISB) and comparison to the experiment of Orr Arienzo et al. [56] at 950 °C. After [5])

full interaction between boron atoms and self-interstitials into account: Boron-self-interstitial pairs form via (35.48) predominantly close to the interface to the polysilicon layer where the boron concentration is highest. When diffusing into the bulk, the boron concentration reduces, and the pairs are more and more likely to dissociate into substitutional boron and self-interstitials. This results, as shown by the line "C_I/C_I^{eq}" in Fig. 35.10, in an oversaturation of self-interstitials which increases with depth. There, the increase of the self-interstitial concentration compensates for the decrease of the effective diffusion coefficient with the charge carrier concentration so that the resulting doping profile becomes nearly error-function-like but with a much higher effective diffusion coefficient than in the case of intrinsic diffusion. Following their gradient, the self-interstitials will diffuse back to the surface so that their oversaturation depends on the interplay of transport into the bulk via dopant diffusion and transport back to the surface by self-diffusion. While the effect is rather unspectacular for boron, it is responsible also for the formation of pronounced kink and tail features in high-concentration phosphorus profiles and the broadening of the base region of bipolar transistors in areas below high-concentration phosphorus profiles, the so-called emitter-push effect [58].

At even higher phosphorus background concentrations, Nylandsted Larsen et al. [59] found that the diffusion of a variety of dopants increases steeply with the phosphorus concentration. Following the suggestion of Mathiot and Pfister [60], this was explained in terms of a percolation phenomenon. However, this explanation was discussed controversially, and Ramamoorthy and Pantelides [61], as an example, argued that the rapid diffusion should give rise to fast dopant clustering and the break-up of the percolation cluster.

35.3.5 The Influence of Surface Processes on Dopant Diffusion

First indications for the influence of surface chemical processes on dopant diffusion date back to the 1960s, when the (111)-oriented wafers prevalently used in industry were replaced by (100)-oriented wafers. Comparative diffusion studies at that time indicated an orientation-dependence of the diffusion of dopants which would not be expected for semiconductors with a diamond lattice. However, some researchers reported already then that such effects would be seen only for diffusion process in oxidizing ambient and not in inert ambient [62]. Later studies confirmed the oxidation-

enhanced diffusion of boron [63] and phosphorus [64] during dry oxidation of (100)-oriented silicon, while at the same time an oxidation-retarded diffusion of antimony was found [65]. Based on the observation of the concurrent growth of stacking faults identified unambiguously as self-interstitial agglomerates, it was suggested by Dobson [66] and Hu [67] that overstoichiometric silicon atoms are incorporated during the oxidation into the growing oxide layer and that these silicon atoms may segregate as self-interstitials into the silicon where they increase the concentration of self-interstitials beyond their equilibrium concentration. Because of bulk recombination of self-interstitials and vacancies (35.49), an oversaturation of the former ($C_\mathrm{I}/C_\mathrm{I}^\mathrm{eq} > 1$) will inevitably lead to an undersaturation of the latter ($C_\mathrm{V}/C_\mathrm{V}^\mathrm{eq} < 1$) and vice versa. The resulting effective diffusion coefficient under non-equilibrium conditions

$$D^\mathrm{eff} = D^\mathrm{eq}\left(f_\mathrm{I}\frac{C_\mathrm{I}}{C_\mathrm{I}^\mathrm{eq}} + (1-f_\mathrm{I})\frac{C_\mathrm{V}}{C_\mathrm{V}^\mathrm{eq}}\right) \tag{35.66}$$

will be higher than the diffusion coefficient D^eq under equilibrium conditions ($C_\mathrm{I} = C_\mathrm{I}^\mathrm{eq}$, $C_\mathrm{V} = C_\mathrm{V}^\mathrm{eq}$) for dopants diffusing preferentially via self-interstitials ($f_\mathrm{I} > 0.5$). Dopants diffusing preferentially via vacancies ($f_\mathrm{I} < 0.5$), on the other hand, may be retarded in their redistribution. In process simulation programs, the injection of self-interstitials is usually modeled empirically as a flux of self-interstitials which increases sublinearly with the oxidation rate.

While the dry oxidation of (100)-oriented silicon was always found to result in an enhanced self-interstitial concentration, opposite effects were found for the diffusion of (111)-oriented samples at high temperatures and long diffusion times. This was explained by Taniguchi et al. [68] by a preferential segregation of self-interstitials into the growing oxide for small oxidation rates.

More problematic to explain was the retarded diffusion of boron and phosphorus, the enhanced diffusion of antimony, and the shrinkage of self-interstitial agglomerates reported by Mizuo et al. [69] during the nitridation of silicon. Interpreted in terms of (35.66), the nitridation-enhanced diffusion of antimony indicated an injection of vacancies. However, kinetic models in analogy to those for the injection of self-interstitials during oxidation had the problem that the growth of surface nitrides almost stopped after a short time, while the effects on dopant diffusion and stacking-fault growth lasted for much longer. In addition, it was shown by Ahn et al. [70] that similar effects can be observed below deposited nitrides. An explanation for these phenomena was finally suggested by Cowern [71] who noted that the work done against overlayers has to be taken into account in the formulation of the formation energies of the intrinsic point defects.

Finally, it should be noted that also other surface chemical processes like the nitridation of oxide layers or the formation of silicides were reported to lead to non-equilibrium diffusion effects.

35.3.6 Transient Diffusion Effects During Post-Implantation Annealing

Because of its superior homogeneity and dose control, ion implantation has become the main process for the doping of semiconductors. Inevitably associated with ion implantation is the creation of damage due to elastic collisions of the impinging atoms with the lattice atoms. Depending on the mass and energy of the implanted atoms, some ten to many hundred self-interstitials and vacancies are generated per implanted atom. For high enough doses, an amorphous layer is formed in the semiconductor. To remove the damage, semiconductors need to be annealed after ion implantation. With all the intrinsic point defects being far from equilibrium, such annealings result in significant implantation-enhanced diffusion of the dopants.

To illustrate typical effects during post-implantation annealing, simulations of a 20 keV boron implantation with a dose of 5×10^{15} cm^{-2} and subsequent isothermal annealings at 900 °C are shown in Fig. 35.11. During the first 10 to 40 s, significant diffusion is observed in the tail of the boron profile. During this time interval, diffusive broadening is limited to concentrations up to about 1×10^{19} cm^{-3}. This value corresponds to the concentration of electrically active, i.e., substitutional boron atoms, which remains nearly the same. Increasing the annealing time to 1 min results already in a much smaller broadening, and increasing the time further to 10 min has an even much smaller effect. In contrast, a significant increase of the electrically active boron concentration is observed. Because of their eminent technological importance, transient diffusion and transient activation have been main research topics for decades. For the sake of brevity, we can only present the most important results here and must refer the interested reader to some more extensive reviews in this area [73, 74].

While it was clear already at an early stage that implantation damage was the cause of the implantation-enhanced diffusion, the exact mechanism was not as clear for some time. The consensus today is that the implantation leads to an excess of self-interstitials in the crystal which agglomerate during annealing and undergo Ostwald ripening. The oversaturation which drives dopant diffusion results from the cloud of self-interstitials that the extended defects maintain in their vicinity [75]. Quantitative information about the extended defects could be obtained by numerous TEM (transmission electron microscopy) studies with the work of Eaglesham et al. [76] and Bonafos et al. [77] just to give some prominent examples. Complementary information about the energetics of self-interstitial clusters which are too small to be investi-

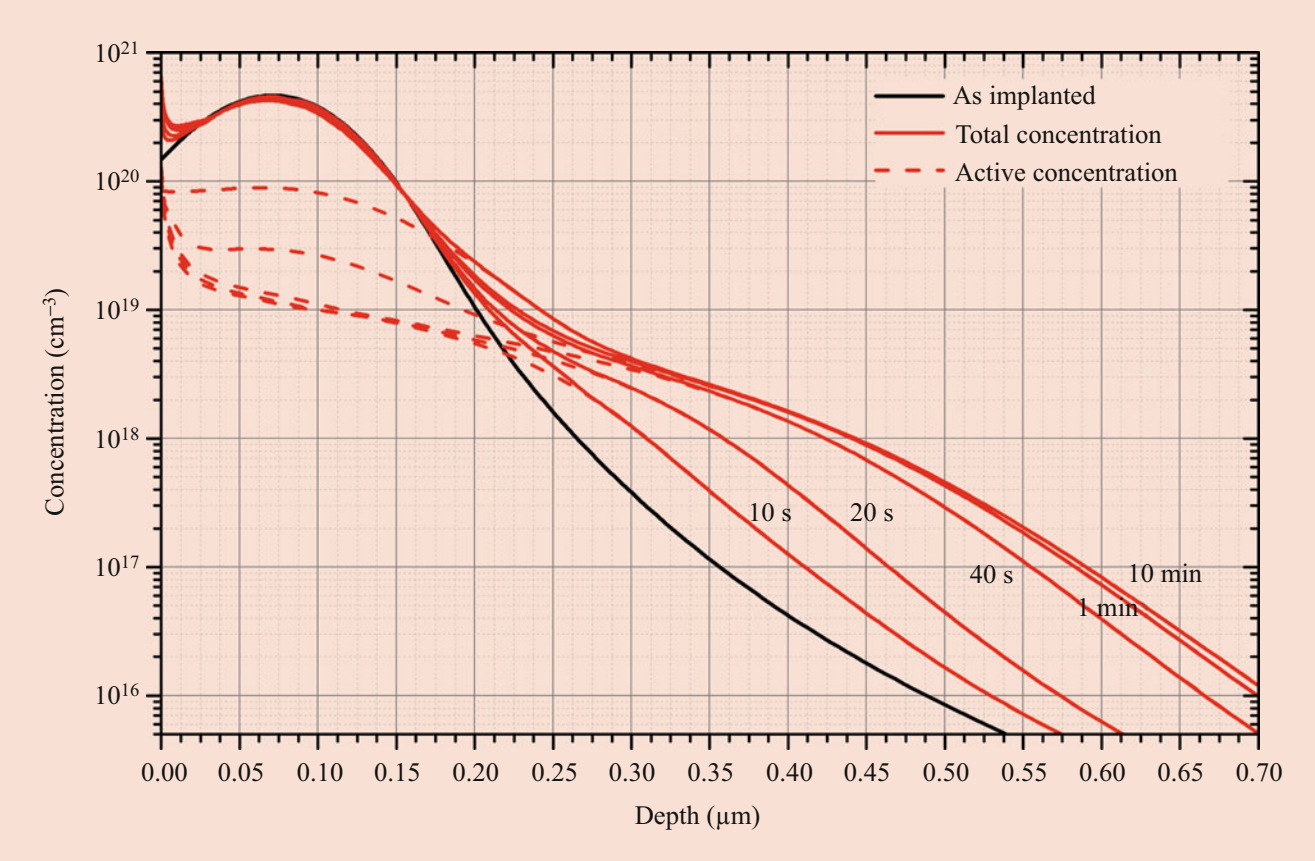

Fig. 35.11 Boron profiles after implantation with 20 keV and 5×10^{15} cm^{-2} and annealing at 900 °C simulated with Sentaurus Process [72]

gated by TEM became available by the experiment of Cowern et al. [78] in which the implantation-enhanced diffusion of narrow boron layers was induced by silicon implants. For a comprehensive review of the Ostwald ripening of extended defects, the review article of Claverie et al. [79] can be recommended. Among the many models suggested to capture the main aspects of the Ostwald ripening of small silicon clusters and extended {311} defects, the one of Zechner et al. [80] is particularly frequently used in process simulation since it combines predictive power with a minimum number of equations to be solved. For longer annealing times for which the {311} defects transform into stacking faults and perfect dislocation loops, extensions have been suggested by Zographos et al. [81] and Wolf et al. [82].

As initial conditions for the abovementioned models, the relevant concentration of self-interstitials needs to be calculated. This can, in principle, be done by the Monte Carlo techniques discussed in Sect. 35.2.2. However, the concentration of defects obtained would be far too high since vacancies and self-interstitials are created in pairs during the collisions with the impinging atoms and are likely to recombine early in the annealing stage. Accordingly, Giles [83] suggested for sub-amorphizing implants that only the extra atom introduced by the implantation needs to be taken into account as self-interstitial. While this assumption works well, e.g., for boron, it was found by Pelaz et al. [84] that the number of self-interstitials per implanted atom needs to be increased for heavier ions. Finally, for amorphizing implants, the amorphized region will regrow defect-free already at low temperatures like during the ramping stage of annealing. Accordingly, only the excess of self-interstitials in depths beyond the amorphous/crystalline interface needs to be taken into account and can be calculated by Monte Carlo simulations or by assuming an effective plus factor as for non-amorphizing implants [85].

35.3.7 Electrical Activation, Clusters, and Solid Solubility

One of the phenomena apparent from Fig. 35.11 is that a significant part of the atoms are immobile as well as electrically inactive. To explain such phenomena for arsenic in silicon, small electrically neutral clusters of two [86] and four arsenic atoms [87] were assumed to form. While the formation of such clusters can be described by binary reactions or chains of binary reactions, clusters Cl^n comprising n dopant atoms are usually assumed to form by the reaction

$$n\,M_s \underset{k_{Cl\leftarrow}}{\overset{k_{Cl\rightarrow}}{\rightleftharpoons}} Cl^n \tag{35.67}$$

which results in an additional continuity equation

$$\frac{\partial C_{Cl^n}}{\partial t} = k_{Cl\rightarrow}\left(C_{M_s}\right)^n - k_{Cl\leftarrow}C_{Cl^n} \tag{35.68}$$

for the clusters. Because of mass conservation, the right-hand term multiplied by n also appears in the continuity equation of the substitutional impurities. Since the total concentration of impurities C_M includes now also the atoms in the cluster, adding all contributions leads again to an equation similar to (35.61) but with the substitutional concentration C_{M_s} instead of the total concentration C_M in the term on the right hand side. The substitutional concentration can now be considerably smaller than the total concentration, which leads already to a significant retardation of the diffusion of the impurities. In addition, the clustering also reduces the charge-carrier concentration in the high-concentration regions and thus also the effective diffusivity (35.62) of the non-clustered dopant atoms.

Coming back to the post-implantation annealing of boron shown in Fig. 35.11, it is noticeable that the electrical active concentration remains virtually the same during the period of transient-enhanced diffusion, while it increases significantly thereafter. This indicates an involvement of self-interstitials in the formation of the complexes responsible. Accordingly, for the latter, the term boron-interstitial clusters (BICs) was introduced in literature. Based on ab initio calculations, schemes of binary reactions of substitutional boron atoms and BICs with boron interstitial atoms and self-interstitials were developed (see, e.g., [88]) and shown to be able to capture the main features of transient boron diffusion and activation. For arsenic and phosphorus, the reaction schemes were even extended toward mixed clusters involving self-interstitials or vacancies [89].

Particularly by ion implantation, the total concentrations of dopants can be increased almost unlimitedly. However, when a certain total impurity concentration, known as solid solubility, is exceeded, an impurity-rich phase is expected to form in equilibrium. Depending on the impurity and temperature, the impurity-rich phase may be a liquid, a pure impurity phase, or a silicide phase [90]. Dynamically, such a phase can form by spinodal decomposition or, often more likely, by nucleation and growth of precipitates. Since the latter process is kinetically limited, dopant precipitates are often observed only after annealing processes with high thermal budgets [91]. However, dopant precipitates are not only observed after ion implantation. During growth and annealing of phosphosilicate glasses, as a prominent example, so many phosphorus atoms segregate into the silicon that the (binary) solid solubility of phosphorus in silicon is exceeded there and SiP precipitates form [92].

35.3.8 Segregation

In real applications, semiconductors will always be in contact to other materials like silicon dioxide, silicides, or metals. During annealing processes, the atoms being present in either material will diffuse not only therein but also across the interfaces between the materials. In equilibrium, because of their different formation energies, discontinuous distributions of the atoms are expected at the interfaces. An example in this sense already mentioned above is the formation of large SiP precipitates in silicon where the phosphorus concentration is 50 at.% in the SiP, while the total concentration in silicon corresponds largely to the temperature-dependent solid solubility. At the interfaces, the discontinuous distributions of atoms in equilibrium are characterized by the segregation coefficients m as ratios of the respective concentrations at the two sides. During thermal processing, the flux of species between the phases A and B is usually written in form of a first-order kinetic model

$$J_X = h\left(C_X^A - mC_X^B\right) \tag{35.69}$$

as being proportional to the interface transport coefficient h and the difference in concentration normalized by the segregation coefficient.

Segregation of dopants from highly doped phosphosilicate or borosilicate glasses into silicon is used in solar and power electronics for the doping of silicon with concentrations which may be even above solid solubility. At lower concentrations, diffusion of dopants in silicon dioxide is rather slow so that segregation effects can be observed only when the interface moves during an oxidation process. During such processes, phosphorus, arsenic, and antimony pile up at the silicon side, while boron segregates preferentially into the growing oxide.

Pile-up of donors was observed also at stationary interfaces between silicon and silicon dioxide. Dedicated investigations showed that this pile-up occurs for phosphorus [93] and arsenic [94, 95] within few nm from the interface on the silicon side even if the dopants in the area below are homogeneously distributed. In contrast, a similar pile-up of boron was shown to result rather from large self-interstitial gradients toward the interface during post-implantation annealing [96]. In continuum simulators, interface segregation of phosphorus and arsenic is usually included via an approach suggested by Lau, Orlowski, and coworkers [97, 98]. It assumes that dopants adsorb and desorb from both materials to energetically favorable sites at the interface.

35.3.9 Simulation Methodologies

The dawn of numeric diffusion simulation began around 1980 with programs like SUPREM [6, 7] and ICECREM [8], when diffusion theories were already too complicated to be solved analytically. These programs like their two- and three-dimensional successors were based on a discretization of the diffusion-reaction equations discussed above. A big advantage of such continuum approaches is that the mesh used for discretization of the equations can be adjusted to the problem, i.e., made fine where necessary, while it can be left coarse elsewhere. A second potential advantage is that empirical models like the clustering Eq. (35.67) or the self-interstitial-complex ripening models mentioned in Sect. 35.3.6 can be implemented easily to reduce parameters and equations to be solved. On the other hand, there is an over-linear increase of computer resources and simulation time associated with an increase of the number of equations to be solved. Due to their excellent prediction accuracy and robustness for a wide range of applications from nanoelectronics to power electronics, continuum models are currently the workhorses of TCAD simulations in industry.

As an alternative, atomistic simulators like DADOS [99] were introduced at the end of the 1990s. These programs consider directly the diffusive jumps of non-lattice atoms and defects as well as the reactions among them by a kinetic Monte Carlo (KMC) algorithm. The big advantage of KMC simulators is that a plethora of different defects and defect reactions can be taken into account with a linear increase of computational efforts only. On the other hand, all non-lattice atoms and defects must be taken along in the simulations which make them feasible only for comparatively small volumes. However, with the continuing miniaturization of devices, this is becoming all the easier.

To simulate crystal-orientation-dependent phenomena like faceting during epitaxial deposition or shape changes during laser annealing, both continuum and KMC approaches lack predictive power. For such effects, it is necessary to include the host atoms in the calculations as in lattice kinetic Monte Carlo (LKMC) schemes [100]. However, it should be noted that classical LKMC implementations lack the ability to simulate other defects apart from vacancies and substitutional impurities.

35.4 Simulation of Oxidation

For many years, the simulation of oxidation was both a very important and a very difficult part of process simulation: Local oxidation ("LOCOS") was indispensable to generate three-dimensional structures for electrical isolation. It led to transition domains between the thin gate oxide and the isolation oxide, as shown in Fig. 35.12. The basic effect is

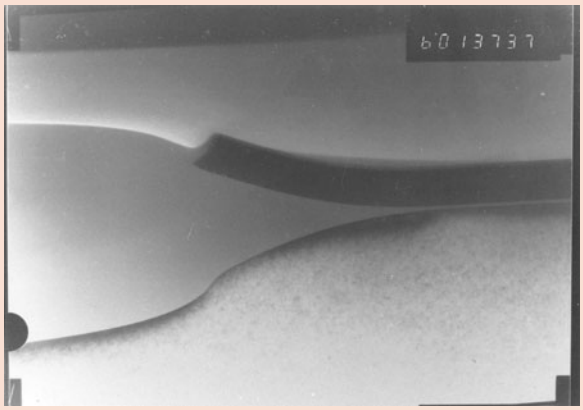

Fig. 35.12 SEM micrograph of transition domain ("bird's beak") between thick field oxide and thin gate oxide. Technology from the 1980s, with gate oxide thickness of about 100 nm

that during oxidation 2.27 volumes of oxide are generated from one volume of silicon. For local oxidation as shown in Fig. 35.12, the excess volume of oxide generated leads to a flux of oxide and the need to solve the resulting mechanical problem.

Simulation of oxidation includes simultaneously the diffusion of dopants and defects in the bulk semiconductor and in the (growing) oxide, the mechanics of the oxide flux, and the transport of dopant atoms across the moving interface between the semiconductor and the oxide, which in many cases critically affected the total amount of dopants near the channel, and in turn even top electrical parameters like the threshold voltage. In turn, the generation and adaptation of meshes to properly resolve the transport of dopants across moving interfaces was a key problem for three-dimensional process simulation.

For current nanoelectronic devices, the simulation of oxidation is far less important, because advanced device architectures do not include LOCOS oxidation, but merely thin oxides. Shallow trench oxidation is performed by growth of a thin oxide followed by oxide deposition. However, for applications like power electronics, thicker oxides are still needed, and the three-dimensional simulation of oxidation stays important for such cases.

35.4.1 One-Dimensional Simulation of Oxidation

The basic physical processes to be included in the one-dimensional simulation of oxidation are shown in Fig. 35.13. They are all fast compared with the oxide growth and can therefore be considered as stationary. At the interface between oxide and silicon, the oxidizing species O_2 in case of

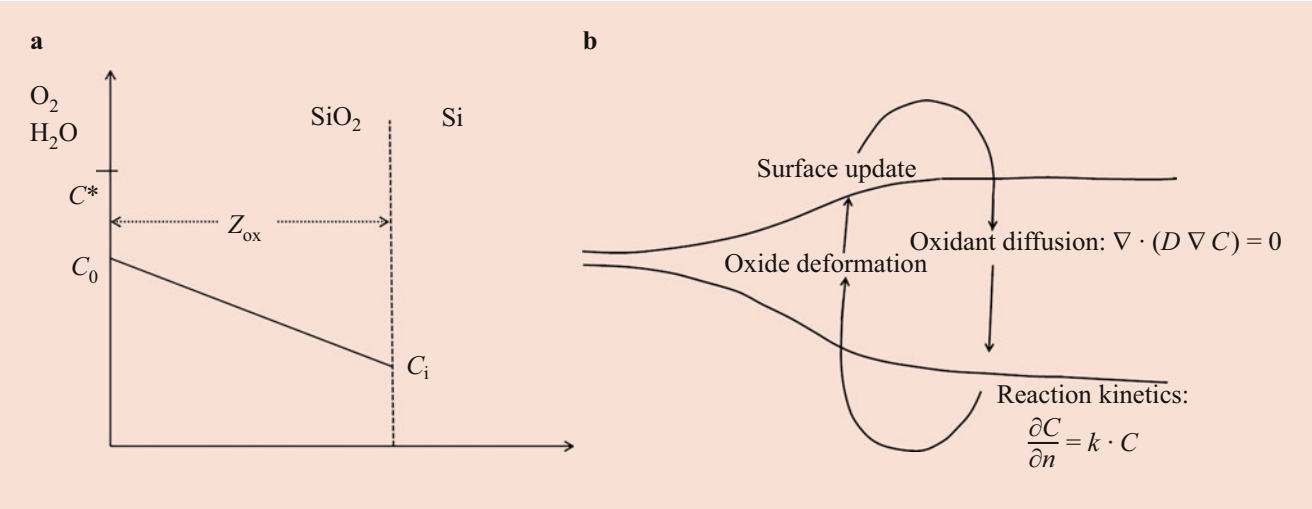

Fig. 35.13 Physical processes involved in the oxidation of silicon. (**a**) One-dimensional case (planar oxidation); (**b**) Two−/three-dimensional case as discussed in Sect. 35.4.2

dry oxidation and H_2O in case of wet oxidation react with silicon according to

$$\mathrm{Si} + \mathrm{O_2} \rightarrow \mathrm{SiO_2} \tag{35.70}$$

$$\mathrm{Si} + 2\,\mathrm{H_2O} \rightarrow \mathrm{SiO_2} + 2\,\mathrm{H_2} \tag{35.71}$$

The corresponding Deal-Grove model [101] consists of three steps, which can all be expressed as fluxes F of the oxidizing species. These species are first adsorbed at the oxide surface, resulting in a concentration C^*, which depends on the partial pressure of the oxidizing ambient (O_2 or H_2O). A parameter h describes the transfer of the species across the surface, giving rise to the concentration C_0 at the oxide side of the surface:

$$F = h \cdot \left(C^* - C_0\right) \tag{35.72}$$

Stationary diffusion with a diffusion coefficient D leads to a concentration C_i of the oxidizing species at the oxide side of the interface to silicon:

$$F = D \cdot \frac{(C_0 - C_\mathrm{i})}{z_\mathrm{ox}} \tag{35.73}$$

A constant k describes the first-order reaction of the oxidizing species at the interface between oxide and silicon:

$$F = k \cdot C_\mathrm{i} \tag{35.74}$$

Since the three fluxes in Eqs. (35.72), (35.73), and (35.74) are equal, a differential equation for the oxide thickness z_ox results [101]:

$$\frac{\mathrm{d}z_\mathrm{ox}}{\mathrm{d}t} = \frac{{kC^*}/{N}}{1 + \frac{k}{h} + k \cdot {z_\mathrm{ox}}/{D}} \tag{35.75}$$

Here, N is the density of the atoms in the silicon crystal. The solution of Eq. (35.75) is the well-known linear-parabolic relationship for the time dependence of the oxide thickness:

$$\frac{{z_\mathrm{ox}}^2}{k_\mathrm{p}} + \frac{z_\mathrm{ox}}{k_\mathrm{l}} = t + t_0 \tag{35.76}$$

Here, k_p and k_l are the parabolic and the linear oxide growth coefficients. They relate to the physical parameters given above according to

$$k_\mathrm{l} = \frac{C^*}{N\left(\frac{1}{k} + \frac{1}{h}\right)} \tag{35.77}$$

$$k_\mathrm{p} = 2D \cdot {C^*}/{N} \tag{35.78}$$

The linear regime applies for small oxide thicknesses z_ox and is determined by the transfer of the oxidant across the oxide surface and the reaction at the interface between oxide and silicon, expressed by the parameters k and h. For larger oxide thickness, the transport through the existing oxide layer limits the process, resulting in a growth asymptotically

approaching the square root of the oxidation time. The initial time t_0 is used to express the native oxide which is grown almost instantaneously. An increase of the initial oxidation rate can be described by Massoud's model [102], which adds an exponential term to Eq. (35.75):

$$\frac{\mathrm{d}z_{\mathrm{ox}}}{\mathrm{d}t} = \frac{kC^* \Big/ N}{1 + \frac{k}{h} + k \cdot z_{\mathrm{ox}} \Big/ D} + C\,\mathrm{e}^{\left(-\frac{z_{\mathrm{ox}}}{L}\right)} \tag{35.79}$$

In this case the oxide thickness is no more given in the analytical form of Eq. (35.76), but must be calculated as solution of the differential Eq. (35.79).

In Eqs. (35.75), (35.76), (35.77), (35.78), and (35.79), the physical parameters D, k, h, C, and L depend in various respects on the process to be simulated, including temperature, the orientation of the silicon crystal, the oxidizing species (O_2 or H_2O) and its partial pressure, additional HCl in the atmosphere, the dopant concentration on the silicon side of the interface between silicon and oxide, and stress.

35.4.2 Multidimensional Simulation of Oxidation

The one-dimensional oxidation model summarized above describes the situation where a homogeneous oxide layer is grown on a flat silicon surface. This does no more apply in areas where the silicon is structured (e.g., a trench) or partly masked. This situation is visualized in two dimensions in Fig. 35.13b. In this case, Eqs. (35.72), (35.73), and (35.74) are replaced by a stationary partial differential equation and the corresponding boundary conditions for the concentration C of the oxidizing species, depending on space and time. Here, $\frac{\partial}{\partial n}$ is the derivative in direction normal to the surface or interface:

$$\nabla\,(D \cdot \nabla C) = 0 \text{ in the oxide;} \tag{35.80}$$

$$D \cdot \frac{\partial C}{\partial n} = h \cdot \left(C^* - C\right) \text{ at the oxide surface;} \tag{35.81}$$

$$D \cdot \frac{\partial C}{\partial n} = k \cdot C \text{ at the interface between oxide and silicon.} \tag{35.82}$$

The dependence of the physical constants D, h, and k on the process to be simulated is in principle similar to the one-dimensional case. However, for non-planar or masked structures, the stress-dependent flux of the oxide must be simulated, which results from the generation of 2.27 volumes of oxide from one volume of silicon. In addition to the standard Arrhenius dependence on the temperature, this leads to

$$D = D_0 \cdot \exp\left(-\frac{E_{\mathrm{D}}}{kT}\right) \cdot \exp\left(-\frac{p \cdot V_{\mathrm{D}}}{kT}\right); \tag{35.83}$$

$$C^* = C_0 \cdot \exp\left(-\frac{E_{\mathrm{C}}}{kT}\right) \cdot \exp\left(-\frac{p \cdot V_{\mathrm{C}}}{kT}\right); \tag{35.84}$$

$$k = k_0 \cdot \exp\left(-\frac{E_{\mathrm{k}}}{kT}\right) \cdot \exp\left(\frac{\sigma_{\mathrm{nn}} \cdot V_{\mathrm{k}}}{kT}\right); \tag{35.85}$$

$$\eta = \eta_0 \cdot \exp\left(-\frac{E_\eta}{kT}\right) \cdot \exp\left(p \cdot \alpha(T)\right) \tag{35.86}$$

where the symbols have partly been adapted from the literature [103]. Here, E_{d}, E_{C}, E_k, and E_η are the activation energies in the respective Arrhenius laws, with k the Boltzmann constant. p is the hydrostatic pressure and σ_{nn} the normal stress at the interface between oxide and silicon, counted as positive if the oxide executes a pull on the silicon. V_{D}, V_{c}, V_{k}, and V_η (see Eqs. (35.83), (35.84), (35.85), (35.86), and(35.87)) are the activation energies for the stress dependencies of the respective parameters and α a parameter depending on temperature. Whereas according to [103], V_{k} is the difference between the molecular volume of SiO_2 and the atomic volume of Si, and equals to 25 Å^3, the other volumes are fitting parameters. It was shown [104] that for the oxidation of cylindrical structures, Eq. (35.86) leads to an equation for the hydrodynamic pressure p, which has no solution in case of some concave structures. It was therefore suggested to replace Eq. (35.86) by a model proposed by Eyring [105, 106]:

$$\eta = \eta_0 \cdot \exp\left(-\frac{E_\eta}{kT}\right) \cdot \frac{\sigma \Big/ \sigma_c}{\sinh\left(\sigma \Big/ \sigma_c\right)}, \text{ with } \sigma_c = 2kT \Big/ V_\eta \tag{35.87}$$

35.4.3 Multidimensional Simulation of Stress-Dependent Oxidation

Besides the specific physical models for the diffusion and reaction of the oxidizing species also the mechanical problem resulting from the generation of 2.27 volumes of oxide from

one volume of silicon must be solved numerically. In general, this needs the simulation of the viscoeleastic oxide flow. For this, the stress $\boldsymbol{\sigma}$ and strain $\boldsymbol{\varepsilon}$ must be considered. They are given by tensors (here displayed as six-dimensional vectors), and the hydrodynamic pressure p relates to them as follows:

$$\boldsymbol{\sigma} = \left(\sigma_x, \sigma_y, \sigma_z, \tau_{xy}, \tau_{xz}, \tau_{yz}\right) \tag{35.88}$$

$$\boldsymbol{\varepsilon} = \left(\varepsilon_x, \varepsilon_y, \varepsilon_z, \gamma_{xy}, \gamma_{xz}, \gamma_{yz}\right) \tag{35.89}$$

$$P = -\left(\sigma_x + \sigma_y + \sigma_z\right)/3 \tag{35.90}$$

Here, the indices of the first three components give the direction of the stress or strain.

For the shear stresses in last three components of the stress $\boldsymbol{\sigma}$, the first index indicates the normal to the surface to which the shear stress is applied, and the second index gives the direction of the shear stress. In this nomenclature one could also use σ_{xx} instead of σ_x, etc. The stain components give the changes of the shifts u, v, and w in directions x, y, and z:

$$\varepsilon_x = \frac{\partial u}{\partial x};\ \varepsilon_y = \frac{\partial v}{\partial y};\ \varepsilon_y = \frac{\partial w}{\partial y}; \tag{35.91}$$

$$\gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x};\ \gamma_{xz} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x};\ \gamma_{yz} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \tag{35.92}$$

The space available here does not allow for the discussion of the various approaches and approximations used for the simulation of stress in the literature. It is important to note that for temperatures of 960 °C and above, the viscous behavior of the oxide dominates [107] whereas below the oxide increasingly becomes elastic. In the viscous case, the velocity field $\boldsymbol{V}$ of the oxide flow can then be related to the hydrodynamic pressure P via

$$\eta \cdot \Delta \mathbf{V} = \nabla P \tag{35.93}$$

If the oxide is approximated as incompressible, Eq. (35.93) reduces to $\Delta \mathbf{V} = 0$. In that case all stress dependencies given in Eqs. (35.83), (35.84), (35.85), and (35.86) are neglected and only that Laplace equation is used to simulate the flow of the incompressible oxide caused by the extra volume generated during oxidation. This also means that masks are considered as flexible, executing no pressure on the growing oxide.

Figure 35.14 shows a sample oxide structure with the different kinds of interfaces at which boundary conditions for

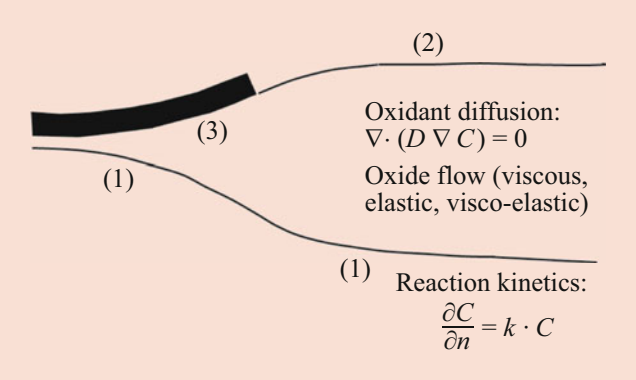

Fig. 35.14 Boundary conditions for multidimensional simulation of oxidation

$\boldsymbol{v}$ and P must be defined: (1) At the interface between oxide and silicon, $\boldsymbol{v}$ is normal to the interface, and its value is given by the rate at which silicon is transformed into oxide (equal to 0.44 times the oxide growth rate); (2) at the oxide surface, P is equal to the ambient pressure minus the surface tension; (3) at the interface between oxide and nitride, P is equal to the mechanical pressure executed by the nitride layer. This needs either mechanical calculations of the nitride bending or the use of suitable analytical approximations. For the then still missing boundary condition for the velocity at the free oxide surface, Chin used an additional relationship provided by an artificial compressibility algorithm [108].

35.5 Lithography Simulation

One of the most important process steps in semiconductor manufacturing is lithography, because it enables the transfer of the chip design onto the silicon wafer. Here, three properties are most important: the capability to generate tiny features (currently, the smallest dense features for single exposure are in the range of 20 nm); to establish the pre-defined links foreseen in the chip design between the transistors and capacitors acting as switches, amplifiers, or storage elements; and moreover to process up to hundreds of billion elements at the same time. Because a separate chapter of this handbook is dedicated to the lithography equipment and technology, below only a few technological aspects are outlined, which are necessary to present lithography simulation in a self-contained section.

35.5.1 Basic Principle of Lithography

Figure 35.15 shows the principle of a projection lithography step. Light from a suitable source illuminates a mask, where it is diffracted at the mask features. The diffracted light is

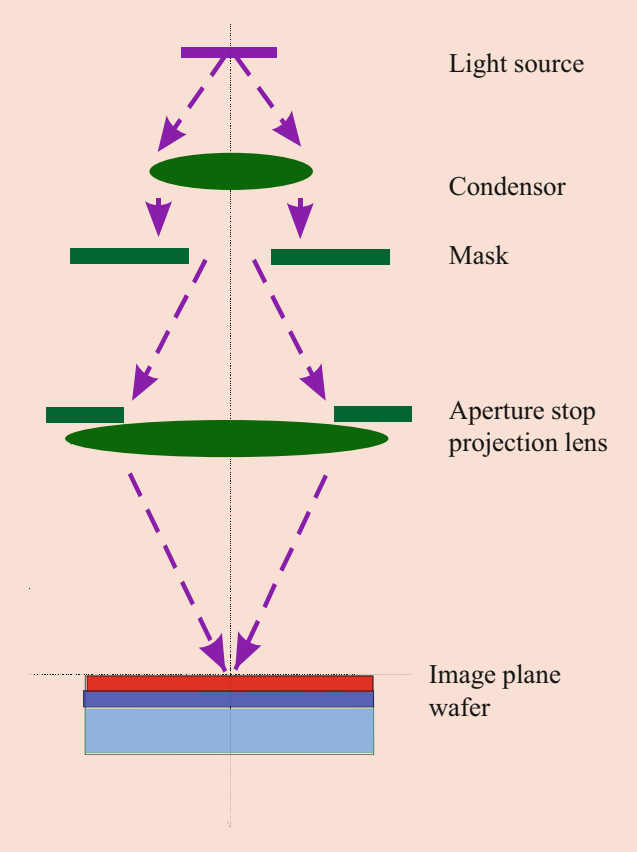

Fig. 35.15 Schematics of imaging in optical lithography

then collected via a suitable optical system and focused onto a photoresist. This part of the lithography process is called imaging and depends both on the mask and the lithography equipment, namely, the light source and the optical system. The resolution of this optical system is then given by the Rayleigh criterion [109].

$$d_{\min} = k_1 \cdot \frac{\lambda}{\mathrm{NA}} \tag{35.94}$$

where $d_{\min}$ is the minimum pitch which can be printed, λ is the wavelength of the light used, NA is the numerical aperture (equal to the relative refractive index of the medium times the sine of the opening angle of the last lens), and k_1 is the so-called technology factor, with a minimum value of 0.5. Because 193 nm is the smallest wavelength of laser light currently used in high-volume semiconductor device manufacturing, for which lenses are sufficiently transparent, the theoretical minimum pitch which can be printed in the so-called "dry" optical lithography (with air as medium between the last lens and the photoresist) is about 104 nm. Smaller pitches can either be printed via so-called multiple patterning lithography [110], with immersion lithography [111] or with extreme ultraviolet (EUV) lithography [112]. In the latter case, soft X-rays at a wavelength of about 13.5 nm are used, which then necessitate the replacement of the lenses in all parts of the optical system by multilayer MoSi mirrors. The projection process transfers an image of the mask patterns into the photoresist, leading to local deposition of energy into the photoresist. The image is diffraction limited, because the lenses cannot collect all diffraction orders from the mask. Furthermore, the image is disturbed by several other effects such as defocus, lens imperfections, or defects on the mask. After resist development parts of the resist which were exposed (positive tone resist) or not exposed (negative tone resist) are chemically modified and in turn (partly) removed. This latter part is influenced by chemistry and diffusion effects in the resist.

35.5.2 Principle of Lithography Simulation

Figure 35.16 illustrates the lithography process and its simulation, which is divided into two steps: First, for the imaging step, the intensity distribution, generated by the projection of the mask through the optical system, inside the photoresist is simulated. Second, the modification of the photoresist caused by the energy deposited during exposure, and governed by chemical reactions, diffusion, and temperature in case of a post-exposure bake process, is simulated. Different to the other process steps described in the other subsections, the imaging step requires simultaneous simulation on equipment, and feature-scale level to calculate from characteristics of the illumination source, the mask, and the optical system used the energy deposition in photoresists on a nanometer scale.

35.5.3 Simulation of Imaging

The physics of projection is well understood and could in principle be fully described by the well-known Maxwell's equations. However, due to the different size dimensions to be simulated during the projection step, different simulation methods derived from the Maxwell's equations must be applied. For example, the projection of the mask can be simulated very accurately with derivatives of the Hopkins's equation [113], whereas the mask diffraction is typically simulated by directly solving the Maxwell's equations either without any simplifications or, depending on the mask area and accuracy to be simulated, by using some derived simplified methods.

One common derivative of the Hopkins' equation is the Abbe approach [111], which basically consists of a Fourier transformation F of the mask transmission, a multiplication with pupil functions P in the Fourier space to describe the transmission behavior of the optical system, and finally an inverse Fourier transformation F^{-1} to simulate the intensity

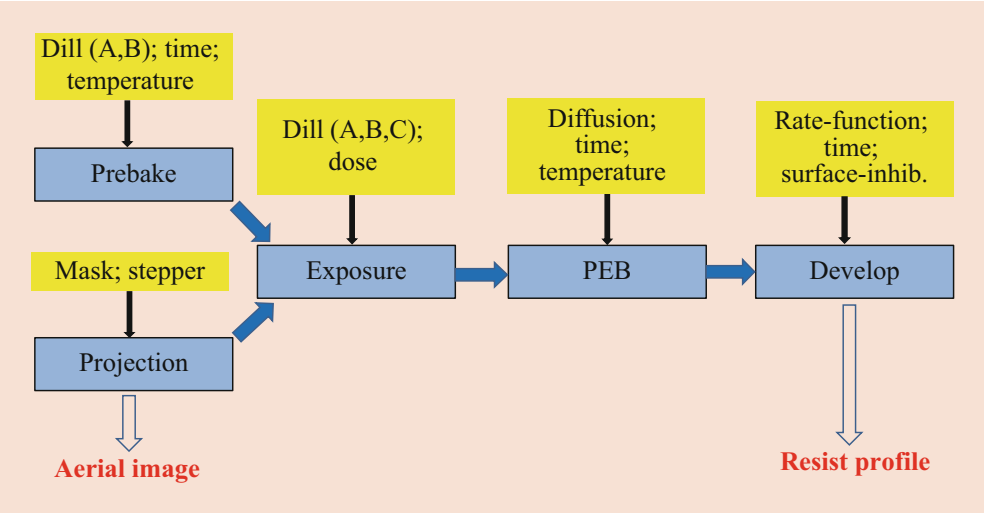

Fig. 35.16 Principle of lithography simulation

distribution in the image plane. This approach is based on the assumptions of an illumination with a single plane wave along the z-axis or with a tilt angle (t_x,t_y), a given complex mask transmission $t(x,y)$, and projection along the z-axis. Spatial frequencies f_x and f_y are introduced, which depend on the diffraction angles Θ_x and Θ_y in x- and y-directions, and the wavelength λ, and are used for the mask diffraction spectrum $s(f_x,f_y)$. In the following formulas, a scalar description not considering polarization is given:

$$f_x = \frac{\sin(\theta_x)}{\lambda}; f_y = \frac{\sin(\Theta_y)}{\lambda} \tag{35.95}$$

$$s(f_x,f_y) = F\{t(x,y)\} = \int t(x,y) \cdot \mathrm{e}^{-i2\pi\pi(f_x \cdot x + f_y \cdot y)} \mathrm{d}x\,\mathrm{d}y \tag{35.96}$$

For illumination with the tilt angle (τ_x,τ_y), the mask diffraction spectrum is shifted accordingly:

$$s(f_x,f_y) \to s\left(f_x - \frac{\sin\tau_x}{\lambda}, f_y - \frac{\sin\tau_y}{\lambda}\right) \tag{35.97}$$

The pupil function $P(f_x,f_y)$ expresses within the numerical aperture NA, for example, focus and aberrations, and is zero outside:

$$P(f_x,f_y) = 0 \text{ for } \sqrt{\sin^2\theta_x + \sin^2\theta_y} > \mathrm{NA} \tag{35.98}$$

The complex amplitude a_P of the light in the image plane resulting from a single source point P is then given by the inverse Fourier transformation of the pupil function times the diffraction spectrum, where the tilt is considered in the pupil function P:

$$a_P(x,y) = F^{-1}\left\{P\left(f_x - \frac{\sin\tau_x}{\lambda}, f_y - \frac{\sin\tau_y}{\lambda}\right) \cdot F\{t(x,y)\}\right\} \tag{35.99}$$

Alternatively, the tilt could also be considered in the diffraction spectrum s according to Eq. (35.97) while using the pupil function P without tilt.

The overall light intensity is then calculated as the incoherent sum across the images of all points P of the light source:

$$I_{\mathrm{tot}} = \sum_P a_P(x,y) \cdot a_P^*(x,y) \tag{35.100}$$

However, for state-of-the-art lithography technologies, the real topography of the masks and their materials, described by the complex refractive indices $n + ik$, must be considered as well as polarization effects. This is not possible with analytical approaches like the Kirchhoff approximation [114], which assumes an infinitely thin mask. Moreover, for some investigations, it is not sufficient to only calculate the image generated in the image plane (the so-called aerial image). Instead, the light transmission within the photoresist must be calculated, because the intensity changes due to absorption and reflection.

A possible approach, not using the Kirchhoff approximation, is to simulate the diffraction at the mask via an efficient numerical solution of Maxwell's equations, for example, via the so-called finite-difference time-domain (FDTD) method (see the standard reference [115]) or in Fourier space via a variant of the so-called rigorous coupled-wave analysis (RCWA) (see [116]). The key feature of FDTD is that Maxwell's equations are solved on a staggered grid, one subgrid for the electrical field $\boldsymbol{E}$ and another subgrid for the magnetic field $\boldsymbol{H}$, as visualized in Fig. 35.17: Here, the values of one field vector (either $\boldsymbol{E}$ or $\boldsymbol{H}$) at the time

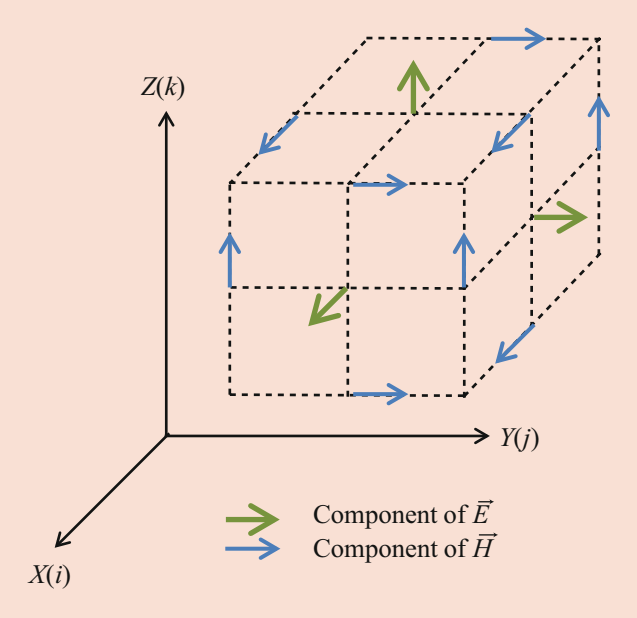

Fig. 35.17 Spatial discretization in the FDTD algorithm: distribution of E and H across the two staggered grids

t_n is calculated from the values of the other field vector (either $\boldsymbol{H}$ or $\boldsymbol{E}$) at the preceding time step t_{n-1}. Both the accuracy and the computation time are about proportional to the number of mesh points. Because the typical mesh size is about 5% of the wavelength λ, the computation time scales with about $1/\lambda^2$ [117]. The method is more appropriate for optical lithography than for EUV lithography where the ratio between wavelength and feature size is much smaller than in optical lithography. Figure 35.18a shows a schematic discretization of an alternating-phase-shift mask AltPSM.

The waveguide method (WG) [117] is a variant of the RCWA which is well suited for the simulation of the impact of EUV masks. Such masks consist of absorbers placed on top of the multilayer MoSi mirror. For the simulation the mask is divided into slices with homogeneous optical properties in the vertical direction; see Fig. 35.18b. Inside these slices or waveguides, both the electromagnetic fields and the permittivity profiles are expanded into Fourier series and are inserted into Maxwell's equations. The problem statement based on Maxwell's equations is transformed into the solution of an eigenvalue problem, which yields the eigenmodes of all mask slices. Using proper boundary conditions, the coupling of the modes of all slices leads to the overall physical response of the system. The computation time scales linearly with the number of inhomogeneous slices (more than one material inside the slice) and cubically with the numbers of the modes considered in both lateral directions. Both FDTD and WG and their advantages and drawbacks are explained more in detail in the literature [117].

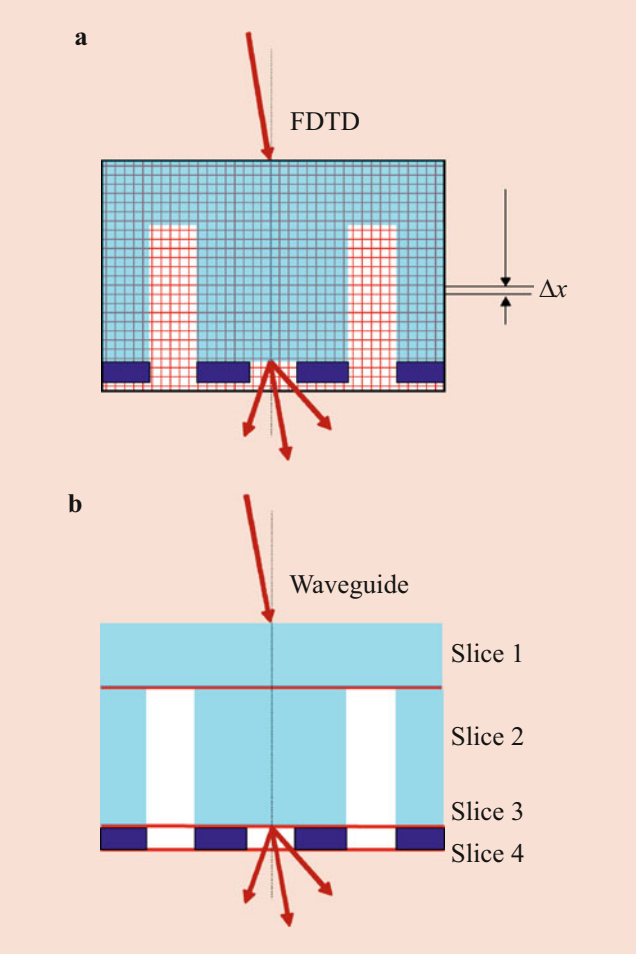

Fig. 35.18 Schematic mask representation for (**a**) FDTD and (**b**) waveguide. The figure shows one and a half periods of a standard alternating phase-shift mask AltPSM and the corresponding FDTD mesh and waveguide slices

Another approach used for the simulation of parts of resist exposure is the transfer matrix method for homogeneous layers. Here, the light intensity within the layer stack is calculated for a given number of layers with their refractive indices $n + ik$, angle of incidence, and polarization. The two variables considered are the amplitude of the incident and the reflected light within the system. Incident and reflected light within a layer propagate as a plain wave with damping constant k, described by a diagonal matrix. Transmission and reflection at the interfaces between layers depend on the complex refractive indices of the layer together with the angles of incidence and the polarization of the light and are expressed by a matrix where the off-diagonal elements describe the reflection. Besides the orientation of the mask features, the difference in the reflectivity between a transversal-electric and a transversal-magnetic wave may result in important polarization effects. A more detailed description of the transfer matrix method can be found in the literature, for example [114].

35.5.4 Simulation of Resist Development

The imaging process outlined above modifies the photoresist due to the locally deposited energy. In the subsequent development step, depending on the resist type used, either the (sufficiently) exposed or the (sufficiently) unexposed parts of the resists are removed.

The common description of this process is given by the Dill model [118]:

$$\frac{\partial M(r,t)}{\partial t} = -C\,\tilde{I}(r,t)\,M(r,t) \tag{35.101}$$

$$a(r,t) = A\,M(r,t) + B \tag{35.102}$$

Here, the concentration of the photoactive compound $M(r,t)$ decreases due to the deposited energy density $\tilde{I}(r,t)$, and the absorption $\alpha(r,t)$ depends on $M(r,t)$. A, B, and C are the Dill model parameters for the photoresist in question. Furthermore, the photoactive compound M diffused with a diffusion coefficient D:

$$\frac{\partial M(r,t)}{\partial t} = D\Delta M(r,t) \tag{35.103}$$

Finally, the local resist development rate $R(M)$ depends on M. Various refinements of this standard reaction-diffusion model were developed in order to describe state-of-the-art photoresists, e.g., chemically amplified resists (CAR).

35.5.5 State-of-the-Art Lithography Simulation

Current state-of-the-art lithography simulation tools employ selections of the basic approaches summarized below in various combinations, depending on the tool and the application in question. Commercially supported tools such as PROLITH [119], Sentaurus-Lithography [120], and OPTOLITH [121] additionally provide elaborated user interfaces, and especially Sentaurus-Lithography and OPTOLITH are integrated with other TCAD tools of the respective vendors. Examples shown in the following subsection have been generated with the research and development simulator Dr.LiTHO [122], which is designed especially for efficiency and flexibility in the implementation of physical models and algorithms.

The semi-analytical Kirchhoff approximation allows for some simple simulation studies where the mask can be approximated as a two-dimensional pattern of transparent and opaque arrays and where polarization effects can be neglected. State-of-the-art masks need to be simulated with numerical approaches such as FDTD, RCWA, or WG, which are also mandatory if polarization comes into play. Whereas these are needed for the near field of the mask, the imaging of this near field onto the wafer may further be simulated, for example, with the Abbe approach outlined above, utilizing the result of the mask simulations. As described above, energy deposition in the photoresist is simulated with the transfer matrix approach, and resist development is being simulated based on the Dill model.

Besides these aspects which are specific to lithography simulation, several more general techniques are also needed, customized, and employed in lithography simulation: During resist development, its surface is moved with one of the techniques described below in Sect. 35.7 on deposition and etching. In order to further improve the efficiency of simulation and to extend the possible sizes and use cases of the masks to be simulated, different domain decomposition methods [123] can be employed which may include not only three-dimensional but partly also two- or even one-dimensional simulations. This may also reuse results of prior simulations which were stored in a repository [123]. To enable important and promising technological approaches such as source-mask co-optimization [124], advanced global optimization algorithms such as genetic algorithms [125] are being employed. Furthermore, as mentioned below in Sect. 35.8 on process variations, lithography simulation is also an essential part of TCAD-based Design-Technology Co-Optimization (DTCO) approaches, in order to establish the link between mask layout and the performance of real devices and circuits.

35.5.6 Examples for State-of-the-Art Lithography Simulation

In the following, a few examples of results obtained with the research and development lithography simulator Dr.LiTHO [122] in the context of current research on the development of advanced lithography technologies are shown.

Figure 35.19 shows the impact of a particle located on an EUV mask pellicle on the printed feature size (critical dimension, CD) for an EUV system with a NA of 0.55 under specific imaging conditions [125]. The pellicle is a polysilicon membrane at 2.5 mm mask distance. One can see that larger particles are critical even in the presence of a mask protection membrane.

Figure 35.20 shows the impact of mask absorber 3D effects on the process window of 20 nm semi isolated lines of a NA 0.33 EUV system [123]. The black curve shows the result for an ideal absorber in combination with a real multilayer and the gray curve the same for a real absorber in combination with a real multilayer. In the simulations, the real absorber can be replaced by an ideal one to "switch off" the absorber-related 3D mask effects. The comparison

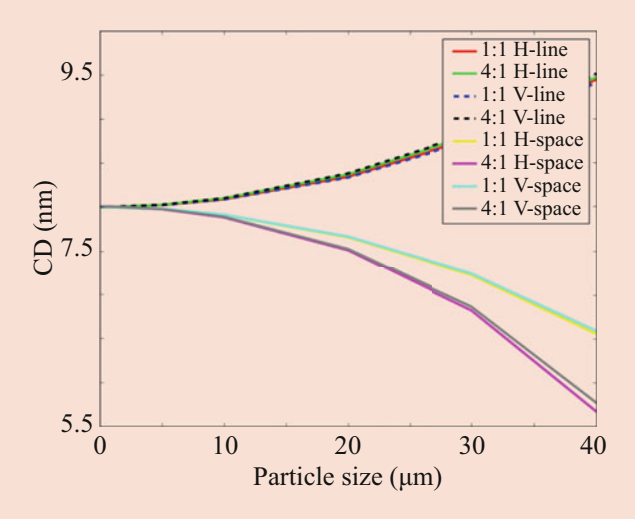

Fig. 35.19 Example for the impact of a particle located on an EUV mask pellicle on the printed CD, for different duty factors *n*:*m* of lines and spaces. The lines and spaces are located either in horizontal (H) direction (perpendicular to the chief ray angle of the system) or in vertical (V) direction (parallel to the chief ray angle of the system) [125]

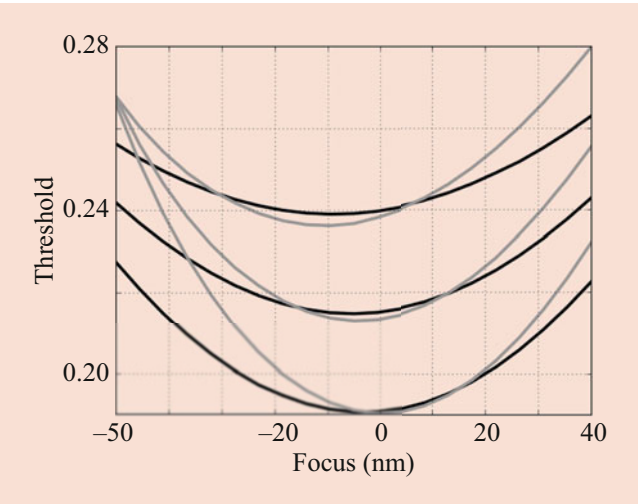

Fig. 35.20 Process windows of an ideal EUV absorber (black, infinitely thin absorber) and a real EUV absorber (gray) both on top of a real EUV multilayer [123]

with the fully real mask shows the effect caused by the real absorber geometry, which is mainly the expected asymmetric through focus behavior.

The defect-induced loss of reflected light and image intensity in the area of an EUV multilayer defect can be partly compensated by a removal of absorber in the vicinity of the defect. Figure 35.21 demonstrates a simulation of this method for 32 nm features at a NA of 0.33 [126]. The repair is done by removal of the absorber in a circle around the center of the defect; see dashed larger circles in the figure, with an optimum of 50 nm (wafer scale). Other defect positions and sizes may require more complex repair shapes, especially at larger NAs where more details of the defect will become visible.

35.6 Simulation of Deposition and Etching

Similar to lithography, also for deposition and etching, it is indispensable to take equipment effects into account when simulating the process results on feature scale. However, here mostly a clear separation can be made between the equipment and the feature-scale level: Equipment simulation (on a scale of centimeters to meters) can be used in a preparatory step to calculate quantities just above the (macroscopically flat) wafer, such as local gas or particle flows and local temperatures, which are affected by the reactor geometry, process recipes, and partly varying further parameters. These intermediate results can then be used as inputs for feature-scale simulation (on the scale of micro- to nanometers) of the local deposition and etching of layers. Figure 35.22 visualizes the separation between these simulation scales.

The area of the simulation of deposition and etching is very diverse in three respects: First, it includes macroscopic equipment and nanoscale feature simulation, and moreover also the (generally three-dimensional) simulation of the evolvement of partly complex surfaces. These aspects are reflected by the following subsections. Second, there is a huge variety of etching and deposition processes which cannot be covered within the space available for this section. Therefore, here only the basic principles and approaches are discussed, and no attempt is made to list the specific equations and parameters for the large variety of processes used in semiconductor technology.

35.6.1 Outline of Equipment Simulation

Whereas in the area of lithography integrated equipment and feature-scale process simulation is mandatory since long, as described in the preceding section, for both deposition and etching, the simulation at equipment level can be separated from the feature-scale simulation. Similar to this, this separation is also possible for diffusion and oxidation, whereas in these two areas, equipment simulation is rarely used. Except for plasma doping, e.g [127], for ion implantation equipment simulation has so far not been an issue.

In most cases equipment simulation consists of the following steps:

1. Three-dimensional discretization of the process reactor or furnace.
2. Establish assumptions on the physical/chemical modeling

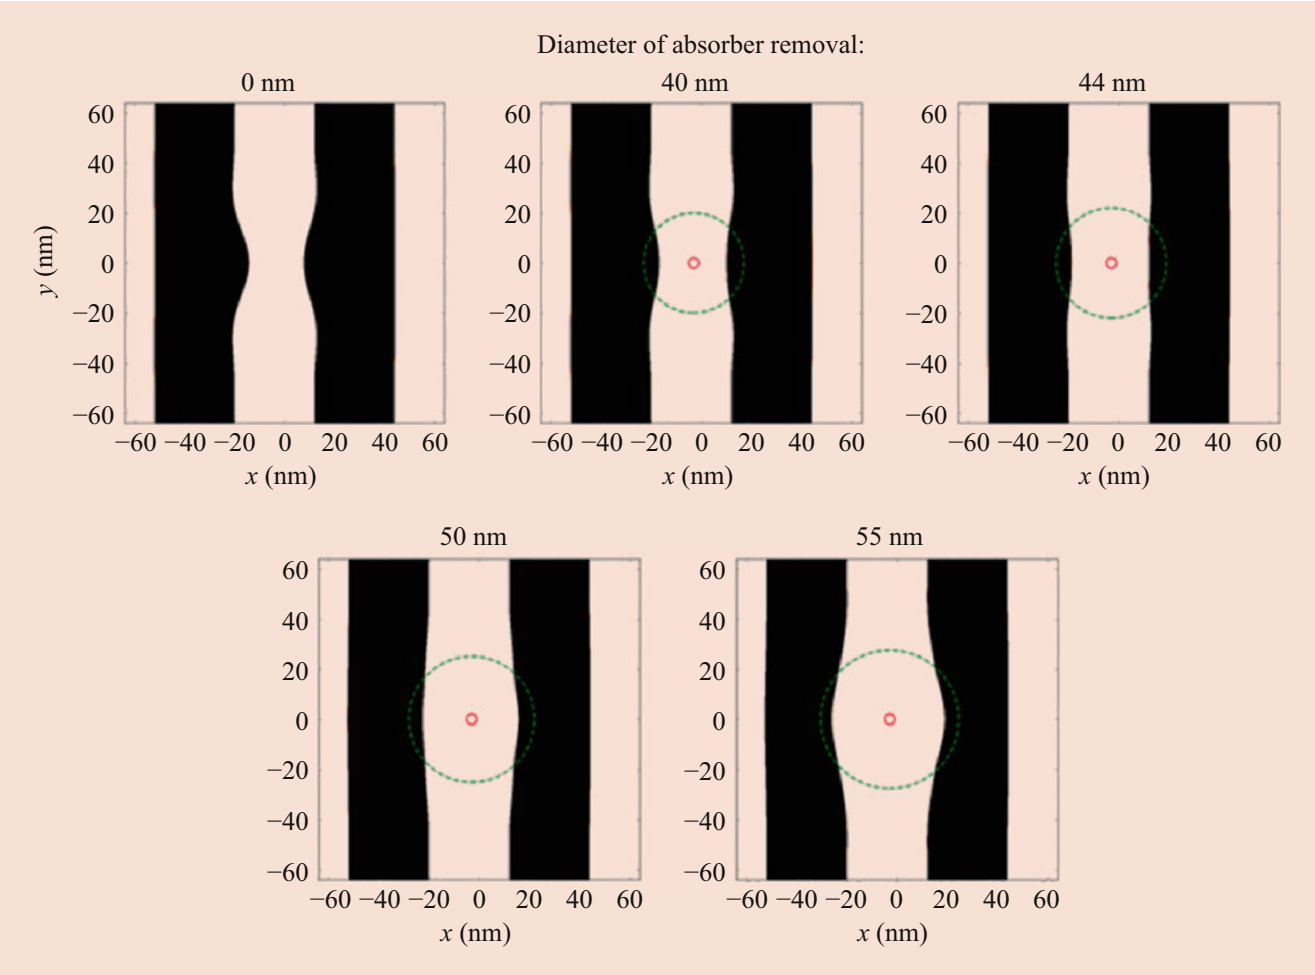

Fig. 35.21 EUV multilayer defect repair by increasing absorber removal around the defect. The defect caused line deformation is reduced with an optimum at 50 nm absorber removal [126]

components for the system in question, e.g., gas flow, resistive or inductive heating, radiative heat transfer, plasma physics, characteristics of sputter targets, chemical reactions, etc.

3. Set up and solve a system of partial differential equations, representing fluid dynamics, thermal behavior, plasma characteristics, electrical properties, and chemical reactions for the equipment, possibly including macroscopic models for the interaction with the wafers (e.g., as sinks or sources for heat or for chemical species). Such macroscopic models do not have to resolve the individual features on the wafer. This step can be omitted if, e.g., the particle flow can be extracted directly in step 4 from the characteristics of a sputter target defined in step 2.
4. Extract from the equipment simulations the quantities of interest directly above the wafer, e.g., temperature, pressure, species concentration, angular or energy distributions of ions, electrical field, or potential (without considering individual features on the wafer).

Whereas all these steps are necessary to define and describe the equipment and process in question, the main numerical effort is needed for step 3, except for cases where no fluid dynamics is involved. In order to efficiently implement step 3, usually well-established computational fluid dynamics [128] or plasma simulation codes [129] are employed, which then have to be supplied by the user with the relevant physical data and models, as described above.

As an example, Fig. 35.22a deals with the equipment simulation of the deposition of silicon oxide in a capacitively coupled plasma-enhanced chemical vapor deposition (PECVD) reactor using oxygen and TEOS chemistry. The contour colors in the figure represent the concentration of the oxygen radicals. The corresponding fluxes of oxygen radicals, together with the fluxes of oxygen ions, provide the boundary conditions for the feature-scale simulation, the result of which is shown in Fig. 35.22b. This figure represents a cross section of a contact hole with a non-conformally deposited silicon oxide layer.

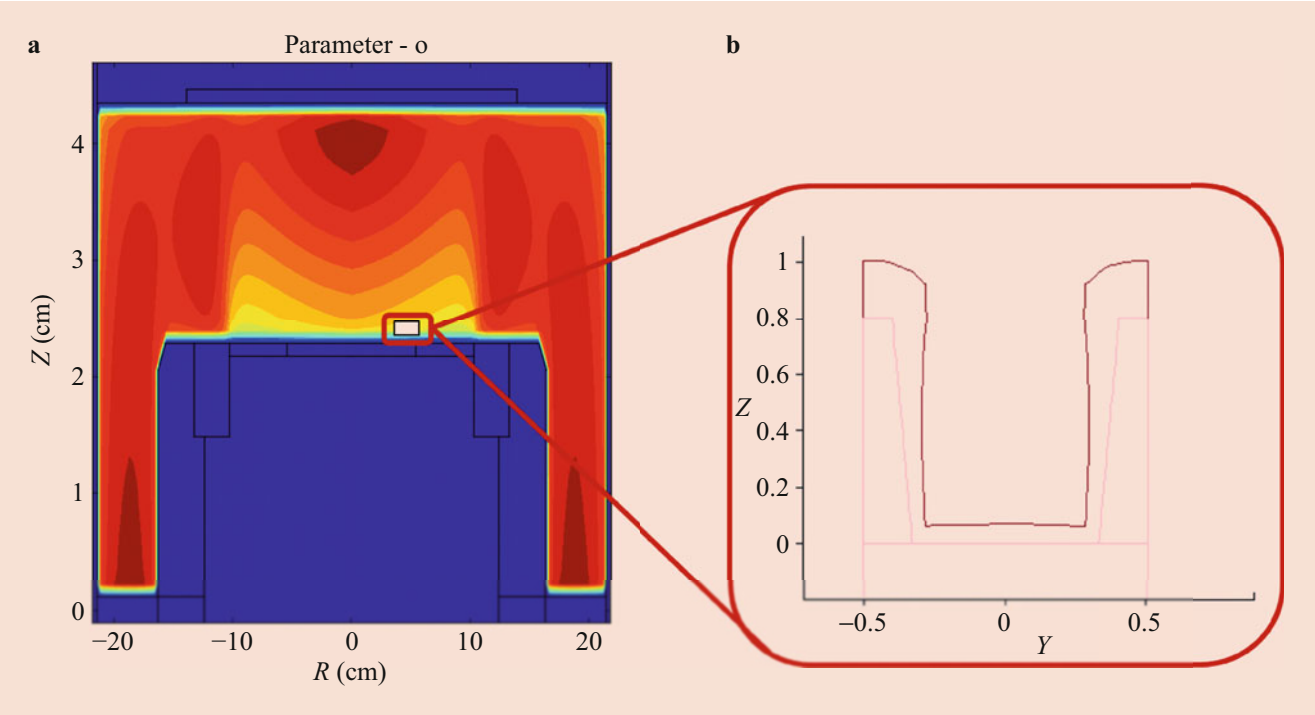

Fig. 35.22 Visualization of the scales of (**a**) equipment and (**b**) feature-scale simulation for deposition and etching. The clipping for feature-scale simulation in the left figure is not to scale

In case of diffusion and oxidation processes, the situation is somewhat easier, because the process gas does not react in the furnace volume, but only on the wafer (in case of oxidation, transforming silicon to silicon oxide). Here, step 3 is reduced to the simulation of fluid dynamics and thermal behavior. However, several transient effects might need to be considered, due to the movement of a wafer or a batch of wafers into or out of the preheated furnace or due to ramping the temperature up and down while the wafer is being processed. This is especially important in case of very short time annealing processes, such as spike or millisecond annealing, which need elaborated simulation of the transient local temperature distributions because these are not in equilibrium. For example, laser thermal annealing was discussed in [130].

35.6.2 Discretization and Movement of Surfaces

Deposition and etching do not only change the geometry of the device or structure during fabrication, but may also change its topology: New layers may be added, old layers may be completely removed, originally connected features may get disconnect and vice versa, and holes may be transferred into voids. Very small features may be critical, because they may, e.g., act as an etch stop. Also curved, tilted, and non-axis-aligned structures must be accurately described. In turn, it is vital to employ surface discretizations and algorithms for their update, which are numerically efficient and stable, can reliably handle arbitrary topographies and their changes and allow for adaptive control of the local number of elements used, to achieve a good compromise between accuracy and efficiency.

Three main methods have been used for the description of geometries and of their changes during processing. The simplest and most stable is the cell-based description and the related cell-removal algorithm [131], which is, however, due to its inherent limitations hardly used any more and here only mentioned for historical and reference purposes. The other two approaches are triangulation and the level set method. Triangulation is the three-dimensional extension [132] of the "string algorithm" which was generally used for two-dimensional topography simulation [133]. Here, surfaces and interfaces are discretized by triangles. Geometrical changes during processes are then described by moving the vertices of the triangles according to rates which result from physical models as described in Sect. 35.6.3. The main advantage is that these models can directly use the position, size, and orientation of these triangles. The main disadvantage is that it is difficult with this approach to deal with topological changes, e.g., in case that during layer deposition the opening of a hole closes to form a void, as it would happen if the process shown in Fig. 35.23 would be continued.

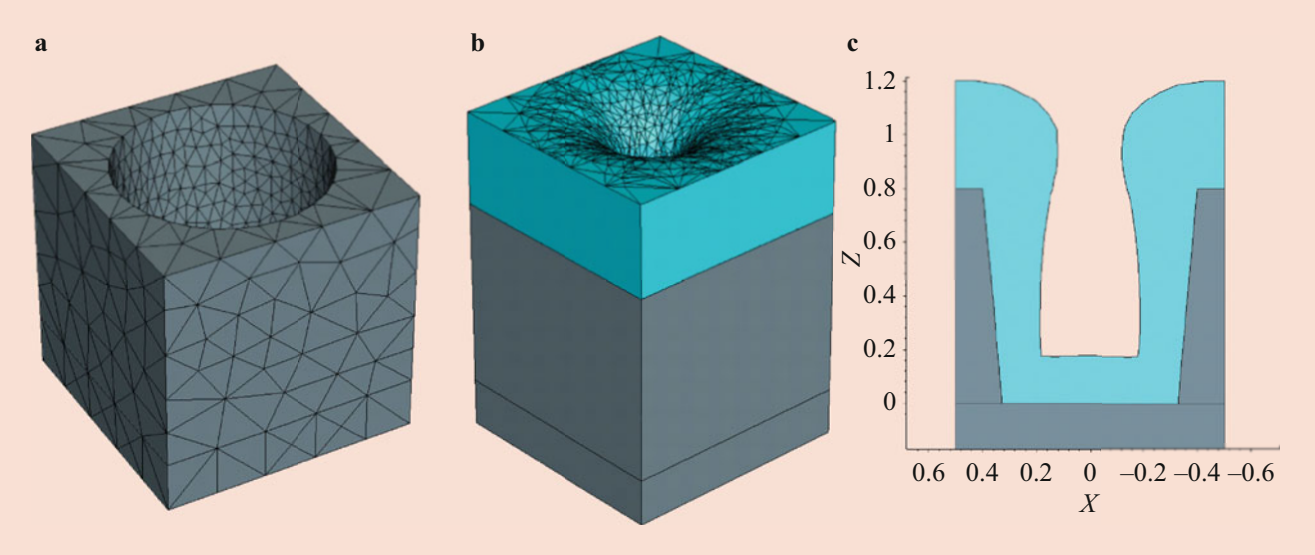

Fig. 35.23 Example for the discretization of a three-dimensional structure using triangles. (**a**) Initial contact hole; (**b**) simulation of non-conformal deposition of low-temperature oxide (LTO). Here, the side-wall faces of the simulation structure are discretized as rectangles; (**c**) cross-sectional view. The scale shown is in microns

The approach which is most frequently used for the discretization of three-dimensional surfaces and interfaces is the level set method: Here, the surface is described as the set of points $\boldsymbol{x}$ where a three-dimensional function $F(\boldsymbol{x}, t)$ equals zero, and the movement of the surface is simulated based on local rates $\boldsymbol{r}(\boldsymbol{x}, t)$:

$$\frac{\partial F(\boldsymbol{x}, t)}{\partial t} + \boldsymbol{r}(\boldsymbol{x}, t) \cdot \nabla F(\boldsymbol{x}, t) = 0 \tag{35.104}$$

The main advantages are that with this approach surfaces and interfaces are given as solutions of partial differential equations, which are solved on a three-dimensional mesh, similar to bulk variables like dopant concentrations, and that changes in topology should not lead to problems if the underlying three-dimensional grid is locally fine enough. The disadvantage is that surface elements and surface normals needed in the implementation of the physical models as outlined in Sect. 35.6.3 are not given directly and must be extracted separately from the level set description.

35.6.3 Models for Deposition and Etching Rates

Physical/chemical models for deposition and etching consider the interaction of different ionic or neutral species with the surface to allow the determination of local deposition or etching rates. Boundary conditions for the feature-scale modeling can be provided by equipment simulations or measurements, e.g., of temperature, pressure, species concentrations, or energies of neutrals and ions. In the following, as an example we discuss low-pressure chemical vapor deposition, where the mean free path is large compared with the feature size and the particles move isotropically in the volume of the reactor far away from the surface.

Assuming a triangulated surface, for each triangle I the reaction flux R_i depends on the flux of particles from free space A_i and from all other triangles j, S_{ij}. Whereas the impinging particles are incorporated into the growing layer with a sticking coefficient sc, the remaining particles are desorbed and may arrive at other parts of the surface. Here, the notation from the literature [132] is used, in which also more details are given:

$$R_i = \mathrm{sc} \cdot \left(A_i + \sum_j S_{ij} \right) \tag{35.105}$$

Here, the fluxes from free space and from all other triangles are calculated based on the solid angle for free sight to gas space Ω_{free}, the solid angle of free sight to all other triangles j, $\Delta\Omega_{ij}$, and the angle ϑ_{ij} between the surface normal of triangle i and the straight line between the centers of triangle i and triangle j; see Fig. 35.24:

$$S_{ij} = R_j \frac{1 - \mathrm{sc}}{\pi\ \mathrm{sc}} \cos\vartheta_{ij} \cdot \Delta\Omega_{ij} \tag{35.106}$$

The flux A_i from the gas volume is obtained by

$$A_i = G \int_{\Omega_{\mathrm{free}}} \cos\vartheta \, \mathrm{d}\Omega \tag{35.107}$$

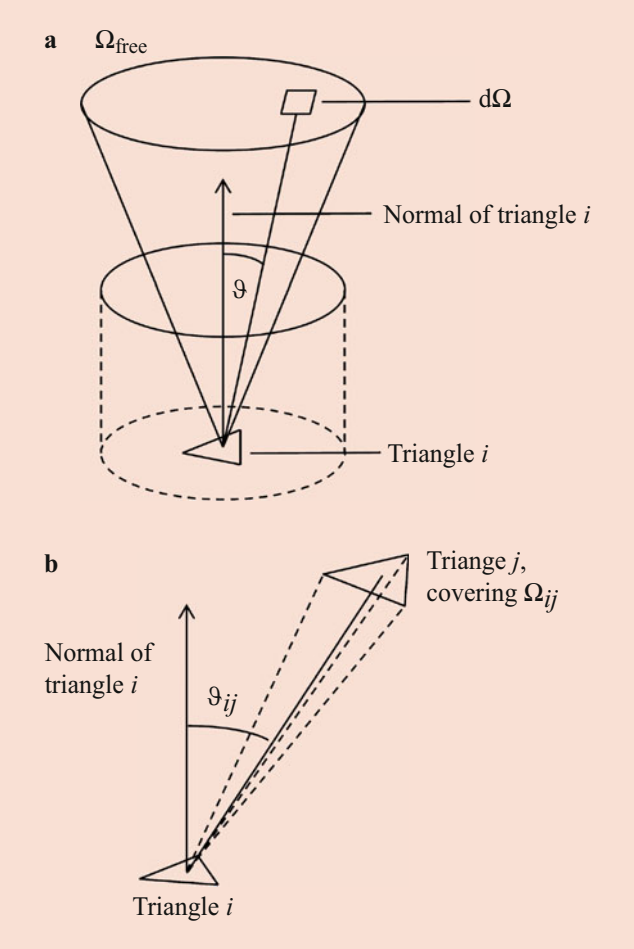

Fig. 35.24 (**a**) Solid angle Ω_{free} covering the region of free sight to gas space for a triangle *i* at the bottom of a cylindrical contact hole; (**b**) geometry for two arbitrary triangles with particle transfer to be calculated

where ϑ is the angle between the normal of triangle i and the direction from triangle i to dΩ (see Fig. 35.24).

Establishing the flux balance between all triangles and with free space results in a system of linear equations for the reaction fluxes R_i, with the transfer matrix T_{ij} between triangles *I* and j:

$$\pi R_i - \sum_{j \neq i} T_{ij} R_j = \pi - \frac{1}{1 - \mathrm{sc}} \sum_{j \neq i} T_{ij} \tag{35.108}$$

$$T_{ij} = (1 - \mathrm{sc}) \cos \vartheta_{ij} \cdot \Delta\Omega_{ij} \tag{35.109}$$

Here, for the transfer matrix elements T_{ij}, the calculation of the angles of free sight to gas space and especially to all other triangles is needed. For the latter, it must be checked if the view is (partly) blocked by any other triangle. In turn, for a surface discretization consisting of *n* triangles, the numerical effort scales with the third power of *n*.

Finally, the absolute deposition rates for each surface segment are obtained by normalizing to the deposition rate for a one-dimensional (flat) geometry. That one-dimensional deposition rate and the sticking coefficient are the only physical parameters of the process, whereas the transfer matrix characterizes the geometry. These have to be re-calculated after each time step to take the changes of the geometry into account.

In terms of computational efficiency, subsequent work has dealt especially with the optimum way to calculate the angles of free sight. Other numerical issues have been the appropriate adaptive surface discretization with one of the methods outlined in Sect. 35.6.2 and the efficient implementation of surface movement.

Figure 35.23 shows an example of a simulation that has been carried out with the model described above assuming a sticking coefficient of 0.15 which is a typical value for the modeling of a low-temperature oxide (LTO) process.

This basic model for deposition has been extended and adapted to the different deposition processes in various respects:

- Processes in which more than one mechanism contributes to the deposition. In the simplest case, the approach is applied simultaneously to two or more reaction species, which show no interaction and are each described by their one-dimensional deposition rate and their sticking coefficient.
- Long-throw sputter deposition which is characterized by the emission characteristics of the sputter source, collisionless movement of the sputtered particles due to low pressure, and a sticking coefficient of unity. Here, the transfer matrix is not needed, and the local deposition rates are calculated by integrating the contributions of the sputter source across the angle of free sight for the surface point in question, as discussed in the literature [134].
- Considering different species which either react on the surface and/or sputter away some already deposited atoms. This leads to additional terms in Eq. (35.105) while not changing the basic approach because the role and computation of the transfer matrix does not change. An example is ionized metal plasma deposition [135].

Such models can also be implemented by using Monte Carlo ray tracing instead of the transfer matrix method [136]: Here, trajectories of pseudo-particles are traced until they hit the layer surface. Similar to above, physical models are employed for the initial emission statistics of the particles and their adsorption, reaction, and desorption at the wafer surface. This also allows for the simulation of deposition

processes which are carried out in two steps, like atomic layer deposition (ALD) [137].

For etching, depending on the process in question, some or all of the elements discussed above for deposition may show up. In most cases of etching, physical and chemical sputtering play major roles, with the corresponding yields introduced as model parameters, replacing or complementing sticking coefficients [138]. However, adsorption/desorption and in turn transfer matrices may still play a role, because for some etching processes the emission and re-adsorption of species need to be modeled.

A detailed open-access review paper [139] deals especially with numerical aspects linked to the usage of the level set algorithm and physical models for etching simulation.

35.7 Process Variations

For advanced micro- and nanoelectronic devices and circuits, both statistical and systematical process variations come into play, which influence the performance of devices and systems. In result, although the nominal product, fabricated under ideal circumstances, may meet the specifications and required figures of merit, a considerable fraction of devices and circuits may fail to do so, causing yield loss and critical increase of fabrication costs per sold unit. In turn, the impact of such process variations must be known and minimized as much as necessary.

Statistical process variations such as random dopant fluctuations RDF [3], line edge roughness LER [140], and metal grain granularity MGG [141] result from the granularity of matter. They have been considered since long in dedicated device studies, employing special efficient device simulation tools [142] and simple but valid assumptions on the statistical distribution of these variations. This is in line with the frequent practice in device simulation to start from assumed idealized device geometries and dopant distributions. However, in a real fabrication environment not only the full process flow must be considered, which leads to non-idealized device geometries and dopant distributions, but also its variations. In the following, a brief overview of the sources of systematic process variations is given, together with a hierarchical approach to simulate their effect on devices and circuits.

35.7.1 Sources of Systematic Process Variations

Systematic process variations may occur in all major process steps. They can be grouped into two categories: First, inhomogeneity which is inherent to the equipment used and which can neither be completely avoided by optimizing the equipment design nor the process flow. Second, some process parameters cannot be controlled precisely or may have some drifts during processing or on the long run between repeated process steps.

For both optical and EUV lithography, both the distance between the optical system (last lens or last mirror) and the wafer and the energy emitted by the light source may change from illumination to illumination in the standard step-and-repeat process, leading to systematic variations between different dies on one wafer and especially between different wafers. The so-called process window in Fig. 35.25 shows examples how these variations of focus and dose, respectively, modify the size of the features generated in the lithography step, the so-called critical dimensions (CD).

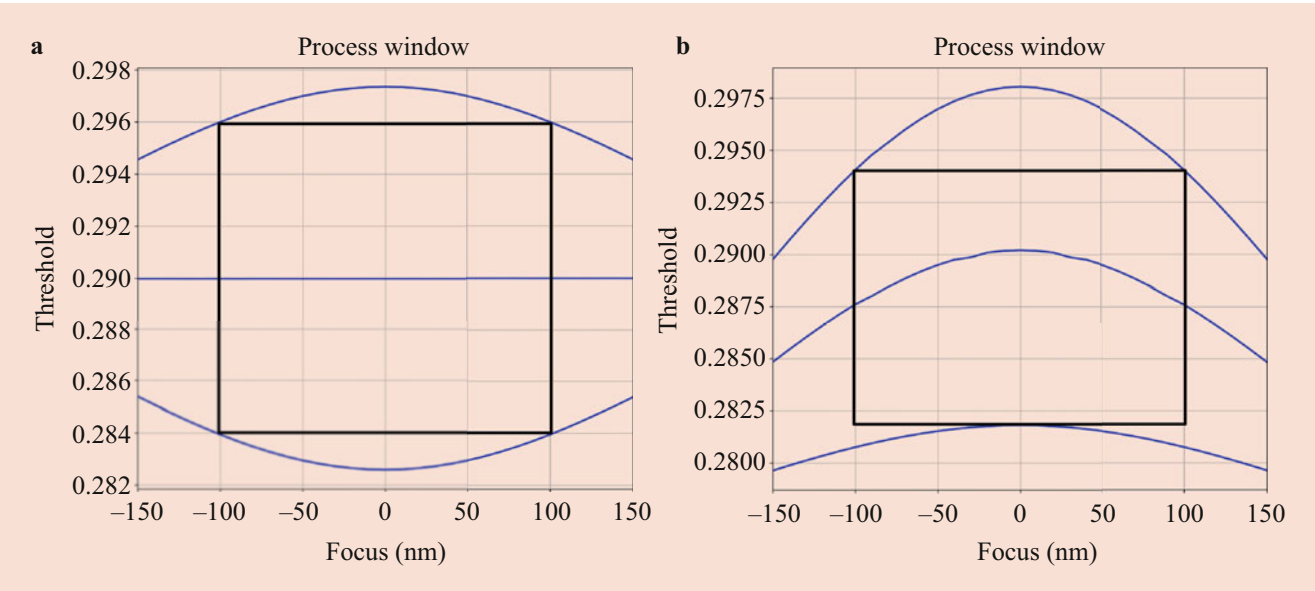

Fig. 35.25 Process window in optical lithography for (**a**) 120 nm pitch with 60 nm lines and (**b**) 72 nm lines

Here, the central line shows the combinations of focus and dose which lead to the nominal CD (60 nm left picture, 72 nm right picture), whereas the upper and lower lines show the combinations of focus and dose which lead to a CD increase or decrease by 10%, respectively. Whereas under specific imaging conditions, the CD stays constant for varying focus at a specific fixed dose, for other imaging conditions, this is not the case. Additionally, also some other process variations may occur in lithography steps, caused, e.g., by defects and imperfections of the optical system or imperfect wafer alignment.

For etching and deposition, especially inhomogeneous concentrations of ions and neutrals, the temperature distribution, or the emission characteristics of the sputter target lead to systematic process variations across the wafers or between wafers. Figure 35.26 shows an example for the dependence of the etch rate on the distance from the center of the wafer for reactive ion etching of silicon based on chlorine chemistry.

Further systematic process variations include among others differences between nominally equal temperature profiles in very short time annealing processes, such as millisecond or laser thermal annealing [130].

35.7.2 Hierarchical Simulation of the Impact of Process Variations

In order to predict the impact of process variations on devices and systems, it is necessary to trace them through the whole fabrications process: Not only the process step where the variation occurs must be simulated, but all subsequent process steps must be simulated, using as starting conditions both the intermediate results without and with the effects of that variation. Furthermore, it is necessary to make sure that numerical errors which occur throughout the simulation or when changing between the data representation of different simulation modules or tools do not invalidate the variability study: They must affect the result significantly less than the variation in question.

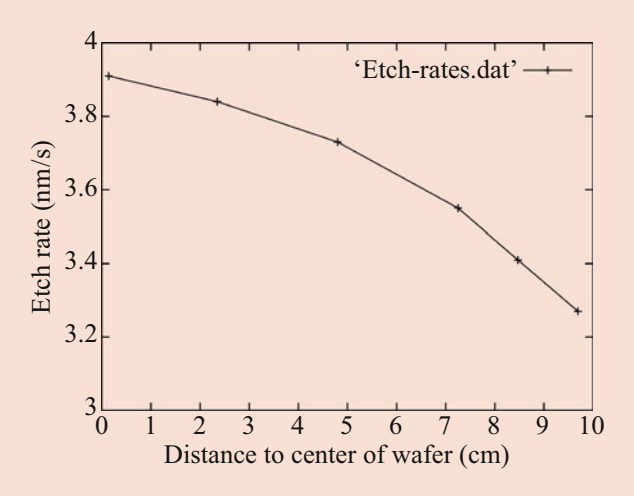

Fig. 35.26 Example for the dependence of etch rate of a silicon etching process on the distance from the center of the wafer

From the modeling point of view, the study of process variations requires to employ appropriate models: First, models which describe the effect of the process variation at the step at which it occurs – e.g., the impact of focus on the CD generated in a lithography step. Next, models must be used which are capable of tracing the changes of the results of that process step (here the CD) through all following process steps. Generally, both requirements can be met by selecting a suitable process model among the ones available.

In real cases, a state-of-the-art process flow may be affected by a large number of process variations. Considering just 10 process variations and just 5 parameter values for each of them would yield a final split of 5^{10} or nearly ten million process simulations, which is of course not feasible. In turn, it is necessary to first select the most relevant process variations (about 3–5) and then to employ a suitable design-of-experiment approach to define the set of process simulations needed, as discussed elsewhere [143].

In result, geometries, dopant distributions, and potentially other quantities which characterize a device (or interconnect) are simulated for different values of the input process variations. Considering, e.g., three process variations which are discretized with three values each, a matrix of $3 \times 3 \times 3$ devices results. In order to extract compact models which are aware of variations, first the nominal compact model for the nominal device without any variations is extracted. In the second step, this compact model is extended to also include the process corners considered, which means in the example addressed here the $3 \times 3 \times 3$ devices [144]. Finally, statistical device simulation is employed to extend this compact model to also include the statistical process variations, such as RDF [144]. A later improvement of this method [145] has enabled the direct usage of the values of the systematic process variations (e.g., defocus) in the second compact model extraction step outlined above [143]; see Fig. 35.27. As an example Fig. 35.28 shows the saturation current of a nanowire transistor.

More detailed descriptions of the sources of process variations and of the hierarchical simulation of their impacts on devices and are given in a related open-access papers [143] [145].

35.8 Conclusions

Process simulation is the virtual image of IC manufacturing on a computer: It covers the whole development from the bare silicon wafer to the final device and circuit. Its full benefit can only materialize if accurate physical models with proper parameters are available within numerically stable and correct simulators.

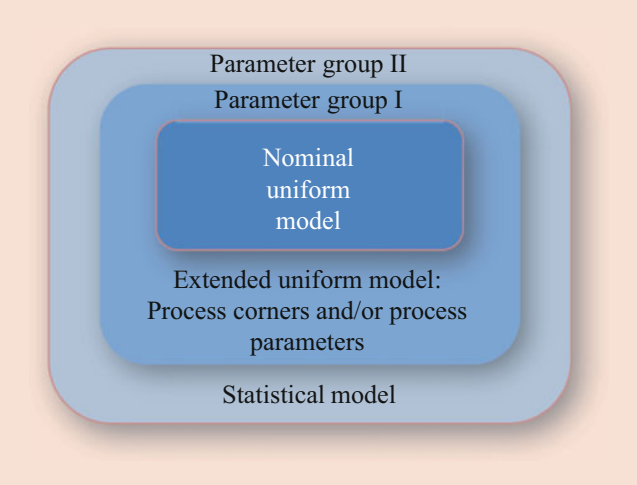

Fig. 35.27 Extraction and generation of hierarchical compact model aware of systematic and statistical process variations, following the approach published before [145]

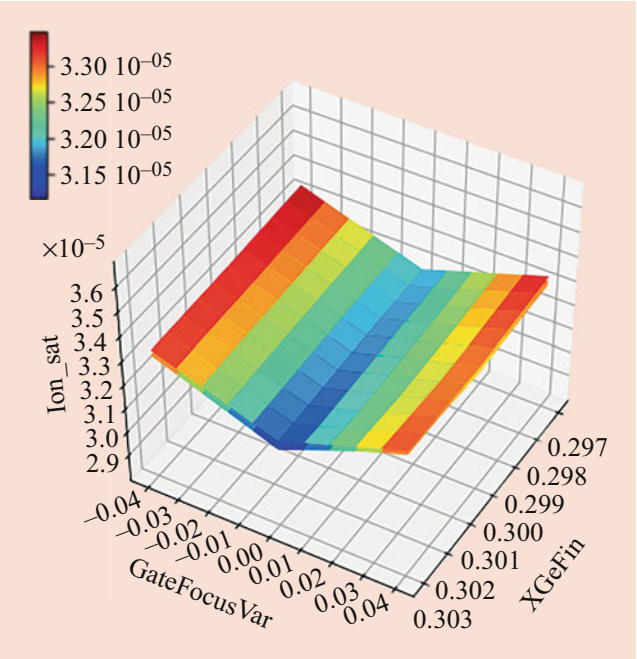

Fig. 35.28 Saturation current (color in amperes) of a nanowire NMOS described by the extended compact model (color in amperes) [145]

The applications of process simulation are manifold. Nowadays it is most frequently used in industry for the development and optimization of the process flows needed for the fabrication of devices. The success of this approach depends on the availability of advanced process simulation tools which cover the whole fabrication sequence, are closely linked with device simulation, and are accompanied by good user support. Because the speed of simulation is a key requirement for the simulation splits used in technology and device optimization, very frequently efficient models are used which depend on calibrations for the process flow in question. On the other hand, physically rigorous models are readily used for development and optimization of new advanced processes or pieces of equipment. Here, predictivity with as little calibration as possible is the key requirement, not the integration into an overall simulation system.

An increasingly important advantage of process simulation is that it can be used not only to study and select process options but also to quantify and minimize the impact of systematic process variations which are caused by the equipment used. Here, it makes indispensable contributions to the simultaneous development and optimization of technologies, devices, circuits, and designs, the so-called Design-Technology Co-Optimization (DTCO), which has in recent year developed into a key and indispensable method for the nanoelectronics industry.

With new semiconductor materials coming into use and new device architectures (including new carriers of information like spin or the phase of the material) emerging, the complexity of the processes to be simulated is continuing to grow. So are the requirements on model accuracy and generality and efficiency of simulation. There will also in future be several (but of course different from the past) challenges left for developers in the process simulation area.

Acknowledgments The authors of this chapter want to acknowledge the funding of some of the research leading to their results presented here by the European Union and by the German Federal Ministry of Education and Research. They want to acknowledge the contributions of colleagues from Fraunhofer IISB in terms of discussions and preparation of some figures, especially by E. Bär, A. Burenkov, and P. Evanschitzky.

Jürgen Lorenz (Diplomas in Physics and Mathematics from TU Munich, Dr.-Ing. from University of Erlangen-Nuremberg, Germany) joined Fraunhofer in 1983. He has been in charge of the simulation activities at the now-called Fraunhofer IISB in Erlangen since 1985, where he is currently head its department "Modeling and Artificial Intelligence." His main interests are physical models and software for process simulation.

Peter Pichler received his Dr.techn. degree from the TU Wien in Austria in 1985 and his Venia Legendi from the Friedrich-Alexander University Erlangen-Nürnberg in Germany in 2004. Since 1986 he has been Group Manager for Doping and Device Simulation at the Fraunhofer IISB in Erlangen, focused on dopant and point defect diffusion phenomena in semiconductors.

Abstract

In this chapter we consider a comprehensive, multiphysical digital twin for NEMS and MEMS, in particular, for a range of effects that are currently of interest in electromechanical MEMS. The chapter first approaches the formation of a digital twin from the viewpoint of analytical equations. Once these approach their validity limit, numerical approaches become necessary. This will, most generally, lead to a topology optimization formulation, in order to drive the discovery of optimal device layout, which is next described. Due to mesh refinement, such models quickly become unwieldly to handle, since they result in to many degrees-of-freedom. In the last section of the chapter, we consider model order reduction as a means to turn large discrete models into compact models, approaching the lower order analytical models in complexity, but retaining the specific accuracy of the general numerical approach.

MEMS · NEMS · Modelling · Simulation · Topology optimization · Model order reduction

36.1 General Considerations

It is not clear who first claimed that "*The essence of engineering is design*", but for many engineering endeavours the statement holds fairly accurately, separating engineering somewhat from the natural sciences. As a result, the role of simulation and modelling has its own focus, namely, supporting the engineer in making better, more reliable, and more manufacturable (product) designs. In this context the special requirements of microelectromechanical systems (MEMS) and their tinier twins, nanoelectromechanical sys-

tems (NEMS) is considered. Such systems are hardly ever conceived of outside of a particular application domain, and are expected to perform subject to the constraints of the application, which may for example demand error free operation for a long time under adverse conditions. As a result, the engineer will need to move her focus during a development cycle, starting with a broad concept to define the borders of focus, then zooming in to details, and once satisfied, zooming out again to the application. This might occur repeatedly. Design is typically iterative, since it is also a discovery process, hence the focus of an engineer (or team) will repeatedly vary so as to ensure meeting various kinds of constraint in the best possible manner. This chapter is hence focusing on numerical techniques that will be useful in supporting the engineer in this process, by facilitating the answering of questions related to design in an efficient manner, hopefully providing the engineer with additional tools to go beyond what is otherwise possible.

36.1.1 Digital Twinning for MEMS and NEMS

MEMS, NEMS, and semiconductor chips share the fact that they are produced at the wafer scale, in dustfree and environmentally controlled cleanrooms, with manufacturing based on a sequence of additive and subtractive processes interleaved by lithography steps, and followed by assembly and packaging. For MEMS and NEMS, significant differences to pure semiconductor manufacturing also exist. They are often physically closer to the application, because of their multiphysical character (measuring a fluid, or a gas, or being buried deep within a process or machine), integrating tiny detectors, actuators, or by being integrated into tiny machines. The differences to pure electronics mean that one requires a larger variety of manufacturing process steps, so that less of the steps are shared among the rather broad number of applications, placing MEMS and NEMS manufacturing also in direct opposition to semiconductor manufacturing.

Technology CAD is a term that has been coined to describe the **digital twin** of the semiconductor, and especially, the CMOS industry. It has been vastly successful, mirroring in software every single manufacturing and operational modality of a semiconductur chip, across the length scales, and even across the experimentation modes. This single fact has enabled the industry to rapidly advance from proof-of-principle considerations to systems and even statistical yield design.

It is therefore tempting to ask whether the CMOS success story can be copied for the MEMS and NEMS industry. Clearly, there is no fundamental reason why this should not be possible. Indeed, most MEMS and NEMS manufacturing steps have, at some point during their exploration, been mapped to a physical simulation program. There are however economic reasons why the task is considerably more difficult to establish in practise. Software is never stationary, and continuously needs to be updated. Computer hardware is evolving, as are compilers and libraries, so that the programmer is constantly adapting the code. The salary of the programmer (who might have a PhD in engineering) needs to be paid, requiring income from a customer, and if a particular manufacturing process step is not used by sufficiently many customers, the programmer cannot be funded.

Of course, not everything is completely hopeless, and indeed careful analysis can reveal common physical (theory) features among the processing steps, so that generic blocks of software may be useful in more than one manufacturing step, returning us back to an economic situation.

It is therefore worthwile to consider some of the differing MEMS processing steps. These are classified into two categories:

- 3D manufacturing:

  Anisotropic etching. Silicon can be wet-etched along its crystal planes. It can also be dry-etched vertically into the wafer using a plasma, such as the Bosch process or the Cryo process. This provides limited 3D patterning capabilities.

  3D (nano) lithography. Photopolymers can be structured using a highly-focused light beam. One method is stereolithography, whereby the upper surface of a liquid resist is transformed by a projected image or by a scanning laser spot. Another method is the use of two-photon absorption, achieving a resolution of 90 nm. Various methods exist to transform the polymer structures into other material patterns, e.g., metals. This provides almost unlimited 3D shaping capabilities [1].

  3D deposition. Using an aerosol jet, it is possible to deposit almost any material that can be formed into a spray (such as nanoparticle suspensions of ceramics and metals, or dissolved polymers) at high resolution on any 3-dimensional surface. Some free-form capabilities exist as well.

- Novel material systems:

  Carbon. Certain polymers, deposited in 3D at the nano to micro length scale, can be converted into pure glassy carbon by pyrolysis. Apart from the fairly high temperature required (ca. 700 °C), the method is very general, and the geometrical transformation highly predictable [2].

  Glass. By mixing glass nanopowder with a photopolymer of similar refractive index, it is possible to nanostructure green parts at the full resolution of current nanolithography. Subsequent sintering at sufficiently high temperature produces glass parts with exquisite fidelity [3].

Polymers. Increasingly, polymers are being introduced into MEMS and NEMS as tunable functional material systems. They are often available as photopolymers, which can be lithographically patterned, or otherwise, after plasma deposition, patterned by mask assisted plasma etching.

Self-assembly chemical frameworks. Using dipcoating processes, and simplified bonding chemistry (such as click chemistry), it is possible to form sophisticated quasi crystalline layers, layer by layer, conformally onto a 3-dimensional surface. Full molecular control of porosity is possible, for example by using metal-organic frameworks.

For many of the above processing steps (the exception is the crystalline wet-etching of Si), the manufacturing operations are sufficiently well described by either existing CMOS process simulation programs, or CAD-like geometry transforming processes, so that physical based simulation is often not even necessary at the digital twin level.

The situation is dramatically different for device and system simulation. The reason is that MEMS and NEMS are ultimately multi-physical, with novel opportunities emerging constantly, driven by current and future application domains. As a result, and in contrast to microelectronics with a focus on current and voltage effects at ever smaller dimensions and ever higher frequencies but with the roadmap fairly well laid out, MEMS and NEMS requires more planning to find the common elements to facilitate a possible roadmap, and a digital twin plan. Some of these ideas are now considered.

36.1.2 A Formal Classification System for MEMS and NEMS

In the late 1980s Professor Simon Middelhoek from Delft University of Technology defined [4] the famous sensor cube, an organisational device to bring structure to the field of transducers, and relevant to this day. The basic idea is that, every MEMS or NEMS device known transforms energy (power) among the basic energy domains *ED*, $ED \in$ {electrical, magnetic, mechanical, optical, chemical, spin, thermal, nuclear}. Thus a thermo-electric sensor operates between the thermal and the electrical domain. By forming a table of two or more dimensions, with the orthogonal table edges having an entry for each of the energy domains, it is possible to define for each square or cube in the matrix a particular coupling effect, such as the Seebeck, Faraday, Nerst, etc. effects. Some devices operate between three energy domains, through the use of an intermediate domain, hence the need for a cube in the relationship, and of course additional dimension is added when influence terms are also needed (such as the case of a transistor whose gate adds an influence axis to the table entry for an electrical to electrical transducer). The most successful system components are those that provide for influence or output terms in the electrical domain, making them intregratable with electrical circuitry (Fig. 36.1).

Physical Scales and Details

Often it is necessary to refer to the scale of things. For example, as sizes reduce, the importance of volume to area reduces, so that surface effects dominate at the micro and nano metre scale, and mass effects becomes relatively unimportant. An easily grasped example is the mosquito, which is held above water by surface tension effects, whereas humans are prone to sink. Similarly, time scales of volumetric effects reduce, increasing the importance of very fast inertial effects which can under circumstance catch up with the time scales of radiative effects. Here an interesting example is the ability of a nanobeam to oscillate as fast as radiofrequency waves, opening up interesting application opportunities. It is thus advisable to consider sensor effects under scaling laws (for example, by replacing each variable by its scaled version, then scaling the entire expression). This might necessitate to reconsider the modelling equations, and provide opportunities for simplification.

Numerical Techniques and Computational Methodologies

Software construction has become hugely successful due to the concept of reuseability, i.e., a software component is seen as a generic block that finds employment in a number of vastly different situations. At that point, it is important to standardise the interface to the component, so that software design can be performed for the remaining parts. A common understanding among component designs will naturally lead to even more efficiency for designing new software modules. It is a bit like agreeing on a metric system for nuts and bolts.

There are of course many levels of structure that can be organised. The most common are specific data structures that are particularly efficient in maintaining particular collections. Some interesting elements are:

List, or vector. This is the easiest form of data structure, since it easily maps to computer memory, simply occupying a contiguous section of it, and linearly indexed from the start. If contiguity is sacrificed, the list becomes a tree.

Lists of lists, or matrix. A concatenation of equal length lists can be grouped to form a matrix, which also can be efficiently stored in contiguous memory. The list unit then is either the row or column of the matrix.

Sparse matrix. Because many numerical methods operate on matrices that are very sparsely populated, vast amounts of memory can be saved by implementing suitable data structures that remove some or most of the reduncancy. A popular structure is the Matrix Market container for numerical matrices.

Tree. Tree structures are a useful efficient technique to localise sparse data w.r.t. ordering parameters. Binary,

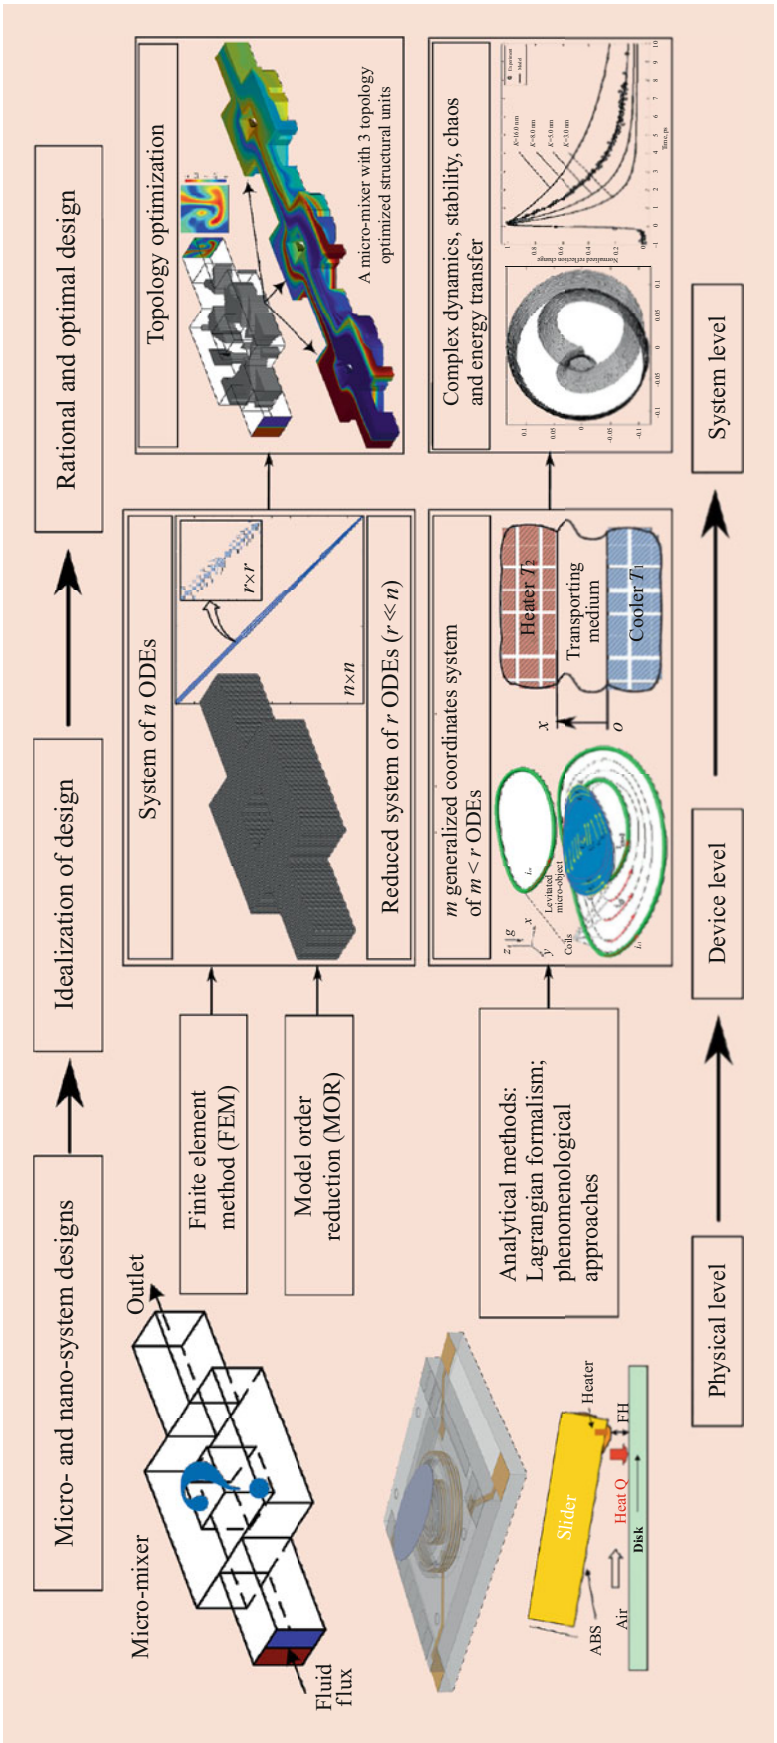

Fig. 36.1 Analytical ling and numerical simulation are twinned methods, differing in the degree of geometrical generality, and the number of unknowns. Analytical modelling always precedes numerical models, but without necessarily striving for simplicity. Analytical models are reduced in complexity by simplification and the application of symmetries. Numerical models are compacted using model order reduction. The forward problem (analytical or numerical) may be inversely solved using an iterative procedure, thereby directly facilitation the act of design

quad, and oct-trees are used when 1D, 2D and 3D spatial data is involved, but of course any form of abstraction is possible, as is anisotropy of the tree. In principle, a tree is grown according to a splitting rule, which might be decided on the fly, then leading to mixed trees.

Mesh. A mesh data structure is needed for certain computational methods, notably finite elements, boundary elements, or finite volume methods. The primitives are nodes, edges, faces, and volumes. All items will have local and global numbers, and knowing these will completely define the mesh, which is a form of graph. Numerous schemes have been invented to represent such a structure, and mainly depend on the degree of modifiability required. See next entry.

Winged edge. The winged edge is a special kind of 2D mesh representation that is particularly useful for mesh generation and mesh refinement. Essentially, the mesh edges surrounding an element face have pointers in all possible directions to all items, including nodes, faces, and other edges. Modifications of the mesh can only perform Euler operations, ensuring invariant consistency after modification.

Solid geometry. The Euler concept is also a foundation of any solid geometry representation, but now the represented object is 3-dimensional, and of various topological genus. Because only the surface of a solid object needs to be represented, a winged edge structure is also possible.

Parametrised data. Any computed solution is a set of data with discrete "tags", and typically an interpolation of the data is required (for a plot, or other reason). The tags are part of a parameter set. Generalising such a data set aids the handling of complex multidimensional data.

It is immediately clear that each data structure comes with its package of operations, which will include ways to instantiate, delete, modify, transform, and fill the data structure. It is therefore understandable that object oriented programming has become so successful, offering the programmer with a formal method of design, and a mechanism for maintaining the consistency of data.

Also of consequence are the data structures that arise from system simulation tasks. These are implicitly described by the following equations:

Linear system. This is the prototype equilibrium system. There is a complementary minimization problem associated with the linear system $A \cdot x = f$ with $A \in \mathbb{R}^{n\times n}$, $x, f \in \mathbb{R}^n$. The task is to find x that minimizes $g(x, f)$, where $g(x, f) = x^{\mathrm{T}} \cdot (A \cdot x/2 - f)$. The goal is to determine x corresponding to the loading f.

First order partial differential equation system. $A \cdot \dot{x} + B \cdot x = f$ with $A, B \in \mathbb{R}^{n\times n}$, $x, f \in \mathbb{R}^n$. The goal is to find $x[t]$ as a function of the excitation $f[t]$.

Linear time invariant system (LTI). Related to the previous entry, consider a key description popular in systems theory. $A \cdot \dot{x} + B \cdot x = f$ and $y = C \cdot x + D \cdot f$ with $A, B \in \mathbb{R}^{n\times n}$, $x, f \in \mathbb{R}^n$, $y \in \mathbb{R}^m$, and $C, D \in \mathbb{R}^{m\times n}$. The goal is to find the output $y[t]$ as a function of the excitation $f[t]$. This permits us to also define the transfer function in after Laplace transformation A.

Second order partial differential equation system. $M \cdot \ddot{x} + C \cdot \dot{x} + K \cdot x = f$ with $M, C, K \in \mathbb{R}^{n\times n}$, $x, f \in \mathbb{R}^n$. The goal is to find $x[t]$ as a function of the excitation $f[t]$. Also see Sect. 36.2.4.

Port Hamiltonian system. Many problems permit the definition of a Hamiltonian $H(x)$, so that a port-Hamiltonian system can be described with $\dot{x} = (J - R) \cdot \nabla_x H(\mathbf{x}) + B \cdot u(t)$, $y = B^{\mathrm{T}} \cdot \nabla_x H(x)$. Here $H(x) : \mathbb{R}^n \mapsto [0, \infty)$ is the Hamiltonian, $x \in \mathbb{R}^n$ the state vector, $\mathbf{y} \in \mathbb{R}^m$ is the output vector, $J = -J^{\mathrm{T}} \in \mathbb{R}^{n\times n}$ the connectivity of energy storage elements, $R = R^{\mathrm{T}} \geq 0 \in \mathbb{R}^{n\times n}$ the dissipation, and $B \in \mathbb{R}^{n\times m}$ the excitation weighting. The goal is the same as for the LTI system, and for certain manipulations such as model order reduction the structure can be preserved. Also see Sect. 36.4.2 and Eq. (36.14) of Sect. 36.2.2.

Eigensystem. The simpler eigensystem, typically arising in stability problems and first order differential equations under harmonic excitation, is prototypically written as $K \cdot x - \lambda I_n = 0$ with $K \in \mathbb{R}^{n\times n}$, $x \in \mathbb{R}^n$, $\lambda \in \mathbb{R}$, and I_n the n-dimensional identity matrix. A complimentary eigensystem arising from second order partial differential equations under harmonic excitation is $(K - \lambda M) \cdot x = 0$ with additionally $M \in \mathbb{R}^{n\times n}$. The goal is to find the eigenvectors x_i that correspond to the eigenvalues λ_i.

36.1.3 The Structure of the Chapter

The concept behind the chapter is to visualise that an analyst progresses from a mathematical description of a physical problem, to discretization and implementation of the forward problem into a numerical simulation program, after which design issues necessitate optimization, which leads to very large simulation tasks, which in turn necessitates conversion to a more efficient implementation. Because much of routine modelling and simulation is already the focus of many papers and monographs, it was thus decided to focus on three of the most challenging tasks, namely:

- the initial modelling effort, which requires considerable physical insight but which ultimately could also yield highly compact analytical solutions. The topic of levitation, which also requires concepts of control beside the considerations of the physical model;

- the optimization task, which requires a physical model and numerical discretization, before the actual optimization task and the formulation of appropriate constraints can be considered. Here fluidic and electromagnetic phenomena are considered;
- the efficiency task, for which a look at the formal methods of model order reduction is considered, which also offers an opportunity for direct integration into the discretization and optimization approaches.

These approaches or tasks thus form the contents of the following three sections.

36.2 Analytical Modeling

For the rational design of MEMS and NEMS, the analysis and investigation of their properties, as for the theoretical investigation of any other real physical system, adequate and accurate mathematical models based on differential equations describing diverse physical processes and phenomena, as well as their combinations in the designed system, are required to be developed. A mathematical model assumes to apply a certain idealization, which can never be avoided, to a system in order to simplify its true physical properties. Indeed, an enormous spectrum of physical processes occurring in MEMS and NEMS, upon applying such an idealization, can be reduced to a problem in which the space configuration of the system is completely defined by a particular limited number of *generalized coordinates* q and *generalized velocities* $\dot{q}$. In this case, differential equations can be compiled by *analytical methods*, in particular, including methods developed in analytical mechanics based on the Lagrangian and Hamiltonian formalisms, as well as *phenomenological approaches* derived in the field of energy transfer (thermodynamics, fluid mechanics, and heat transfer).

36.2.1 Introduction

Obtaining the mathematical model of the system in a form of a closed set of differential equations (DE) allows us to use the powerful apparatus of ordinary differential equations (ODE) and partial differential equations (PDE) for the model analysis and, consequently, the system under consideration. Thus, the system can be comprehensively studied both qualitatively as well quantitatively by covering its static, dynamic, and stability issues, including linear and non-linear aspects of the behaviour of the system. Developed numerical methods have been established and are widespread by means of commercially available software, as a standard tool of engineers, for designing MEMS and NEMS. However, emerging new technologies, created for further improvement of the performance of MEMS and NEMS, require new operational principles and physical phenomena to be accounted for in designing of these systems. Unfortunately, using available numerical methods will not always be successful in addressing these requirements, especially when compared with the agility of analytical methods.

For a particular case at hand, the recent progress in the technology of permanent micro-magnets [7] and 3D micro-coil fabrication [8] promotes the very promising application of electromagnetic levitation in micro-actuator systems. The stability or stable dynamics of levitating micro-actuators is the main and crucial issue requiring to be addressed at the onset of designing such actuators. In order to simultaneously solve all four types of forces, namely force, force, force, and force forces, and concomitant non-linear effects due to pull-in phenomena, mechanical contacts and impact must also be taken into account. Unfortunately, state-of-the-art multi-physics software does not offer the capability to solve such complex problems. However, a developed analytical technique based on the Lagrangian formalism [9,10] was successfully applied to a number of problems arising in inductive and hybrid levitation micro-actuators [11] related to their stability [12–14] and pull-in dynamics [15–17]. By taking into account dissipative, conservation and circulatory forces acting on a levitated micro-object, this analytical technique provides the fundamental understanding of the influence of these forces on its dynamics and stability in general, as well as its application to design a particular levitating micro-actuator.

In fact for MEMS and NEMS, due to shrinking device sizes, (especially when the size becomes comparable with the characteristic length in the material of the device,) leads to a change of the physical mechanisms of energy transport. Individual behaviors of energy carriers and their interactions with the device boundaries become more pronounced. As a result, to describe the energy transport at those scales, the classical phenomenological laws, such as the Fourier law for heat transfer and the Newton law for viscosity, are no longer applicable. In order to overcome this difficulty in the application of classical phenomenological laws at the micro and nano scales, they can be reformulated by accounting for *spatial* and *temporal* effects occurring in the transporting media [18, 19] through introducing the nonlocal (in space) and lagging (in time) behaviors in constitutive laws [20,21], and applied to study ultra-fast energy transport [22–25], also at the nano level [26–28].

36.2.2 Analytical Mechanics of MEMS

The systems which essentially couple mechanical and electromagnetic processes, and which occur at a micrometer-scale, are referred to as micro-electro-mechanical systems (MEMS). Studying such systems requires, at the beginning,

to formulate the prime assumptions, and to accept models which take into account only the essential phenomena (the major physical properties,) and neglect other phenomena of minor influence [5].

It is assumed, as usual in analytical mechanics, that the state of a mechanical part of MEMS can be modeled by n independent *generalized coordinates* $\mathbf{q} = (q_1, \ldots, q_n)$. The number of these independent coordinates is defined by constraints applied to the system, which are assumed to be holonomic and ideal [6]. For instance, let us consider a system of N point masses, which represents the mechanical part of MEMS, and this system has s holonomic constraints, then the number n of independent generalized coordinates is equal to $3N - s$. In the case of a rigid body, the number of coordinates is reduced to $6 - s$.

In order to define the state of an electromagnetic part of MEMS, the spatial distribution of vectors of the magnetic flux density $\vec{B}$ and the electric field intensity $\vec{E}$, as well their changing with time must be known. Considering the system as continuous one, the description of its state requires the application of the infinite number of time functions. However, vectors of $\vec{B}$ and $\vec{E}$ can be also modeled by means of electrical and magnetic circuits utilizing a finite number of parameters such as electrical current, voltage, magnetic flux, etc. Replacing vectors of magnetic and electric fields through these parameters is equivalent to introducing the generalized coordinates into the electromagnetic system. Let us suppose that the electromagnetic part of MEMS is represented by m electric circuits, each of them consists of the capacitor, inductor and resistor connecting in series. These electric circuits have no direct electrical connection to each of other, but of course they are coupled electromagnetically. Such the representation becomes possible if conditions of quasistationarity are hold. Also, it is assumed that a cross-section of conductor is much smaller than its length. Then, for an alternating current with relatively a high frequency, the inductance of circuit is defined by a shape of the conductor. The effect of the distribution of the current along the cross-section of the conductor on the inductance of the circuit can be neglected.

Let us denote i_k $(k = 1, 2, \ldots, m)$ as the current in the k-circuit and u_k as the electromotive force (e.m.f) applied to the k-circuit. The charges accumulated by capacitors are denoted as e_k $(k = 1, 2, \ldots, m)$ and they have the following relation with the current $\mathrm{d}e_k = i_k \mathrm{d}t$. Then, the resistor and capacitor belonged to the k-circuit are denoted as R_k and C_k, respectively. In general, the relative motion of mechanical elements of MEMS leads to changing in positions of electrodes of capacitors with respect to each other and the shape of conductors. Consequently it is assumed that the capacitor and inductor are functions of generalized coordinates, namely, $C_k = C_k(q_1, \ldots, q_n)$, $L_{kk} = L_{kk}(q_1, \ldots, q_n)$ and $L_{kr} = L_{kr}(q_1, \ldots, q_n)$, where L_{kk} is the self-inductance of the k-circuit and L_{kr} $(k \neq r)$ is the mutual inductance between the k- and r-circuit. Now, the Lagrange function of the electromechanical system can be compiled in the following form

$$L = T(q_j, \dot{q}_j) - \Pi(q_j) + W_m(q_j, i_k) - W_e(q_j, e_k), \tag{36.1}$$

where $T(q_j, \dot{q}_j)$ and $\Pi(q_j)$ are the kinetic and potential energy of the system, respectively, $W_\mathrm{m}(q_j, i_k)$ and $W_\mathrm{e}(q_j, e_k)$ are magnetic and electrical energy stored in the system, respectively. In a case of stationary constraints, the kinetic energy of the system has the quadratic form such as

$$T = \frac{1}{2} \sum_i^n \sum_j^n a_{ij} \dot{q}_i \dot{q}_j, \tag{36.2}$$

where $a_{ij} = a_{ij}(\mathbf{q}, t)$ are coefficients of inertia, depending on the generalized coordinates. The potential energy Π is also the function of the generalized coordinates, namely,

$$\Pi = \Pi(q_1, \ldots, q_n). \tag{36.3}$$

The electrical energy stored between the electrodes of capacitors can be found by the following known equation

$$W_\mathrm{e} = \frac{1}{2} \sum_k^m \frac{e_k^2}{C_k}. \tag{36.4}$$

The magnetic energy stored by the system of m-loops with electrical currents is

$$W_\mathrm{m} = \frac{1}{2} \sum_k^m \sum_r^m L_{kr} i_k i_r. \tag{36.5}$$

Besides, the energy from the system is dissipated due to Joule heating and friction. This dissipation energy can be taken into account by introducing the following function, which sums up the dissipation occurring in electrical and mechanical parts of the system, such as

$$\Psi = \Psi_\mathrm{e}(i_k) + \Psi_\mathrm{mech}(q_j, \dot{q}_j). \tag{36.6}$$

Noting that the electrical dissipation function Ψ_e is independent of the generalized coordinates and the mechanical dissipation function Ψ_mech of the currents, thus it can be concluded that

$$\frac{\partial \Psi}{\partial i_k} = \frac{\partial \Psi_\mathrm{e}}{\partial i_k}; \quad \frac{\partial \Psi}{\partial \dot{q}_j} = \frac{\partial \Psi_\mathrm{mech}}{\partial \dot{q}_j}. \tag{36.7}$$

Using Lagrangian (36.1) and dissipation function (36.6), the set of the Lagrange-Maxwell equations of electromechanical system can be obtained

$$\begin{cases} \dfrac{\mathrm{d}}{\mathrm{d}t}\left(\dfrac{\partial L}{\partial \dot{e}_k}\right) - \dfrac{\partial L}{\partial e_k} + \dfrac{\partial \Psi}{\partial \dot{e}_k} = u_k;\ k = 1, \ldots, m; \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\left(\dfrac{\partial L}{\partial \dot{q}_j}\right) - \dfrac{\partial L}{\partial q_j} + \dfrac{\partial \Psi}{\partial \dot{q}_j} = Q_j;\ j = 1, \ldots, n, \end{cases} \tag{36.8}$$

where Q_j is the generalized forces applied to the system. The obtained equations are called the Lagrange-Maxwell equations. Equation (36.8) is the set of $n+m$ ordinary differential equations of the second order with respect to the generalized coordinates and charges. Worth noting that methods of analytical mechanics were developed by two physicists, namely, Joseph Louis Lagrange (1736–1813) and William Rowan Hamilton (1805–1865) in eighteenth and nineteenth centuries. In particular, in 1873 using the Lagrange approach, James Clerk Maxwell (1831–1879) derived the equations describing electromechanical systems in his famous work "A Treatise on Electricity and Magnetism" [31]. In general, set (36.8) is nonlinear because of the terms, which are defined by

$$\sum_{j}^{n}\sum_{k}^{m}\frac{\partial L_{kr}}{\partial q_j}\dot{q}_j i_k, \tag{36.9}$$

representing the induced e.m.f by moving conductors with currents. Set (36.8) includes also ponderomotive forces, which are

$$Q_j^* = \frac{\partial}{\partial q_j}\left(W_{\mathrm{m}} - W_{\mathrm{e}}\right) = \frac{1}{2}\sum_{k}^{m}\sum_{r}^{m}\frac{\partial L_{kr}}{\partial q_j} i_k i_r + \frac{1}{2}\sum_{k}^{m}\frac{\partial C_k}{\partial q_j}\frac{e_k^2}{C_k^2}. \tag{36.10}$$

Formally, ponderomotive forces arise as a result of changing the electrical and magnetic energy with the generalized coordinates. The generalized coordinates q_j determine the positions of electrodes of capacitors and wires of conductors, as well as the distribution of magnetic permeability μ and dielectric constant ε in space. For this, the different types of ponderomotive forces are responsible for the force interaction, for instance, the force interaction between wires with currents, the force interaction between charged bodies, force acting on a body due to the difference between the magnetic permeability of the body and surrounding space, etc. However, in any case, equation for ponderomotive force (36.10) is still applicable. For some treatments, it is convenient to define the state of the electromechanical system through *the generalized momentum*, which is defined as follows

$$p_j = \frac{\partial L}{\partial \dot{q}_j}, \tag{36.11}$$

and *the generalized magnetic flux* such as

$$\phi_k = \frac{\partial L}{\partial \dot{e}_k}. \tag{36.12}$$

Using the generalized momentum and magnetic flux defined by (36.11) and (36.12), respectively, the *Hamiltonian* of the system can be explicitly obtained through the Legendre transform of the *Lagrangian* such as

$$H(\mathbf{p}, \boldsymbol{\phi}, \mathbf{q}, \mathbf{e}) = \mathbf{p}\dot{\mathbf{q}} + \boldsymbol{\phi}\mathbf{i} - L(\dot{\mathbf{q}}, \mathbf{q}, \mathbf{i}, \mathbf{e}). \tag{36.13}$$

Then $n+m$ Lagrange-Maxwell equations can be equivalently represented by the set of $2(n+m)$ first-order Hamilton's equations as follows

$$\begin{cases} \dfrac{\mathrm{d}}{\mathrm{d}t}e_k = \dfrac{\partial H}{\partial \phi_k};\ k = 1, \ldots, m; \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\phi_k = u_k - \dfrac{\partial H}{\partial e_k}; \\ \dfrac{\mathrm{d}}{\mathrm{d}t}q_j = \dfrac{\partial H}{\partial p_j};\ j = 1, \ldots, n; \\ \dfrac{\mathrm{d}}{\mathrm{d}t}p_j = Q_j - \dfrac{\partial H}{\partial q_j}. \end{cases} \tag{36.14}$$

36.2.3 Dynamics of Electromagnetic Levitation Micro-Systems

Electromagnetic levitation is defined as the stable or indifferent equilibrium of a body without material contact to its surrounding environment, which is reached by means of stored electromagnetic energy inducing, in turn, the ponderamotive forces acting on the levitated body and equilibrating gravitational forces. Electromechanical systems implement the principle of electromagnetic levitation on a micro-scale is referred as electromagnetic levitation micro-systems or *levitation micro-systems*.

Levitation micro-systems offer a fundamental solution to overcome the domination of friction over inertial forces at the micro-scale. This fact makes levitation micro-systems to be very attractive for their applications in micro-inertial-sensors, micro-motors, switches, micro-accelerators, particle traps, digital micro-fluidics, nano-force sensors, micro-transporters, micro-bearings, etc. There are a number of techniques, which provide the implementation of electromagnetic levitation into a micro-system and can be classified according to using materials and the sources of the force fields as follows [11]:

- Electric levitation: force interaction between dielectric and conducting materials located into electric field;
- Magnetic levitation: force interaction between magnets and direct current (dc) or magnetic materials and dc ;
- Diamagnetic levitation: force interaction between diamagnetic materials and magnet;
- Superconducting levitation: force interaction between superconducting materials and magnet;
- Inductive levitation: force interaction between conducting materials and alternating current (ac);

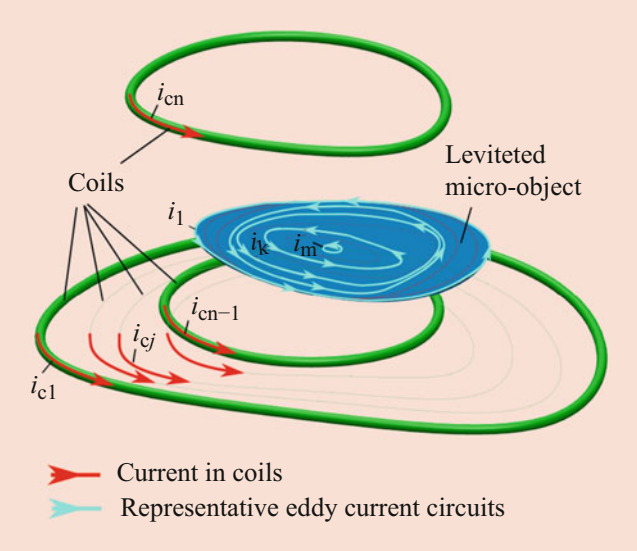

Fig. 36.2 Scheme of inductive levitation system with induced eddy current represented by the m eddy current circuits: YXZ is the fixed coordinate frame; g is the gravity acceleration directed along the Z axis; i_k is the eddy current in the k-th eddy current circuit; i_{cj} is the current in the j-coil

- Hybrid levitation: combination of different force fields.

The analysis of such levitation systems requires the application of the Maxwell equations. Although, these equations are universally applicable, but their application even for simple designs is extremely difficult task [29], which is not able to cover all required aspects of the behavior of a proposed design of the levitation system related to its stability or stable levitation and dynamics including nonlinear effects [30].

Let us consider the scheme of an inductive levitation system shown in Fig. 36.2, which consists of a system of n coils, and a levitated micro-object. Each j-th coil is fed by its own alternating current denoted by i_{cj} and generates a time-variable magnetic field in space. The alternating magnetic flux passes through the conducting micro-object and induces an eddy current. Since the density of eddy current induced within the levitated micro-object is not homogeneous, it can be assumed that the m eddy current circuits can be selectively chosen to represent the behaviour of the entire eddy current, as shown in Fig. 36.2. As seen from Fig. 36.2, i_k is the eddy current in the k-th eddy current circuit.

An equilibrium position of the levitated micro-object is characterized with respect to the fixed coordinate frame YXZ. The micro-object is considered as a rigid body. Hence its behaviour relative to the equilibrium position can be characterized in general by six generalized coordinates corresponding to three linear and three angular displacements, which can be denoted by q_l, $l = 1...6$. Let us define that coordinates, q_l, with indexes $l = 1, 2, 3$ are the generalized linear coordinates, while indexes $l = 4, 5, 6$ correspond to the generalized angular coordinates. Thus, the state of the levitation system can be described by m independent currents i_k and six independent displacements. Hence, instead of the field equations, the methods of analytical mechanics can be applied to study the system.

Adapting the generalized coordinates and the assumptions introduced above, the model of electromagnetic levitation system can be written by using the Lagrange-Maxwell equations as follows

$$\begin{cases} \dfrac{\mathrm{d}}{\mathrm{d}t}\left(\dfrac{\partial L}{\partial i_k}\right) + \dfrac{\partial \Psi}{\partial i_k} = 0; \ k = 1, \ldots, m; \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\left(\dfrac{\partial L}{\partial \dot{q}_l}\right) - \dfrac{\partial L}{\partial q_l} + \dfrac{\partial \Psi}{\partial \dot{q}_l} = F_l; \ l = 1, 2, 3; \\ \dfrac{\mathrm{d}}{\mathrm{d}t}\left(\dfrac{\partial L}{\partial \dot{q}_l}\right) - \dfrac{\partial L}{\partial q_l} + \dfrac{\partial \Psi}{\partial \dot{q}_l} = T_l; \ l = 4, 5, 6, \end{cases} \tag{36.15}$$

where $L = T - \Pi + W_\mathrm{m}$ is the Lagrange function for the micro-object-coil system; $T = T(\dot{q}_1, \ldots, \dot{q}_6)$ is the kinetic energy of the system; $\Pi = \Pi(q_1, \ldots, q_6)$ is the potential energy of the system;$W_\mathrm{m} = W_\mathrm{m}(q_1, \ldots, q_6, i_{c1}, \ldots, i_{cn}, i_1, \ldots, i_m)$ is the energy stored in the electromagnetic field; $\Psi = \Psi(\dot{q}_1, \ldots, \dot{q}_6, i_1, \ldots, i_m)$ is the dissipation function; F_l ($l = 1, 2, 3$) and T_r ($l = 4, 5, 6$) are the generalized forces and torques, respectively, acting on the micro-object relative to the appropriate generalized coordinates. The kinetic energy is

$$T = \frac{1}{2}\sum_{l=1}^{3} M\dot{q}_l^{\,2} + \frac{1}{2}\sum_{l=4}^{6} J_l\dot{q}_l^{\,2}, \tag{36.16}$$

where M is the mass of the micro-object; J_l is its moment of inertia in terms of the appropriate generalized angular coordinates. The linear generalized coordinates, q_l, $l = 1, 2, 3$, are defined in the orthogonal coordinate frame. Assuming that the generalized coordinate q_3 is directed along the gravity acceleration g, as shown in Fig. 36.2, then the potential energy can be defined simply as follows

$$\Pi = Mgq_3. \tag{36.17}$$

The dissipation function is

$$\Psi = \frac{1}{2}\sum_{r=1}^{6} \mu_r\dot{q}_r^{\,2} + \frac{1}{2}\sum_{k=1}^{m} R_k i_k^2 \pm \sum_{k=1}^{m}\sum_{s=1, s\neq k}^{m} R_{ks} i_k i_s, \tag{36.18}$$

where μ_r is the damping coefficient corresponding to the appropriate generalized coordinates; R_k is the electrical resistance for the k-th eddy current circuit within the micro-object; R_{ks} is the resistance of a common circuit for k-th and s-th eddy current circuits (for example, this case is shown in Fig. 36.2 for eddy currents i_1, i_2, and i_3). For generality, it is assumed that the k-th eddy current may share a common path with the s-th eddy current. The plus-minus sign corresponds

to eddy currents having the same or opposite direction on the common circuit. The energy stored within the electromagnetic field can be written as

$$W_{\mathrm{m}}=\frac{1}{2}\sum_{j=1}^{n}\sum_{s=1}^{n}L_{js}^{\mathrm{c}}i_{\mathrm{c}j}i_{\mathrm{c}s}+\frac{1}{2}\sum_{k=1}^{m}\sum_{s=1}^{m}L_{ks}^{\mathrm{o}}i_k i_s+\frac{1}{2}\sum_{k=1}^{m}\sum_{j=1}^{n}M_{kj}i_k i_{\mathrm{c}j}, \tag{36.19}$$

where L_{jj}^{c} is the self inductance of the j-coil; L_{js}^{c}, $j \neq s$ is the mutual inductance between j- and s-coils; $L_{kk}^{\mathrm{o}} = L_{kk}^{\mathrm{o}}(q_1, \ldots, q_6)$ is the self inductance of the k-eddy current circuit; $L_{ks}^{\mathrm{o}} = L_{ks}^{\mathrm{o}}(q_1, \ldots, q_6)$, $k \neq s$ is the mutual inductance between k- and s-eddy current circuits; $M_{kj} = M_{kj}(q_1, \ldots, q_6)$ is the mutual inductance between the k-eddy current circuit and the j-coil.

The induced eddy currents i_k can be expressed in terms of coil currents $i_{\mathrm{c}j}$ under a particular condition discussed below. Assuming that for each coil, the current $i_{\mathrm{c}j}$ is a periodic signal with an amplitude of $I_{\mathrm{c}j}$ at the same frequency ω, we can write

$$i_{\mathrm{c}j} = I_{\mathrm{c}j}e^{\jmath\omega t}, \tag{36.20}$$

where $\jmath = \sqrt{-1}$. Taking the derivative of the Lagrange function with respect to the eddy current i_k, we have:

$$\frac{\partial L}{\partial i_k} = \frac{\partial W_m}{\partial i_k} = \sum_{s=1}^{m} L_{ks}^{\mathrm{o}} i_s + \sum_{j=1}^{n} M_{kj} i_{cj}, \tag{36.21}$$

or

$$\frac{\partial L}{\partial i_k} = \frac{\partial W_m}{\partial i_k} = L_{kk}^{\mathrm{o}} i_k + \sum_{s=1,\ s\neq k}^{m} L_{ks}^{\mathrm{o}} i_s + \sum_{j=1}^{n} M_{kj} i_{cj}. \tag{36.22}$$

Substituting (36.22) into (36.15), the first equation of set (36.15) becomes

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial i_k}\right)+\frac{\partial \Psi}{\partial i_k} &= \sum_{r=1}^{6}\frac{\partial L_{kk}^{\mathrm{o}}}{\partial q_r}\frac{\mathrm{d}q_r}{\mathrm{d}t}i_k + L_{kk}^{\mathrm{o}}\frac{\mathrm{d}i_k}{\mathrm{d}t}\\ &+\sum_{s=1,\ s\neq k}^{m}\left(\sum_{r=1}^{6}\frac{\partial L_{ks}^{\mathrm{o}}}{\partial q_r}\frac{\mathrm{d}q_r}{\mathrm{d}t}i_s + L_{ks}^{\mathrm{o}}\frac{\mathrm{d}i_s}{\mathrm{d}t}\right)\\ &+\sum_{j=1}^{n}\left(\sum_{r=1}^{6}\frac{\partial M_{kj}}{\partial q_r}\frac{\mathrm{d}q_r}{\mathrm{d}t}i_{cj} + M_{kj}\frac{\mathrm{d}i_{cj}}{\mathrm{d}t}\right) + R_k i_k\\ &\pm\sum_{s=1,\ s\neq k}^{m} R_{ks}i_s = 0.\end{aligned} \tag{36.23}$$

Accounting for (36.20), the k-eddy current can be represented as

$$i_k = I_k \mathrm{e}^{\jmath\omega t}, \tag{36.24}$$

where I_k is the amplitude. Hence, Eq. (36.23) can be rewritten in term of the current amplitudes as follows

$$\begin{aligned}&\sum_{r=1}^{6}\frac{\partial L_{kk}^{\mathrm{o}}}{\partial q_r}\frac{\mathrm{d}q_r}{\mathrm{d}t}I_k + L_{kk}^{\mathrm{o}}\jmath\omega I_k\\ &+\sum_{s=1,\ s\neq k}^{m}\left(\sum_{r=1}^{6}\frac{\partial L_{ks}^{\mathrm{o}}}{\partial q_r}\frac{\mathrm{d}q_r}{\mathrm{d}t}I_s + L_{ks}^{\mathrm{o}}\jmath\omega I_s\right)\\ &+\sum_{j=1}^{n}\left(\sum_{r=1}^{6}\frac{\partial M_{kj}}{\partial q_r}\frac{\mathrm{d}q_r}{\mathrm{d}t}I_{\mathrm{c}j} + M_{kj}\jmath\omega I_{\mathrm{c}j}\right)\\ &+R_k I_k \pm\sum_{s=1,\ s\neq k}^{m} R_{ks}I_s = 0.\end{aligned} \tag{36.25}$$

Analysis of Eq. (36.25) shows that due to the velocities of generalized coordinates, $\mathrm{d}q_r/\mathrm{d}t$ the equation is nonlinear. However, the velocity of the levitated micro-object in microsystems is not essential factor and its value is as usually small enough that the velocity $\mathrm{d}q_r/\mathrm{d}t$ can be neglected. Moreover, the frequency ω is commonly larger than 1 MHz, which corresponds to $\sim 10^7$ rad/s. Hence, Eq. (36.25) can be rewritten [32] as follows

$$\left(L_{kk}^{\mathrm{o}}+R_k/(\jmath\omega)\right)I_k + \sum_{s=1,\ s\neq k}^{m}(L_{ks}^{\mathrm{o}} \pm R_{ks}/(\jmath\omega))I_s = -\sum_{j=1}^{n} M_{kj}I_{\mathrm{c}j}. \tag{36.26}$$

The later equation provides the linear relationship between coils and eddy currents. Solving Eq. (36.26) by the Cramer rule, set (36.15) of m+6 equations is reduced to six equations. Hence, the behavior of the suspension is defined only by the generalized coordinates of its mechanical part. Thus,

$$\begin{cases} M\ddot{q}_l + \mu_l\dot{q}_l - \dfrac{\partial W_{\mathrm{m}}}{\partial q_l} = F_l;\ \ l = 1, 2;\\ M\ddot{q}_3 + \mu_3\dot{q}_3 + mg - \dfrac{\partial W_{\mathrm{m}}}{\partial q_3} = F_3;\\ J_l\ddot{q}_l + \mu_l\dot{q}_l - \dfrac{\partial W_{\mathrm{m}}}{\partial q_l} = T_l;\ \ l = 4, 5, 6, \end{cases} \tag{36.27}$$

Assuming that the displacements are small, set (36.27) can be linearized near an equilibrium point. Hence, model (36.27) becomes

$$\begin{cases} M\ddot{q}_l + \mu_l\dot{q}_l + \sum\limits_{r}^{6}\bar{c}_{lr}q_r = F_l;\ \ l = 1, 2, 3;\\ J_l\ddot{q}_l + \mu_l\dot{q}_l + \sum\limits_{r}^{6}\bar{c}_{lr}q_r = T_l;\ \ l = 4, 5, 6, \end{cases} \tag{36.28}$$

where $\bar{c}_{l0}$ and $\bar{c}_{lr}$ $(l, r = 1, \ldots, 6)$ are complex coefficients analytically defined by expanding (36.19) into the Taylor series. Noting that the imaginary part of $\bar{c}_{lr}$ is due to the resistance, R, of the levitated micro-object. At the equilibrium point, the following coefficients must hold:

$$\bar{c}_{30} = -Mg;\ \ \bar{c}_{l0} = 0;\ \ l = 1, 2, 4, 5, 6. \tag{36.29}$$

The obtained dynamical model of a levitation system (36.28) based on the assumption of the discretization of the induced eddy current into a levitation object implements, on the one hand, naturally the concept of model order reduction (the details of the concept are provided below in Sect. 1.5). On the other hand, using Eq. (36.26) an optimization problem about the shape of the levitated object, which provides, for instance, the minimum value of the excitation current into the coils necessary for its levitation can be defined. At the same time the optimistation must be preformed under the constrains related to the condition of stability, which also is dependent on the shape of the excitation coils. Thus, the topology optimization problem (other details are given in Sect. 1.3) of the distribution material of the levitated object for a particular design of the excitation coils is arisen.

36.2.4 Stability of Electromagnetic Levitation Micro-Systems

Let us write linear model (36.28) in a matrix form as

$$\underline{A}\ddot{\underline{q}} + \underline{B}\dot{\underline{q}} + \left(\underline{R} + \jmath\underline{P}\right)\underline{q} = f, \tag{36.30}$$

where $\underline{q} = [\overline{q}_1 \ \ldots \ \overline{q}_6]^{\mathrm{T}}$ is the column-matrix of generalized coordinates, which are complex variables due to (36.28); $\underline{f} = [F_1 \ F_2 \ F_3 \ T_4 \ T_5 \ T_6]^{\mathrm{T}}$ is the column-matrix of generalized forces and torques applied to the micro-object; $\underline{A} = \mathrm{diag}[m \ m \ m \ J_4 \ J_5 \ J_6]$ is the diagonal matrix of the micro-object mass and its moments of inertia; $\underline{B} = \mathrm{diag}[\mu_1 \ \ldots \ \mu_6]$ is the diagonal matrix of damping coefficients; $\underline{R} = [\mathrm{Re}\{\overline{c}_{lr}\}]$ and $\underline{P} = [\mathrm{Im}\{\overline{c}_{lr}\}]$.

The physical meanings of matrices $\underline{A}$, $\underline{B}$ and $\underline{R}$ are obvious. While, matrix $\underline{P}$ presents the coefficients of *circulatory forces* (the nonconservative positional forces) due to the dissipation of eddy current. Equation (36.30) can be rewritten by using only real values, and at the equilibrium point the linear model is equivalent to

$$\left[\begin{array}{c|c} \underline{A} & \underline{0} \\ \hline \underline{0} & \underline{A} \end{array}\right]\left[\begin{array}{c} \ddot{\underline{q}} \\ \hline \ddot{\underline{q}}* \end{array}\right] + \left[\begin{array}{c|c} \underline{B} & \underline{0} \\ \hline \underline{0} & \underline{B} \end{array}\right]\left[\begin{array}{c} \dot{\underline{q}} \\ \hline \dot{\underline{q}}* \end{array}\right] + \left[\begin{array}{c|c} \underline{R} & -\underline{P} \\ \hline \underline{P} & \underline{R} \end{array}\right]\left[\begin{array}{c} \underline{q} \\ \hline \underline{q}* \end{array}\right] = 0, \tag{36.31}$$

where $[q|q*]^{\mathrm{T}}$ is the block column-vector of twelve variables; $q = \mathrm{Re}\{\overline{q}\}$, $q* = \mathrm{Im}\{\overline{q}\}$, $\underline{0}$ is a zero matrix and all block matrices have 12×12 elements. It is visible that

$$\left[\begin{array}{c|c} \underline{R} & -\underline{P} \\ \hline \underline{P} & \underline{R} \end{array}\right] = \left[\begin{array}{c|c} \underline{R} & \underline{0} \\ \hline \underline{0} & \underline{R} \end{array}\right] + \left[\begin{array}{c|c} \underline{0} & -\underline{P} \\ \hline \underline{P} & \underline{0} \end{array}\right], \tag{36.32}$$

and

$$\left[\begin{array}{c|c} \underline{0} & -\underline{P} \\ \hline \underline{P} & \underline{0} \end{array}\right] = -\left[\begin{array}{c|c} \underline{0} & -\underline{P} \\ \hline \underline{P} & \underline{0} \end{array}\right]^{\mathrm{T}} \tag{36.33}$$

is a skew-symmetric matrix which corresponds to the positional nonconservative forces.

Analysis of model (36.30) reveals the following general issues related to stability of inductive levitation micro-systems, which are in particular formulated in terms of three theorems.

Theorem 1 (Unstable Levitation I) *If a inductive levitation micro-system is subjected to only electromagnetic forces defined by (36.19) (without dissipation forces, so that $\underline{B} = 0$), then stable levitation in the micro-system is impossible.*

This theorem can be referred to the main feature of inductive levitation systems. However, if the levitating micro-object is a perfect conductor, then $\underline{P} = 0$. Hence, when matrix $\underline{R}$ is the positive definite matrix, stable levitation without dissipative forces becomes possible. Also another conclusion can be formulated in the following corollary.

Corollary 1.1 *If a micromachined inductive levitation system is subjected to only electromagnetic forces, and the potential part of the electromagnetic forces is absent ($\underline{R} = 0$), then stable levitation in the system is impossible.*

Even if the dissipative forces are added to such a system without potential forces, the stable levitation is still impossible, this fact can be formulated in the second theorem below.

Theorem 2 (Unstable Levitation II) *If a micromachined inductive levitation system is subjected to electromagnetic forces having only positional $\underline{P} \neq 0$ ($\underline{R} = 0$) and dissipative forces ($\underline{B} > 0$), then stable levitation is impossible.*

The stable inductive levitation can be only achieved by adding the dissipative force. Upon holding the following necessary and sufficient conditions given in the theorem below, the system can be asymptotically stable.

Theorem 3 (Asymptotically Stable Levitation) *By adding dissipative forces ($\underline{B} > 0$) to a micromachined inductive levitation system subjected to electromagnetic forces defined by (36.19) and having a positive definite matrix of potential forces ($\underline{R} > 0$), the system can be asymptotically stable.*

The necessary condition is that matrix $\underline{A}$, $\underline{B}$ and $\underline{R}$ should be positive definite. The condition follows from the statement of the theorem. According to Metelitsyn's inequality [33,34, page 32], a sufficient practical condition for asymptotically stable levitation for the present case becomes as follows

$$\mu_{\min} > p_{\max}\sqrt{a_{\max}/r_{\min}}, \tag{36.34}$$

where $\mu_{\min}$, and $r_{\min}$ are the respective minimum values of $\underline{B}$ and $\underline{R}$; $p_{\max}$ and $a_{\max}$ are the respective maximum values of $\underline{P}$ and $\underline{A}$.

Operating levitation micro-systems in air, inequality (36.34) automatically holds due to the fact that damping

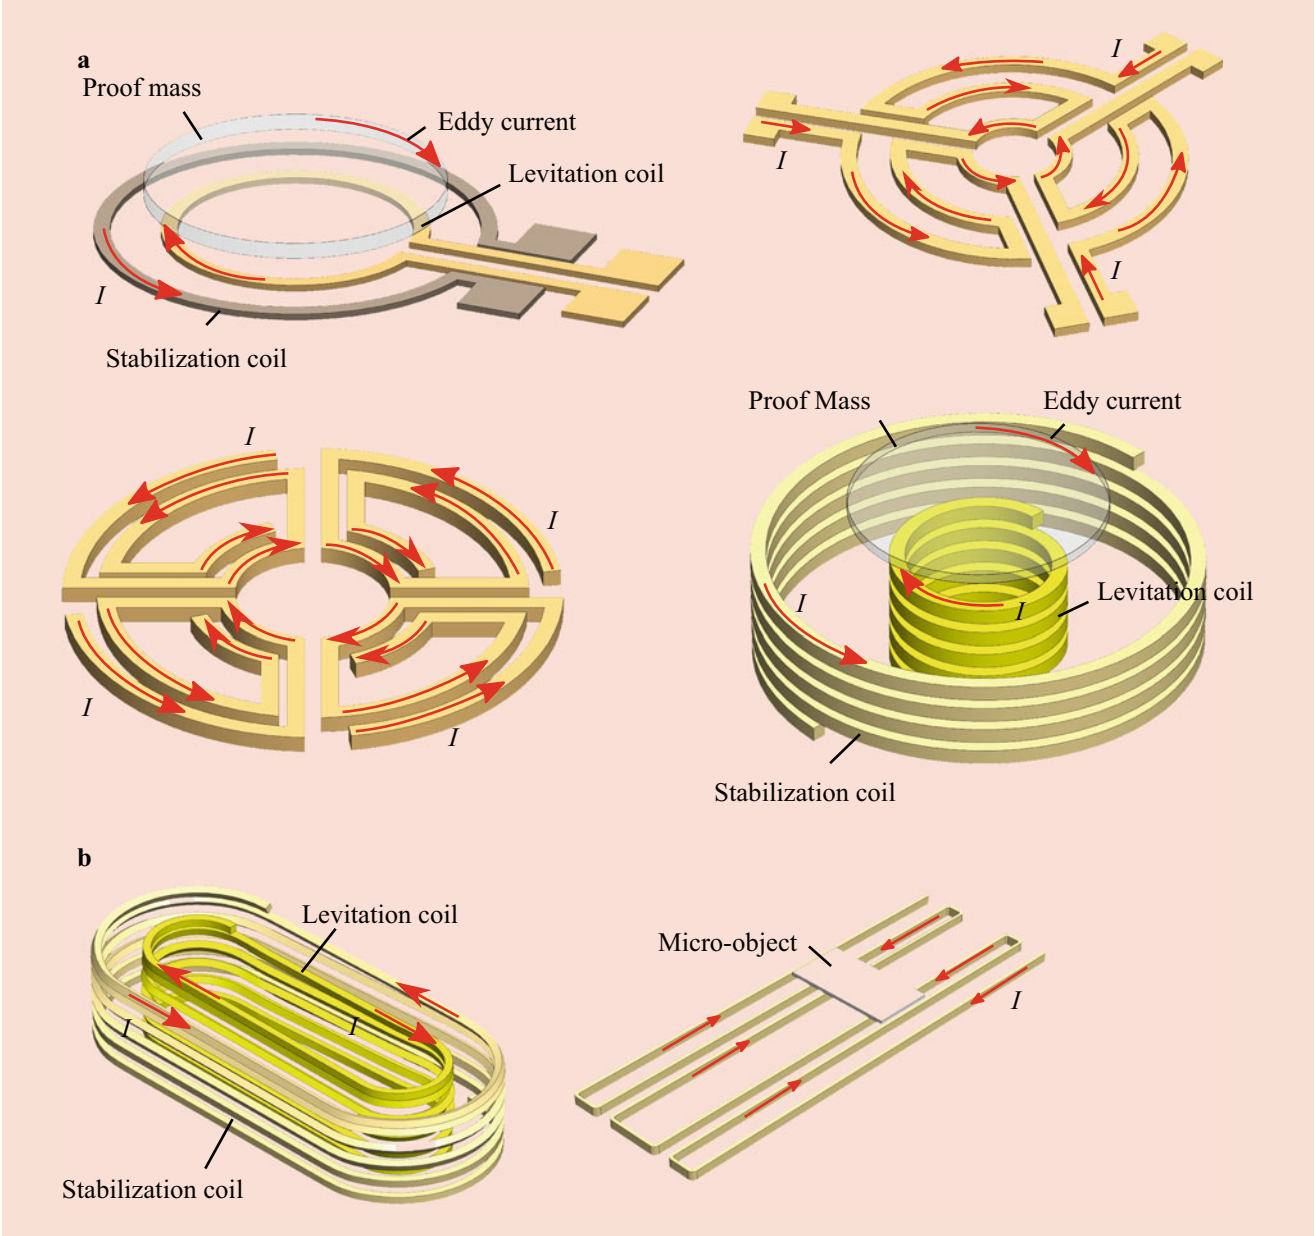

Fig. 36.3 Different designs based on planar and 3D micro-coils: (**a**) axially symmetric and (**b**) symmetric designs (I is the electric current)

forces dominate in the micro-world. Note that inequality (36.34) should be separately verified upon using levitation micro-systems in a vacuum environment.

Application

The analytical approach developed above can be applied to analyze the dynamics and stability of symmetric and axially symmetric designs of micromachined levitation micro-actuators as shown in Fig. 36.3. Due to the symmetry in the considered designs, the number of equations in set (36.28) can be reduced. Structures of their analytical models are obtained as shown in Table 36.1.

It can be proposed the following procedure for designing levitation micro-systems. If the system is intended for using in air, the application of the developed approach is reduced to the analysis of the coefficients of matrix $\underline{R} = (\mathrm{Re}\{\overline{c}_{lr}\})$, whose elements are defined in (36.29) as functions of the design parameters. A result of this analysis would be to find the domains of these design parameters where the matrix $\underline{R} > 0$ is positive definite, or to demonstrate that such domains do not exist ($\underline{R} < 0$ is everywhere negative definite). Additionally, for a vacuum environment, it becomes necessary to define the coefficients of the matrix $\underline{P} = (\mathrm{Im}\{\overline{c}_{lr}\})$, which give the required values of the damping coefficients, μ_{r}, in order to fulfill the condition for stable levitation as defined in Theorem 3.

Table 36.1 The structures of the analytical models of the levitation micro-systems as a function of design

Design	Levitating micro-object	Model Structure
Axially symmetric		$\begin{cases} M\ddot{q}_v+\mu_v\dot{q}_v+\bar{c}_{vv}q_v=F_v; \\ M\ddot{q}_1+\mu_1\dot{q}_1+\bar{c}_{11}q_1=F_1. \end{cases}$ $\begin{cases} M\ddot{q}_v+\mu_v\dot{q}_v+\bar{c}_{vv}q_v=F_v; \\ M\ddot{q}_1+\mu_1\dot{q}_1+\bar{c}_{11}q_1+\bar{c}_{1\theta}\theta=F_1; \\ J_\theta\ddot{\theta}+\mu_\theta\dot{\theta}+\bar{c}_{\theta 1}q_1+\bar{c}_{\theta\theta}\theta=T_\theta. \end{cases}$
Symmetric		$\begin{cases} M\ddot{q}_v+\mu_v\dot{q}_v+\bar{c}_{vv}q_v=F_v; \\ M\ddot{q}_1+\mu_1\dot{q}_1+\bar{c}_{11}q_1+\bar{c}_{1\alpha}\alpha=F_1; \\ J_\alpha\ddot{\alpha}+\mu_\alpha\dot{\alpha}+\bar{c}_{\alpha l}q_l+\bar{c}_{\alpha\alpha}\alpha=T_\alpha; \\ J_\beta\ddot{\beta}+\mu_\beta\dot{\beta}+\bar{c}_{\beta\beta}\beta=T_\beta. \end{cases}$

Table 36.2 Comparison of suspension stiffness from modelling and experiment results

Stiffness component	Measured values reported in [35]	Modelling reported in [35]	Analytical modelling
Lateral, ($N{\cdot}m^{-1}$)	3.0×10^{-3}	3.0×10^{-3}	2.0×10^{-3}
Vertical, ($N{\cdot}m^{-1}$)	4.5×10^{-2}	4.2×10^{-2}	4.5×10^{-2}
Angular, ($m{\cdot}N{\cdot}rad^{-1}$)	1.5×10^{-8}	0.8×10^{-8}	1.4×10^{-8}

The micromachined levitation actuator design based on 3D micro-coils shown in Fig. 36.4a is analyzed. Let us assume that the actuator is operated in air. Hence, the elements of the matrix (see, Table 36.1) will be defined as functions of the design parameters [9, 10, 35]. Thus, d is the difference between the radius of the disk-shaped proof mass and the radius of the levitation coil, and h is the levitation height. The same design of 3D micromachined levitation actuator and the experimental parameters given in [35]: the radii of the stabilization and levitation coils are 1.9 mm and 1.0 mm, respectively; the pitch of coil winding is 25 μm ; the number of windings for the stabilization and levitation coils are 12 and 20, respectively; the radius of the proof mass is 1.6 mm are used.

For an excitation current of 109 mA in both coils, the maps of the stiffness coefficients are shown in Fig. 36.4. The results of the modelling are shown in Table 36.2 together with experimental ones published in [35] in order to enable the direct comparison. The analysis of Table 36.2 shows that the developed technique allows us to evaluate the stiffness with a good enough accuracy.

36.2.5 Phenomenological Model of Heat Transfer in Hard-Disk Air Bearing

To achieve higher areal density, a flying height of air bearing is required to be significantly reduced to a few nanometers. For instance, to support areal density 10 Tbit in^{-2}, the flying height has to be less than 4 nm. Thus, heat transfer processes between a slider and disk surface in hard disk drives (HDD) becomes an extremely important issue. Recently, the Thermal Fly-height Control (TFC) technology has been developed to provide such a nano-scale flying height [36, 37]. In TFC technology, a microheater embedded in-situ slider is used to control the protrusion and gap by means of measuring Joule heating current. Moreover, a nano-level slider-disk gap leads to a thermal deformation of the slider's air bearing surface as well as air bearing cooling affect which have a great influence on a performance of HDD [38, 39]. Thus, it becomes a very important to accurately describe heat transfer in hard-disk air bearing, in order to provide further HDD improvement.

To solve this issue, a number of models were developed and discussed in the literature. The analytical heat transfer model in a thin slider/disk air bearing based on the reduced Navier-Stokes equation with velocity slip and temperature jump boundary conditions was proposed by S. Zhang and D.B. Bogy as reported in [40]. Then the result of Zhang's work was extended by Chen et al. accounting for the pressure gradient and their model agreed well with experiment for the flying heights of air bearing between 80 and 100 nm [41].

Worth noting that in mentioned above studies, bulk values of thermal conductivity and viscosity were assumed to be constant. However, this fact is in contradiction with reality. This point was reflected in the continuum model based on the assumption of the nonlocal behavior in air molecule heat transport in the slider/disk interface developed by Poletkin and Kulish in [28, 42].

Nonlocal Behavior in Air Molecule: Governing Equation in Air Bearing

Schematic of slider/disk interface is shown in Fig. 36.5a. A part of disk moves with a linear speed, U, relative to the slider as shown in the scheme. The spacing between the head of slider and the surface of disk is defined by variable, s. In this analysis, the slider/disk interface can be idealized as a channel between two boundary plates, in which air flow moves along these plates. Assuming that the top plate is

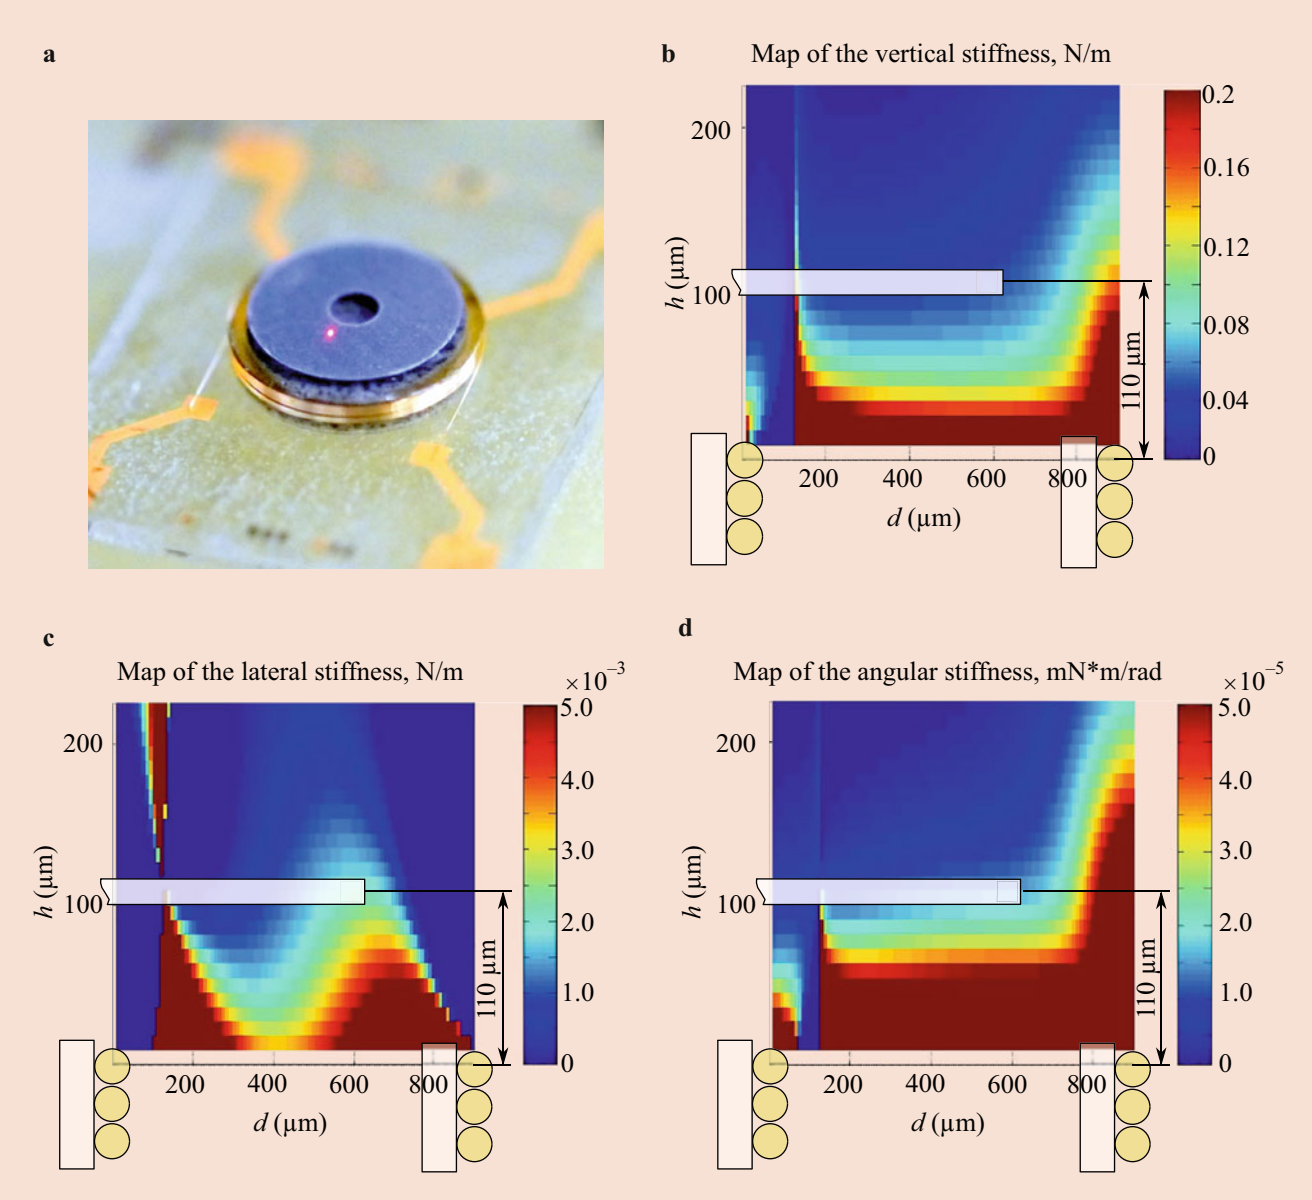

Fig. 36.4 (**a**) Axially symmetric 3D micromachined levitation actuator; (**b**) Map of angular stiffness as a function of d and levitation height, h; (**c**) Map of the vertical stiffness; (**d**) Map of the lateral stiffness

movable and a positive pressure gradient with respect to the y axis is applied as shown in Fig. 36.5b. We consider in this analysis a steady state; hence, time dependent terms in the related equations disappear. Assuming the nonlocal behavior (in space) in air molecular gas due to its scattering from the boundaries of the domain through which air flow is moved, we can write the following equations similar to the Fourier law along the x axis:

$$q''(s + l_q, x) = -k\frac{\partial T}{\partial x}, \tag{36.35}$$

and Newton's law of viscosity:

$$\varphi(s + l_\varphi, x) = \mu\frac{\partial u}{\partial x}, \tag{36.36}$$

where q'' is the heat flux, T is the temperature, l_q is the length measuring the nonlocality of the heat flux, k is the bulk value of the thermal conductivity of air, φ is the shearing stress, u is the y axis component of air flow velocity, μ is the bulk value of the dynamic viscosity of air, l_φ is the length measuring the nonlocality of the shearing stress, s is the size of the domain along the x axis through which air flow is moved. Equations (36.35) and (36.36) are the primary assumption.

The reduced Navier-Stokes equation [40] for two dimension problem can be written as follows:

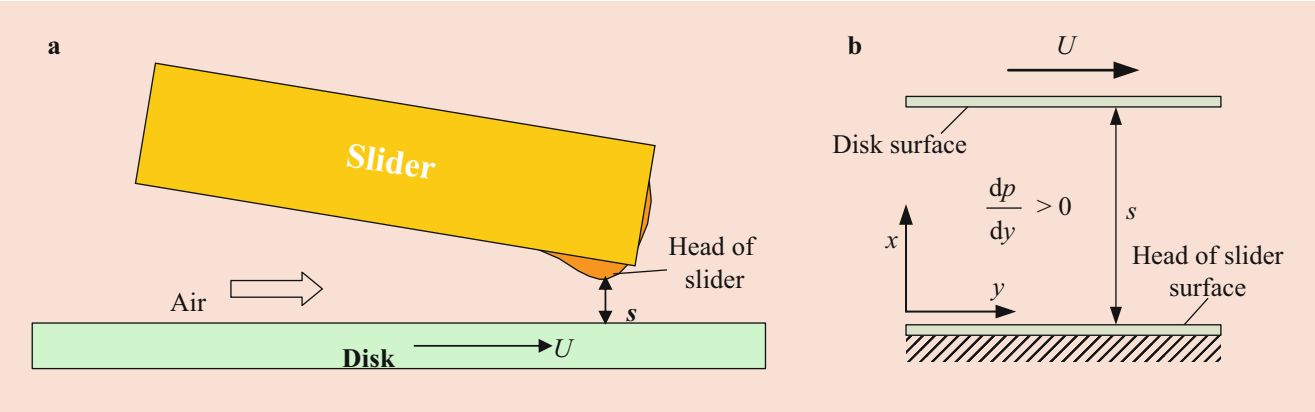

Fig. 36.5 (**a**) Schematic of slider/disk interface: U is the linear speed of the disk with regard to the slider; s is the spacing between the head of slider and the disk surface; (**b**) The slider/disk system idealization and coordinate

$$\frac{\mathrm{d}p}{\mathrm{d}y} = \frac{\partial \varphi}{\partial x}, \tag{36.37}$$

$$\frac{\mathrm{d}p}{\mathrm{d}x} = 0, \tag{36.38}$$

where p is the pressure. Using the result of analysis for the energy equation conducted in [40], and accounting for Eq. (36.36), the general form of the energy equation can be written as follows:

$$\frac{\partial q''_{\mathrm{v}}}{\partial x} + \varphi(s,x)\left(\frac{\partial u}{\partial x}\right) = 0, \tag{36.39}$$

where q''_{v} is the heat flux due to the viscous dissipation. Assuming that the nonlocal behavior in air molecular gas exists in the immediate vicinity of the interest point at s, hence Eqs. (36.35) and (36.36) can be expanded into the Taylor series containing the first order effects in l_{q} and l_{φ} are as follows

$$q''(s,x) + l_{\mathrm{q}}\frac{\partial q''(s,x)}{\partial s} = -k\frac{\partial T}{\partial x}, \tag{36.40}$$

$$\varphi(s,x) + l_{\varphi}\frac{\partial \varphi(s,x)}{\partial s} = \mu\frac{\partial u}{\partial x}. \tag{36.41}$$

Gradients of temperature and velocity are assumed to be constant against the change of the domain size, s. The physical meaning for this assumption can be supported by the following analysis of conservation laws applied to the one-dimensional case. For energy conservation, we have

$$-\frac{\partial q''(s+l_{\mathrm{q}},x)}{\partial x} = c_p\rho\frac{\partial T}{\partial t}, \tag{36.42}$$

where c_p is the specific heat, ρ is the density. Since we study the steady state process, the derivative of T with respect to time is eliminated. Hence, Eq. (36.42) can be rewritten as the deferential equation of the first order:

$$\frac{\partial q''(s+l_{\mathrm{q}},x)}{\partial x} = 0. \tag{36.43}$$

The solution of the last equation is

$$q''(s+l_{\mathrm{q}},x) = C, \tag{36.44}$$

where C is the constant. Assuming that l_{q} is small, Eq. (36.44) becomes

$$q''(s,x) + l_{\mathrm{q}}\frac{\partial q''(s,x)}{\partial s} = C. \tag{36.45}$$

Applying to (36.45) boundary condition $q''(0,x) = 0$, solution of Eq. (36.45) is

$$q''(s,x) = C\left(1 - \mathrm{e}^{-s/l_{\mathrm{q}}}\right). \tag{36.46}$$

On the other hand, substituting (36.35) into (36.44), we come to conclusion that $C = -k\dfrac{\partial T}{\partial x}$. Hence, heat transport due to the nonlocal behavior in air molecular gas becomes

$$q''(s,x) = -k\frac{\partial T}{\partial x}\left(1 - \mathrm{e}^{-s/l_{\mathrm{q}}}\right). \tag{36.47}$$

For momentum conservation law, we have

$$-\frac{\partial \varphi(s+l_{\varphi},x)}{\partial x} = \rho\frac{\partial u}{\partial t}. \tag{36.48}$$

Then, applying the same analysis conducted above to (36.48), we obtain the equation for shear stress in air due to the nonlocal behavior as follows

$$\varphi(s,x) = \mu\frac{\partial u}{\partial x}\left(1 - \mathrm{e}^{-s/l_{\varphi}}\right). \tag{36.49}$$

Now, let us define functions $k_{\mathrm{eff}}(s)$ and $\mu_{\mathrm{eff}}(s)$, as

$$k_{\text{eff}}(s) = k\left(1 - \mathrm{e}^{-s/l_{\text{q}}}\right), \tag{36.50}$$

$$\mu_{\text{eff}}(s) = \mu\left(1 - \mathrm{e}^{-s/l_{\varphi}}\right). \tag{36.51}$$

Taking into account (36.50) and (36.51), Eqs. (36.47) and (36.49) can be rewritten in the similar to the Fourier and Newton laws forms as

$$q''(s,x) = -k_{\text{eff}}(s)\frac{\partial T}{\partial x}, \tag{36.52}$$

$$\varphi(s,x) = \mu_{\text{eff}}(s)\frac{\partial u}{\partial x}, \tag{36.53}$$

where k_{eff} and μ_{eff} are size dependent the effective conductivity and dynamic viscosity. Thus, Eqs. (36.52) and (36.53) represent phenomenological models for heat transport and shear stress in assuming the nonlocal behavior (in space) in air molecular gas due to its scattering from the boundaries of the domain through which air flow is moved. Finally, combining Eq. (36.53) with (36.39), the energy equation can be rewritten as

$$\frac{\partial q''_{\text{v}}}{\partial x} + \mu_{\text{eff}}(s)\left(\frac{\partial u}{\partial x}\right)^2 = 0. \tag{36.54}$$

Let us consider the heat flux due to the viscous dissipation for the case of Couette and Poiseuille flows. In this case, the velocity distribution can be obtained by direct integrating reduced Navier-Stokes Eq. (36.37) with accounting for (36.53). For the following boundary conditions such as $u(s) = U$ and $u(0) = 0$, accounting for the pressure gradient $\mathrm{d}p/\mathrm{d}y$ is constant, the velocity distribution becomes

$$u = \frac{U}{s}x - \frac{s^2}{2\mu_{\text{eff}}}\left[\frac{x}{s} - \left(\frac{x}{s}\right)^2\right]\frac{\mathrm{d}p}{\mathrm{d}y}. \tag{36.55}$$

It is worth to note that Eq. (36.55) is the similar to classical result of velocity distribution due to Couette and Poiseuille flows between two parallel plates.

The net heat transfer between the two bounding surfaces, in particular, due to the Couette flow can be computed by subtracting viscous heating terms from the heat conduction term:

$$q''_{\text{n}} = \frac{k_{\text{eff}}}{s}\left(T_{\text{s}} - T_{\text{d}}\right) - \mu_{\text{eff}}\frac{U^2}{s}, \tag{36.56}$$

where T_{s} and T_{d} are surface temperatures of the slider and disk, respectively. Thus, Eq. (36.56) is the phenomenological model of heat transfer in hard-disk air bearing based on the nonlocal behavior in air molecular gas.

The nonlocal length, l_{q}, is corresponded to the back-scattering process of air molecules from the boundary surfaces of the plates [21]. At the same time, the energy transfer of this process has the wave nature, which can be defined by the propagation of thermal waves [43]. Hence, the nonlocal length becomes the same as the characteristic length traveled by the thermal wave [27]. Applying the same reasoning to define the nonlocal length, l_{φ}, via the wave nature of the energy transfer, the nonlocal lengths can by defined as

$$l_{\text{q}} = \frac{3k}{c_p\rho c} = 3\frac{\alpha}{c} = 3l, \tag{36.57}$$

$$l_{\varphi} = \frac{3\mu}{\rho c} = 3\frac{\nu}{c} = 3\frac{\text{Pr}\cdot\alpha}{c} = 3\text{Pr}\cdot l, \tag{36.58}$$

where c is the speed of sound in air, α is the air thermal diffusivity, ν is the air kinematic viscosity, Pr is the Prandtl number, l is the mean free path of air molecule.

Discussion

Let us compare the developed model (36.56) with known ones, namely, based on temperature jump theory by Znang and Bogy [40], kinematic theory by Shen and Chen [44], Monte Carlo simulation by Ju [45]. To do so, model (36.56) in the non-dimensional form is represented. Employing (36.57) and (36.58), and accounting for the relationship between conductivity and dynamic viscosity of air, $k = 15/4\ \mu R$, we have

$$Q_{\text{n}} = \frac{lq''_{\text{n}}}{k\Delta T} = \frac{1 - \exp\left(-\frac{D}{3}\right)}{D} - \frac{4}{15}\frac{1 - \exp\left(-\frac{D}{3\text{Pr}}\right)}{D}\widetilde{U}^2, \tag{36.59}$$

where $\Delta T = T_{\text{s}} - T_{\text{d}}$, $D = s/l$ is the inverse Knudsen number, $\widetilde{U} = U/\sqrt{R\Delta T}$, R is the gas constant, $\widetilde{p} = (lp)/(\mu\sqrt{R\Delta T})$, $\widetilde{y} = y/s$. Hence, the contribution in heat transfer between the slider and disk surface in HDD due to heat conduction is defined by

$$Q' = \frac{1 - \exp\left(-\frac{D}{3}\right)}{D}. \tag{36.60}$$

Consequently, the contribution in heat transfer between the slider and disk surface in HDD due to the viscous dissipation for Couette and Poiseuille flows are as follow

$$Q''_{\text{c}} = \frac{4}{15}\frac{1 - \exp\left(-\frac{D}{3\text{Pr}}\right)}{D}. \tag{36.61}$$

Results of comparison of the different models with nonlocal one are shown in Fig. 36.6a, b. Analysis of Fig. 36.6a, b reveals that the new model prediction for heat conduction agrees well with known models namely based on Boltzmann equation and the temperature jump theory. For the viscous dissipation due to Couette flow, the nonlocal model prediction qualitatively agrees with models base on Boltzmann equation and Monte Carlo simulation. The nonlocal model agrees quantitatively well with model based on Monte Carlo simulation, the difference is less than 7%.

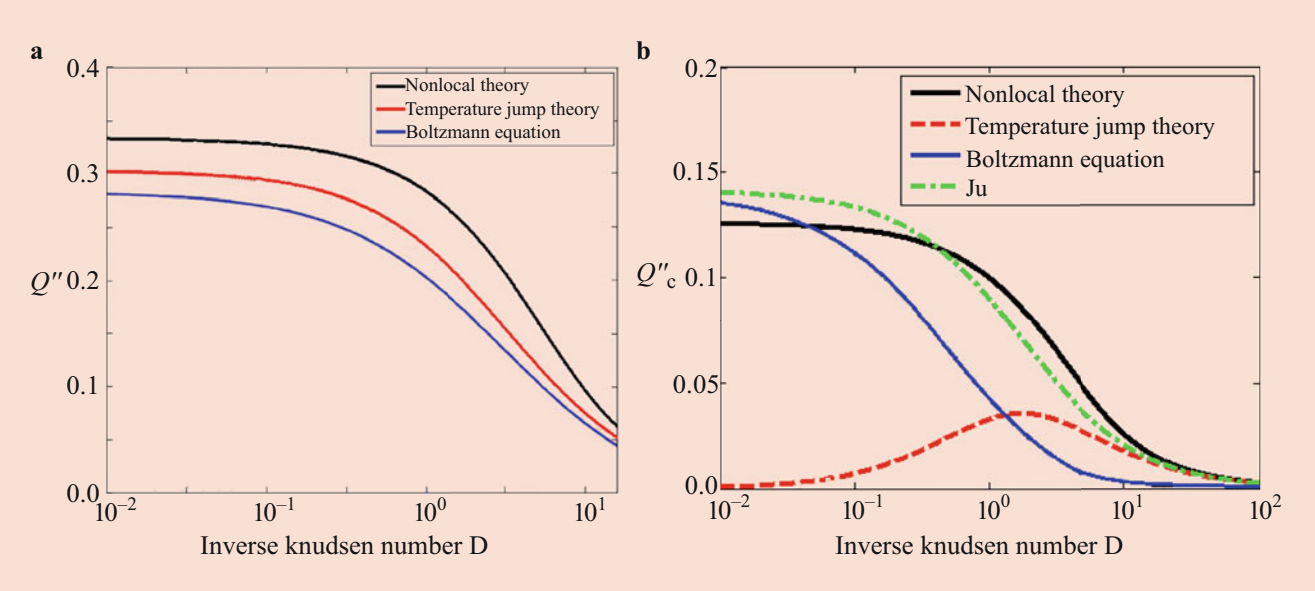

Fig. 36.6 (**a**) Comparison of Q'', representing heat conduction between two parallel plate obtained from nonlocal theory with other existing solutions; (**b**) Comparison of Q''_c, representing viscous dissipation due to Couette flow between two parallel plate obtained from nonlocal theory with other existing solutions

36.3 Topology Optimization

Topology optimization is currently regarded to be the most robust methodology for the inverse determination of material distribution in the structures that meet given structural performance criteria. It can provide a powerful approach for inverse design of micro-/nano-structures in the areas of and, with synthetically considering the device performance, scale effect and manufacturability. Therefore, this section focuses on the introduction of topology optimization in an abstract mathematical form and demonstration of its applications in the areas of microfluidics and nano-optics.

36.3.1 General Considerations in Topology Optimization

Layout optimization problems have attracted research interest of mathematicians and engineers for several decades [46, 47]. Usually, they are categorized into three types, i.e. size optimization, shape optimization and topology optimization. Those three types can be distinguished as demonstrated in Fig. 36.7, where the compliance of the cantilever shown in Fig. 36.7a is minimized respectively using the size optimization, shape optimization and topology optimization approaches. In size optimization, the structure is parameterized by the sizes and positions of geometrical characteristics, and the corresponding parameters are chosen to be the optimization variables; meanwhile, the shape optimization parameterizes the geometrical characteristics of structures using the spline interpolation [48, 49] etc, where the sample points are the optimization variables. After parameterization, the optimization variables are iteratively evolved in the preset feasible regions, using global optimization or gradient information-based optimization algorithm [50]. Size optimization and shape optimization are subjected to the inflexibility on changing the topology of the initial guesses of the structure, and hence have relatively strong dependence on the initial guesses of the optimization variables.

Being different from the size and shape optimization, topology optimization is a full-parameter method used to inversely determine the geometrical configuration, which represents distribution of materials in a structure [51]. It can be used to implement the structural design for the cases where the scale is large enough to ensure the reasonability for using physical parameters of materials fitting in with statistical or continuum hypothesis. In contrast to designing devices by tuning a handful of structural parameters in size and shape optimization, topology optimization utilizes the full-parameter space to design structures solely based on the user's desired performance specification. It is more flexible and robust, because of its low dependence on initial guess of structures and implicitly expression of the material distribution in structures. Therefore, topology optimization is currently regarded to be the most robust methodology for the inverse determination of material distribution in the structures that meet given structural performance criteria.

Structural topology was investigated as early as 1904 for trusses by Michell, and this resulted in structure types carrying his name [52]. The topology optimization method

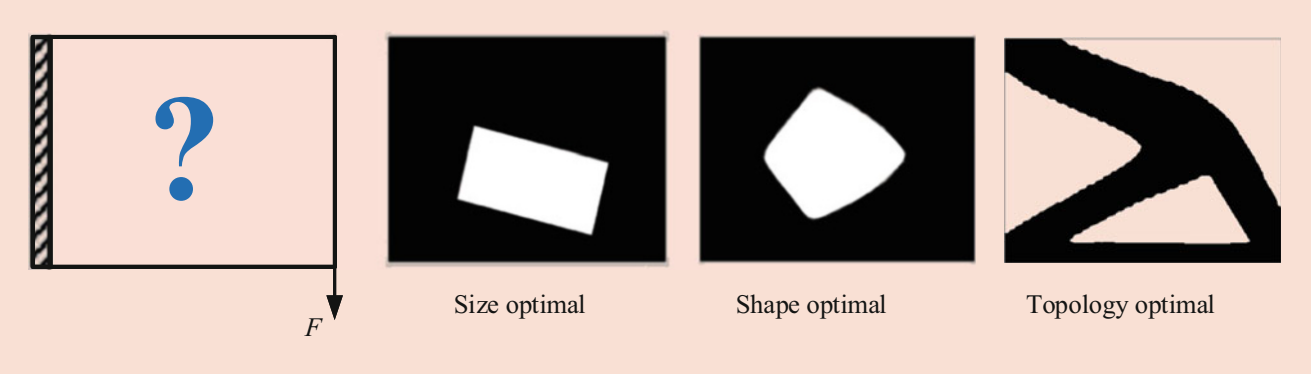

Fig. 36.7 Size optimization, shape optimization and topology optimization of a cantilever with minimizing compliance [111]

was pioneered by Bendsøe and and Kikuchi for elasticity in 1988 [53]; then, it was extended to a variety of application areas, e.g., acoustics, electromagnetics, fluid dynamics and thermodynamics [54–81], to list the most prominent. Currently, the density method [72, 73] and level set method [82–85] have been widely used to describe the material distribution in gradient-based topology optimization. Several other approaches have also been developed for the implementation of topology optimization, e.g., evolutionary techniques [86–88], moving morphable components [89, 90] and phase field method [92], to list the most prominent. In all those researches, the design variable used to represent the structure was usually defined on three-dimensional domains or reduced two-dimensional planes, with the deficiency on the general two-dimensional manifolds. To solve this deficiency, a topology optimization on two-dimensional manifolds has been developed recently [91].

The density method was firstly used to design stiffness and compliance mechanisms [53–55], and it has been extended to multiple physical problems, such as acoustic, electromagnetic, fluidic, optical and thermal problems [51, 56, 70, 71, 74, 75, 79]. The level set method, pioneered by Osher and Sethian [93], accomplishes a change of topology by evolving and merging the zero contour of the level set function, i.e., embedding the boundary in a higher dimension space. This method provides a general approach to track the implicit interface between two phases, and it has been applied to shape and topology optimization [77, 82–85, 94–96]. One of the major advantages of the level set method lies in expressing continuously moving interfaces, and abstracting the material domains that correspond to the structural topology. Compared to the level set method, the density method has the merits of rapid and robust convergency, weak dependence on the initial distribution of the design variable, and the ability to deal with multiple constraints. It is therefore our method of choice for this chapter.

Variational Problem and Regularization

The variational problem for topology optimization is typically in the mathematical form of optimization problem constrained by partial differential equations, and it can be written in the following abstract form

$$\text{find } \gamma \in \mathrm{K}_\gamma \text{ to minimize } J(y;\gamma), \text{ subject to } e(y;\gamma) = 0 \tag{36.62}$$

where $y \in \mathrm{Y}$ is the state variable which can be a scalar or vector; $\gamma \in \mathrm{V}$ is the design variable; y and γ are functionals defined on the open and bounded domain Ω with Lipschitz boundary; $J : \mathrm{Y} \times \mathrm{V} \to \mathbb{R}$ and $e : \mathrm{Y} \times \mathrm{V} \to \mathrm{Z}$ are bounded continuous mapping operator; Y, V and Z are Banach spaces; $\mathrm{K}_\gamma \subset \mathrm{V}$ is the feasible set of γ. A common situation is that $e : \mathrm{Y} \times \mathrm{V} \to \mathrm{Z}$ is continuously Fréchet differentiable and $e_y(y;\gamma) \in \mathcal{L}(\mathrm{Y}, \mathrm{Z})$ has the bounded inverse. Then, according to the implicit function theorem [97], the partial differential equation $e(y;\gamma) = 0$ locally defines a continuously Fréchet differentiable map $\gamma \mapsto y(\gamma)$, which has the following Fréchet derivative

$$y'(\gamma) = -e_y^{-1}(y;\gamma)\, e_\gamma(y;\gamma) \tag{36.63}$$

Therefore, the optimization problem in Eq. (36.62) is transformed into

$$\min \hat{J}(\gamma) = J(y(\gamma);\gamma);\ \gamma \in \mathrm{K}_\gamma \tag{36.64}$$

In density method-based topology optimization, the design variable is relaxed and bounded in a given interval, typically $[0, 1]$, where the values 0 and 1 respectively represent two different materials. Then the set of the feasible values of the design variable in Eq. (36.62) is $\mathrm{K}_\gamma = [0, 1]$. Based on the gradient information of the optimization problem, the design variable is penalized and evolved to the value 0 or 1 at a fixed point in the design domain. Based on the above

regularization, the optimization problem in Eq. (36.64) can be transformed furthermore

$$\min \hat{J}(\gamma) = J(y(\gamma); \gamma); \ \gamma \in [0, 1] \tag{36.65}$$

The gradient information of γ in Eq. (36.65) can be obtained after the adjoint analysis. Based on the gradient information, the variational problem for topology optimization can be solved using an iterative procedure.

Adjoint Analysis

Adjoint method is an efficient approach to derive the descent direction of the objective in the partial differential equation constrained optimization problem [98–100]. From the Gâteaux derivative of $\hat{J}$, one can obtain

$$\begin{aligned} &\left\langle \hat{J}', s \right\rangle_{\mathrm{V}^*,\mathrm{V}} \\ &= \langle J_y, y's \rangle_{\mathrm{Y}^*,\mathrm{Y}} + \langle J_\gamma, s \rangle_{\mathrm{V}^*,\mathrm{V}} \\ &= \langle y'^* J_y, s \rangle_{\mathrm{V}^*,\mathrm{V}} + \langle J_\gamma, s \rangle_{\mathrm{V}^*,\mathrm{V}} \\ &= \langle y'^* J_y + J_\gamma, s \rangle_{\mathrm{V}^*,\mathrm{V}} \\ &= \left\langle e_\gamma^* \left(-e_y^{-1}\right)^* J_y + J_\gamma, s \right\rangle_{\mathrm{V}^*,\mathrm{V}}; \ \forall s \in \mathrm{V} \end{aligned} \tag{36.66}$$

where $(\cdot)^*$ is the adjoint operator of $(\cdot)$; $\langle \cdot, \cdot \rangle$ represents the dual pairing of V^* and V. By setting

$$\lambda = \left(-e_y^{-1}\right)^* J_y = -\left(e_y^*\right)^{-1} J_y \tag{36.67}$$

one can obtain

$$\left\langle e_y^* \lambda, v \right\rangle_{\mathrm{Y}^*,\mathrm{Y}} = \langle -J_y, v \rangle_{\mathrm{Y}^*,\mathrm{Y}}, \ \forall v \in \mathrm{Y} \tag{36.68}$$

where $\lambda \in Z^*$ is the adjoint variable of y; e_y^* is the adjoint operator of e_y. And the Gâteaux derivative of $\hat{J}$ can be reduced to be:

$$\left\langle \hat{J}', s \right\rangle_{\mathrm{V}^*,\mathrm{V}} = \langle e_\gamma^* \lambda + J_\gamma, s \rangle_{\mathrm{V}^*,\mathrm{V}}, \ \forall s \in \mathrm{V} \tag{36.69}$$

If $\hat{J}$ is Fréchet differentiable, the adjoint equation

$$e_y^* \lambda = -J_y \tag{36.70}$$

and the adjoint derivative

$$\hat{J}' = e_\gamma^* \lambda + J_\gamma \tag{36.71}$$

can be obtained, where the adjoint derivative is utilized as the gradient information of the objective.

In engineering, the variational problem may need to be regularized furthermore by some integral constraints, e.g., volume constraint. The adjoint analysis of these integral constraints is the same as that for the objective. The variational problem in Eq. (36.62) usually has strong nonlinearity and it is difficult to solve the system directly. Therefore, the iterative approach is widely adopted. In the iterative approach, the descent direction can be defined based on the adjoint derivative, where the state and adjoint variables are respectively obtained by solving the partial differential equations and corresponding adjoint equations.

Numerical Implementation

The procedure for the iterative approach includes the following steps (Fig. 36.8):

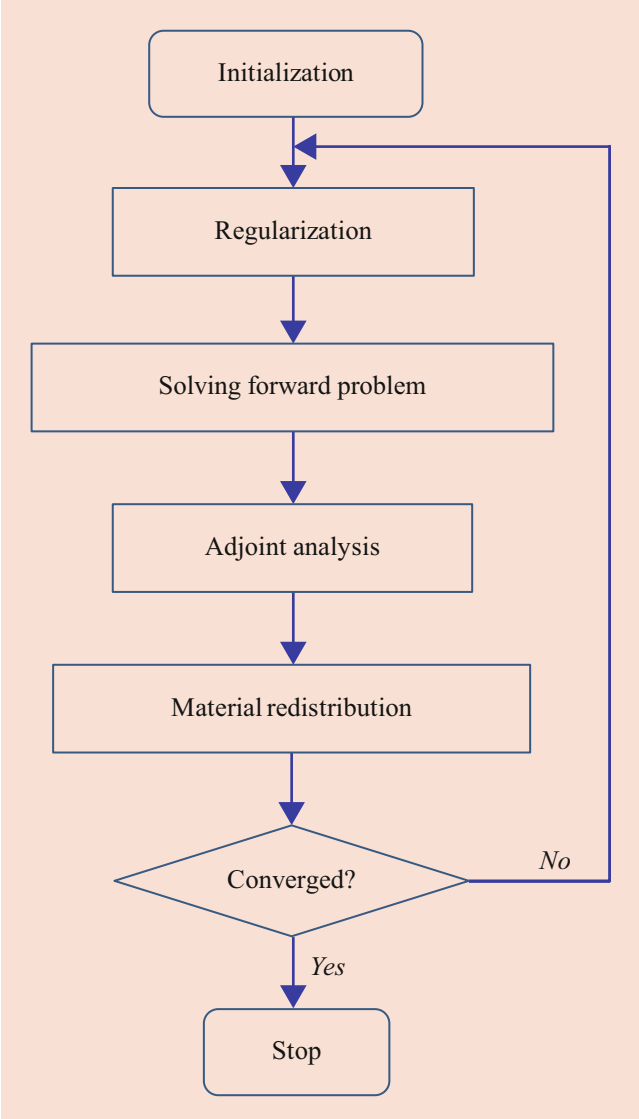

Fig. 36.8 Flowchart for the iterative solution of the optimization problem

1. the design variable is regularized by a PDE filter and threshold method [101–105];
2. the partial differential equations are solved with the regularized design variable;
3. the adjoint equations are solved based on the numerical solution of the partial differential equations;
4. the adjoint derivatives of the objective functional and integral constraint are computed;
5. the design variable is updated using the method of moving asymptotes (MMA), which can be used to deal with the optimization problem with multiple integral constraints and bound constraint of the design variable [107].

These steps are implemented iteratively until the stopping criteria are satisfied. The stopping criteria are usually specified as a maximal iterative number or the change of the objective values in 5 consecutive iterations satisfying

$$\sum_{i=0}^{4} |J_{k-i} - J_{k-i-1}| / |J_k| < \epsilon \tag{36.72}$$

in the k-th iteration, where J_k and γ_k are the objective value and the distribution of the design variable in the k-th iteration, respectively; ϵ is the tolerance typically chosen to be 1×10^{-3}. In the above iterative procedure, the partial differential equations and corresponding adjoint equations can be solved by reasonably chosen numerical methods. During the iterative procedure, the design variable can be filtered by the PDE filter [101, 102] to ensure the distribution smoothness, where the PDE filter is implemented by solving the following equation:

$$\begin{aligned} -r^2 \nabla \cdot \nabla \tilde{\gamma} + \tilde{\gamma} &= \gamma, \text{ in } \Omega \\ \mathbf{n} \cdot \nabla \tilde{\gamma} &= 0, \text{ on } \partial\Omega \end{aligned} \tag{36.73}$$

where r is the filter radius chosen based on numerical experiments [102]; $\tilde{\gamma}$ is the filtered design variable. To ensure the minimum scale length and remove the gray area in the obtained material topology, the filtered design variable is projected by the threshold method [103–105]:

$$\bar{\tilde{\gamma}}(\tilde{\gamma}) = \frac{\tanh(\beta\xi) + \tanh(\beta(\tilde{\gamma} - \xi))}{\tanh(\beta\xi) + \tanh(\beta(1 - \xi))} \tag{36.74}$$

where $\bar{\tilde{\gamma}}$ is the projected design variable called physical density representing the material topology [105]; $\xi \in [0, 1]$ and β are the threshold and projection parameters for the threshold projection, respectively. On the choice of the values of ξ and β, one can refer to [103, 106]. Because the design variable is filtered by the PDE filter, the filter equation is included in the partial differential equation constraints of the variational problem (Eq. 36.62). Then, $\tilde{\gamma}$ is regarded as one component of the state vector y. And the adjoint equation of the filter equation is included in the adjoint analysis.

36.3.2 Applications in Microfluidics and Nano-Optics

Topology optimization can provide a powerful approach for inverse design of structures in the area of MEMS and NEMS, with synthetically considering the device performance, scale effect and manufacturability. In this section, topology optimization of MEMS and NEMS are demonstrated respectively for microfluidics and nano-optics.

Topology Optimization for Microfluidics

Lab on a chip is a recent trend in analytical chemistry and the life sciences. In the past two decades, the lab-on-a-chip for fluid handling and analysis has emerged in the interdisciplinary research field of microfluidics [108, 109]. The use of microfluidics in these applications has attracted the interest of industry and academia, because of its potential and advantages, such as small amounts of sample and reagent, less time consumption, lower cost, and high throughput [110]. Miniaturization gives rise to the scale effects of microfluidics. Therefore, it is required to synthetically consider the microscale effects and manufacturability with achieving the desired microfluidic performance.

Two of the most important scale effects in microfluidics are the low Reynolds number and large surface-to-volume ratio. They result in the inefficient mass-transfer and dominance of the surface tension in microfluidics. Because of these specialities, the usually used design approaches encounter the problem on synthetically considering the microscale effects and manufacturability to achieve required microfluidic performance. Therefore, it was inspired to utilize the topology optimization method and implement the inverse design of microfluidics. Based on the topology optimization method, several researches on the inverse design of typical microfluidic components have been implemented [111]. To demonstrate the capability of such a synthetic method, passive micromixers are inversely designed to increase the mass-transfer efficiency, and the periodic microtextures are inversely designed to enhance the robustness of Cassie-Baxter mode of wetting behavior.

Low Reynolds-Number: Topology Optimization of Micromixers

The low-Reynolds-number effect of microfluidics results in the low mass-transfer efficiency. For this effect, passive micromixer is the most typical microfluidic component, where it is desired to enhance the chaotic advection of microflows based on the reasonable design of a microchannel; it is also an important microfluidic component, with wide chemical, biological and detection/analysis applications [112].

The passive micromixer implements the mixing of reagents for the steady flow. By the reasonable layout of the microchannel in a micromixer, the chaotic advection can be

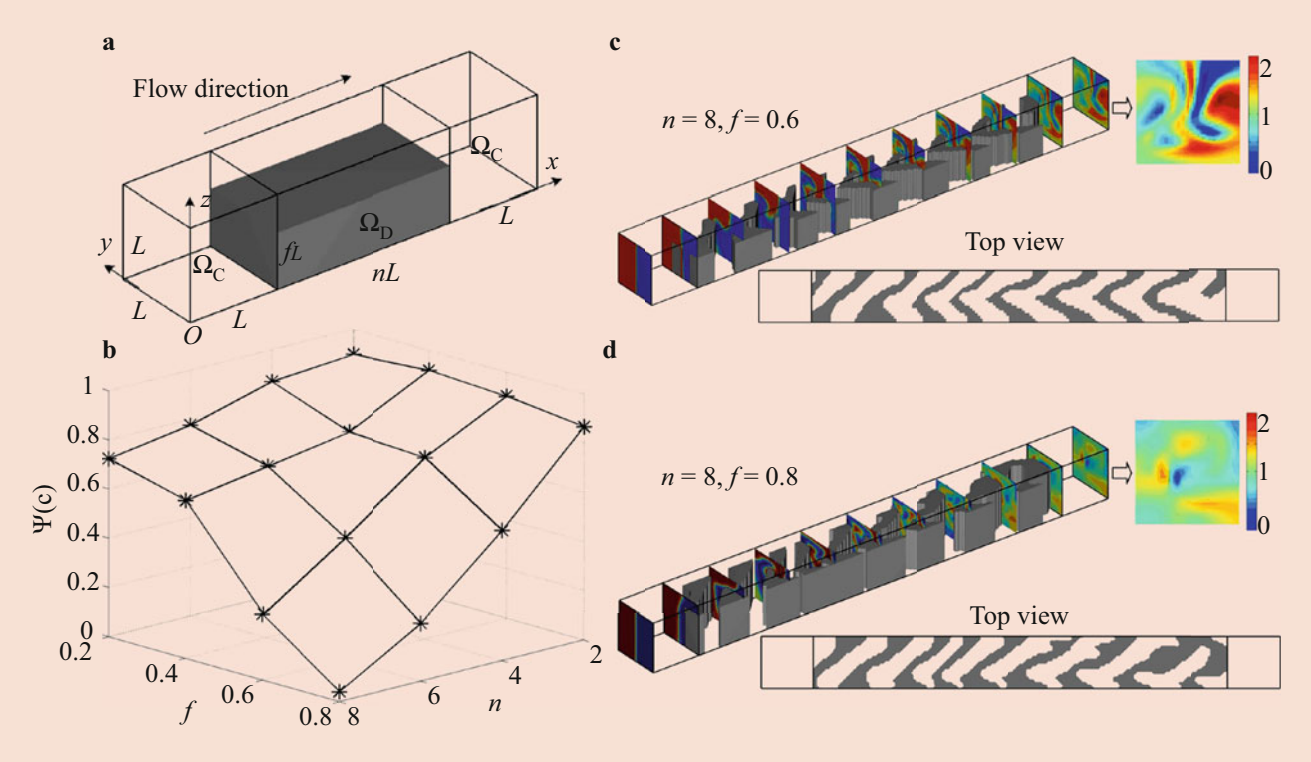

Fig. 36.9 (**a**) Design domain of the passive micromixer. Ω_C is the channels connected to the design domain Ω_D; the length and height of Ω_D are nL and fL, respectively; (**b**) plotting of the mixing measurement of the micromixers for design domains with different values of n and f; (**c**) layout of the micromixer with $n = 8, f = 0.6$, and the corresponding value of the mixing measurement is 0.267; (**d**) layout of the micromixer with $n = 8, f = 0.8$, and the corresponding value of the mixing measurement is 0.041. The characteristic length L is 400 μm; the Reynolds number and Péclet number are 10 and 10^3, respectively [113]

strengthened, and the mixing performance can be improved. In the cases of mixing two fluid streams with different concentration of solutions, the ideal concentration distribution of the solute at the outlet, is the average concentration. The mixing performance of the micromixer can be measured by $\Psi(c) = \int_{\Gamma_o} (c - c_a)^2 \, d\Gamma / \int_{\Gamma_i} (c_r - c_a)^2 \, d\Gamma$, where c_a is the ideal concentration distribution at the outlet Γ_o; c_r is the reference concentration distribution at the inlet Γ_i. A lower value of $\Psi(c)$ corresponds to better mixing performance. Therefore, the design task is to find the reasonable layout of a micromixer corresponding to the lowest value of the mixing measurement in a given design domain with designer specified inlet and outlet. Then a variational problem with the mixing measurement $\Psi(c)$ as the objective functional can be constructed for the inverse design of the micromixer in the specified design domain. The variational problem is solved using the topology optimization approach, with the model setting and results as shown in Fig. 36.9, where the soft lithography-like manufacturability of the micromixers is ensured by enforcing the quasi-3D dimension of the derived geometry [113].

Large Surface-to-Volume Ratio: Topology Optimization of Microtextures for Cassie-Baxter Wettability

Large surface-to-volume ratio results in the dominance of surface tension in microfluidics, and this is typically presented by the wetting behavior on a solid surface. Recent achievements in the construction of artificial surfaces for special wettability are widespread focused on superhydrophobicity, which means the contact angle of water larger than 150° for a hydrophobic solid substrate [114]. Because the wettability of the solid surface is commonly determined by its geometric morphology and surface free energy, creating microtextures on hydrophobic surfaces has been commonly used to design artificial surfaces with Cassie-Baxter wettability [115].

On a hydrophobic surface with microtextures, two different solid/liquid contact modes can exist. They are the Wenzel and Cassie-Baxter modes. The Cassie-Baxter mode corresponds to a stronger hydrophobicity. When the liquid is pressed physically, the solid/liquid contact mode can change from the Cassie-Baxter case to the Wenzel case, along with

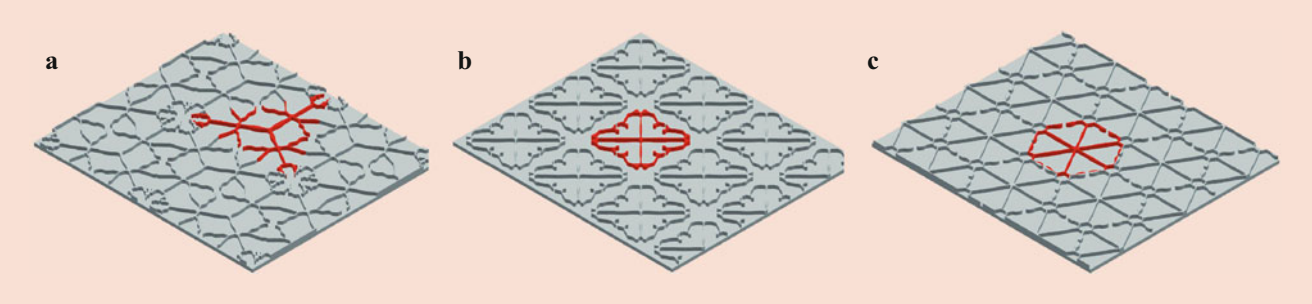

Fig. 36.10 Microtextures for Cassie-Baxter wettability derived by topology optimization method, respectively for the periodic tilling with regular-triangle, regular-quadrangle and regular-hexagon lattices. (**a**) Regular triangle. (**b**) Regular quadrangle. (**c**) Regular hexagon

a decrease of the hydrophobicity. Therefore, reasonable microtextures on a solid surface can keep the Cassie-Baxter mode from transition, and enhance the robustness of the hydrophobicity-like wetting behavior. The reasonability of a microtexture can be measured by the volume of the liquid bulges hold by the liquid/vapor interface, when a fixed static pressure is loaded. And smaller liquid-bulge volume corresponds to more robust Cassie-Baxter mode. Therefore, the microtexture on a solid surface can be inversely designed by minimizing the volume of the liquid bulges. Then, based on the topology optimization method, the microtextures in Fig. 36.10 are derived for the special periodicity with regular-triangle, regular-quadrangle and regular-hexagon lattices, which can respectively strew a flat surface [116, 117].

Topology Optimization for Nano-Optics

Control of optical waves is realized by the nanostructures with complicated geometrical configurations and preselected materials, where the Maxwell's equations are widely used to describe the electromagnetics of the corresponding wave propagation. For the complication of electromagnetics, physical intuition-based electromagnetic structure design has its limitations to achieve the desired performance. To overcome these bounds, several inverse design tests have been implemented based on the structural optimization methods [56–71, 118–122], in which topology optimization method is the one of the most employed.

This section provides the researches on inversely finding the optimal geometric topology of photonic nanostructures, with synthetically considering the performance and manufacturability. The optimal geometric configuration of the nanostructure is determined by the topology optimization approach including the geometric constraints (e.g. the feature size and geometric dimension) brought by the used fabrication process (e.g. ebeam lithography). The related researches have been implemented for both the dielectric and metal material-based nanostructures [123–126]. And those researches have permitted the one-shot design and prediction of nanostructures with satisfied performances in the area of photonics and wave optics, where nanostructures play the key role.

Dielectric Nanostructure: Topology Optimization of Metalens

Metalenses are able to achieve diffraction-limited focusing through localized phase modification of the incoming light beam [127–132]. Because these structures are ultrathin, less than a wavelength, this has the potential of achieving ultrathin optical elements, with a thickness limited mainly by the mechanical strength of the transparent substrate. Recently proposed metalenses are based on either dielectric nanofin arrays, or nanoparticles of large number, which leads to severe manufacturing challenges [133]. To overcome these challenges, a new type of metalens has been predicted with concentric-nanoring configuration, where the number and size of the nanorings are determined using an topology optimization method [123]. By focusing the electrical field energy at a specified position, the convex-like metalens is inversely predicted with desired numerical aperture and a diffraction-limited focal spot (Fig. 36.11a). The Poynting vector distribution found demonstrates the mechanism of the lensing function, in which optical vortices are generated in the nanorings to achieve a matching of the phase and impedance between the substrate and free space, and further, to form a spherical wavefront and enhance the transmission of the optical energy (Fig. 36.11b–d). This method can also be extended to predict an axicon-like metalens with focal beam. The improved manufacturability is concluded from the geometry of the concentric-nanoring configurations.

Metal Nanostructure: Topology Optimization for Localized Surface Plasmon Resonances

Localized surface plasmon resonances (LSPRs) are the strong interaction between metal nanostructures and visible light through the resonant excitations of collective oscillations of conduction electrons. In LSPRs, the local electromagnetic fields near the nanostructure can be many orders of magnitude higher than the incident fields, and the incident light around the resonant-peak wavelength is

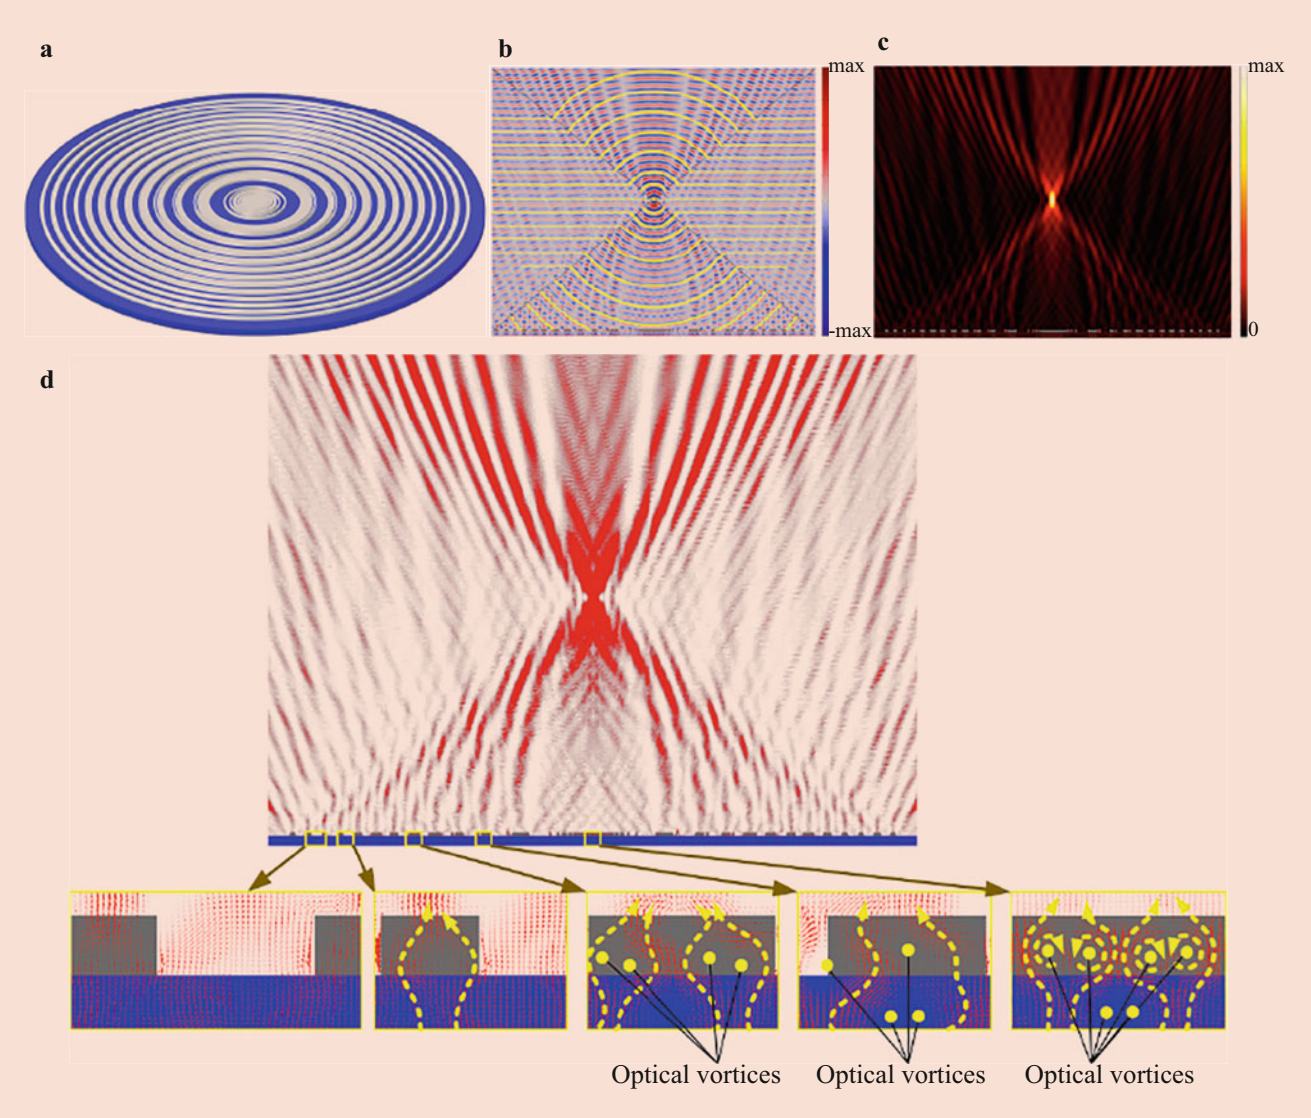

Fig. 36.11 (**a**) Convex-like metalens with ring thickness 200 nm for an incident wavelength of 700 nm; (**b**) real part distribution of the field in the metalens, with spherical phase distribution indicated by the yellow-colored circular arcs; (**c**) electric energy density distribution in the symmetrical plane of the metalens; (**d**) Poynting vector distribution in the metalens with incident wavelength 700 nm, ring thickness 200 nm, and NA = 0.8. The used material is titanium oxide [123]

scattered strongly. The enhanced electric fields are confined within only a tiny region of the nanometer length scale near the surface of the nanostructures and decay significantly thereafter [134].

Due to the deficiency on the inverse problem to find the optimized spatial distribution of metal material in air or dielectric to cater to the performance requirement, an inverse design methodology of metal nanostructures has been presented for LSPRs, based on the topology optimization approach [124,125]. Using the proposed method, determination of the metal distribution in nanostructures is implemented to maximize the enhancement factor of the electric field. The topologically optimized nanostructure was obtained with resonant peak at the specified incident wavelength (Fig. 36.12). Red or blue shift of the resonant peak can be controlled by specifying larger or smaller wavelength for the outlined topology optimization approach. Therefore, the outlined approach can be used to design metal nanostructure with resonant peak and improved enhancement factor at specified incident wavelength and control the shift of the resonant peak by topologically optimizing the nanostructure. This inverse design method for LSPRs can be further extended to other metal nanostructures, e.g. optical antenna and optical trapping.

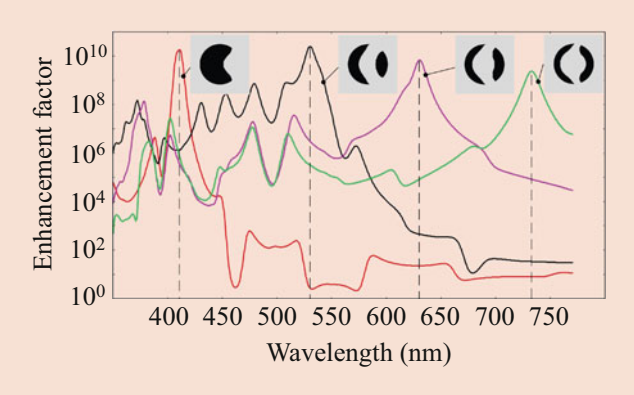

Fig. 36.12 Enhancement-factor spectra of the topologically optimized metal nanostructures. The four nanostructures respectively correspond to the incident wavelengths 410, 533, 633 and 733 nm, in which the resonant peak is red shifted by topology optimization implemented at larger incident wavelengths. The used material for the metal nanostrucutres is silver [124]

36.4 Model Order Reduction

The design domain in topology optimization is usually meshed finely in order to derive a design with accurate representation of the geometry; such fine mesh leads to a large-scale system with many degrees of freedom, especially in the design of three dimensional structures. Therefore, the optimization process is very time consuming due to the need of solving a large-scale system at each iteration. This also poses high demand for computational resources. Model order reduction (MOR) aims to construct a model with much smaller number of degrees of freedom, which gives rise to an approximate solution to the original large-scale system with acceptable error, and at the same time, preserves the key structure of the original large-scale system, so that the small system can play as a surrogate for the large-scale system in simulation. The original large-scale system is called full-order model (FOM) and the model with smaller degrees of freedom is named as the reduced order model (ROM).

Parametric model order reduction (pMOR) is especially useful in design, such as optimization, control, and uncertainty quantification, since the ROM preserves the parametric structure of the original system and is constructed to be accurate for every parameter variation happened during each query of the task.

In this section, we review the reduced basis method which is efficient for linear steady systems with a general parametric form; those systems may arise from topology optimization as discussed in the previous section. Since port-Hamiltonian systems are also very common in MEMS design, we review typical MOR methods for nonlinear port-Hamiltonian systems.

36.4.1 Reduced Basis Method for Steady Linear Parametric Systems

In this section, we review the reduced basis (RB) method for steady linear parametric systems.

$$A(\mu)x(\mu) = f(\mu, x(\mu)), \tag{36.75}$$

where, $\mu \in \mathbb{R}^d$ is the vector of parameters in the parameter domain $\mathcal{P} \subset \mathbb{R}^d$, $x(\mu) \in \mathbb{R}^N$ is the state vector, $f(\mu, x(\mu)) \in \mathbb{R}^N$ is the nonlinear vector. $A(\mu) \in \mathbb{R}^{N\times N}$ is the system matrix.

Such systems may arise from discretization of parametric partial differential equations (PDEs) in space, using finite difference, finite element or finite volume methods. The number of degrees of freedom N is usually large; MOR techniques are developed to find a system of reduced order $r \ll N$, that approximates the original FOM with acceptable accuracy.

If the solution to (36.75) lies in a low dimensional subspace, then it is possible to construct an orthogonal basis of the subspace, such that the solution can be approximated by the basis vectors. Then a ROM can be constructed via Galerkin projection as,

$$A_r(\mu)x_r(\mu) = f_r(\mu, x_r(\mu)), \tag{36.76}$$

where $A_r(\mu) = V^{\mathrm{T}}A(\mu)V \in \mathbb{R}^{r\times r}$ is the reduced system matrix; $x_r(\mu) \in \mathbb{R}^r$, is the reduced state vector; $f_r(\mu, x_r(\mu)) = V^{\mathrm{T}}f(\mu, Vx_r(\mu)) \in \mathbb{R}^r$ is the reduced nonlinear vector. The solution $x(\mu)$ can be recovered via the approximation: $x(\mu) \approx Vx_r(\mu)$.

Algorithm 1 Greedy algorithm for steady systems

Require: $\mathcal{P}_{\text{train}}$, tol_{RB}
Ensure: Projection matrix V representing the reduced basis.
1: Initialization: $V = [\,]$, $\mu^\star = \mu^1$, $\eta(\mu^\star)(> \text{tol}_{\text{RB}})$
2: **while** the error $\eta(\mu^\star) > \text{tol}_{\text{RB}}$ **do**
3: Solve (36.75) to get the solution $x(\mu^\star)$.
4: Update: $V :=$orth $[V, \mathbf{x}(\mu^\star)]$.
5: Find $\mu^\star := \arg\max_{\mu\in\mathcal{P}_{\text{train}}} \eta(\mu)$.
6: **end while**

The RB method for a linear parametric steady system (36.75) can be summarized as below

- Specify $\mathcal{P}_{\text{train}} := \{\mu^1, \ldots, \mu^m\}$, a training set of parameter samples.
- Specify an error estimator/indicator/bound $\eta(\mu)$.
- Use Greedy algorithm to compute the projection matrix V.
- Form the ROM (36.76).

The essence of the RB method is that performing limited number of full simulations of the original large-scale system, a ROM with sufficient accuracy at all possible samples of μ can be constructed, so that it can act as a surrogate of the FOM in the subsequent multi-query tasks.

For efficient simulating the ROM, it is required that the system matrix $A(\mu)$ is affine with the parameter μ, i.e.,

$$A(\mu) = A_1 h_1(\mu) + \ldots + A_q h_q(\mu),$$

where $h_1(\mu), \ldots, h_q(\mu)$ are scalar functions of the parameter vector μ and $A_1, \ldots, A_q$ are parameter independent matrices. If $A(\mu)$ is in the affine form of μ, then $A_r(\mu)$ can be efficiently computed as

$$A_r(\mu) = \big(V^{\mathrm{T}} \cdot A_1 \cdot V\big)h_1(\mu) + \ldots + \big(V^{\mathrm{T}} \cdot A_q \cdot V\big)h_q(\mu),$$

where $V^{\mathrm{T}} \cdot A_1 \cdot V, \ldots, V^{\mathrm{T}} \cdot A_q \cdot V$ can be precomputed and repeatedly called during solving the ROM. Ideally, the right-hand side $\mathbf{f}(\mu, x(\mu))$ is also affine with the parameter μ and is independent of the state vector $x(\mu)$, then $\mathbf{f}_r(\mu)$ can also be efficiently computed as

$$\mathbf{f}_r(\mu) = \big(V^{\mathrm{T}} \cdot \mathbf{f}_1\big)\tilde{h}_1(\mu) + \ldots + \big(V^{\mathrm{T}} \cdot \mathbf{f}_m\big)\tilde{h}_m(\mu),$$

where the parameter-independent vectors $V^{\mathrm{T}} \cdot \mathbf{f}_1, \ldots, V^{\mathrm{T}} \cdot \mathbf{f}_m$ can be precomputed and repeatedly called during solving the ROM. However, in many cases $\mathbf{f}(\mu, x(\mu))$ is non-affine and is also a nonlinear function of $x(\mu)$. In this case, we can use interpolation methods introduced in the next section to reduce the complexity of computing $\mathbf{f}_r$ in the ROM.

Reducing the complexity of $\mathbf{f}_r(\mu, x_r(\mu))$ in the ROM (36.76)

From (36.76), we observe that if the right-hand side $f(\mu, x(\mu))$ is not affine with the parameter μ, evaluating the nonlinear term $f_r(\mu, x_r(\mu))$ still depends on the dimension N of the FOM, since we need to first evaluate $f(\mu, Vx_r(\mu))$ and then multiply with V^{T}. Some interpolation techniques are proposed in the literature to reduce this complexity, such as the Empirical interpolation method (EIM) [135, 136], and the Discrete empirical interpolation method (DEIM) [137].

EIM is proposed associated with the reduced basis method. Both the interpolation indices and the interpolation basis vectors are chosen within the greedy algorithm. DEIM can be considered as a discrete version of EIM. The main difference of DEIM from EIM is in the interpolation basis construction. EIM computes the basis from the snapshots of the nonlinear vector, whereas DEIM constructs basis from the POD basis of the nonlinear snapshots.

Either EIM or DEIM considers approximation for the nonlinear term as below,

$$f(\mu, x(\mu)) \approx U_{\mathrm{f}} c(\mu),$$

where U_{f} is the matrix of interpolation basis vectors and $c(\mu)$ is the vector of parameter dependent coefficients. The approximation $U_{\mathrm{f}} c(\mu)$ interpolates $f(\mu)$ in the sense that it matches $f(\mu)$ at the selected interpolation points, i.e.

$$P^{\mathrm{T}} f(\mu, x(\mu)) = P^{\mathrm{T}} U_{\mathrm{f}} c(\mu),$$

where $P^{\mathrm{T}} = [e_{\wp_1}, e_{\wp_2}, \ldots, e_{\wp_\ell}]^{\mathrm{T}}$ is a row permutation matrix, and $e_{\wp_i}$ is the $\wp_i$-th unit vector. Here, $\wp_1, \ldots, \wp_\ell$ are the interpolation points (indices). To be self-contained, we list both algorithms as Algorithms 2 and 3.

Algorithm 2 EIM for steady systems

Input: Snapshots of $f(\mu, x(\mu)) : F = \{f^1, \ldots, f^m\}, f^k := f(\mu^k, x(\mu^k)), k = 1, \ldots m.$

Output: EI basis: $U = [u_1, \ldots, u_M]$ and indices: $\{\wp_1, \ldots, \wp_M\}$, index matrix: $P = [e_{\wp_1}, \ldots, e_{\wp_M}]$.

$P = [\,], U_{\mathrm{f}} = [\,]$.

$s = 1$, $\xi_1 := \arg\max_{f^k \in F} \|f^k\|_2$, $\wp_1 := \arg\max_{j \in \{1,\ldots,n\}} |\xi_{1,j}|$, $u_1 := \xi_1 / \xi_{1,\wp_1}$. $P = [P, e_{\wp_1}]$, $U_{\mathrm{f}} = [U_{\mathrm{f}}, u_1]$.

while $\|\xi_s\|_2 > \epsilon$ **do**

  $s := s + 1$. For each f^k, $k = 1, \ldots, m$: $f^k \approx \sum_{i=1}^{s-1} \beta_{ki} u_i$, i.e.

$$f^k \approx U_{\mathrm{f}} \beta_k, \beta_k = (\beta_{k1}, \ldots, \beta_{ks-1})^{\mathrm{T}}$$

  β_k is determined by interpolation:

$$P^{\mathrm{T}} f^k = P^{\mathrm{T}} U \beta_k,$$

  so that $\beta_k = (P^{\mathrm{T}} U_{\mathrm{f}})^{-1} P^{\mathrm{T}} f^k$.

  Let $f^{k^\star} := \arg\max_{f^k \in F} \|f^k - U_{\mathrm{f}} \beta_k\|_2$, $\xi_s = f^{k^\star} - U_{\mathrm{f}} \beta_{k^\star}$

  if $\|\xi_s\|_2 \le \epsilon$ **then**

    Stop and set $M = s - 1$.

  else

    Define $\wp_s := \arg\max_{j \in \{1,\ldots,N\}} |u_{s,j}|$, $u_s := \xi_s / \xi_{s,\wp_s}$.

    $P = [P, e_{\wp_s}]$, $U_{\mathrm{f}} = [U_{\mathrm{f}}, u_s]$.

  end if

end while

ROM After Applying EIM or DEIM Using either EIM or DEIM, the ROM in (36.76) is then formulated as,

$$A_r(\mu) x_r(\mu) = V^{\mathrm{T}} U_{\mathrm{f}} \big(P^{\mathrm{T}} U_{\mathrm{f}}\big)^{-1} P^{\mathrm{T}} f(\mu, Vx_r(\mu)). \tag{36.77}$$

The term $V^{\mathrm{T}} U_{\mathrm{f}} \big(P^{\mathrm{T}} U_{\mathrm{f}}\big)^{-1}$ in (36.77) can be precomputed. When evaluating $P^{\mathrm{T}} f(\mu, Vx_r(\mu))$, only a few terms (say, $\ell_{\mathrm{EI}} \ll N$ terms) of the function $f(\cdot, \cdot)$ need to be evaluated, so that the complexity of computing the nonlinear term of the ROM is reduced from $O(N)$ to $O(\ell_{\mathrm{EI}} \ll N)$. When the matrix $A(\mu)$ is also nonaffine with the parameter μ, then the matrix DEIM method [138] could be applied to obtain an affine approximation of $A(\mu)$, so that for each evaluation of $A_r(\mu)$,

Algorithm 3 Discrete empirical interpolation method (DEIM) [137]

Input: Snapshots of $f(\mu)$ at a set of parameter samples, $F = \{f^1, \ldots, f^m\}, f^k := f(\mu^k, x(\mu^k)), k = 1, \ldots m, \epsilon_{\text{svd}}$.
Output: DEIM basis vectors U_f, index matrix $P = [e_{\wp_1}, e_{\wp_2}, \ldots, e_{\wp_\ell}]$.
1: $U_f = [\,], P = [\,]$.
2: Apply SVD: $F \xrightarrow{\text{SVD}} U\Sigma Q^{\mathrm{T}}$, where $U := [u_1, u_2, \ldots, u_N]$, $\Sigma := \begin{bmatrix} D_f & 0 \\ 0 & 0 \end{bmatrix}$, $D_f := \text{diag}(\sigma_1, \sigma_2, \ldots, \sigma_{r_{\text{F}}})$.
3: Find ℓ, s.t., $\sum_{i=\ell+1}^{r_{\text{F}}} \sigma_i^f / \sum_{i=1}^{r_{\text{F}}} \sigma_i^f < \epsilon_{\text{svd}}$, r_{F} is the number of non-zero singular values of Σ.
4: Select the first interpolation index as the position of the row element with maximal magnitude in the first column of U: $\wp_1 = \arg \max_{j \in \{1,2,\ldots,N\}} |u_{1j}|$, where $u_1 = [u_{11}, u_{12}, \ldots, u_{1N}]^{\mathrm{T}}$.
5: $U_f \leftarrow u_1, P \leftarrow [e_{\wp_1}]$.
6: **for** $i = 2$ to ℓ **do**
7: Solve $(P^{\mathrm{T}} U_{\text{f}})c = P^{\mathrm{T}} u_i$, for c.
8: Compute the residual, $r_i = u_i - U_{\text{f}} c$.
9: $\wp_i = \arg \max_{j \in \{1,2,\ldots,N\}} |r_{ij}|$. Here, $r_i = [r_{i1}, r_{i2}, \ldots, r_{iN}]^{\mathrm{T}}$.
10: $U_{\text{f}} \leftarrow [U_{\text{f}}, u_i], P \leftarrow [P, e_{\wp_i}]$.
11: **end for**

the matrix $A(\mu)$ of full dimension needs not be evaluated, and only some terms which are independent of μ need be precomputed. Detailed analysis of the method can be found in [138] and the references therein. Algorithm 1 can be combined with either EIM or DEIM for MOR linear systems with right-hand side $f(\mu)$ being non-affinely dependent on the parameter. The interpolation basis are precomputed before the greedy loop starts. Algorithm 4 provides the Greedy-(D)EIM algorithm.

36.4.2 Structure Preserving MOR for Nonlinear Port-Hamiltonian Systems

In this section, we review a recently proposed structure preserving MOR method for nonlinear port-Hamiltonian systems [139]. Finite dimensional nonlinear port-Hamiltonian (NLPH) system is in the form of

$$\begin{aligned} \dot{\mathbf{x}} &= (J - R)g(\mathbf{x}) + Bu(t), \\ \mathbf{y} &= B^{\mathrm{T}} g(\mathbf{x}), \end{aligned} \tag{36.78}$$

Algorithm 4 Greedy algorithm with (D)EIM for steady systems

Input: Training set of parameter samples $\Xi \subset \mathcal{P}$, tolerance *tol*, snapshot matrix of $f(\mu, x(\mu))$: $F = [f^1, \ldots, f^{n_{\text{train}}})], f^k := f(\mu^k, x(\mu^k)), k = 1, \ldots n_{\text{train}}$, n_{train} is the number of samples in Ξ.
Output: Basis V.
1: (D)EIM interpolation basis obtained from Algorithm 2 or Algorithm 3.
2: Call Algorithm 1, where the ROM in (36.76) is replaced by the ROM in (36.77) at each iteration.

where $\mathbf{x} \in \mathbb{R}^n$ is the n-dimensional state vector; $g(\mathbf{x}) := \nabla_{\mathbf{x}} H(\mathbf{x})$; the scalar-valued function $H : \mathbb{R}^n \mapsto [0, \infty)$ is called the Hamiltonian, which is continuous and differentiable. It describes the internal energy of the system as a function of state. $J = -J^{a\mathrm{T}} \in \mathbb{R}^{n \times n}$ is the structure matrix describing the interconnection among energy storage elements in the systems; $R = R^{\mathrm{T}} \geq 0 \in \mathbb{R}^{n \times n}$ is the dissipation matrix describing energy loss in the system; and $B \in \mathbb{R}^{n \times O_l}$ is the port matrix describing how energy enters and exists the system. It is assumed that the Hamiltonian is bounded below and strictly positive, i.e., $H(\mathbf{x}) > 0, \forall \mathbf{x}$. Note that the method in [139] considers only non-parametric systems without parameter variations.

A ROM of the NLPH can be obtained using the above mentioned POD method based on Petrov-Galerkin projection, i.e.

$$\begin{aligned} W^{\mathrm{T}} \cdot V \cdot \dot{\mathbf{x}}_r &= W^{\mathrm{T}} \cdot (J - R) \cdot \mathbf{g}(V \cdot \mathbf{x}_r) + W^{\mathrm{T}} \cdot B \cdot u(t), \\ \mathbf{y} &= B^{\mathrm{T}} \cdot \mathbf{g}(V \cdot \mathbf{x}_r). \end{aligned} \tag{36.79}$$

Unfortunately, system in (36.79) does not preserve the Hamiltonian form and some properties of the Hamiltonian systems might be lost. Furthermore, if the Hamiltonian function $H(\cdot)$ is nonquadratic, then $\mathbf{g}(V \cdot \mathbf{x}_r)$ is a nonlinear vector-valued function, so that DEIM or EIM is necessary to reduce the cost of evaluating $\mathbf{g}(V \cdot \mathbf{x}_r)$.

In [139], a structure preserving method is proposed, so that the ROM is also a Hamiltonian system. It is based on the following heuristic assumption: the internal force $\mathbf{g}(\mathbf{x})$ approximately locates in the subspace spanned by the columns of W, so that $\mathbf{g}(\mathbf{x}) \approx W \cdot \mathbf{g}_r$, for some $\mathbf{g}_r \in \mathbb{R}^r$. Assume that $V^{\mathrm{T}} \cdot W = I$, which can be satisfied by many MOR methods, e.g., the structure-preserving POD method in Algorithm 5. From $\mathbf{x} = V \cdot \mathbf{x}_r$, we get $\mathbf{g}(\mathbf{x}) \approx \mathbf{g}(V \cdot \mathbf{x}_r)$. Since we have $\mathbf{g}(\mathbf{x}) \approx W \cdot \mathbf{g}_r$, then

$$\mathbf{g}(V \cdot \mathbf{x}_r) \approx \mathbf{g}(\mathbf{x}) \approx W \cdot \mathbf{g}_r. \tag{36.80}$$

Using $V^{\mathrm{T}} \cdot W = I$ and from (36.80), we can compute $\mathbf{g}_r$ as

$$\mathbf{g}_r \approx V^{\mathrm{T}} \cdot \mathbf{g}(V \cdot \mathbf{x}_r). \tag{36.81}$$

Finally, $\mathbf{g}(\mathbf{x})$ can be approximated as

$$\mathbf{g}(\mathbf{x}) \approx W \cdot \mathbf{g}_r \approx W \cdot V^{\mathrm{T}} \cdot \mathbf{g}(V \cdot \mathbf{x}_r).$$

Applying the approximation $\mathbf{x} \approx V \cdot \mathbf{x}_r$ and $\mathbf{g}(\mathbf{x}) \approx W \cdot V^{\mathrm{T}} \cdot \mathbf{g}(V \cdot \mathbf{x}_r)$ to the original Hamiltonian system (36.78), we obtain the ROM as below,

$$\begin{aligned} \dot{\mathbf{x}}_r &= (J_r - R_r) \cdot V^{\mathrm{T}} \cdot \mathbf{g}(V \cdot \mathbf{x}_r) + B_r \cdot u(t), \\ \mathbf{y} &= B_r^{\mathrm{T}} \cdot V^{\mathrm{T}} \cdot \mathbf{g}(V \cdot \mathbf{x}_r), \end{aligned} \tag{36.82}$$

Algorithm 5 Structure-preserving POD for NLPH systems

1: Snapshots $X = [\mathbf{x}(t_1), \mathbf{x}(t_2), \ldots, \mathbf{x}(t_K)]$: solution vector $\mathbf{x}(t)$ at discrete time instances $t_i, i = 1, \ldots, K$.
2: Simultaneously collect associated *force*(nonlinear) snapshots: $G = [\mathbf{g}(\mathbf{x}(t_0)), \mathbf{g}(\mathbf{x}(t_1)), \ldots, \mathbf{g}(\mathbf{x}(t_K))]$.
3: Perform $X \xrightarrow{\text{SVD}} U \cdot \Sigma \cdot Q^{\mathrm{T}}$ to get the projection matrix $V = U(:, 1 : r)$.
4: Perform $G \xrightarrow{\text{SVD}} U_g \cdot \Sigma_g \cdot Q_g^{\mathrm{T}}$ to get the projection matrix $W = U_g(:, 1 : r)$.
5: Biorthoganolize the two matrices such that $W^{\mathrm{T}} \cdot V = I$. This can be achieved by e.g., modified Gram-schmidt process.
6: Using W, V to obtain the ROM in (36.82).

where $J_r = W^{\mathrm{T}} \cdot J \cdot W$, $R_r = W^{\mathrm{T}} \cdot R \cdot W$, and $B_r = W^{\mathrm{T}} \cdot B$. Note that $J_r = -J_r^{\mathrm{T}}$ and $R_r = R_r^{\mathrm{T}} \geq 0$, so that (36.82) preserves the Hamiltonian structure and is a port-Hamiltonian system. In Algorithm 5, we review the structure preserving POD method for NLPH system proposed in [139].

Structure Preserving MOR with DEIM

To solve the ROM in (36.82), the nonlinear function $\mathbf{g}(V \cdot \mathbf{x}_r)$ must be computed at each time step. Directly computing $\mathbf{g}(V \cdot \mathbf{x}_r)$ needs evaluating a vector of length N, the complexity is not reduced. Therefore, interpolation methods, e.g., DEIM or EIM are useful for reducing the complexity of evaluating the nonlinear term. In [139], DEIM is applied to $\mathbf{g}(V \cdot \mathbf{x}_r)$, and the resulting ROM with DEIM still preserves the Hamiltonian structure.

In the following, we first present an algorithm of DEIM being applied to approximate the nonlinear function $\mathbf{g}(V \cdot \mathbf{x}_r)$, as shown in Algorithm 6. A straight-forward application of DEIM to the ROM in (36.82) is as following. Using $U_g := W$ computed from Algorithm 5 to obtain a DEIM approximation of $g(V\mathbf{x}_r)$, we get

$$g(V \cdot \mathbf{x}_r) \approx W(P^{\mathrm{T}} \cdot W)^{-1} \cdot P^{\mathrm{T}} \cdot g(V \cdot \mathbf{x}_r),$$

where the index matrix P can be computed from Algorithm 6 with SVD of G (Step 2) already being available from Algorithm 5. inserting the above DEIM approximation into (36.82), and using $V^{\mathrm{T}} \cdot W = I$, we obtain

$$\begin{aligned} \dot{\mathbf{x}}_r &= (J_r - R_r) \cdot (P^{\mathrm{T}} \cdot W)^{-1} \cdot P^{\mathrm{T}} \cdot g(V \cdot \mathbf{x}_r) + B_r \cdot u(t), \\ \mathbf{y} &= B_r^{\mathrm{T}} \cdot (P^{\mathrm{T}} \cdot W)^{-1} \cdot P^{\mathrm{T}} \cdot g(V \cdot \mathbf{x}_r). \end{aligned} \tag{36.83}$$

However, it is stated in [139] that the ROM in (36.83) is not port-Hamiltonian and might no longer be stable. A DEIM Hamiltonian method is proposed in [139] to produce a ROM which is still Hamiltonian. An algorithm of computing a structure preserving Hamiltonian ROM with DEIM can be found in [139].

Algorithm 6 Discrete empirical interpolation method (DEIM) for $g(\mathbf{x})$

Input: Snapshots of $g(\mathbf{x})$ at a set of time instances $t_i, i = 1, \ldots, K$, $G = [g(\mathbf{x}_1) \ldots, g(\mathbf{x}_K]$, $\mathbf{x}_i, i = 1, \ldots, K$ is the solution $\mathbf{x}$ at time instances t_i.
Output: DEIM basis U_g, index matrix $P = [e_{\wp_1}, e_{\wp_2}, \ldots, e_{\wp_\ell}]$.
1: $U_g = [\,], P = [\,]$.
2: Compute SVD of G: $G \xrightarrow{\text{SVD}} U\Sigma Q^{\mathrm{T}}$, where $U := [u_1, u_2, \ldots, u_N]$, $\Sigma := \begin{bmatrix} D_g & 0 \\ 0 & 0 \end{bmatrix}$, $D_g := \text{diag}(\sigma_1, \sigma_2, \ldots, \sigma_{r_G})$.
3: Find ℓ, s.t., $\sum_{i=\ell+1}^{r_G} \sigma_i^f / \sum_{i=1}^{r_F} \sigma_i^f < \epsilon_{\text{svd}}$, r_{G} is the number of non-zero singular values of Σ.
4: Select the first interpolation index as the position of the row element with maximal magnitude in the first column of U: $\wp_1 = \arg \max_{j \in \{1,2,\ldots,N\}} |u_{1j}|$, where $u_1 = [u_{11}, u_{12}, \ldots, u_{1N}]^{\mathrm{T}}$.
5: $U_g \leftarrow u_1, P \leftarrow [e_{\wp_1}]$.
6: **for** $i = 2$ to ℓ **do**
7: Solve $(P^{\mathrm{T}} U_g)c = P^{\mathrm{T}} u_i$, for c.
8: Form the residual, $r_i = u_i - U_g c$.
9: $\wp_i = \arg \max_{j \in \{1,2,\ldots,N\}} |r_{ij}|$. Here, $r_i = [r_{i1}, r_{i2}, \ldots, r_{iN}]^{\mathrm{T}}$.
10: $U_g \leftarrow [U_g, u_i], P \leftarrow [P, e_{\wp_i}]$.
11: **end for**

36.4.3 Application to Topology Optimization

Iterative approach is widely employed to solve the topology optimization problem in Sect. 36.3. At every iteration step, the discrete counterparts of $e(y, \gamma)$ and $e_y^* \cdot \lambda = -J_y$ need to be solved. Their discrete forms are

$$\begin{aligned} K(\gamma) \cdot \nu &= \mathbf{f}(\gamma), \\ K(\gamma) \cdot \boldsymbol{\lambda} &= \frac{\partial \Phi}{\partial \nu}, \end{aligned} \tag{36.84}$$

where ν and $\boldsymbol{\lambda}$ are the discrete physical variable and adjoint variable, respectively, $K(\boldsymbol{\gamma})$ is the global stiffness matrix, and it depends on the discrete design variable γ; Φ corresponds to the discretized design objective. Based on the above analysis, the computational cost in topology optimization is mostly spent on solving the linear systems in (36.84).

MOR could be applied to obtain ROM of the system in (36.84), so as to reduce the computational cost. Note that the system in (36.84) is a one-way coupled system of ν and $\boldsymbol{\lambda}$, where a possibly nonlinear function of ν appears on the right-hand side of the second system of $\boldsymbol{\lambda}$. From the literature [140], constructing a single ROM of (36.84) is usually no more efficient than constructing two ROMs for the systems of ν and $\boldsymbol{\lambda}$, respectively.

Consider the system of ν, it is a linear parametric system, which is of the same form as the system in (36.75), therefore the reduced basis method as discussed in Sect. 36.4.1 can be applied to construct the ROM, and the EIM or DEIM algorithm could be applied to reduce the complexity of the

right-hand side $\mathbf{f}(\gamma)$, if it is a non-affine or nonlinear function of γ. As for the second equation, once ν is solved from its ROM, it can be substituted into the right-hand side of the system of $\boldsymbol{\lambda}$, which then becomes a linear system of $\boldsymbol{\lambda}$ with right-hand side $\partial\Phi/\partial\nu$ being a function of γ, which can then be reduced using the reduced basis method combined with the EIM or DEIM method, in case $\partial\Phi/\partial\nu$ is non-affine with γ. For clarity we show the process of constructing the ROM of the coupled system (36.84) in Algorithm 7.

Algorithm 7 Greedy algorithm for the coupled system (36.84)

Input: $\mathcal{P}_{\text{train}}$: a set of samples of γ, tol_{RB}
Output: Projection matrix V_1 for MOR of the system of ν, V_2 for MOR of the system of $\boldsymbol{\lambda}$.
1: Initialization:$V_1 = [\,]$, $V_2 = [\,]$, $\gamma^\star = \gamma^1$, $\eta(\gamma^\star)(> \text{tol}_{\text{RB}})$
2: **while** the error $\eta(\gamma^\star) > \text{tol}_{\text{RB}}$ **do**
3: Solve $K(\gamma)\cdot\nu = \mathbf{f}(\gamma)$ to get the solution $\nu(\gamma^\star)$.
4: Substitute $\nu(\gamma^\star)$ into $K(\gamma)\cdot\boldsymbol{\lambda} = \partial\Phi/\partial\nu$, and solve for $\boldsymbol{\lambda}(\gamma^\star)$.
5: Update: V_1 :=orth $[V_1, \nu(\gamma^\star)]$, V_2 :=orth $[V_2, \boldsymbol{lambda}(\gamma^\star)]$
6: Find $\gamma^\star := \arg\max_{\gamma\in\mathcal{P}_{\text{train}}} \eta(\gamma)$.
7: **end while**

Once V_1 and V_2 are obtained from Algorithm 7, the ROM of system (36.84) can be constructed as below,

$$\begin{aligned}\left(V_1^{\mathrm{T}}\cdot K(\gamma)\cdot V_1\right)\cdot\nu_r &= V_1^{\mathrm{T}}\cdot f(\gamma),\\ \left(V_2^{\mathrm{T}}\cdot K(\gamma)\cdot V_2\right)\cdot\boldsymbol{\lambda}_r &= V_2^{\mathrm{T}}\cdot\frac{\partial\Phi}{\partial(V_1\cdot\nu_r)},\end{aligned}\qquad(36.85)$$

where $V_1^{\mathrm{T}}\cdot K(\gamma)\cdot V_1 \in \mathbb{R}^{r\times r}$ is a small matrix with $r \ll n$. If the right-hand side $\mathbf{f}(\gamma)$ or $\partial\Phi/\partial(V_1\cdot\nu_r)$ is non-affine with the parameter γ, then EIM or DEIM can be applied to obtain interpolation of $\mathbf{f}(\gamma)$ or $\partial\Phi/\partial(V_1\cdot\nu_r)$ and to reduce the computational complexity of evaluating $V_1^{\mathrm{T}}\cdot\mathbf{f}(\gamma)$ or $V_2^{\mathrm{T}}\cdot\partial\Phi/\partial(V_1\cdot\nu_r)$. During optimization, the small ROM in (36.85) can be used as a surrogate of the original large system in (36.84), which is aimed to produce accurate results not only at the samples of γ in the training set $\mathcal{P}_{\text{train}}$ but also at every other possible variation of the parameter γ.

36.5 Conclusions

This chapter brings together three diverse topics and seeks a single descriptive framework. These topics form, in one way or another, and with varying degrees of intensity, the necessary tasks that advance computational design and the digital twin. Much work must be done still to complete the consolidation process. In particular, if model order reduction and topology optimization can be consistently integrated (or merged), the task of finding optimal designs may one day be performed with the speed necessary for interactive design processes performed in real time. Furthermore, model order reduction as presented is applicable only to linear systems. Nonlinear problems, especially those of stability, are potentially complex enough that MOR cannot be applied with sufficient computational efficiency. Advancing this area is also one of the priorities for the future.

Acknowledgments The authors have collaborated with each other in the past, and these collaborations have in turn involved numerous other persons who have greatly contributed to many of the concepts presented here. Since the list is very long, we wish to acknowledge these persons collectively, referring instead to the co-author names on our own publications in the reference list. Nevertheless, we particularly want to highlight the following persons who had a particularly large influence on our thinking. In alphabetical order they are: Peter Benner, Ulrike Wallrabe, and Zhenyu Liu. We also sincerely acknowledge our host organisations, which include the Max Planck society, the Karlsruhe Institute of Technology, the Helmholtz association, and the Chinese Academy of Sciences, for their continued financial support. We also thank our generous funding agencies. In particular, JGK acknowledges the ERC, the EU, the DFG, and the BMBF for repeated support. KP thanks the Humboldt Foundation, and the Deutsche Forschungsgemeinschaft for support via the priority programme SPP 2206/1, and together with JGK for support via grant KO 1883/37-1. YD acknowledgements a Humboldt Research Fellowship for Experienced Researchers (Humboldt-ID: 1197305) and additional support from the National Natural Science Foundation of China (No. 51875545).

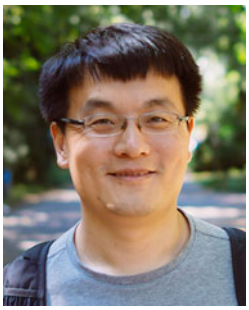
Kirill V. Poletkin is an associate scientist at the Institute of Microstructure Technology at Karlsruhe Institute of Technology and leads a project "A 2D array of cooperative hybrid levitation micro-actuators" funded by German Research Foundation. In 2020, he has been also appointed as an assistant professor at Innopolis University, Kazan, Russia. He received the Diploma (Hons.) of electromechanical engineer majoring in aviation devices and measurement systems in 2001 from Nizhny Novgorod State Technical University and the Ph.D. degree from Moscow Aviation Institute (State University of Aerospace Technologies), Russia, in 2007. His master's thesis was awarded by the Ministry of Education and Science of the Russian Federation as the best research work at all-Russian student competition in 2002. Then, he was awarded Humboldt Research Fellowship for Experienced Researchers in 2012 and had successfully performed his Humboldt project titled "Micromachined contactless suspension with zero spring constant for application as an accelerometer" at the University of Freiburg, Germany, since 2013 until 2015. Since 2009 until 2013, he was in Nanyang Technological University, Singapore, where he did postdoctoral research at the School of EEE and MAE. Also, he was previously with Giesecke & Devrient GmbH, JSC Temp-Avia, and Russian Federal Nuclear Center. His research interest includes micro- and nano-scale devices and processes of the energy transfer within these scales.

Lihong Feng received her Ph.D. at Fudan University, Shanghai, in 2002. She has worked at Fudan University and the University of Freiburg, Germany. She was a Alexander-von-Humboldt research Fellow from 2007 to 2009. Since 2010, she is a senior scientist and a team leader at Max Planck Institute, Magdeburg. Her research interests include model order reduction, fast simulation of complex systems, etc.

Jan G. Korvink received his PhD from the ETH Zurich in 1993, after which he joined the group of Prof Henry Baltes for a postdoc. In 1997 he became a full professor at the University of Freiburg, Germany. In 2007 he became one of the directors of the Freiburg Institute of Advanced Studies (FRIAS). In 2015 he moved to the Karlsruhe Institute of Technology to direct the Institute of Microstructure Technology (IMT). In 2011 he was awarded an ERC Advanced Grant, and in 2021 an ERC Synergy Grant, both in the area of miniaturized nuclear magnetic resonance.



Yongbo Deng is a professor at Changchun Institute of Optics Fine Mechanics and Physics (CIOMP), Chinese Academy of Sciences, China. In 2012, he received his Ph.D. from Changchun Institute of Optics Fine Mechanics and Physics (CIOMP), Chinese Academy of Sciences (CAS). In 2018, he derived a Humboldt Research Fellowship for Experienced Researchers and was elected as the member of Youth Innovation Promotion Association of Chinese Academy of Sciences in the same year. During the period from September of 2018 to February of 2020, he worked in the Institute of Microstructure Technology, Karlsruhe Institute of Technology as a Humboldt Fellow. During the periods from May to July of 2016 and from September to November of 2017, he worked in the Institute of Microstructure Technology, Karlsruhe Institute of Technology, based on support of a Guest Professor Fellowship. During the period from December of 2014 to March of 2015, he worked in IMTEK, University of Freiburg, for his research collaboration on electromagnetic metamaterial. His research mainly focuses on topology optimization, microfluidics, and nano-optics.

Macroscopic Transport Models for Classical Device Simulation

Abstract

We review macroscopic transport models as used in classical device simulation such as drift-diffusion, hydrodynamic, and energy transport models. Using a systematic approach, these transport models are derived from the semiclassical Boltzmann equation by applying the method of moments. The drift-diffusion model is based on the first two moments of the Boltzmann equation, while hydrodynamic and energy transport models consider three or four moments. Within the framework of the diffusion approximation, the convective terms in the hydrodynamic models can be neglected, resulting in the much simpler diffusive energy transport models. A discussion of the physical assumptions needed for the validity of these models is given.

In cases where the energy distribution is insufficiently described by a heated Maxwellian distribution, energy transport models give poor results. Based on the diffusion approximation, a six-moment model generalizing the energy transport model is presented. All model parameters can be extracted from fullband bulk Monte Carlo simulations. The six-moment model is applied for the simulation

of devices with channel length in the deca-nanometer regime. Short-channel and hot-carrier effects for which the heated Maxwellian assumption introduces particularly large errors are studied. Comparing all models, it is demonstrated that the six-moment model can improve on the drift-diffusion and energy transport models.

37.1 History of Classical Device Simulation

The success of microelectronic technology has been partly enabled and supported by sophisticated technology computer-aided design (TCAD) tools which are used to assist in development and engineering at practically all stages from process definition to circuit optimization. The modern technology development cost and time reduction from the use of TCAD has been estimated at around 40% [1].

At the early days of transistor technology, relatively simple compact models based on the drift-diffusion formalism, idealized doping profiles, and quasi-one-dimensional assumptions produced sufficiently accurate results. To reduce the costs of the chip manufacturing process, the number of devices on a chip has been continually increased by increasing the chip size and decreasing the size of the individual devices. For these devices, the simplifying assumptions valid before became increasingly violated, thus requiring a more rigorous description. Development of compact models, though still possible and of fundamental importance, became more complicated, requiring large development times and continuous modifications.

The drift-diffusion (DD) model was first presented by Van Roosbroeck in the year 1950 [2]. Instead of a closed-form compact model, the basic semiconductor equations can be solved directly for a given doping profile and geometry. The same model was later derived from the Boltzmann transport equation (BTE) by the method of moments [3] or from basic principles of irreversible thermodynamics [4, 5]. The self-consistent numerical solution of carrier transport models dates back to the famous seminal work of Scharfetter and Gummel [6, 7] and eliminates many of the assumptions required for compact models. Due to its simplicity and its excellent numerical properties, the drift-diffusion equations have become the workhorse for most applications in technology computer-aided design.

In the 1980s, the first tools appeared which offered a solution of the drift-diffusion equations on two-dimensional domains. The first monograph comprehensively covering aspects from modeling and discretization to applications was Selberherr [3], which was published in 1984. Since then, current transport models have been continuously refined and extended to more accurately capture transport phenomena occurring in state-of-the-art semiconductor devices.

The steady need for refinement and extension is caused by the ongoing feature size reduction in technology. As the supply voltages cannot be scaled accordingly without compromising the circuit performance, the electric fields inside the devices have increased. Large electric fields, which rapidly change over small length scales, give rise to nonlocal and hot-carrier effects which begin to dominate device performance. These phenomena are a concern for industrial applications, and an accurate description is required.

To deal with nonlocal and hot-carrier effects, extended models have been proposed which consider the carrier energy as an independent solution variable. The most prominent examples of such models are the hydrodynamic and energy transport (ET) models. These models are based on the work of Stratton [8] and Bløtekjær [9] who solved the BTE using the method of moments with three or four moments. Many variants of these models have been published, which are reviewed in [10]. However, detailed examinations in the deep submicron area show that using three or four moments is still not sufficient for specific problems which depend on high-energy tails. One method for improving the approximation is the six-moments (SM) model [11].

Figure 37.1 gives an overview of transport models in use for modern TCAD. The most accurate methods solve the Boltzmann equation directly, either by Monte Carlo methods or by the spherical harmonic expansion. Yet the computational costs of these methods are challenging even today, and in many cases, simpler moment-based methods are preferred. In addition, for the simulation of small state-of-the-art devices, quantum effects have to be included.

This handbook chapter is concerned with macroscopic transport models based on the method of moments as used in classical device simulation. Other chapters in the handbook specialize on modeling with spherical harmonic expansion, the Monte Carlo simulation method, and quantum transport modeling. Classical monographs on macroscopic transport models are [3] and [12]. A modern mathematical reference on macroscopic transport models is [13]. A review article about general classical device simulation is [5]. The limits of validity for classical macroscopic models and models for nanoscale device simulation beyond these limits are discussed in [14].

37.1.1 Structure of the Review

Following the historical notes in Sect. 37.1, we start our exposition in Sect. 37.2 with a phenomenological derivation

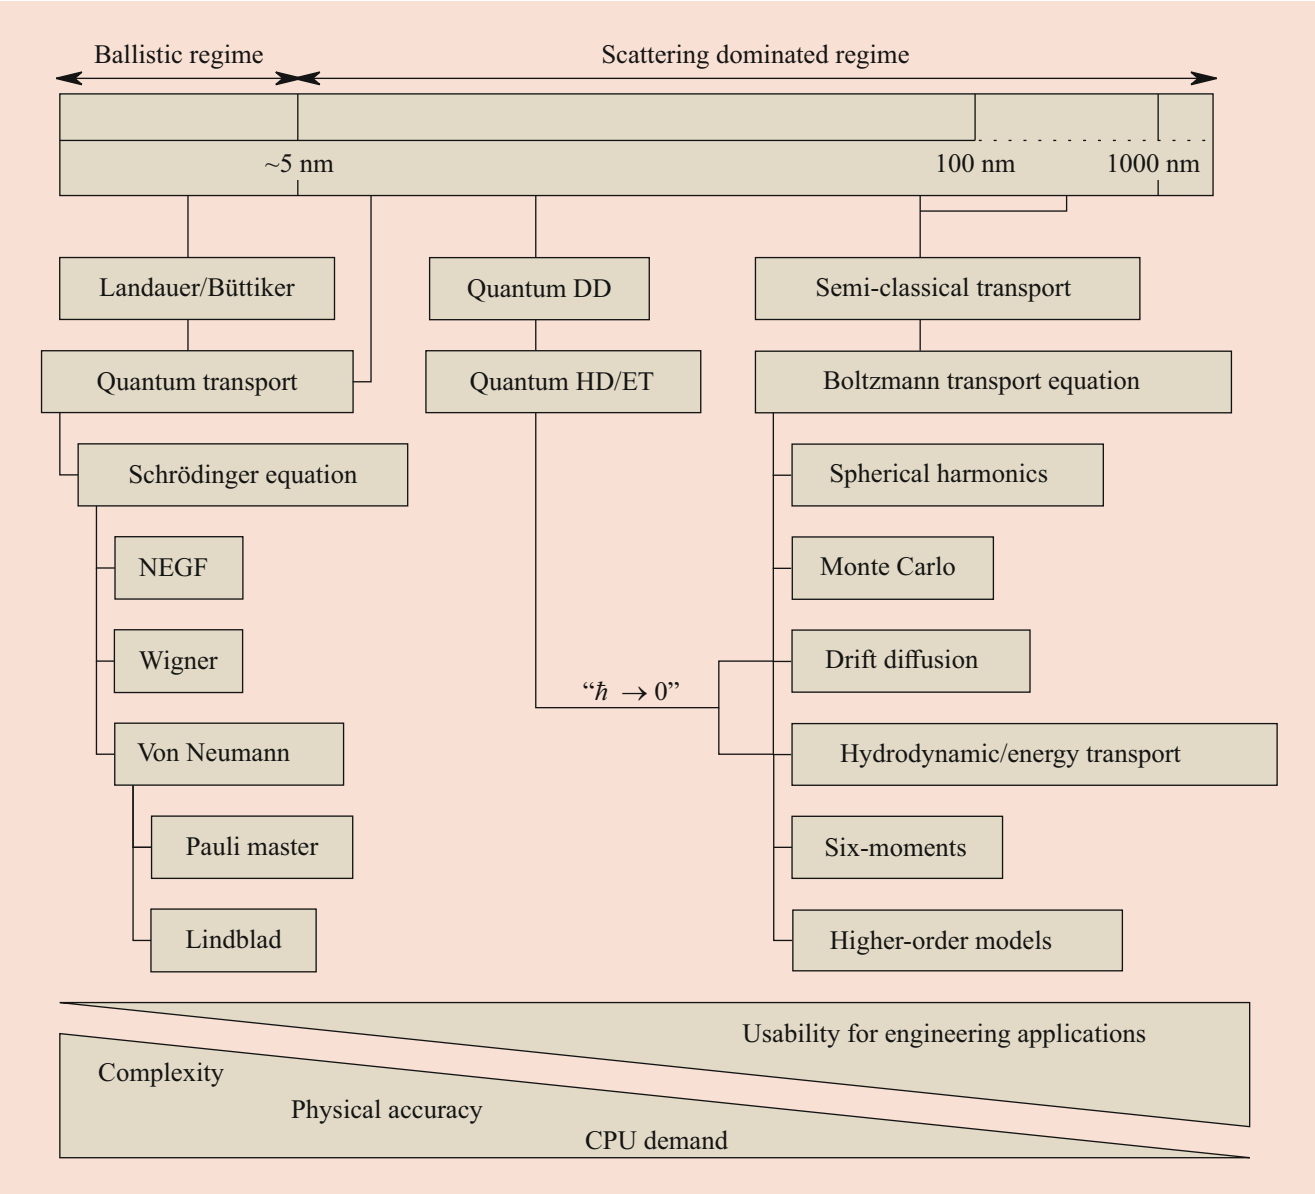

Fig. 37.1 Hierarchy of transport models

of the drift-diffusion model which is the simplest reasonable macroscopic transport model. The drift-diffusion model assumes an equilibrium between carrier energy and electric field, which however is no longer valid in modern electronic devices. Several assumptions are required for its validity to hold, and a heuristic derivation is instructive for a good physical understanding.

The theoretical cornerstone of classical device simulation is the Boltzmann equation which is discussed in Sect. 37.3. In classical device simulation, electron transport is dominated by the scattering operator. We introduce the relaxation time approximation in the Boltzmann equation which allows an analytical treatment of the scattering term.

Macroscopic transport models based on the Boltzmann equation are derived by the method of moments, which is a powerful approach to obtain a series of weighted balance and flux equations. This approach is studied in Sect. 37.4. To enable an analytical treatment, we assume parabolic bands and give the corresponding equations for the first four moments. Following Bløtekjær's approach, we derive a hydrodynamic model based on the first three moments by assuming an isotropic thermal energy tensor and a phenomenological closure for the heat flow.

In Sect. 37.5, we derive energy transport models starting from the hydrodynamic model by making additional simplifications, which are known as the diffusion approximation. To motivate the diffusion approximation, the drift-diffusion equations are derived from the Boltzmann equation using the method of moments. The assumptions necessary for the derivation are analyzed.

The validity of drift-diffusion and energy transport models is investigated theoretically and numerically in Sect. 37.6. Differences and common features of transport models can be understood by looking closely at the assumptions used in their derivation from the Boltzmann equation. Based on this analysis, we discuss critical issues for the validity of energy transport and hydrodynamic models. The highest-order even moment available in typical energy transport models is the temperature. Based on Monte Carlo simulation data, it is demonstrated that the energy distribution in n^+nn^+ test structures strongly deviates from a heated Maxwellian distribution below 100 nm channel length. We then compare results from drift-diffusion and energy transport models with Monte Carlo simulations.

A natural extension of energy transport and hydrodynamic models is the inclusion of higher-order moments. A transport model based on six moments of the distribution function is presented in Sect. 37.7. This model does not assume any particular shape of the distribution function. The additional even order moment, the kurtosis of the distribution function, is shown to contain fundamental information about the shape of the distribution function.

In Sect. 37.8, we present applications of higher-order transport models to n^+nn^+ test structures and double-gate MOSFETs. We compare results of the energy transport model and the six-moment model with Monte Carlo simulation results and discuss short-channel effects.

Finally, we close the review by summarizing our results in Sect. 37.9.

37.2 The Phenomenological Drift-Diffusion Model

In this section, the drift-diffusion current relations will be derived using a phenomenological approach. This set of equations has first been presented by van Roosbroeck in 1950 [2]. Together with the Poisson equation and the carrier continuity equations, these equations constitute the basic semiconductor equations, the simplest reasonable transport model possible [3]. The presentation in this section follows conceptionally [15].

37.2.1 Poisson's Equation and the Continuity Equation

The Poisson equation is a common constituent to all charge transport models for semiconductor devices and serves as the link between the electrostatic potential and the charge distribution within a semiconductor device.

In the eddy-current-free quasi-stationary case (electro-quasistatic model), which typically holds true for semiconductor devices [16–18], the electric field $\mathbf{E}$ is expressed as the gradient of a scalar potential ψ.

$$\mathbf{E} = -\nabla\psi \tag{37.1}$$

Using Gauss's law and the proper material equation for the quasi-stationary case one obtains the Poisson equation:

$$\nabla \cdot (\varepsilon \nabla\psi) = -\rho \tag{37.2}$$

ε is the dielectric permittivity (assumed to be scalar hereafter). In semiconductors, two separate particle systems are responsible for charge transport, namely, electrons (n) and holes (p). Neglecting defects and fixed charges, the total space charge density in semiconductors is primarily composed of the charges of electrons, the holes, and the ionized dopant atoms:

$$\rho = q\,(p + N_\mathrm{D}^+) - q\,(n + N_\mathrm{A}^-) = q\,(p - n + N) \tag{37.3}$$

In order to obtain a complete description, the Poisson equation has to be solved self-consistently with the transport equation system.

Charge transport is described by the current continuity equation which expresses local charge conservation:

$$\nabla \cdot \mathbf{J} + \partial_t \varrho = 0 \tag{37.4}$$

Like the Poisson equation, the continuity equation can be derived from Maxwell's equations. The conduction current density $\mathbf{J}$ can be written as the sum of two components:

$$\mathbf{J} = \mathbf{J}_\mathrm{n} + \mathbf{J}_\mathrm{p} \tag{37.5}$$

$\mathbf{J}_\mathrm{n}$ and $\mathbf{J}_\mathrm{p}$ are the electron and hole current density.

It is convenient to split up also the current continuity equation (37.4) into two equations by introducing a formal separation parameter R:

$$\nabla \cdot \mathbf{J}_\mathrm{n} - q\partial_\mathrm{t} n = qR \tag{37.6}$$

$$\nabla \cdot \mathbf{J}_\mathrm{p} + q\partial_\mathrm{t} p = -qR \tag{37.7}$$

R can be interpreted as the net recombination rate defined as:

$$R = R_\mathrm{n} - G_\mathrm{n} = R_\mathrm{p} - G_\mathrm{p} \tag{37.8}$$

where $R_\mathrm{n}/G_\mathrm{n}$ and $R_\mathrm{p}/G_\mathrm{p}$ are the recombination/generation rates for electrons and holes, respectively.

37.2.2 Drift and Diffusion Current

The simplest current transport model at hand is based on the so-called drift-diffusion assumption. This model distinguishes between two charge carrier transport mechanisms: the drift of charge carriers due to an electric field caused by a gradient in the electric potential and the diffusion of the charge carriers due to a spatial gradient in the charge carrier concentration.

Drift Current

The component of the current which is caused by the electric field is called drift current. From a macroscopic point of view, the current density and the electric field are related by Ohm's law:

$$\mathbf{J}^{\text{drift}} = \sigma\,\mathbf{E} \tag{37.9}$$

σ is the electric conductivity.

Semiconductors are in principle anisotropic due to their crystal structure. However, due to symmetry properties, especially in the case of germanium and silicon, the anisotropicity of the conductivity is very small, and the electric conductivity can be well approximated by a scalar.

From a microscopic point of view, the current density can be expressed as

$$\mathbf{J}^{\text{drift}} = q\,p\,\bar{\mathbf{v}}_{\text{p}} - q\,n\,\bar{\mathbf{v}}_{\text{n}} \tag{37.10}$$

where q is the elementary charge, n and p the electron and hole concentrations, and $\bar{\mathbf{v}}_{\text{n}}$ and $\bar{\mathbf{v}}_{\text{p}}$ the mean velocities of electrons and holes, respectively. The electric field accelerates the carriers, but due to various scattering mechanisms, the velocity of the carriers in a constant field is bounded and is proportional to the electric field:

$$\bar{\mathbf{v}}_{\text{n}} = -\mu_{\text{n}}(\mathbf{E})\,\mathbf{E} \tag{37.11}$$

$$\bar{\mathbf{v}}_{\text{p}} = \mu_{\text{p}}(\mathbf{E})\,\mathbf{E} \tag{37.12}$$

μ_{n} and μ_{p} are the respective mobilities of electrons and holes. In order to improve the applicability range of the drift current expression, a field-dependent mobility is generally used (see Sect. 37.2.4). By inserting these equations into (37.10), we get

$$\mathbf{J}^{\text{drift}} = q\,p\,\mu_{\text{p}}\,\mathbf{E} + q\,n\,\mu_{\text{n}}\,\mathbf{E}. \tag{37.13}$$

Comparing (37.13) with (37.9) and (37.5), the following relations are obtained:

$$\mathbf{J}_{\text{n}}^{\text{drift}} = \sigma_{\text{n}}\,\mathbf{E} \tag{37.14}$$

$$\mathbf{J}_{\text{p}}^{\text{drift}} = \sigma_{\text{p}}\,\mathbf{E} \tag{37.15}$$

The conductivities are are given as

$$\sigma_{\text{n}} = q\,n\,\mu_{\text{n}} \tag{37.16}$$

$$\sigma_{\text{p}} = q\,p\,\mu_{\text{p}}. \tag{37.17}$$

Diffusion Current

The component of the current which is caused by the thermal motion of the carriers is called diffusion current. It is driven by a gradient in the carrier concentration. The law of diffusion, which originally stems from the theory of dilute gases, defines the flux densities:

$$\mathbf{F}_{\text{n}} = -D_{\text{n}}\,\nabla n \tag{37.18}$$

$$\mathbf{F}_{\text{p}} = -D_{\text{p}}\,\nabla p \tag{37.19}$$

Here, D_{n} and D_{p} are the diffusion coefficients for electrons and holes. The particle flux densities $\mathbf{F}_{\text{n}}$ and $\mathbf{F}_{\text{p}}$ have to be multiplied by the charge of the particle to get the electric current densities:

$$\mathbf{J}_{\text{n}}^{\text{diffusion}} = -q\,\mathbf{F}_{\text{n}} \tag{37.20}$$

$$\mathbf{J}_{\text{p}}^{\text{diffusion}} = q\,\mathbf{F}_{\text{p}} \tag{37.21}$$

37.2.3 The Semiconductor Equations

Superposition of the current components yields the drift-diffusion current relations:

$$\mathbf{J}_{\text{n}} = q\,n\,\mu_{\text{n}}\mathbf{E} + q\,D_{\text{n}}\nabla n \tag{37.22}$$

$$\mathbf{J}_{\text{p}} = q\,p\,\mu_{\text{p}}\mathbf{E} - q\,D_{\text{p}}\nabla p \tag{37.23}$$

For conditions close to thermal equilibrium and for nondegenerate carrier systems where Boltzmann statistics are valid, the diffusion coefficients are related to the mobilities by the Einstein relation:

$$D_{\text{n}} = \mu_{\text{n}}\,\frac{k_{\text{B}}\,T_{\text{n}}}{q} \tag{37.24}$$

$$D_{\text{p}} = \mu_{\text{p}}\,\frac{k_{\text{B}}\,T_{\text{p}}}{q} \tag{37.25}$$

k_{B} is Boltzmann's constant, and T_{n} and T_{p} are the temperatures of electrons and holes.

Since no information about the carrier temperature is available, the carrier temperature is set equal to the lattice temperature T_{L}, assuming the thermal equilibrium approximation [19]. We finally write the equations for the electrons as:

$$\nabla\cdot\mathbf{J}_{\text{n}} = q\,(R + \partial_{\text{t}}\,n) \tag{37.26}$$

$$\mathbf{J}_{\text{n}} = \mu_{\text{n}}\,k_{\text{B}}\left(\nabla(n\,T_{\text{L}}) + \frac{\text{q}}{k_{\text{B}}}\,\mathbf{E}\,n\right). \tag{37.27}$$

The analogous equations for holes, namely

$$\nabla \cdot \mathbf{J}_\mathrm{p} = -q\,(R + \partial_\mathrm{t}\, p) \tag{37.28}$$

$$\mathbf{J}_\mathrm{p} = \mu_\mathrm{p}\, k_\mathrm{B} \left(-\nabla (p\, T_\mathrm{L}) + \frac{\mathrm{q}}{k_\mathrm{B}}\, \mathbf{E}\, p \right) \tag{37.29}$$

are added to complete the system. Together with Poisson's equation (37.2), the set of basic semiconductor equations is obtained.

The drift-diffusion scheme takes only local quantities into account. As such, it completely neglects nonstationary transport effects which occur in response to a sudden variation of the electric field, either in time or in space. A robust discretization of the drift-diffusion equations was proposed by Scharfetter and Gummel [6,7], which is still in use today.

As one of the basic limitations of the drift-diffusion model, it should be pointed out that the Einstein relations are only valid near equilibrium and the diffusivity relations are largely underestimated, if the lattice temperature rather than the carrier temperature is being used [20, p.145]. In order to account for hot-carrier effects, the average energy can be estimated via the homogeneous energy balance equation:

$$T_\mathrm{n} = T_\mathrm{L} + \frac{2}{3}\, \frac{q}{k_\mathrm{B}}\, \tau_\mathcal{E}\, \mu_\mathrm{n}\, E^2 \tag{37.30}$$

This equation can be derived from the homogeneous limit of an energy transport model based on the Boltzmann equation (see Sect. 37.5.4). However, for rapidly increasing electric fields, the average energy lags behind the electric field and can be considerably smaller than the one predicted by the homogeneous energy balance equation (37.30). Purely phenomenological approaches to describe heat transport in semiconductors are available [5], but are not further discussed here.

37.2.4 Parameter Modeling

Even though this set of basic semiconductor equations is complete, it cannot be solved without the further description of the material parameters for the mobilities μ_n and μ_p and the generation/recombination rate R.

Mobility

The carrier mobilities in semiconducting materials are determined by various physical mechanisms, because the charge carriers experience scattering events by thermal lattice vibrations, ionized impurities, neutral impurities, vacancies, interstitials, dislocations, surfaces, and with each other.

The engineering approach to take all this into account is to use fitted analytical models based on measurements or to extract parameters from sophisticated Monte Carlo simulations. Rigorous first principle models for the carrier mobilities exist, but they are complicated and hard to implement.

In the drift-diffusion equations, mobility models depending on the electric field are usually employed. Various models have been developed; examples can be found in [21–23]. For weak electric fields, the mobility is constant with respect to the field, and therefore the relation between the velocity and the electric field is linear. For large electric fields, the relationship begins to deviate from linear, and the velocity saturates for very high fields. The maximum velocity observed in bulk silicon measurements is the saturation velocity v_sat requiring the mobility to be of the form $\mu \to v_\mathrm{sat}/E$. In silicon, the value of v_sat is 10^7 cm/s [24]. Simulation tools commonly differentiate between low- and high-field mobilities and allow the user to select the models independently.

However, as will be shown below, the carrier mobility does not depend on E, but is a functional of the carrier distribution function. Mobility models in higher-order transport models can use more information from the distribution function. In energy transport models, for example, the carrier temperature can be used as a solution variable. As a consequence, effects like the velocity overshoot can be approximately described.

Carrier Generation and Recombination

The recombination rate R was formally introduced in the drift-diffusion equations (37.6) and (37.7) by splitting the continuity equation into two individual parts for electrons and holes. From a physical point of view, this term includes the generation and the recombination of electron-hole pairs.

Various physical mechanisms can cause the generation/recombination of an electron-hole pair. For instance, the absorption or emission of a photon, the absorption or emission of a phonon, three particle transitions, and transitions assisted by recombination centers can occur. The impact of these mechanisms depends on the operation conditions and the properties of the employed materials.

One important generation/recombination process is the well-known Shockley-Read-Hall (SRH) mechanism [25,26] which describes a two-step phonon transition. A trap level, which is energetically located within the bandgap and enables the electron to recombine with a hole, is utilized. Four partial processes can be separated: the capture and the emission of both, electrons and holes, on the trap level. Balance equations can be formulated for the trap occupancy function which leads to the Shockley-Read-Hall model. In the stationary limit, the rate dependence on the carrier concentration is described by the expression

$$\begin{aligned} R &= R_\mathrm{n} - G_\mathrm{n} = R_\mathrm{p} - G_\mathrm{p} \\ &= \frac{n\,p - n_i^2}{\tau_\mathrm{p}\,(n + n_1) + \tau_\mathrm{n}\,(p + p_1)} \end{aligned} \tag{37.31}$$

$$n_1 p_1 = n_i^2. \tag{37.32}$$

Here n_i denotes the intrinsic carrier concentration (constant). The auxiliary concentrations n_1 and p_1 depend on lattice temperature and the trap energy level. The parameters τ_n and τ_p are the lifetimes for electrons and holes depending on the lattice temperature. Various physical mechanisms may influence the recombination/generation process. A doping dependence of recombination lifetimes is experimentally observed in silicon technology.

In thermal equilibrium, the net recombination rate vanishes ($n_0 p_0 = n_i^2$). An excess number of carriers ($np > n_i^2$) lead to an increased recombination, and a low-carrier concentration ($np < n_i^2$) leads to an increased generation. Lifetimes can be modeled depending on trap concentration, temperature, and doping.

The carrier recombination process is critical for any device that involves both electron and hole flows. Generation/recombination phenomena are involved in many fundamental effects, like leakage current and device breakdown.

37.3 Microscopic Transport Modeling

Following a more rigorous approach, macroscopic transport equations used in semiconductor device simulation are normally derived from the Boltzmann transport equation (BTE), which determines the microscopic phase space distribution function $f = f(\mathbf{r}, \mathbf{k}, t)$ for a stochastic ensemble of particles of a single-carrier type. The unknown distribution function in the BTE is considered as a classical, everywhere positive, distribution function.

However, the Boltzmann transport equation requires information only accessible by quantum mechanical considerations [14]. These are the band structure, expressions for the scattering and generation/recombination rates, and the Pauli exclusion principle reflecting the Fermi statistics of carriers. In this section, we discuss the Boltzmann equation and simplified models for band structure, scattering, and generation/recombination processes, which are employed in the derivation of macroscopic transport models.

37.3.1 The Boltzmann Transport Equation

The BTE describing charge transport in semiconductors is an integro-differential equation in the seven-dimensional space $(\mathbf{r}, \mathbf{k}, t)$. Here $\mathbf{r}$ is the spatial variable, t is time, and the variable $\mathbf{k}$ is called the wave vector. Alternatively, one can use the crystal momentum $\mathbf{p} = \hbar\,\mathbf{k}$ as variable.

The BTE is a classical kinetic equation which reads for electrons [27]

$$\partial_t f + \mathbf{v}\cdot\nabla_{\mathbf{r}} f + \frac{\mathbf{F}}{\hbar}\cdot\nabla_{\mathbf{k}} f = C[f] - R[f]. \tag{37.33}$$

The operator C on the right-hand side is called the collision operator (see Sect. 37.3.5). In general, this operator is nonlinear and nonlocal in the variable $\mathbf{k}$. The operator R on the right-hand side describes generation/recombination terms and depends on the electron and hole distribution function (see Sect. 37.3.6). Mathematically, the operators C and R are integral operators nonlocal in k-space. Scattering and generation/recombination have an interpretation in terms of stochastic processes for classical point particles. In general, these operators depend also on any local impurities and material defects.

The quantity $\mathbf{v} = \mathbf{v}(\mathbf{r}, \mathbf{k})$ on the left-hand side in (37.33) is the group velocity of the carrier

$$\mathbf{v}(\mathbf{r}, \mathbf{k}) = \frac{1}{\hbar}\nabla_{\mathbf{k}}\mathcal{E}(\mathbf{r}, \mathbf{k}). \tag{37.34}$$

The energy of the carrier $\mathcal{E}(\mathbf{r}, \mathbf{k})$ is determined by the band structure of the material (see Sect. 37.3.2).

In (37.33), $\mathbf{F}$ is an external force exerted on the electrons, which in general depends on both $\mathbf{r}$ and $\mathbf{k}$. It is given as

$$\begin{aligned}\mathbf{F}(\mathbf{r}, \mathbf{k}) = &-\nabla_{\mathbf{r}} E_c(\mathbf{r}) \\ &-q\big(\mathbf{E}(\mathbf{r}) + \mathbf{v}(\mathbf{r}, \mathbf{k})\times\mathbf{B}(\mathbf{r})\big) \\ &-\nabla_{\mathbf{r}}\mathcal{E}(\mathbf{r}, \mathbf{k})\end{aligned} \tag{37.35}$$

where E_c is the conduction band minimum.

The Boltzmann equation is valid for general inhomogeneous materials with arbitrary band structure [28]. If the influence of the magnetic field is omitted and a homogeneous material is assumed, then $\mathbf{F}$ depends only on the local electric field as

$$\mathbf{F}(\mathbf{r}) = -q\,\mathbf{E}(\mathbf{r}). \tag{37.36}$$

Like in the drift-diffusion model (see Sect. 37.2.1), the electric field $\mathbf{E} = -\nabla\psi$ must be determined by Poisson's equation (37.2), where we have

$$\nabla\cdot(\varepsilon\nabla\psi) = q\,(n - p - N) \tag{37.37}$$

with N representing the net doping. The right-hand side contains the electron and hole concentrations, n and p. These are the zeroth-order moments of the distribution functions $f_n(\mathbf{r}, \mathbf{k}, t)$ and $f_p(\mathbf{r}, \mathbf{k}, t)$. For a complete description of the system of charge carriers, two Boltzmann equations with different physical parameters have to be solved self-consistently, one equation for the electron distribution f_n and a second one for the hole distribution f_p. The electron and hole ensembles

couple through the Poisson equation and through generation and recombination of electron-hole pairs. The coupling of the transport equations with the Poisson equation requires an iterative self-consistent solution procedure [6].

37.3.2 The Band Structure

For the evaluation of the transport equation, some information about the band energy $\mathcal{E}(\mathbf{r}, \mathbf{k})$ must be provided. The inverse effective mass tensor is defined by the second-order derivative of $\mathcal{E}(\mathbf{r}, \mathbf{k})$ as

$$\hat{\boldsymbol{m}}^{-1}(\mathbf{r}, \mathbf{k}) = \frac{1}{\hbar}\nabla_{\mathbf{k}} \otimes \mathbf{v}(\mathbf{r}, \mathbf{k}) \tag{37.38}$$

$$= \frac{1}{\hbar^2}\nabla_{\mathbf{k}} \otimes \nabla_{\mathbf{k}} \mathcal{E}(\mathbf{r}, \mathbf{k}) \tag{37.39}$$

where $\otimes$ denotes the tensor product.

A common assumption in macroscopic transport models is that the band structure is isotropic, that is, the kinetic energy depends only on the magnitude of the wave vector $\mathbf{k}$. Then, an isotropic effective mass approximation via the trace of the mass tensor is employed as [29]

$$m^{-1} = \frac{1}{3}\,\mathrm{tr}\,\langle \hat{\boldsymbol{m}}^{-1} \rangle. \tag{37.40}$$

The simplest isotropic model is given by a parabolic relationship between the energy and the crystal momentum $\mathbf{p} = \hbar\,\mathbf{k}$, which is assumed to be valid for energies close to the band minimum:

$$\mathcal{E} = \frac{p^2}{2m} \tag{37.41}$$

With increasing carrier energies, non-parabolic bands must be taken into account. A first-order non-parabolic relationship was given by Kane [30]. However, an analytical treatment of the corresponding carrier energy and group velocity is no longer possible.

In the parabolic case, we get for the group velocity

$$\mathbf{v} = \frac{\hbar\,\mathbf{k}}{m} = \frac{\mathbf{p}}{m} \tag{37.42}$$

and the band energy can be expressed in various equivalent ways as

$$\mathcal{E} = \frac{\hbar^2\,k^2}{2\,m} = \frac{p^2}{2\,m} = \frac{\mathbf{v}\cdot\mathbf{p}}{2} = \frac{m\,v^2}{2}. \tag{37.43}$$

Using the crystal momentum $\mathbf{p}$ as variable, the Boltzmann equation for electrons simplifies in the parabolic case for a homogeneous material to

$$\partial_t f + \frac{\mathbf{p}}{m}\cdot\nabla_{\mathbf{r}} f - q\,\mathbf{E}\cdot\nabla_{\mathbf{p}} f = C[f] - R[f] \tag{37.44}$$

where the left-hand side is the classical Liouville equation.

37.3.3 Macroscopic Observables

Rather than looking at the microscopic distribution function $f(\mathbf{r}, \mathbf{k})$ itself, a common simplification is to investigate only some macroscopic counterparts which are averages over $\mathbf{k}$-space. As a consequence, the moments no longer depend on $\mathbf{k}$ but only on $\mathbf{r}$. Macroscopic quantities are obtained by the integration of an according microscopic weight function multiplied by the distribution function f. A general moment of the distribution function can be defined as

$$\langle \Phi \rangle = \int \Phi f \; \mathrm{d}^3\mathbf{k} \tag{37.45}$$

with a suitable weight function $\Phi = \Phi(\mathbf{k})$. In the definition of the physical observables, we will use moments rescaled with a fixed constant:

$$\langle\!\langle \Phi \rangle\!\rangle = \frac{1}{4\pi^3}\langle \Phi \rangle \tag{37.46}$$

Here, the prefactor $1/(4\pi^3)$ incorporates the density of states in three-dimensional $\mathbf{k}$-space [31, p.26]. This factor is composed of the spin degeneracy which implies a factor of two; a further factor of $1/(2\pi)$ per degree of freedom results from the transition from discrete states to a continuum distribution function.

The moments contain information about the full microscopic distribution function, and they are used to define macroscopic observables or state variables. Some common physical observables (e.g., carrier temperature and velocity) are derived by additionally normalizing the moment with the local carrier concentration $n(\mathbf{r})$ (see table below). The angular bracket always denotes integration without normalization. As normalization of a distribution function is a nonlinear transformation, the models derived by the method of moments (see Sect. 37.4.1) are more naturally written in terms of (non-normalized) moments.

In the following, the group velocity $\mathbf{v}$ is separated into a random part $\mathbf{c}$ and the mean value $\bar{\mathbf{v}} = \langle\!\langle \mathbf{v} \rangle\!\rangle / \langle\!\langle 1 \rangle\!\rangle$ such that $\mathbf{c} = \mathbf{v} - \bar{\mathbf{v}}$. We then define the following symbols:

Electron density: $n = \langle\!\langle 1 \rangle\!\rangle$ (37.47)

Velocity: $\bar{\mathbf{v}} = \frac{1}{n}\langle\!\langle \mathbf{v} \rangle\!\rangle = -\frac{\mathbf{J}}{qn}$ (37.48)

Energy: $w = \frac{1}{n}\langle\!\langle \mathcal{E} \rangle\!\rangle$ (37.49)

$$\text{Thermal energy:}\quad w_{\mathrm{T}} = \frac{1}{n}\langle\!\langle \frac{m}{2}c^2 \rangle\!\rangle = \frac{3}{2}k_{\mathrm{B}}T_{\mathrm{n}} \tag{37.50}$$

$$\text{Energy flux:}\quad \mathbf{S} = \langle\!\langle \mathcal{E}\mathbf{v} \rangle\!\rangle \tag{37.51}$$

$$\text{Heat flux:}\quad \mathbf{Q} = \langle\!\langle \frac{m}{2}c^2\mathbf{c} \rangle\!\rangle. \tag{37.52}$$

Here T_{n} is the electron gas temperature and $\mathbf{J}$ the electron current density.

Macroscopic moments provide the link between the microscopic description in terms of a distribution function f and a phenomenological description such as described in Sect. 37.2. Using the method of moments (see Sect. 37.4), a system of equations for a given set of observables can be systematically derived from the Boltzmann equation.

37.3.4 Analytical Distributions

The Boltzmann equation can be solved approximately by making a suitable ansatz for the distribution function. An ansatz can also be used to derive closure relations for higher-order moment models (see Sect. 37.4.3). Important analytical classes of distribution functions are described below.

Fermi-Dirac and Maxwell-Boltzmann

The Fermi-Dirac and Maxwell-Boltzmann distribution functions (see Fig. 37.2) are frequently used to model the distribution of carriers in equilibrium which describes the case of a negligible applied electric field.

The Fermi-Dirac distribution is defined as

$$f(\mathbf{r},\mathbf{p}) = \frac{1}{1+\exp\left(\dfrac{E_{\mathrm{tot}}(\mathbf{r},\mathbf{p}) - E_{\mathrm{F}}}{k_{\mathrm{B}}T_{\mathrm{L}}}\right)} \tag{37.53}$$

$$E_{\mathrm{tot}}(\mathbf{r},\mathbf{p}) = E_{\mathrm{c}}(\mathbf{r}) + \mathcal{E}(\mathbf{r},\mathbf{p}). \tag{37.54}$$

For $E_{\mathrm{c}} \gg E_{\mathrm{F}}$, the Fermi-Dirac distribution (37.53) can be approximated by a Maxwell-Boltzmann distribution (see Fig. 37.3):

$$f(\mathbf{r},\mathbf{p}) = \exp\left(-\frac{E_{\mathrm{tot}}(\mathbf{r},\mathbf{p}) - E_{\mathrm{F}}}{k_{\mathrm{B}}T_{\mathrm{L}}}\right). \tag{37.55}$$

This is valid for nondegenerate, lowly doped semiconductors and corresponds to a neglect of the Pauli principle. While the assumption of lowly doped semiconductors is virtually never justified for semiconductor devices, the Maxwell-Boltzmann distribution is still preferentially used, since it gives closed-form results when integrated, for example, for the calculation of moments.

Rewriting the Maxwell distribution gives

$$\begin{aligned} f(\mathbf{r},\mathbf{p}) &= \exp\left(-\frac{E_{\mathrm{c}}(\mathbf{r}) + \mathcal{E}(\mathbf{r},\mathbf{p}) - E_{\mathrm{F}}}{k_{\mathrm{B}}T_{\mathrm{L}}}\right) \\ &= A\,\exp\left(-\frac{\mathcal{E}}{k_{\mathrm{B}}T_{\mathrm{L}}}\right). \end{aligned} \tag{37.56}$$

Here the prefactor A is given by

$$A = \exp\left(\frac{E_{\mathrm{F}} - E_{\mathrm{c}}(\mathbf{r})}{k_{\mathrm{B}}T_{\mathrm{L}}}\right) \tag{37.57}$$

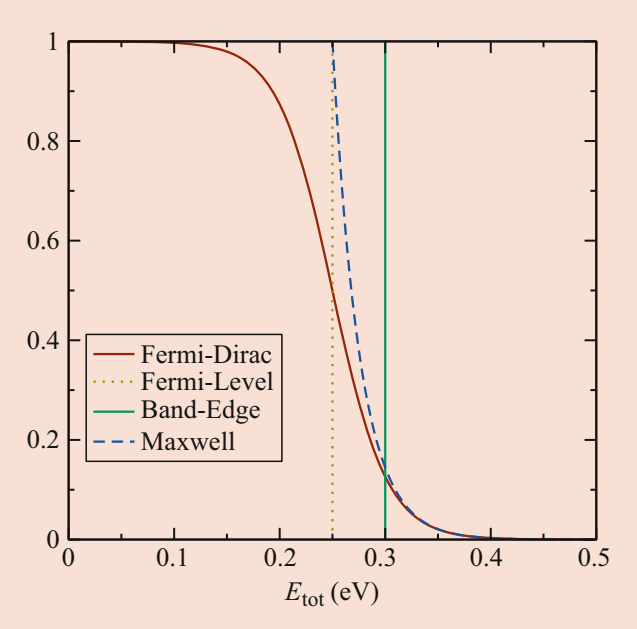

Fig. 37.2 Fermi-Dirac versus Maxwell-Boltzmann distribution

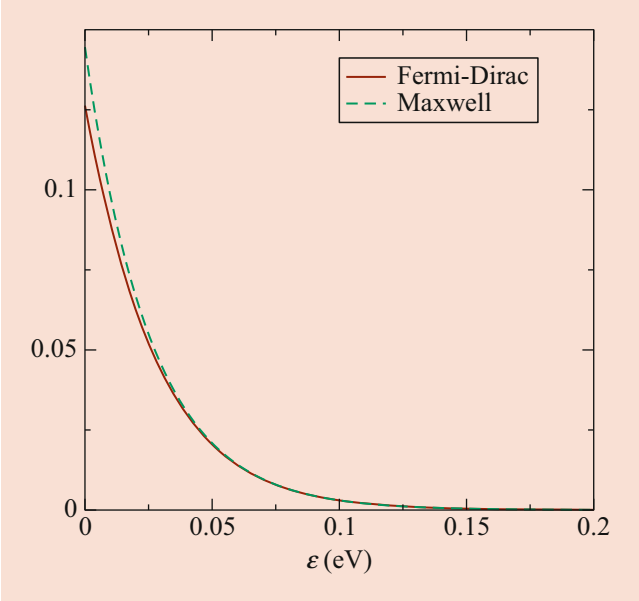

Fig. 37.3 In the limit $E_{\mathrm{c}} \gg E_{\mathrm{F}}$, the Fermi-Dirac distribution can be approximated by a Maxwell-Boltzmann distribution

and does not depend on **p**. For parabolic bands, we get

$$f(\mathbf{r},\mathbf{p}) = A\exp\Big(-\frac{\mathbf{p}^2}{2mk_{\mathrm{B}}T_{\mathrm{L}}}\Big). \tag{37.58}$$

which is often referred to as "cold Maxwellian," as the lattice temperature appears in it.

Heated Displaced Maxwellian

A heated displaced Maxwellian distribution function (also called shifted Maxwellian)

$$f_{\mathrm{sM}}(\mathbf{k}) = \exp\left(a + \mathbf{b}\cdot\mathbf{k} - c\,k^2\right) \tag{37.59}$$

is a frequently used ansatz for the distribution function in the Boltzmann equation. In terms of its moments (37.45), this distribution can be parameterized as

$$f(\mathbf{k}) = \frac{n_0}{(2\pi T_2)^{\frac{3}{2}}}\exp\Big(-\frac{(\mathbf{k}-\mathbf{k}_0)^2}{2T_2}\Big) \tag{37.60}$$

where

$$n_0 = \langle 1\rangle = \Big(\frac{\pi}{c}\Big)^{\frac{3}{2}}\exp\Big(a+\frac{b^2}{4c}\Big) \tag{37.61}$$

$$\mathbf{k}_0 = \frac{\langle\mathbf{k}\rangle}{n_0} = \frac{1}{2c}\,\mathbf{b} \tag{37.62}$$

$$T_2 = \frac{\langle(\mathbf{k}-\mathbf{k}_0)^2\rangle}{3\,n_0} = \frac{1}{2c}. \tag{37.63}$$

For $k_0 = 0$, we get a heated Maxwellian as a special case, while $k_0 \neq 0$ is required to result in a current density. Note, however, that a shifted Maxwellian has zero heat flow. Hence, this ansatz cannot represent solutions where the heat flow is physically relevant.

Diffusive Maxwellian

If the displacement **b** in (37.59) is small, then it is justified to approximate the shifted Maxwellian by a linearized shifted Maxwellian:

$$\begin{aligned} f(\mathbf{k}) &= \exp\left(a + \mathbf{b}\cdot\mathbf{k} - c\,k^2\right)\\ &= \exp\left(a - c\,k^2\right)\,\exp\left(\mathbf{b}\cdot\mathbf{k}\right)\\ &\approx f_{\mathrm{M}}(|\mathbf{k}|)\,(1+\mathbf{b}\cdot\mathbf{k}) = \tilde{f}(\mathbf{k}). \end{aligned} \tag{37.64}$$

Note that the distribution $\tilde{f}$ is no longer positive on all of $\mathbf{R}^3$. In terms of its moments (37.45), a linearized shifted Maxwellian can be parameterized as

$$\tilde{f}(\mathbf{k}) = \frac{n_0}{(2\pi M_2)^{\frac{3}{2}}}\exp\Big(-\frac{\mathbf{k}^2}{2M_2}\Big)\Big(1+\frac{\mathbf{k}\cdot\mathbf{k}_0}{M_2}\Big) \tag{37.65}$$

where

$$n_0 = \langle 1\rangle = \Big(\frac{\pi}{c}\Big)^{\frac{3}{2}}\exp(a) \tag{37.66}$$

$$\mathbf{k}_0 = \frac{\langle\mathbf{k}\rangle}{n_0} = \frac{1}{2c\,\mathbf{b}} \tag{37.67}$$

$$M_2 = \frac{\langle\mathbf{k}^2\rangle}{3\,n_0} = \frac{1}{2c}. \tag{37.68}$$

The expression "diffusive Maxwellian" stems from the fact that this distribution is implicitly used in the context of the diffusion approximation (see Sect. 37.5.1) to derive parabolic equation systems from the Boltzmann equation.

37.3.5 The Microscopic Relaxation Time Approximation

Electron transport is often dominated by the scattering operator. In a crude approximation, the collision term on the right-hand side of equation (37.33) represents the various scattering processes and can be approximately modeled as

$$C[f] \approx -\frac{f-f_0}{\tau} \tag{37.69}$$

which is commonly referred to as relaxation time approximation [32, p.144]. Here the index 0 represents the quasi-equilibrium distribution function $f_0(\mathbf{k})$. Depending on the type of model, both the distribution f_0 and the relaxation time τ can depend on the distribution function f or its moments. The relaxation time approximation can only be justified near quasi-equilibrium and even then only for specific types of scattering processes, i.e., elastic or isotropic. In contrast, energy relaxation by optical inter-valley scattering can hardly be accounted for by a relaxation time approximation.

One consequence of the relaxation time approximation is that the distribution decays exponentially toward its quasi-equilibrium value f_0 with the time constant τ, whenever it is disturbed from its quasi-equilibrium value. To allow for an easy analytic treatment, a Fermi-Dirac or a Maxwellian equilibrium distribution might be used. While this is a crude approximation, it allows for a straight forward numerical implementation. In a more rigorous way, scattering is modeled based on Fermi's golden rule and doping-dependent rates. A discussion on the validity of the relaxation time approximation is given in [31, p.139].

37.3.6 Microscopic Generation and Recombination

Similar to the relaxation time approximation for scattering, there are microscopic models for generation and recombina-

tion of electron-hole pairs. A simple model for generation/recombination is presented in [15].

The Shockley-Read-Hall model (see Sect. 37.2.4) has a microscopic formulation in terms of the distribution function f. The generation-recombination term $R[f]$ in the Boltzmann equation for electrons (37.33) is based on the assumption that generation-recombination occurs via a trap level E_t. Carriers in the valence and conduction band can be transferred to this trap level via phonon-assisted transitions. In k-space, the model reads

$$R[f] = \frac{1}{\tau_n}\left((1-f_t)f^e(k) - f_t \exp(-\tfrac{\mathcal{E}(k)-\mathcal{E}_t}{k_B T_L})\right). \quad (37.70)$$

Here f^e denotes the even part of the distribution function f, and f_t is the trap occupancy. The parameter $\mathcal{E}_t$ denotes the fixed trap level inside the semiconductor bandgap, while for the transition rates an energy-independent carrier lifetime τ_n is assumed. The simple model (37.70) allows for an analytical treatment under stationary conditions. Generation-recombination terms do not enter into the macroscopic flux equations, because $R[f]$ is an even function in k.

In general, generation/recombination terms depend on both, electron and hole distribution functions, in an integral, nonlocal manner [3]. This makes the task of solving the corresponding coupled transport equations for electrons and holes extremely difficult and represents a significant challenge [33].

37.4 Macroscopic Transport Models

To solve the Boltzmann equation deterministically by discretization of the differential and integral operators is computationally very expensive. A widely used stochastic method for solving the Boltzmann equation is the Monte Carlo method. The Monte Carlo method has been proven to give accurate results but may be computationally expensive, too. In particular, due to its stochastic nature, very large computation times are required for rare events. For instance, if the distribution of high energetic carriers is relevant or if the carrier concentration is very low in specific regions of the device, Monte Carlo simulations tend to produce high variance in the results.

An approximate deterministic solution method for the Boltzmann equation, which is often sufficient for TCAD demands, is the method of moments, which transforms the Boltzmann equation into a macroscopic transport model, i.e., a small system of partial differential equations in the four-dimensional space $(\mathbf{r}, t)$. The solution variables are a selected set of moments, which often correspond to macroscopic observables. In this section, we give the basic steps of this method.

37.4.1 The Method of Moments

The method of moments is characterized by multiplying the Boltzmann equation with weight functions and integrating the whole equation over $\mathbf{k}$-space. The moments of the distribution then become the unknowns of the equation system. The integration eliminates the coordinates in $\mathbf{k}$-space and leaves a set of partial differential equations in $(\mathbf{r}, t)$ space.

Generation and recombination processes are not considered in the following. Application of the method of moments to the Boltzmann equation gives the moment equations. For a general scalar Φ, we obtain a scalar equation:

$$\partial_t\langle\Phi_j\rangle + \nabla_{\mathbf{r}}\cdot\langle\mathbf{v}\,\Phi_j\rangle + q\,\mathbf{E}\cdot\langle\nabla_{\mathbf{p}}\Phi_j\rangle = \int \Phi_j\, C[f]\ \mathrm{d}^3\mathbf{k} \quad (37.71)$$

and for a vectorial $\mathbf{\Phi}$, we obtain a vectorial equation:

$$\partial_t\langle\mathbf{\Phi}_j\rangle + \nabla_{\mathbf{r}}\cdot\langle\mathbf{v}\otimes\mathbf{\Phi}_j\rangle + q\,\mathbf{E}\cdot\langle\nabla_{\mathbf{p}}\otimes\mathbf{\Phi}_j\rangle = \int \mathbf{\Phi}_j\, C[f]\ \mathrm{d}^3\mathbf{k} \quad (37.72)$$

where $\otimes$ denotes the tensor product [28]. In the derivation, partial integration for integrals over product terms of type $(\Phi\nabla_{\mathbf{p}} f)$ is used.

If we assume a parabolic band and a weight function Φ which is a (multivariate) polynomial in $\mathbf{p}$, then $\mathbf{v} = \frac{\mathbf{p}}{m}$, and the terms in the angular brackets on the left-hand side in the moment equations are polynomials again.

37.4.2 The Macroscopic Relaxation Time Approximation

In analogy to the microscopic relaxation time approximation, the collision term on the right-hand side of equations (37.71) and (37.72), which represents the various scattering processes, can be approximately modeled as

$$\int \hat{\mathbf{\Phi}}_j\, C[f]\ \mathrm{d}^3\mathbf{k} \approx -\frac{\langle\hat{\mathbf{\Phi}}_j\rangle - \langle\hat{\mathbf{\Phi}}_j\rangle_0}{\tau_{\hat{\mathbf{\Phi}}_j}} \quad (37.73)$$

which is commonly referred to as macroscopic relaxation time approximation [32, p.144]. Here the index 0 represents the average over the equilibrium distribution. Both the equilibrium moments and the relaxation times depend on moments of the distribution function f. In this approach, the moment decays exponentially toward its equilibrium value $\langle\hat{\mathbf{\Phi}}_j\rangle_0$ with the time constant $\tau_{\hat{\mathbf{\Phi}}_j}$ under homogeneous conditions. As we may have different time constants for each moment, the macroscopic relaxation time approximation is

in some way more general than the microscopic relaxation time approximation (37.69).

The equilibrium distribution function $f_0(\mathbf{k})$ is a symmetric function. Since the even weight functions are symmetric in $\mathbf{k}$ and the odd weight functions are antisymmetric in $\mathbf{k}$, only the even moments of the equilibrium distribution function will be nonzero, whereas the odd moments will vanish

$$\langle \mathbf{\Phi}_{j_{\text{odd}}} \rangle_0 = \int \mathbf{\Phi}_j(\mathbf{k}) f_0(\mathbf{k}) \, \mathrm{d}^3\mathbf{k} = 0. \tag{37.74}$$

Nonlinearity enters into the moment equations through the relaxation time approximation of the scattering operator, because both the equilibrium distribution f_0 (and hence its moments) and the relaxation time parameters τ depend on the distribution function f.

37.4.3 The Closure Problem

The weight functions for the moment method are usually chosen as being proportional to powers of increasing order of the wave vector $\mathbf{k}$ or equivalently (in the parabolic case) as powers of the momentum $\mathbf{p}$. Using polynomial weight functions of all orders, the method of moments transforms the parabolic band BTE into an infinite set of equations for the polynomial moments. To obtain a practically relevant model, the infinite hierarchy has to be truncated to a finite number of equations by restricting the set of weight functions to a finite number.

With this finite set of polynomial weight functions, an equation system containing only polynomial moments is obtained. The unknowns of the resulting system are the moments corresponding to the weight functions. However, in general, additional moments will show up, and the system will contain more unknowns than equations. The additional moments have to be expressed by the available moments. This is a nontrivial task and known as the closure problem.

A simple way to close the system of equations is to make a suitable ansatz for the shape of the distribution function. Then all moments can be calculated explicitly in terms of the ansatz parameters. With this kind of closure, the method of moments becomes equivalent to the Petrov-Galerkin method. This is a finite element method where the set of ansatz functions (e.g., shifted Maxwellians) and the set of test functions (e.g., polynomials) are not identical, in contrast to the usual Galerkin method. If the equation is linear and the ansatz is linear in the unknown parameters, we get a linear system of equations; else it is nonlinear (this would be the case for a shifted Maxwellian ansatz).

No form of the distribution function has to be assumed in the derivation of the moment equations, but in that case separate closure relations are needed. We can distinguish three types of closure relations:

- First, the highest-order moment closure. The equation of highest order contains the moment of the next order, which has to be suitably approximated using available information, typically the lower-order moments.
- Second, approximation of the tensors appearing in the equation system. They have to be expressed by the available scalar and vectorial moments in order to make the final equation system tractable.
- Finally, approximations for the moments of the scattering term. Practical implementations use the macroscopic relaxation time approximation and the closure problem consists in finding models for the mobilities and relaxation times. These parameters depend in general on all other moments.

37.4.4 Moment Equations for a Parabolic Band

Commonly used macroscopic models like hydrodynamic or energy transport models use polynomial moments up to order four. To derive a four-moment system, we use the following weight functions of even order:

$$\Phi_0 = 1 \tag{37.75}$$

$$\Phi_2 = \mathcal{E} = \frac{p^2}{2m} \tag{37.76}$$

while the weight functions for the odd orders are

$$\mathbf{\Phi}_1 = \mathbf{v} = \frac{\mathbf{p}}{m} \tag{37.77}$$

$$\mathbf{\Phi}_3 = \mathcal{E}\,\mathbf{v} = \frac{p^2}{2m}\frac{\mathbf{p}}{m}. \tag{37.78}$$

As will be seen, using these weight functions in the method of moments, the scalar weight functions will lead to the balance equations, whereas the vectorial weight functions will lead to the flux equations. The calculation of the gradients of the weight functions of even order is straightforward:

$$\nabla_{\mathbf{p}} \Phi_0 = 0 \tag{37.79}$$

$$\nabla_{\mathbf{p}} \Phi_2 = \mathbf{v} \tag{37.80}$$

while the gradients of the odd weight functions can be written as

$$\nabla_{\mathbf{p}} \otimes \mathbf{\Phi}_1 = \frac{\hat{\boldsymbol{\delta}}}{m} \tag{37.81}$$

$$\nabla_{\mathbf{p}} \otimes \mathbf{\Phi}_3 = \frac{\mathcal{E}}{m}\hat{\boldsymbol{\delta}} + \mathbf{v}\otimes\mathbf{v}. \tag{37.82}$$

Here $\hat{\boldsymbol{\delta}}$ is the unit matrix in three dimensions.

Applying the macroscopic relaxation time approximation and inserting the calculated gradients from the previous section into equations (37.71) and (37.72) lead to the equation set

$$\Phi_0: \quad \partial_t \langle 1\rangle + \nabla\cdot\langle\mathbf{v}\rangle = -\frac{\langle 1\rangle - \langle 1\rangle_0}{\tau_n} \tag{37.83}$$

$$\mathbf{\Phi}_1: \quad \partial_t \langle\mathbf{v}\rangle + \nabla\cdot\langle\mathbf{v}\otimes\mathbf{v}\rangle + \frac{q}{m}\mathbf{E}\cdot\langle\hat{\boldsymbol{\delta}}\rangle = -\frac{\langle\mathbf{v}\rangle}{\tau_v} \tag{37.84}$$

$$\Phi_2: \quad \partial_t \langle\mathcal{E}\rangle + \nabla\cdot\langle\mathbf{v}\,\mathcal{E}\rangle + q\,\mathbf{E}\cdot\langle\mathbf{v}\rangle = -\frac{\langle\mathcal{E}\rangle - \langle\mathcal{E}\rangle_0}{\tau_\mathcal{E}} \tag{37.85}$$

$$\mathbf{\Phi}_3: \quad \partial_t \langle\mathbf{v}\,\mathcal{E}\rangle + \nabla\cdot\langle\mathbf{v}\otimes\mathbf{v}\,\mathcal{E}\rangle + q\,\mathbf{E}\cdot\langle\frac{\mathcal{E}}{m}\hat{\boldsymbol{\delta}} + \mathbf{v}\otimes\mathbf{v}\rangle = -\frac{\langle\mathbf{v}\,\mathcal{E}\rangle}{\tau_S} \tag{37.86}$$

where τ_n, $\tau_m = \tau_v$, $\tau_\mathcal{E}$, and τ_S are the relaxation times for particle density, momentum/velocity, energy, and energy flux density, respectively.

Complementing the macroscopic observables already defined in Sect. 37.3.3, all moment equations will be written using the following observables [34]:

$$\text{Momentum:} \quad \bar{\mathbf{p}} = \frac{1}{n}\langle\!\langle\mathbf{p}\rangle\!\rangle \tag{37.87}$$

$$\text{Thermal tensor:} \quad \hat{\boldsymbol{T}} = \frac{1}{n}\langle\!\langle\frac{m}{2}\mathbf{c}\otimes\mathbf{c}\rangle\!\rangle \tag{37.88}$$

$$\text{Energy-like tensor:} \quad \hat{\boldsymbol{U}} = \frac{1}{n}\langle\!\langle\frac{1}{2}\mathbf{v}\otimes\mathbf{p}\rangle\!\rangle \tag{37.89}$$

$$\text{Fourth-order tensor:} \quad \hat{\boldsymbol{R}} = \frac{1}{n}\langle\!\langle\mathbf{v}\otimes\mathbf{p}\,\mathcal{E}\rangle\!\rangle. \tag{37.90}$$

In these definitions, the even moments w, $\hat{\boldsymbol{U}}$, $\hat{\boldsymbol{R}}$ are normalized, while the fluxes $\mathbf{J}$ and $\mathbf{S}$ are not. The energy tensor and thermal energy tensors are also known as stress and pressure tensor in fluid dynamics.

In the parabolic case, we get the following relations:

$$\bar{\mathbf{p}} = m\bar{\mathbf{v}} \tag{37.91}$$

$$w = \frac{1}{n}\langle\!\langle\mathcal{E}\rangle\!\rangle = \frac{1}{n}\langle\!\langle\frac{m}{2}v^2\rangle\!\rangle = \operatorname{tr}\hat{\boldsymbol{U}} \tag{37.92}$$

$$w_T = \frac{3}{2}k_B T_n = \frac{1}{n}\langle\!\langle\frac{m}{2}c^2\rangle\!\rangle = \operatorname{tr}\hat{\boldsymbol{T}} \tag{37.93}$$

Thus, the scalar values for the energy and the thermal energy are the traces of the corresponding tensors.

Average energy w and energy flux $\mathbf{S}$ are raw moments of second and third order. Temperature T_n and heat flux $\mathbf{Q}$ are (up to scaling) the corresponding central moments. In the parabolic case, central and raw moments are related by

$$w = w_T + \frac{m}{2}\bar{v}^2 \tag{37.94}$$

$$\hat{\boldsymbol{U}} = \hat{\boldsymbol{T}} + \frac{m}{2}\bar{\mathbf{v}}\otimes\bar{\mathbf{v}} \tag{37.95}$$

$$\mathbf{S} = \mathbf{Q} + 2n\hat{\boldsymbol{T}}\bar{\mathbf{v}} + nw_T\bar{\mathbf{v}} + n\frac{m}{2}\bar{v}^2\bar{\mathbf{v}}. \tag{37.96}$$

If we define convective energy as

$$w_{conv} = \frac{m}{2}\bar{v}^2, \tag{37.97}$$

the total energy is the sum of thermal and convective energy.

Introducing these state variables (moments) leads to the following form of the transport equations:

$$\Phi_0: \quad \partial_t n + \nabla\cdot n\bar{\mathbf{v}} = -\frac{n - n_0}{\tau_n} \tag{37.98}$$

$$\mathbf{\Phi}_1: \quad \partial_t(n\bar{\mathbf{v}}) + \frac{2}{m}\nabla\cdot n\hat{\boldsymbol{U}} + \frac{q}{m}n\,\mathbf{E} = -\frac{n\bar{\mathbf{v}}}{\tau_v} \tag{37.99}$$

$$\Phi_2: \quad \partial_t(nw) + \nabla\cdot\mathbf{S} - \mathbf{E}\cdot\mathbf{J} = -n\frac{w - w_0}{\tau_\mathcal{E}} \tag{37.100}$$

$$\mathbf{\Phi}_3: \quad \partial_t\mathbf{S} + \frac{1}{m}\nabla\cdot n\hat{\boldsymbol{R}} + q\,\mathbf{E}\Big(\frac{nw}{m} + 2\frac{n\hat{\boldsymbol{U}}}{m}\Big) = -\frac{\mathbf{S}}{\tau_S} \tag{37.101}$$

In three dimensions, this system consists of just eight equations (two scalar plus two vectorial) for the 19 unknowns $\{n, \bar{\mathbf{v}}, \hat{\boldsymbol{U}}, \mathbf{S}, \hat{\boldsymbol{R}}\}$. We also have to find models for the relaxation times. The limitations of the various possible moment models are a consequence of the closure problem and are discussed in the following.

37.4.5 Hydrodynamic Models

A hydrodynamic model for semiconductors was first introduced by Bløtekjær [9], who made several assumptions listed below to derive this system. Due to the hyperbolic nature and the resulting numerical challenges, hydrodynamic models are rarely used in macroscopic device simulation. However, hydrodynamic models are based on fewer assumptions than the energy transport models which actually can be derived from the hydrodynamic models by additional simplifications.

For this reason, the generic hydrodynamic transport model is discussed first. The energy transport models are discussed in Sect. 37.5.

We now consider only the first three moment equations (37.98)–(37.100) as originally done by Bløtekjær (see [9]). This system assumes a single effective parabolic energy band and consists of five equations (line $\mathbf{\Phi}_1$ is vectorial). The unknowns corresponding to the weight functions are $\{n, \bar{\mathbf{v}}, w\}$. Since we have $w = \frac{m}{2}\bar{v}^2 + \frac{3}{2}k_\mathrm{B}T_\mathrm{n}$, an equivalent set of unknowns is $\{n, \bar{\mathbf{v}}, T_\mathrm{n}\}$. All other moments appearing in the system have to be expressed through these unknowns.

Isotropic Symmetry

To reduce the number of unknowns, we use symmetry considerations for the thermal energy tensor. We can split the energy tensor according to (37.95):

$$\hat{\boldsymbol{U}} = \hat{\boldsymbol{T}} + \frac{m}{2}\bar{\mathbf{v}}\otimes\bar{\mathbf{v}} \tag{37.102}$$

The random component of the velocity has zero average, that is, $\langle \mathbf{c} \rangle = 0$. Under the assumption that the even part of the distribution of $\mathbf{c}$ is isotropic, the following relation can be derived:

$$\langle \mathbf{c}\otimes\mathbf{c} \rangle = \frac{1}{3}\langle c^2 \rangle \hat{\boldsymbol{I}} \tag{37.103}$$

This assumption is frequently considered to be justified because of the strong influence of scattering. With this assumption, we can represent the thermal energy tensor $\hat{\boldsymbol{T}}$ by a scalar temperature T_n:

$$\hat{\boldsymbol{T}} = \frac{w_T}{3}\hat{\boldsymbol{I}} = \frac{1}{2}k_\mathrm{B}T_\mathrm{n}\hat{\boldsymbol{I}} \tag{37.104}$$

With this assumption, (37.95) now becomes

$$\hat{\boldsymbol{U}} = \frac{1}{2}k_\mathrm{B}T_\mathrm{n}\hat{\boldsymbol{I}} + \frac{1}{2}m\bar{\mathbf{v}}\otimes\bar{\mathbf{v}} \tag{37.105}$$

and the six unknowns of the (symmetric) energy tensor $\hat{\boldsymbol{U}}$ are reduced to a single unknown T_n.

We employ the usual definition:

$$\mu = \frac{\mathrm{q}\,\tau_m}{\mathrm{m}} \tag{37.106}$$

where μ will be identified by the electron mobility in the drift-diffusion model, which is used in place of the momentum relaxation time.

With the isotropic approximations (37.104) and (37.105), the moment equations (37.98)–(37.100) can be written in the usual variables as [35]:

$$\nabla\cdot\mathbf{J} = \mathrm{q}\partial_\mathrm{t}n \tag{37.107}$$

$$\mathbf{J} - \frac{\tau_\mathrm{m}}{q}\nabla\cdot\left(\mathbf{J}\otimes\frac{\mathbf{J}}{n}\right) = \mu k_\mathrm{B}\nabla(nT_\mathrm{n}) + qn\mu\mathbf{E} - \tau_\mathrm{p}\partial_\mathrm{t}\mathbf{J} \tag{37.108}$$

$$\nabla\cdot\mathbf{S} = -\partial_\mathrm{t}(nw) + \mathbf{E}\cdot\mathbf{J} - n\frac{w-w_0}{\tau_\mathcal{E}}. \tag{37.109}$$

Note that we have set $n_0 = n$ in equation (37.98), i.e., we do not relax the carrier density. The equilibrium value w_0 is given as

$$w_0 = \frac{3}{2}k_\mathrm{B}T_\mathrm{L}. \tag{37.110}$$

Phenomenological Highest-Order Moment Closure

The third equation (37.109) needs to be closed in the energy flux $\mathbf{S}$. A suitable approximation for the energy flux $\mathbf{S}$ has to be found, and different approaches have been published. Assuming isotropic symmetry (37.104) and using definition (37.93), we can express $\mathbf{S}$ from equation (37.96) as

$$\mathbf{S} = (w + k_\mathrm{B}T_\mathrm{n})n\bar{\mathbf{v}} + \mathbf{Q} \tag{37.111}$$

which still contains the heat flux $\mathbf{Q}$ as unknown third-order moment.

A simple way to close the equation is to assume that f is a shifted Maxwellian. For a shifted Maxwellian, the heat flux $\mathbf{Q}$ vanishes which gives

$$\mathbf{S} = (w + k_\mathrm{B}T_\mathrm{n})n\bar{\mathbf{v}} = \left(\frac{5}{2}k_\mathrm{B}T_\mathrm{n} + \frac{m}{2}\bar{v}^2\right)n\bar{\mathbf{v}}. \tag{37.112}$$

By contrast, Bløtekjær [9] took a phenomenological approach and approximated the heat flux $\mathbf{Q}$ by Fourier's law as

$$\mathbf{Q} = -\kappa(T_\mathrm{n})\nabla T_\mathrm{n} \tag{37.113}$$

in which the thermal conductivity is given by the Wiedemann-Franz law as

$$\kappa(T_\mathrm{n}) = \left(\frac{5}{2} - p_\gamma\right)\left(\frac{k_\mathrm{B}}{q}\right)^2 q\mu n T_\mathrm{n} \tag{37.114}$$

where p_γ is an empirical correction factor.

Numerical Properties

Equations (37.107)–(37.109) yield the full hydrodynamic model for parabolic band structures. The system needs to be supplemented by Fourier's law (37.113) which is used in (37.111) to close the system. This equation system is similar to the Euler equations of fluid dynamics with the addition of a

heat conduction term and the collision terms. In the absence of electric fields and scattering terms, equations (37.107)–(37.109) together with the Maxwellian closure (37.112) correspond to the Euler equations of gas dynamics [13, p.201]. Mathematically, they constitute a quasilinear hyperbolic system of conservation laws since mass, momentum, and energy are conserved.

The hydrodynamic model describes the propagation of charge carriers in an electronic device as the flow of a compressible fluid. The electron gas has a sound speed of $v_c = \sqrt{k_B T_n / m^*}$, and the carrier flow may be either supersonic or subsonic. With $T_n = \xi T_L$ and $T_L = 300\,\mathrm{K}$, we have $v_c = \sqrt{\xi}\, 1.3 \times 10^7\,\mathrm{cm/s}$, while for $T_L = 77\,\mathrm{K}$, $v_c = \sqrt{\xi}\, 6.6 \times 10^6\,\mathrm{cm/s}$ [36]. Typical maximum carrier temperatures, which are observed experimentally inside electronic devices, give rise to sound speeds of about $5 \times 10^7\,\mathrm{cm/s}$ which is higher than the maximum velocities observed in typical simulations.

If the flow is supersonic, electron shock waves can occur inside the semiconductor device [36]. Such shock waves arise typically either at low temperatures or at a small length scale. In general, special numerical methods have to be applied, because the system of equations is hyperbolic [36–39]. For this type of system, the traditionally used Scharfetter-Gummel scheme [7] and its extension to the energy transport models [40–45] cannot be applied. A possible approximation consists in treating the convective term as a perturbation by freezing the dependence on the state variables at each step and using the values from the previous recursion [46]. However, in those cases where the temporal or spatial variation is important, this approach degrades the convergence [47]. In order to derive a numerically feasible spatial discretization, methods from fluid dynamics known as upwinding have been applied [47, 48]. In addition, the handling of the boundary conditions is more involved [39, 49].

These numerical properties make the hydrodynamic model challenging to solve, and the energy transport models discussed in the next section are virtually always preferred for practical device modeling.

37.5 Energy Transport Models

The hydrodynamic transport model introduced in Sect. 37.4.5 includes convective terms analogous to the differential equations in fluid dynamics. With these convective terms, we get a system of partial differential equations of hyperbolic type, which is difficult to solve with numerical methods. Therefore, in order to get rid of these inconvenient terms, the diffusion approximation is introduced. The resulting systems are of parabolic type which differs in the numerical properties from the original hyperbolic problem.

In the literature, there often is an arbitrary or synonymous use of the terms hydrodynamic transport and energy transport model. For the sake of consistency, the commonly employed three- or four-moment models incorporating the diffusion approximation should better be addressed as energy transport models [5]. Transport models based on the diffusion approximation are termed diffusive models, the prototypical example being the drift-diffusion model.

Assuming the validity of the diffusion approximation, we are now going to discuss two prototypical schemes to derive energy transport models from the Boltzmann equation which have been proposed by Stratton [8] and Bløtekjær [50], respectively. They use different variants of the method of moments and employ different strategies to close the system of equations.

37.5.1 The Diffusion Approximation

A heuristic way to motivate the diffusion approximation consists in analyzing the assumptions necessary for the derivation of the drift-diffusion model from the Boltzmann equation. We start with the first two equations of the hydrodynamic transport model:

$$\nabla \cdot \mathbf{J} = q \partial_t n \tag{37.115}$$

$$\mathbf{J} - \frac{\tau_m}{q} \nabla \cdot \left(\mathbf{J} \otimes \frac{\mathbf{J}}{n} \right) = \mu k_B \nabla (n T_n) + q n \mu \mathbf{E} - \tau_m \partial_t \mathbf{J} \tag{37.116}$$

This model assumes a parabolic band and an isotropic thermal energy tensor.

In order to derive the drift-diffusion model (37.26)–(37.27) from the hydrodynamic moment equations (37.115)–(37.116) for Φ_0 and $\mathbf{\Phi}_1$, we need two crucial assumptions which form the core of the diffusion approximation. Both assumptions can mathematically be justified in the framework of diffusion scaling [13, p.52].

First, we assume that the equation for the odd moment $\mathbf{J}$ is quasi-stationary. As signal frequencies are well below $1/(2\pi\tau_m) \approx 10^{12}\,\mathrm{Hz}$, the time derivative in (37.116) is neglected [51].

Second, the contribution of the drift kinetic energy to the carrier energy is frequently neglected:

$$w \approx \frac{3}{2} k_B T_n \tag{37.117}$$

This simplification is valid if the thermal energy is much larger than the convective energy (see Sect. 37.6.1 for a discussion of validity). Mathematically, we approximate the raw second-order moment by the central moment. The last assumption has an analogue for the energy tensor. We split the energy tensor according to equation (37.95):

$$\hat{\boldsymbol{U}} = \hat{\boldsymbol{T}} + \frac{m}{2}\bar{\mathbf{v}}\otimes\bar{\mathbf{v}} \tag{37.118}$$

and drop the convective tensor on the right-hand side, which gives

$$\hat{\boldsymbol{U}} \approx \frac{1}{2}k_{\mathrm{B}}T_{\mathrm{n}}\hat{\boldsymbol{I}}. \tag{37.119}$$

With this approximation, we can neglect the convective term:

$$\frac{\tau_{\mathrm{m}}}{\mathrm{q}}\nabla\cdot\left(\mathbf{J}\otimes\frac{\mathbf{J}}{n}\right) \tag{37.120}$$

in the current relation (37.108), and a parabolic equation system is obtained which only covers the subsonic flow regions. This is a very common approximation employed in virtually all device simulators, and we are not aware of any numerically robust scheme which can solve the HD model for realistic and relevant semiconductor devices.

With these simplifications, we still have the continuity equation (37.6) for Φ_0, and the equation (37.116) for $\boldsymbol{\Phi}_1$ turns into

$$\mathbf{J} = qn\mu\mathbf{E} + \mu k_{\mathrm{B}}\nabla(nT_{\mathrm{n}}). \tag{37.121}$$

This still differs from the drift-diffusion current relation:

$$\mathbf{J} = qn\mu\mathbf{E} + \mu k_{\mathrm{B}}T_{\mathrm{L}}\nabla n \tag{37.122}$$

with respect to the term inside the gradient operator. Only, if we assume that the carrier temperature T_{n} is in equilibrium with the lattice temperature T_{L} and that T_{L} is spatially homogeneous, then (37.121) and (37.122) are equivalent.

The derivation of the drift-diffusion model from the Boltzmann equation using the method of moments unmasks the assumptions behind the drift-diffusion model. The assumptions made above can be justified from a mathematical point of view in the sense that they follow consistently from appropriately scaling the BTE and taking the limit $\alpha \to 0$ of vanishing Knudsen number. This is discussed below.

37.5.2 Diffusion Scaling

The Knudsen number α appears as scaling parameter in the Boltzmann equation. It represents the mean free path $\tau_0 v_0$ relative to the device dimension [52]:

$$\alpha = \frac{\tau_0 v_0}{x_0} \tag{37.123}$$

τ_0 is the characteristic time between scattering events, v_0 denotes the velocity scale, and x_0 is given by the size of the simulation domain.

Macroscopic models assume that scattering is dominant in the sense that the mean free path is much smaller than the device dimension [13]. This means that a particle will undergo many collisions along its way through the device. Carriers in a semiconductor at room temperature can be considered a collision-dominated system, for which $\alpha \ll 1$.

The choice of the scaling – hydrodynamic or diffusive – depends on the equilibrium states associated with the collision operator [13, p.47]. Hydrodynamic scaling assumes the characteristic timescale of the system to be

$$t_0 = \frac{\tau_0}{\alpha}. \tag{37.124}$$

This means that we consider a timescale much larger than the collision time. Diffusion scaling assumes the characteristic timescale of the system to be even larger:

$$t_0 = \frac{\tau_0}{\alpha^2} \tag{37.125}$$

In diffusion scaling, the Boltzmann equation for electrons becomes (for parabolic bands)

$$\alpha^2\partial_t f + \alpha\left(\frac{\mathbf{p}}{m}\cdot\nabla_{\mathbf{r}}f - q\,\mathbf{E}\cdot\nabla_{\mathbf{p}}f\right) = C[f]. \tag{37.126}$$

The Boltzmann equation in diffusion scaling can be solved by a Hilbert expansion in the parameter α. This can be used to derive the drift-diffusion equations in a mathematically consistent way (see [13, p.106]). Using diffusion scaling (see [13, p.52]), one obtains that convective terms of the form $\langle\mathbf{v}\rangle\otimes\langle\mathbf{v}\rangle$ are negligible compared to $\langle\mathbf{v}\otimes\mathbf{v}\rangle$. Furthermore, in the diffusion approximation, the drift kinetic energy $\frac{1}{2}m\bar{v}^2$ is neglected against $\frac{3}{2}k_{\mathrm{B}}T_{\mathrm{n}}$, and in the flux equation, the time derivative is ignored. The validity of these assumptions for semiconductor devices is further discussed in Sect. 37.6.1.

37.5.3 Stratton's Approach

Historically, Stratton [8] performed one of the first derivations of an extended system of transport equations. This approach employs a parity decomposition, where the distribution function is split into even and odd parts:

$$f(\mathbf{r},\mathbf{k}) = f^{\mathrm{e}}(\mathbf{r},\mathbf{k}) + f^{\mathrm{o}}(\mathbf{r},\mathbf{k}) \tag{37.127}$$

Because of antisymmetry $f^o(\mathbf{r},-\mathbf{k}) = -f^o(\mathbf{r},\mathbf{k})$, it follows that $\langle f^o\rangle = 0$. Assuming a single microscopic relaxation time approximation for the collision operator

$$C[f] = -\frac{f - f_{\mathrm{eq}}}{\tau(\mathcal{E},\mathbf{r})} \tag{37.128}$$

the Boltzmann equation splits into two coupled equations which allows to express the odd part f^{o} as a function of f^{e} via

$$f^{\mathrm{o}} = -\tau(\mathcal{E}, \mathbf{r})\Big(\mathbf{v}\cdot\nabla_{\mathbf{r}} f^{\mathrm{e}} - \frac{\mathrm{q}}{\hbar}\mathbf{E}\cdot\nabla_{\mathbf{k}} f^{\mathrm{e}}\Big). \tag{37.129}$$

Stratton proposes a power law for the microscopic relaxation time;

$$\tau(\mathcal{E}) = \tau_0\Big(\frac{\mathcal{E}}{k_{\mathrm{B}}T_{\mathrm{L}}}\Big)^{-p_\nu} \tag{37.130}$$

Assuming that f^{e} is a heated Maxwellian distribution, the equation system below is obtained:

$$\nabla\cdot\mathbf{J} = q\partial_t n \tag{37.131}$$

$$\mathbf{J} = q\mu n\mathbf{E} + k_{\mathrm{B}}\nabla(n\mu T_{\mathrm{n}}) \tag{37.132}$$

$$\nabla\cdot\mathbf{S} = -\frac{3}{2}k_{\mathrm{B}}\partial_{\mathrm{t}}(nT_{\mathrm{n}}) + \mathbf{E}\cdot\mathbf{J} - \frac{3}{2}k_{\mathrm{B}}n\frac{T_{\mathrm{n}}-T_{\mathrm{L}}}{\tau_{\mathcal{E}}} \tag{37.133}$$

$$\mathbf{S} = -\Big(\frac{5}{2} - p_\nu\Big)\Big(\mu n k_{\mathrm{B}}T_{\mathrm{n}}\mathbf{E} + \frac{K_{\mathrm{B}}^2}{\mathrm{q}}T_{\mathrm{n}}\nabla(n\mu T_{\mathrm{n}})\Big). \tag{37.134}$$

The inclusion of mobility within the gradient operator in (37.132) is incorrect if doping is not homogeneous and mobility is doping-dependent. In his original paper [8], Stratton discussed a Schottky-barrier junction where doping was assumed to be uniform. This is probably why he included mobility within the gradient operator [53].

Equation (37.132) can be rewritten as

$$\mathbf{J} = q\mu\Big(n\mathbf{E} + \frac{k_{\mathrm{B}}}{q}T_{\mathrm{n}}\nabla n + \frac{k_{\mathrm{B}}}{q}n(1+\nu_{\mathrm{n}})\nabla T_{\mathrm{n}}\Big) \tag{37.135}$$

with

$$\nu_{\mathrm{n}} = \frac{T_{\mathrm{n}}}{\mu}\frac{\partial\mu}{\partial T_{\mathrm{n}}} = \frac{\partial\ln\mu}{\partial\ln T_{\mathrm{n}}} \tag{37.136}$$

which has to be considered a fitting parameter with common values in the range $[-1.0, -0.5]$, since no analytic expression for μ is known. Note that the thermal diffusion term vanishes for $\nu_{\mathrm{n}} = -1.0$.

A problem with the formulation (37.130) for τ is that p_ν has to be approximated in order to cover all scattering processes. Particularly, in the presence of impurity scattering, the parameter p_ν is in the range $[-1.5, 0.5]$, which depends on charge screening [54]. Hence, the average value is dependent on the applied field and on the doping profile, and it is not possible to give a unique value for p_ν.

37.5.4 Bløtekjær's Approach

Without requiring any assumptions on the form of the distribution function, Bløtekjær [9] derived conservation equations by taking the moments of the Boltzmann equation using the weight functions 1, $\hbar\mathbf{k}$, and $\mathcal{E}$, which define the moments of zeroth, first, and second order. The exposition in Sects. 37.4.4 and 37.4.5 is in line with Bløtekjær's approach. The resulting system of equations can be written as follows [34]:

$$\partial_{\mathrm{t}} n + \nabla\cdot(n\bar{\mathbf{v}}) = nC_{\mathrm{n}} \tag{37.137}$$

$$\partial_{\mathrm{t}}(n\bar{\mathbf{p}}) + \nabla\cdot(n\hat{\boldsymbol{U}}) - n\mathbf{F} = n\mathbf{C}_{\mathrm{m}} \tag{37.138}$$

$$\partial_{\mathrm{t}}(nw) + \nabla\cdot\mathbf{S} - n\bar{\mathbf{v}}\cdot\mathbf{F} = nC_{\mathcal{E}} \tag{37.139}$$

Under the assumption that the carrier mass is position-independent, these equations are valid for arbitrary band structures. In the case of a position-dependent mass, additional force terms have to be included in (37.137)–(37.139) [55].

Bløtekjær originally proposed the concept of macroscopic relaxation times introducing one relaxation time for each moment equation:

$$\mathbf{C}_{\mathrm{m}} = -\frac{\bar{\mathbf{p}}}{\tau_{\mathrm{m}}} \tag{37.140}$$

$$C_{\mathcal{E}} = -\frac{w - w_0}{\tau_{\mathcal{E}}} \tag{37.141}$$

which introduces the momentum and energy relaxation times τ_{m} and $\tau_{\mathcal{E}}$, respectively. A discussion of this approximation is given in [56]. Recombination processes are neglected here; thus, $C_{\mathrm{n}} = 0$.

Three-Moment Energy Transport Model

Bløtekjær's system of equations is not closed, because it contains more unknown moments than equations. In order to express the equations by the moments n, $\bar{\mathbf{v}}$, and w (or T_{n}), closure relations have to be introduced.

Customarily, parabolic bands are assumed, and the closure relations (37.91), (37.94), and (37.95) for $\bar{\mathbf{p}}$, $\hat{\boldsymbol{U}}$, and w can be used. In addition, Bløtekjær assumed an isotropic temperature tensor (37.105) and the same phenomenological closure for the highest-order moment as in his hydrodynamic model, i.e., an energy flux based on Fourier's law (37.113) and (37.114). Bløtekjær also used the diffusion approximation as discussed above for the drift-diffusion equation (Sect. 37.5.1). The resulting simplified equations are

$$\nabla\cdot\mathbf{J} = q\partial_t n \tag{37.142}$$

$$\mathbf{J} = \mu k_{\mathrm{B}}\nabla(nT_{\mathrm{n}}) + qn\mu\mathbf{E} \tag{37.143}$$

$$\nabla \cdot \mathbf{S} = -\frac{3}{2}k_\mathrm{B}\partial_\mathrm{t}(nT_\mathrm{n}) + \mathbf{E}\cdot\mathbf{J} - \frac{3}{2}k_\mathrm{B}n\frac{T_\mathrm{n}-T_\mathrm{L}}{\tau_\mathcal{E}} \tag{37.144}$$

$$\mathbf{S} = -\frac{5}{2}\frac{k_\mathrm{B}T_\mathrm{n}}{q}\mathbf{J} - \kappa(T_\mathrm{n})\nabla T_\mathrm{n} \tag{37.145}$$

Equations (37.142)–(37.145) form a typical three-moment model which has been closed using Fourier's law and is commonly known in the literature as energy transport model. Actually, this name is somewhat misleading as the model consists of the two conservation equations (37.142) and (37.144) and the two transport equations (37.143) and (37.145); the latter transport equation is empirical.

In the case of a homogeneous and stationary bulk silicon system, the energy balance equation (37.144) reduces to

$$n\frac{w-w_0}{\tau_\mathcal{E}} = \boldsymbol{E}\cdot\mathbf{J}. \tag{37.146}$$

With

$$w_0 = \frac{3}{2}k_\mathrm{B}T_\mathrm{L} \tag{37.147}$$

$$w = \frac{3}{2}k_\mathrm{B}T_\mathrm{n} \tag{37.148}$$

$$\mathbf{J} = q\mu\boldsymbol{E}n \tag{37.149}$$

one obtains from the homogeneous energy balance equation (37.146) the following relation between the carrier temperature and the electric field [10]:

$$T_\mathrm{n} = T_\mathrm{L} + \frac{2}{3}\frac{\mathrm{q}}{k_\mathrm{B}}\tau_\mathcal{E}\mu E^2 \tag{37.150}$$

The estimated temperature T_n is roughly proportional to the square of the electric field.

Four-Moment Energy Transport Model

To overcome the difficulties associated with the Fourier law closure (37.113) which is empirical and leaves κ undefined, an additional moment equation of the BTE can be taken into account [34]. From (37.101), we have

$$\partial_\mathrm{t}\mathbf{S} + \frac{1}{m}\nabla\cdot n\hat{\boldsymbol{R}} + q\mathbf{E}\Big(\frac{nw}{m} + 2\frac{n\hat{\boldsymbol{U}}}{m}\Big) = -\frac{\mathbf{S}}{\tau_\mathrm{S}}. \tag{37.151}$$

In this equation, the time derivative can be ignored using the same scaling argument that led to a neglect of the time derivative in (37.138). The energy flux mobility is defined in analogy to the mobility as

$$\mu_\mathrm{S} = \frac{q\tau_\mathrm{S}}{m}. \tag{37.152}$$

This gives

$$\mathbf{S} = -\frac{\mu_\mathrm{S}}{q}\Big(\nabla\cdot(n\hat{\boldsymbol{R}}) - qn\mathbf{E}(w+2\hat{\boldsymbol{U}})\Big). \tag{37.153}$$

A closure relation for $\hat{\boldsymbol{R}} = \frac{1}{n}\langle\mathbf{v}\otimes\mathbf{p}\,\boldsymbol{\mathcal{E}}\rangle$ has to be introduced, which can be obtained, for example, by assuming a heated Maxwellian distribution. This gives the Maxwellian closure

$$\hat{\boldsymbol{R}} = \frac{5}{2}k_\mathrm{B}^2T_\mathrm{n}^2\hat{\boldsymbol{I}}. \tag{37.154}$$

Together with the scalar isotropic diffusion approximation

$$(w+2\hat{\boldsymbol{U}}) \approx \frac{5}{2}k_\mathrm{B}T_\mathrm{n} \tag{37.155}$$

one obtains the closure for a four-moment model.

$$\mathbf{S} = -\frac{5}{2}k_\mathrm{B}\frac{\mu_\mathrm{S}}{q}\Big(\nabla(k_\mathrm{B}nT_\mathrm{n}^2) + qnT_\mathrm{n}\mathbf{E}\Big) \tag{37.156}$$

Discussion of Bløtekjær's Closure

The closure (37.156) should be compared with Bløtekjær's phenomenological closure:

$$\mathbf{S} = -\frac{5k_\mathrm{B}T_\mathrm{n}}{2q}\mathbf{J} - \kappa(T_\mathrm{n})\nabla T_\mathrm{n} \tag{37.157}$$

$$\kappa(T_\mathrm{n}) = \Big(\frac{5}{2}-p_\gamma\Big)\Big(\frac{k_\mathrm{B}}{q}\Big)^2 q\mu nT_\mathrm{n}. \tag{37.158}$$

For that purpose, one now rewrites in (37.156)

$$\nabla(nT_\mathrm{n}^2) = T_\mathrm{n}\big(\nabla(nT_\mathrm{n}) + n\nabla T_\mathrm{n}\big). \tag{37.159}$$

Using (37.121) and (37.159), one gets the following expression for the closure (37.156) of the four-moment model:

$$\mathbf{S} = -\frac{5}{2}k_\mathrm{B}T_n\frac{\mu_\mathrm{S}}{q}\Big(k_\mathrm{B}n\nabla T_\mathrm{n} + \frac{\mathbf{J}}{\mu}\Big) \tag{37.160}$$

The last form allows for a direct comparison with Bløtekjær's phenomenological closure. From (37.160), it follows that Bløtekjær's closure and the four-moment closure become identical if $\mu_\mathrm{S}/\mu = 1$ and $p_\gamma = 0$ in the three-moment model. However, Monte Carlo simulations show that the ratio μ_S/μ strongly depends on the average energy and shows a pronounced hysteresis, when plotted over the average energy as shown in Fig. 37.4a. Similar observations can be made for the electron mobility [34], which is shown in Fig. 37.4b. In essence, this implies that neither μ nor μ_S can be accurately expressed as a function of w or T_n.

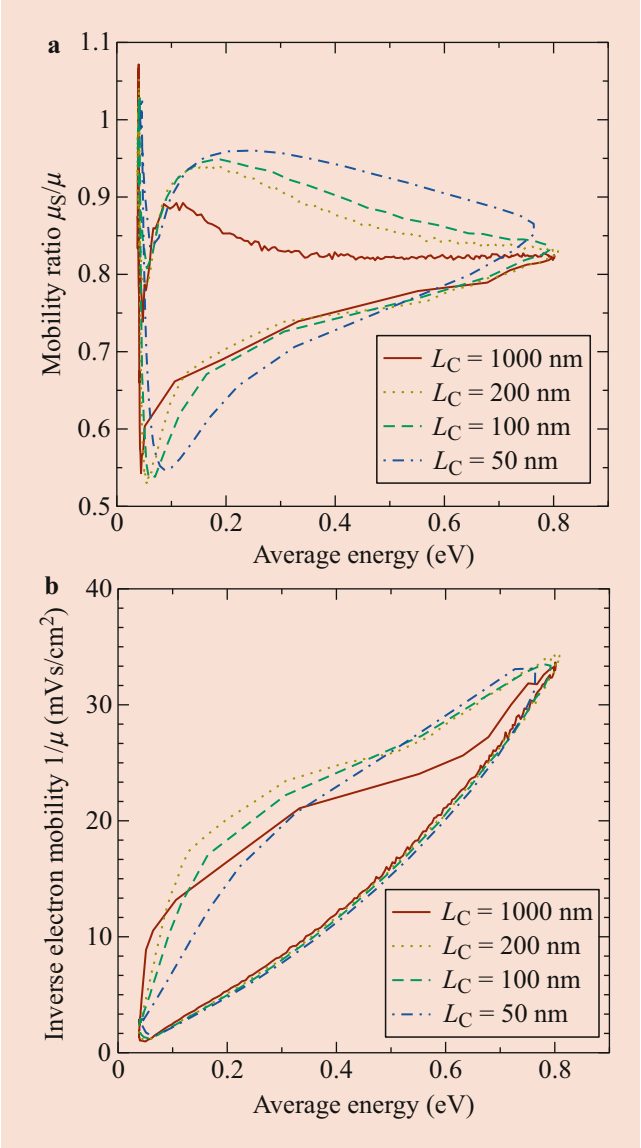

Fig. 37.4 (**a**) Ratio of μ_S and μ as a function of the carrier temperature inside the n^+nn^+ test structures obtained from Monte Carlo simulations. (**b**) Electron mobility inside n^+nn^+ test structures obtained from Monte Carlo simulations

37.5.5 Relaxation Times and Carrier Mobilities

Due to the scattering operator in Boltzmann's equation, the relaxation times and mobilities depend on the distribution function. Since the distribution function is not uniquely determined by the average energy, models only based on the average energy are bound to fail. Furthermore, the band structure can play a dominant role. Nevertheless, all models should be able to correctly reproduce the homogeneous limit for which there is a unique relationship between the electric field and the carrier temperature. Hence, the relaxation times and the mobilities are often derived from homogeneous field measurements or Monte Carlo simulations. In the following, the most commonly used analytical transport parameter models for silicon are discussed. Table-based parameter modeling is discussed later in Sect. 37.7.3.

Mobility

Two models for the energy dependence of the mobility are frequently used, the model after Baccarani and Wordeman [57]:

$$\frac{\mu(T_\mathrm{n})}{\mu_0} = \frac{T_\mathrm{L}}{T_\mathrm{n}} \tag{37.161}$$

and the one-dimensional model going back to Hänsch [58]:

$$\frac{\mu(T_\mathrm{n})}{\mu_0} = \left(1 - \frac{3}{2}\frac{\mu_0}{\tau_\mathcal{E} v_\mathrm{s}^2}\left(\frac{k_\mathrm{B}T_\mathrm{L}}{\mathrm{q}} - \frac{2}{5}\frac{nS}{J}\right)\right)^{-1}. \tag{37.162}$$

Here, μ_0 is the zero-field mobility.

Under homogeneous conditions, the energy flux is proportional to the particle current:

$$\mathbf{S} = \frac{5}{2}\frac{k_\mathrm{B}T_\mathrm{n}}{q}\mathbf{J} \tag{37.163}$$

which can be used to simplify (37.162) to

$$\frac{\mu(T_\mathrm{n})}{\mu_0} = \left(1 + \frac{3}{2}\frac{\mu_0 k_\mathrm{B}}{q\tau_\mathcal{E} v_\mathrm{s}^2}\left(T_\mathrm{n} - T_\mathrm{L}\right)\right)^{-1}. \tag{37.164}$$

As has been shown in [34,59], expression (37.164) reproduces the mobility quite well in the regions with increasing **E**. However, for decreasing **E**, equation (37.162) should be used [34, 60], which, unfortunately, is numerically very difficult due to the vector-valued fluxes **J** and **S**, particularly in two or three dimensions.

In Fig. 37.5, the three models are compared with parameters extracted from Monte Carlo simulation data. All models have been evaluated using the data from the Monte Carlo simulation for an n^+nn^+ test structure with $L_\mathrm{c} = 200\,\mathrm{nm}$, once with $E_\mathrm{max} = 100\,\mathrm{kV/cm}$ and once with $E_\mathrm{max} = 300\,\mathrm{kV/cm}$. For electric fields smaller than 100 kV/cm, equation (37.162) gives reasonable results but breaks down for larger electric fields. Equation (37.162) is the only model that captures the hysteresis properly and, shown in Fig. 37.5a, thus the mobility at the beginning of the drain region. The hysteresis in the other models stems from the doping dependence of μ_0.

Energy Relaxation Time

The simplest and most commonly used model for the energy relaxation time $\tau_\mathcal{E}$ is a constant value. Typically used values for electrons in silicon at room temperature are in the range [0.3, 0.4 ps], although values in the range [0.08, 0.68 ps] have been used [61]. A constant value is justified in view of the fact

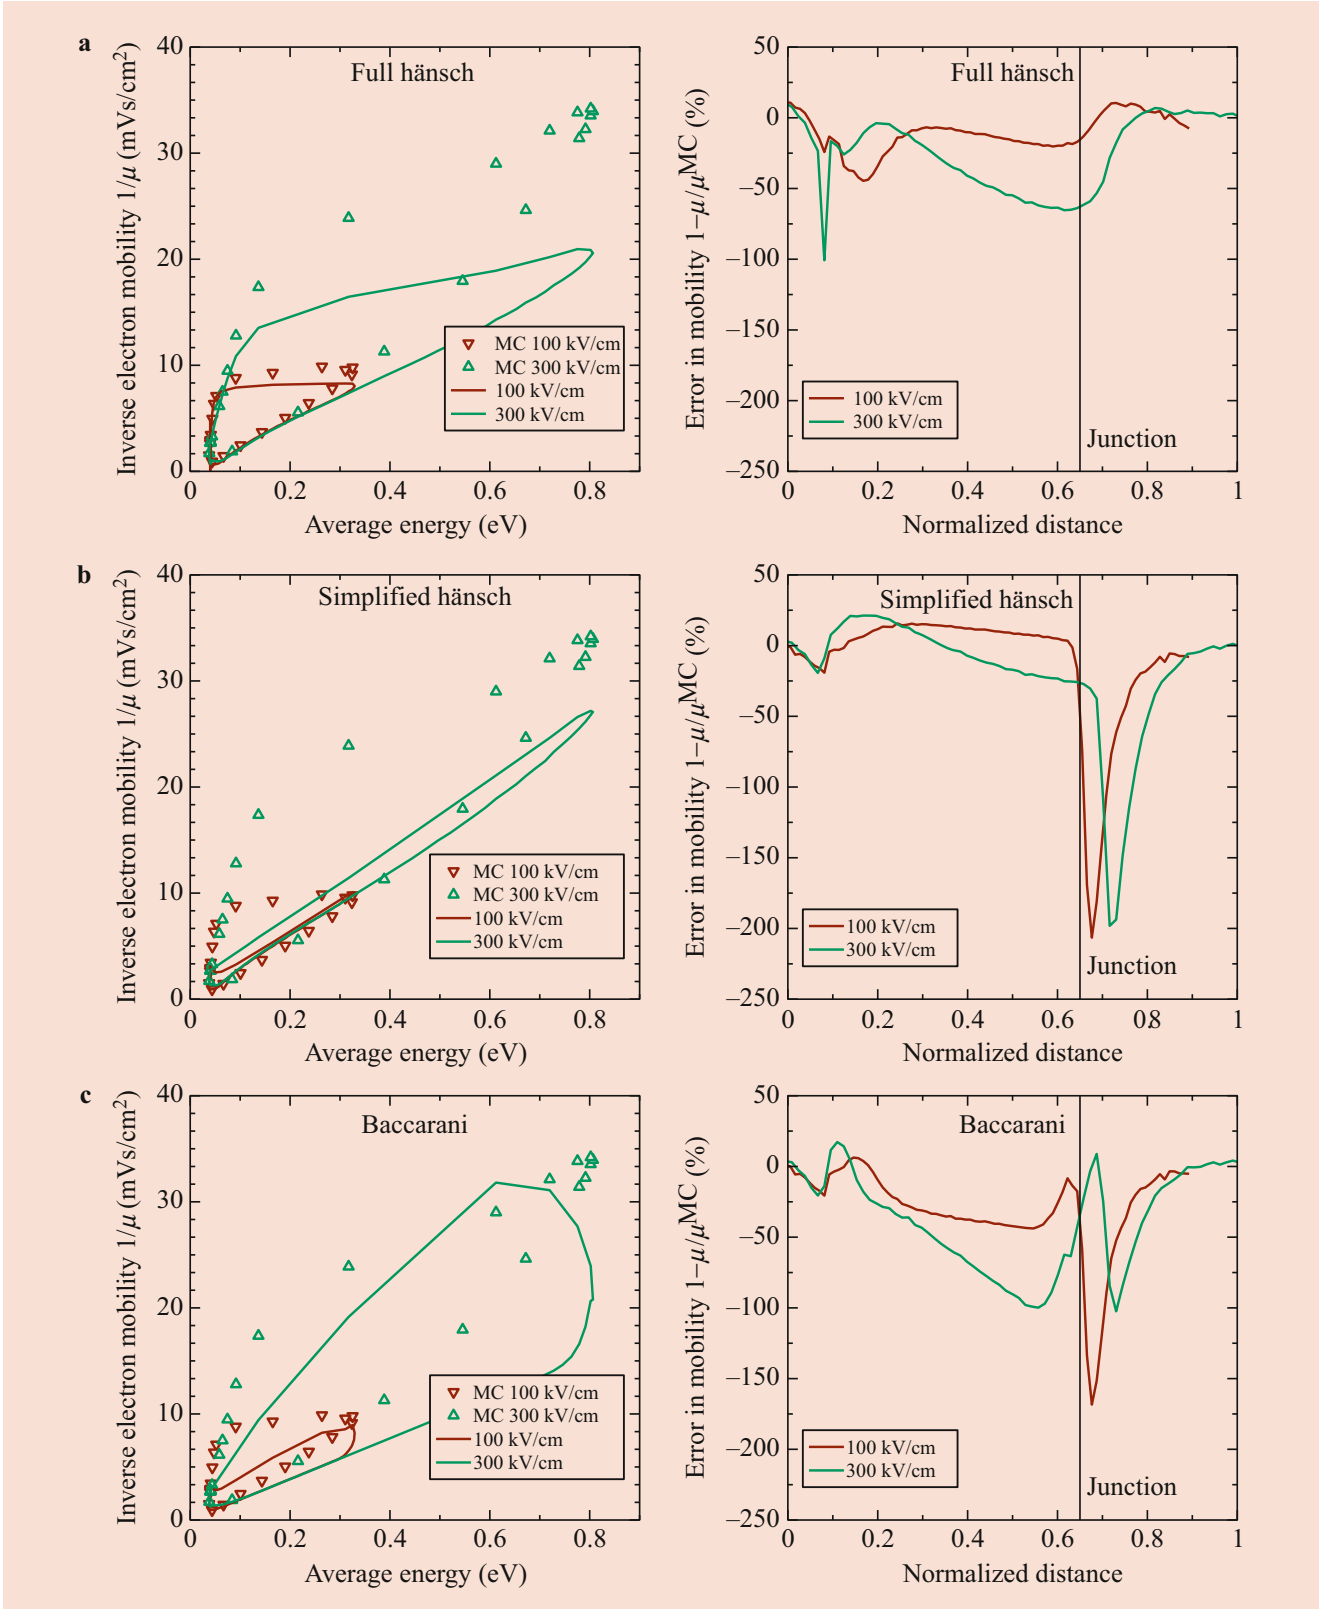

Fig. 37.5 Comparison of the full Hänsch model (**a**), simplified Hänsch model (**b**) and Baccarani mobility model (**c**). The three different mobility models (solid lines) are plotted in contrast to Monte Carlo simulation data (symbols). Only the full Hänsch model (37.162) covers the hysteresis appropriately, at least for lower fields

that Monte Carlo simulations show only a small hysteresis and a small energy dependence [62]. However, different energy dependencies have been published. The differences seem to originate from the different band structures employed in the various Monte Carlo simulation codes.

Based on theoretical considerations, Baccarani and Wordeman [57] proposed the expression

$$\tau_{\mathcal{E}}(T_\mathrm{n}) = \frac{3}{2}\frac{k_\mathrm{B}\mu_0}{qv_\mathrm{s}^2}\frac{T_\mathrm{n}T_\mathrm{L}}{T_\mathrm{n}+T_\mathrm{L}} + \frac{m\mu_0}{2q}\frac{T_\mathrm{n}}{T_\mathrm{L}} \tag{37.165}$$

which should be used together with (37.161) to correctly reproduce the homogeneous limit. Within Hänsch's approach, $\tau_{\mathcal{E}}$ is only required to be independent of the carrier temperature for (37.162) to correctly predict the homogeneous limit. When

$$\tau_{\mathcal{E}} = \frac{3}{2}\frac{k_\mathrm{B}\mu_0 T_\mathrm{L}}{qv_\mathrm{s}^2} \tag{37.166}$$

is used in the Hänsch mobility models (37.162) and (37.164), the models are equivalent to Baccarani's model in the homogeneous case.

37.5.6 Bløtekjær Versus Stratton Approach

Stratton's closure (37.134) is quite different from the four-moment closure (37.156), and it is not clear if both models can be made consistent with each other by a special choice of parameters. A thoroughly discussed difference between Bløtekjær's approach and Stratton's approach is the position of the mobility relative to the gradient in the current relation:

$$\begin{aligned}\text{Bløtekjær}: &\ \mu_1\nabla(nT_\mathrm{n})\\ \text{Stratton}: &\ \nabla(n\mu_2 T_\mathrm{n})\end{aligned}$$

Stratton himself has addressed this issue in [63], and it has also been discussed by Landsberg [64,65]. Further comparisons of the two formulations are given in [60,66–69]. In both formulations, the parameters μ_1 and μ_2 are called mobilities, but these parameters actually differ substantially in their definition. The formulations are compared in [60], and both approaches can be justified if the respective mobilities are modeled properly. The mobilities are equal in the case of bulk simulations and are suitably expressed using energy-dependent models [20,58]. However, in the nonhomogeneous case where the electric field changes abruptly, the mobilities are no longer a single-valued function of the temperature.

The formulation based on μ_1 has the advantage that it can be approximated by its bulk value for increasing values of the electric field, whereas the value of μ_2 is always different from the bulk case. Hence, μ_1 is more useful for numerical simulation as it can be approximately modeled as a function of the temperature. Using an empirical ansatz for $\mathbf{C}_\mathrm{m}$, namely

$$\mathbf{C}_\mathrm{m} = \mathbf{C}_\mathrm{m}^* + \lambda_\mathrm{p}\nabla\cdot\hat{\boldsymbol{U}} \tag{37.167}$$

where λ_p is a dimensionless transport coefficient and $\mathbf{C}_\mathrm{m}^*$ is the homogeneous component, Tang et al. [62] demonstrated that the formulation of Stratton is obtained from Bløtekjær's with $\lambda_\mathrm{p} = \eta_\mathrm{n}$, where

$$\eta_\mathrm{n} = -\frac{T_\mathrm{n}}{\mu^*}\frac{\partial\mu^*}{\partial T_\mathrm{n}}. \tag{37.168}$$

In this expression, $\mu^* = \mu^*(T_\mathrm{n})$ is the bulk mobility which is representable as a function of the temperature. The variable η_n, as given by (37.168), is analogous to $-\nu_\mathrm{n}$, given by (37.136) in the Stratton model. However, by comparing Monte Carlo simulation results, it has been demonstrated that $\lambda_\mathrm{p} \neq \eta_\mathrm{n}$ in the inhomogeneous case [70].

37.6 Limits of Validity for Drift-Diffusion and Energy Transport Models

The range of validity for macroscopic models such as drift-diffusion and energy transport models has been extensively examined [71,72]. When the critical dimensions of devices shrink below a certain value (around 200 nm for silicon at room temperature), Monte Carlo simulations reveal strong off-equilibrium transport effects such as velocity overshoot and nonlocality of important model parameters.

In this section, we start with a discussion of the simplifying assumptions used in the previous sections to derive numerically feasible transport models from the Boltzmann equation.

Then we study energy distribution functions for one-dimensional $\mathrm{n}^+\mathrm{nn}^+$ test structures. Energy transport models use up to four moments of the distribution function, while the highest even moment included is the temperature. Based on Monte Carlo simulation results, it is demonstrated that below 100 nm the energy distribution function strongly deviates from a Maxwellian shape in test structures.

Finally, we compare results from a drift-diffusion model and an energy transport model with Monte Carlo simulation data. In contrast to the drift-diffusion model, higher-order models such as the energy transport model can describe nonlocal effects such as the velocity overshoot as they can make use of the information available in the additional moments.

37.6.1 Critical Issues

The moment-based hydrodynamic and energy transport models given in the previous sections are based on various sim-

plifying assumptions and employ several approximations of different severity. These approximations are crucial to derive numerically feasible models, and they will be discussed in the following.

Non-parabolic Band Structure

Many employed models are based on the single effective parabolic band model. Due to its simplicity, a closed-form solution for the single effective parabolic band model exists, while, even for the relatively simple non-parabolicity correction model by Kane [30], it is not possible to obtain a closed-form representation of the moment equations. Non-analytic table-based correction-terms describing non-parabolicity can be added to macroscopic transport models [73, 74].

Tensor Quantities and Anisotropy

So far we have barely discussed the assumption of isotropic symmetry used in the approximation of tensors by scalar quantities like the carrier mass and temperature. This type of simplification is used in both hydrodynamic and energy transport models.

One-dimensional simulations carried out in [34] demonstrate that the transverse temperature component T_{yy} is smaller than the longitudinal temperature component T_{xx}. This is an indicator that there is an elongation of the distribution function in the direction of the electric field and hence the assumed isotropic symmetry of the energy tensor is not valid (Fig. 37.6). The rigorous approach taken in [75] models all components of the temperature tensor. For ballistic diodes and bipolar transistors, no substantial difference between the scalar temperature and the trace of the temperature tensor is found. In contrast, a difference of up to 15% in the linear region of the transfer characteristics is observed for aggressively scaled MOSFETs.

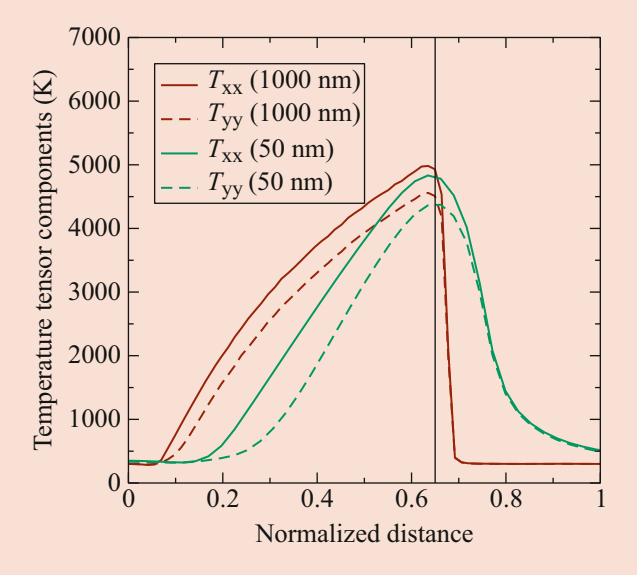

Fig. 37.6 Main components of the temperature tensor $\hat{\boldsymbol{T}}$ for two different n^+nn^+ test structures

Drift Energy Versus Thermal Energy

Another common approximation [76] is to neglect the drift kinetic energy in the average carrier energy:

$$w = \frac{1}{2}m\bar{v}^2 + \frac{3}{2}k_\mathrm{B}T_\mathrm{n} \approx \frac{3}{2}k_\mathrm{B}T_\mathrm{n}. \tag{37.169}$$

However, as has been pointed out by Baccarani and Wordeman [57], the convective energy can reach values comparable to the thermal energy. A plot of the ratio

$$\frac{\frac{1}{2}m\bar{v}^2}{\langle \mathcal{E} \rangle} \tag{37.170}$$

inside n^+nn^+ test structures is given in Fig. 37.7a. As can be seen, the error introduced by neglecting the kinetic energy can reach 30% at the beginning of the channel where the carrier temperature is still low and a velocity overshoot is observed. This effect has been studied in [57, 77].

When looking at the moment equations, it can be seen that not only the absolute value of the convective energy but also its gradient is important. A plot of the ratio

$$\frac{\nabla \frac{1}{2}m\bar{v}^2}{\nabla \langle \mathcal{E} \rangle} \tag{37.171}$$

based on one-dimensional data is given in Fig. 37.7b which indicates that this term becomes increasingly important for nanoscale devices. In particular, pronounced spikes are observed at both junctions.

Highest-Order Moment Closure

The equation of highest order contains the moment of the next order which has to be suitably approximated using available information, typically the lower-order moments. As the lower-order equations remain unchanged by this choice, it is worth noting that the whole information about the remaining higher-order equations has to be packed into this closure.

One approach to derive a suitable closure relation is to assume a distribution function and calculate the fourth-order moment. Typically, a heated Maxwellian distribution is assumed [10]. This assumption is problematic, because it only uses partial, and in general insufficient, information about the distribution function.

Mobilities and Relaxation Times

Particularly in the diffusion-dominant regime, the scattering operator is dominant in the Boltzmann equation and must be modeled with sufficient care [13]. The physical mecha-

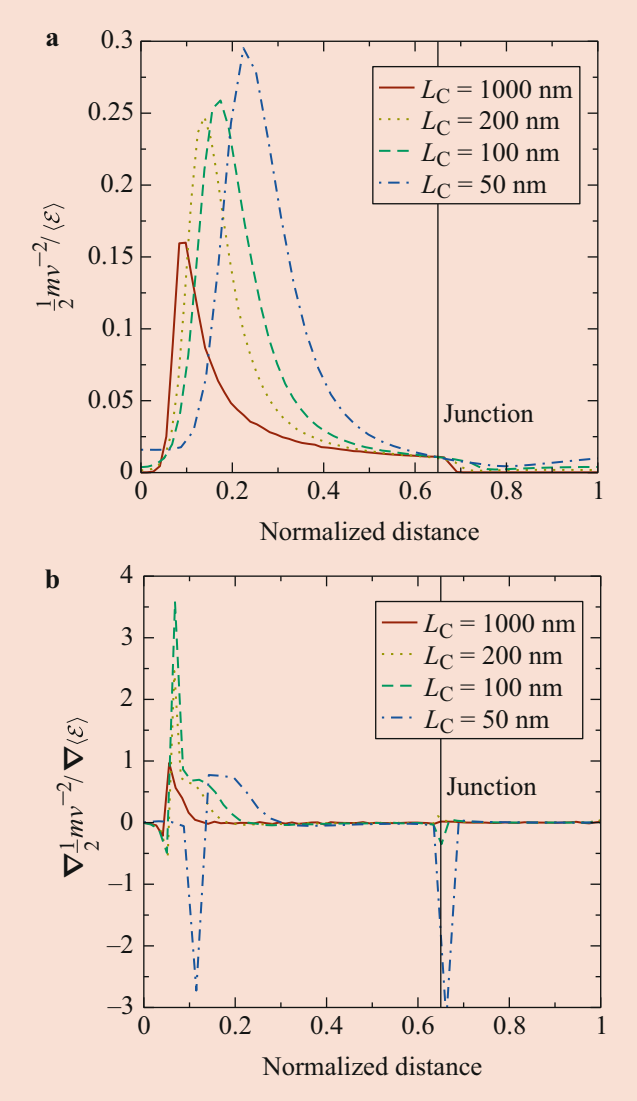

Fig. 37.7 The ratio of $m\bar{v}^2/2$ and $\langle\mathcal{E}\rangle$ and the ratio of the gradients for different n^+nn^+ test structures

nisms behind scattering are typically described using Fermi's golden rule. Using macroscopic transport models, scattering is approximated by transport parameters such as mobilities and relaxation times. From the Boltzmann equation, it is clear that these parameters depend on the full distribution function through the collision operator. Since the distribution function is not uniquely described by the average energy, models based solely on the average energy have limited validity particularly at the drain side of MOSFETs. However, from a practical perspective, this is the only viable option found so far. In order to increase their accuracy, table-based models depending on doping, temperature, and carrier energy can be extracted from bulk Monte Carlo simulations, which is discussed in Sect. 37.7.3.

Complexity of Models

Modeling of carrier transport is far more complex than can be described in this work. Accurate, but complex models for a lot of physical effects from different domains are available. To give just one example, we have hardly discussed the intricacies of carrier generation and recombination. But practical engineering approaches will often rely on fitted analytical models. Models must also be numerically feasible, and one has to compromise between numerical costs and physical sophistication. Handling the trade-off between model accuracy and numerical costs is the craft of technology computer-aided design.

37.6.2 Non-Maxwellian Energy Distribution

Test structures with n^+nn^+ topology exhibit similar features as a MOSFET or a bipolar transistor like, e.g., a distinctive velocity overshoot and a mixture of a hot and a cold distribution in the drain region. As such, given their simplicity, they have been very popular for the study of the basic behavior of macroscopic transport models for very small devices within n^+nn^+ structures without the additional levels of complexity introduced by two-dimensional MOS devices [73, 78].

Qualitative Analysis

Monte Carlo simulations indicate that the shape of the distribution function inside an n^+nn^+ test structure behaves qualitatively as shown in Fig. 37.8.

For cold carriers injected at the contacts, the Maxwellian shape provides a good description. In Region I, carriers diffuse against the built-in energy barrier. While moving along Region I, the amount of low-energy carriers in the distribution function decreases due to reflection at the energy barrier. Therefore, unlike predicted by the Maxwellian approximation, only the low-energy range of the energy distribution is filtered out, whereas nearly no changes in the high-energy tail are observed.

It is interesting to note that inside the channel the slope in the low-energy range is almost the same as at the end of the channel. However, the knee energy E_1, which is the energy of the kink between different slopes of the distribution function, changes. It shifts toward higher energies as the carriers travel through the channel in Region II.

In Region III, the small number of hot carriers from the channel meets the large pool of cold carriers in the drain, which is visible in the distribution function by a rapid increase of the low-energy part. Region III is very small, and there is little change in the high-energy tail. As the hot carriers travel through Region IV, the temperature of the high-energy tail relaxes to the equilibrium temperature.

It will be argued in Sect. 37.7.2 that the kurtosis β of the distribution function, which is defined as the fourth-

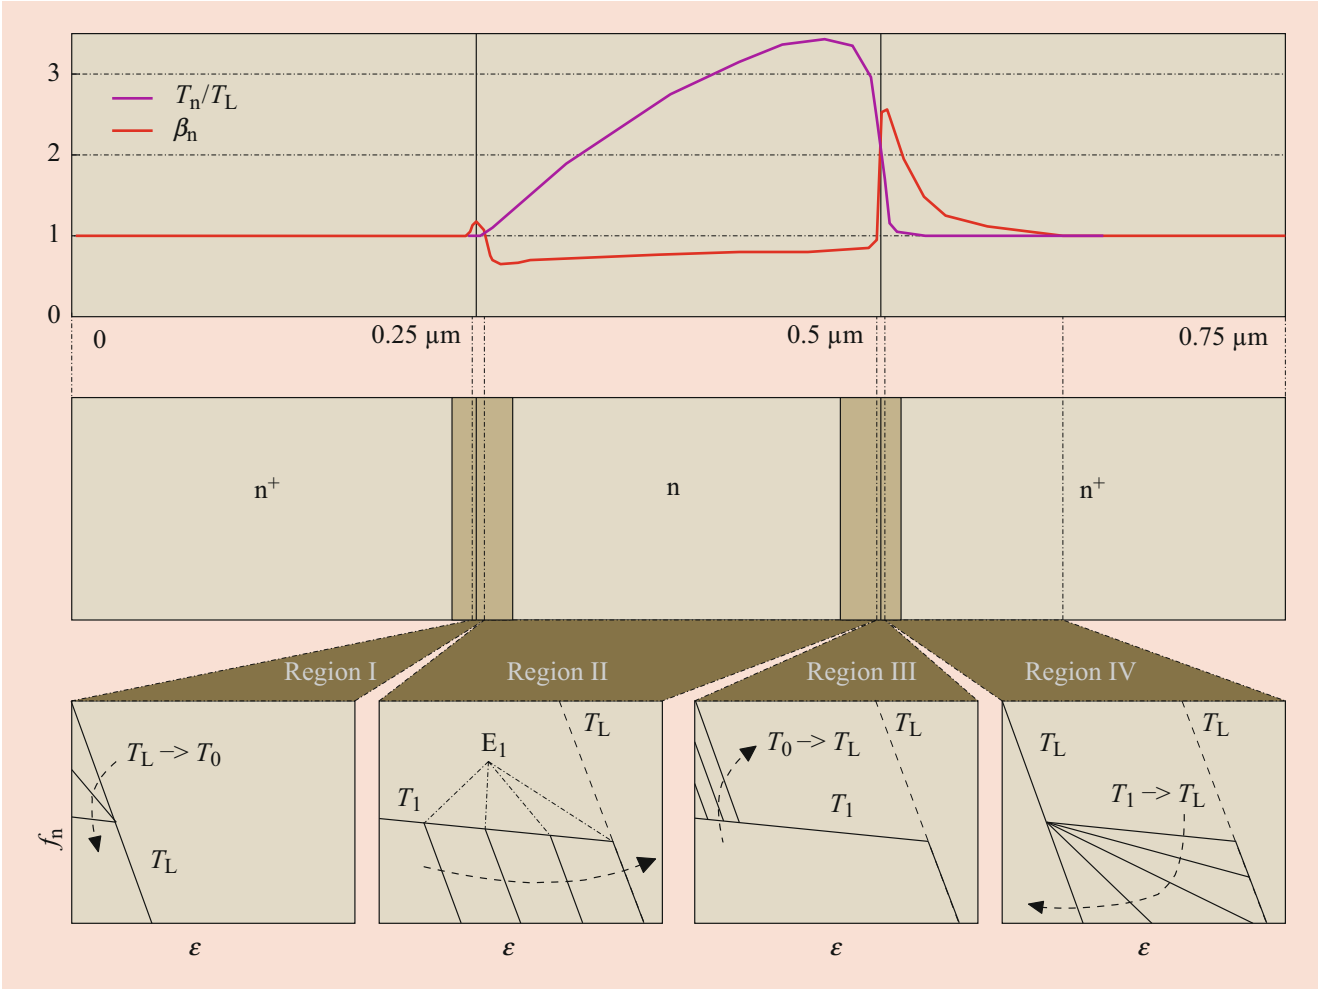

Fig. 37.8 Schematic evolution of the distribution function inside an n^+nn^+ test structure

order standardized moment, provides enough information to distinguish between different regions of the test structure. This provides the basis for the development of more accurate models.

Shape of the Distribution Function

The transport models discussed so far only contain moments up to, and including at most, the third order. In general, the distribution function is insufficiently described by these moments. The only even moments available are the zeroth- and the second-order moment which correspond to particle density and average energy. These moments are the parameters of a heated Maxwell distribution function which often gives only a poor approximation to the actual energy distribution.

This is demonstrated for an n^+nn^+ test structure with $L_c = 200\,\text{nm}$ in Fig. 37.9. Here, the energy distribution function, which is obtained from Monte Carlo simulations, is shown for four characteristic points inside the structure. For points A and C, which have the same average energy, the distribution function is completely different. In particular, the mixture of a cold and a hot-carrier population leads to an inadequate description via the average carrier energy. In such cases, the extension of the energy transport model to a six-moment transport model (see Sect. 37.7.2) increases the accuracy significantly.

A heated Maxwellian distribution neither captures the basic shape of the energy distribution function nor the change in the shape when the end of the channel is reached. This is shown in Fig. 37.10 where the failure of the Maxwellian approximation is obvious. The error is largest for high energetic carriers where the tail of the distribution function is severely either overestimated or underestimated.

The importance of the high-energy tail increases with decreasing channel length. This issue becomes crucial for modeling short-channel and hot-carrier effects, e.g., for gate tunneling or hot-carrier degradation, which will be discussed in Sect. 37.8.3.

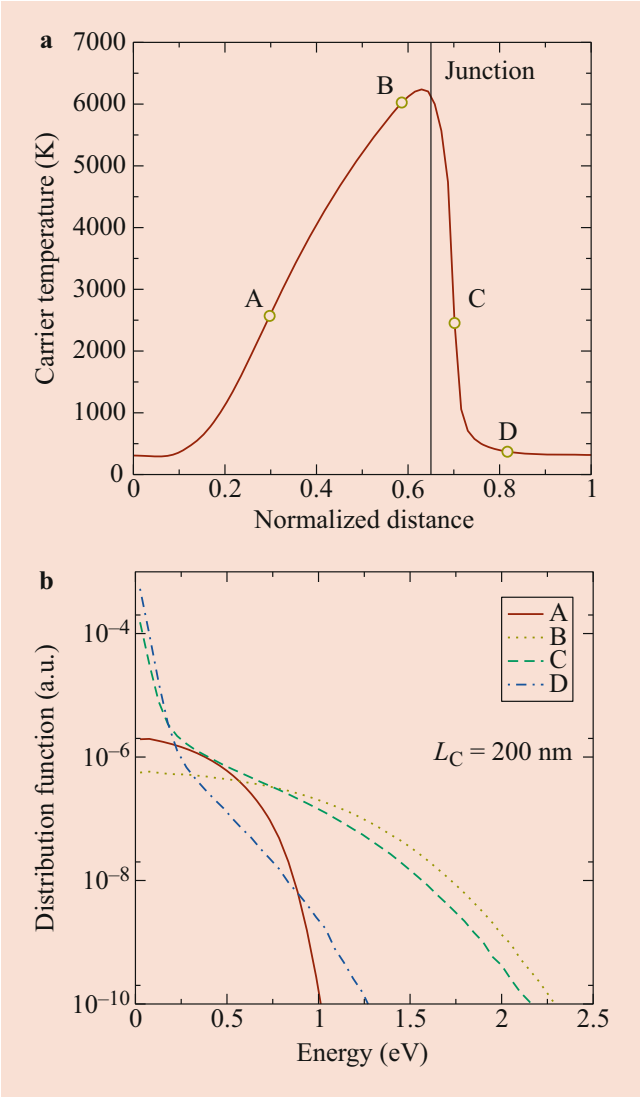

Fig. 37.9 Electron temperature (**a**) and distribution functions (**b**) at four characteristic points inside an n^+nn^+ test structure with L_c = 200 nm. The average energies at points A and C are the same, whereas the distribution function looks completely different. Note the high-energy tail at point D where the carrier temperature is 370 K

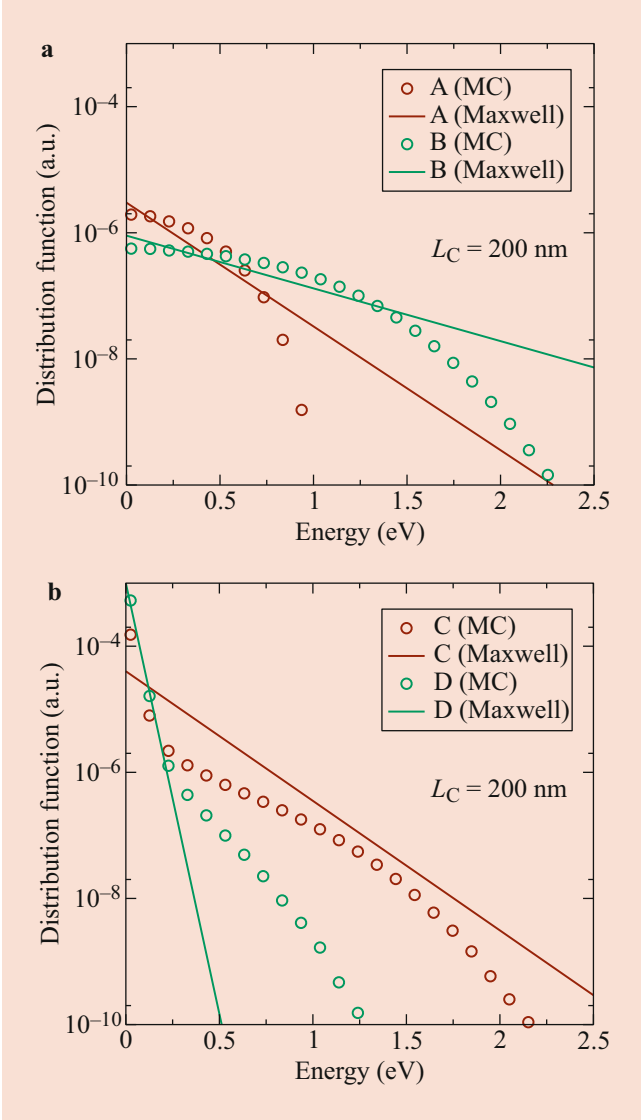

Fig. 37.10 The heated Maxwellian distribution approximation at the four characteristic points of Fig. 37.9. (**a**) Inside the channel, the number of hot electrons is dramatically overestimated because the Maxwell distribution cannot reproduce the thermal tail. (**b**) Inside the drain region, a cold and a hot population are visible, which cannot be resolved with a single Maxwell distribution

37.6.3 Numerical Evaluation

In order to check the validity of the drift-diffusion and energy transport models, we compare simulations of MOS transistors as a function of the channel length.

Modeling of Velocity Overshoot

The carrier velocity in most devices operating near room temperature and under modest bias condition is always limited by scattering. For constant or slowly varying electric fields, carriers cannot go beyond a certain saturation velocity $v_{sat} = 10^7$ cm/s. However, as demonstrated in Fig. 37.11, for short-channel devices, the situation is different. As the channel length decreases, the gradient of the electric field inside the device increases as well. Thus, the carriers will be accelerated without colliding with the lattice ($T_n = T_L$) for at least a few picoseconds. Therefore, the random component of the carrier velocity induced by scattering events is small, which leads to a maximum drift velocity in the range of 10^7 cm/s to 10^8 cm/s [79]. This is known as the velocity overshoot.

In the energy transport model, T_n is an independent solution variable, while in the drift-diffusion model, T_n is only estimated through a local relationship via the electric field. Neglecting diffusion, the velocity follows the mobility as $\bar{v} =$

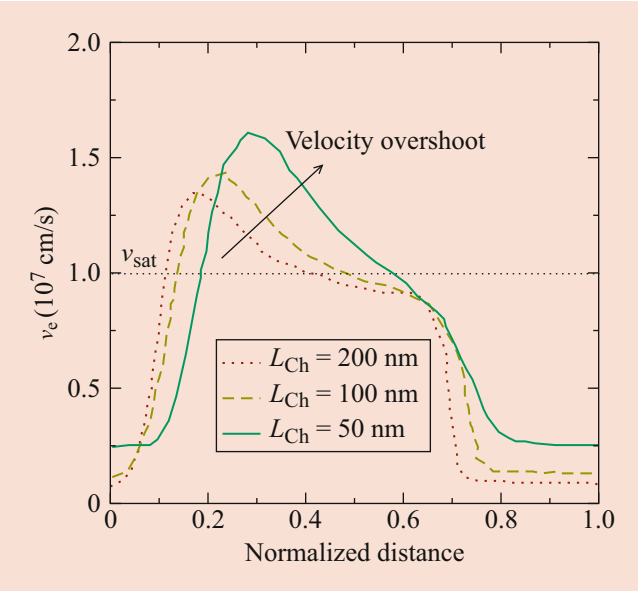

Fig. 37.11 Velocity profiles of a 50 nm, 100 nm, and 200 nm long n^+nn^+ structure calculated with the Monte Carlo method are presented after [10]. The velocity overshoot at the beginning of the lowly doped n-region is clearly visible

μE. Commonly used analytical models for carrier mobilities in the energy transport and drift-diffusion models are given as

$$\text{Energy transport model: } \mu = \mu_0 \frac{T_\mathrm{L}}{T_\mathrm{n}}$$

$$\text{Drift} - \text{diffusion model: } \mu = \mu_0 \frac{1}{1 + \frac{E}{E_\mathrm{crit}}}.$$

Here $E_\mathrm{crit} \approx 10\,\mathrm{kV/cm}$ is the critical field and μ_0 is the zero-field mobility. With this simple model, the velocity in the drift-diffusion model saturates at $v_\mathrm{sat} = \mu_0 E_\mathrm{crit}$.

The drift-diffusion mobility follows the field, while the energy transport mobility follows the temperature. Comparing models, we see that the drift-diffusion mobility model estimates the electron temperature via the electric field as

$$T_\mathrm{n} = T_\mathrm{L}(1 + E/E_\mathrm{crit}). \tag{37.172}$$

In reality, however, the response of the distribution f to the electric field is delayed, because carriers need time to pick up the energy from the field.

As a consequence, this can result in an overshoot in the carrier velocity for rapidly varying electric fields. The reason for this velocity overshoot is that the mobility depends on distribution function rather than on the electric field. As the mobility has not yet been reduced by the increasing temperature but the electric field is already high, an overshoot in the velocity $\bar{v} = \mu E$ is observed until the carrier energy comes into equilibrium with the electric field again. One of the first works dealing with this effect is [80]. Such nonlocal effects cannot be properly modeled using the common drift-diffusion transport model.

Limitations of the Drift-Diffusion Model

It was found in [71] through a comparison with Monte Carlo simulations that relaxation time-based models tend to overestimate nonstationary carrier dynamics, especially the energy distribution.

Figure 37.12 compares the drift-diffusion estimate for temperature with results from Monte Carlo simulations for various MOS transistors. The gate length varies from 1000 nm (Fig. 37.12a) down to 100 nm (Fig. 37.12d). These and other simulation results demonstrate that the drift-diffusion model is a good approximation down to a gate length of about 250 nm but becomes increasingly inaccurate below. At shorter gate lengths, the carrier energy does no longer directly follow the field. In most regions, the temperature is overestimated by the drift-diffusion model. In some parts, it is also underestimated.

For the same MOS transistors as before, we also compare the velocity between the drift-diffusion model and results from Monte Carlo simulations (see Fig. 37.13). The critical gate length for this example is $L_\mathrm{G} \approx 350\,\mathrm{nm}$ (Fig. 37.13b). At 100 nm (Fig. 37.13d), one can see a significant velocity overshoot in a large portion of the channel. This velocity overshoot is not modeled correctly by the drift-diffusion model where the velocity is bounded by v_sat.

Drift-Diffusion Versus Energy Transport

Banoo and Lundstrom [72] compared the results obtained by (37.142)–(37.145) with a drift-diffusion model and a solution of the BTE obtained by using the scattering matrix approach. They found that the used variant of the energy transport model dramatically overestimates both the drain current and the velocity inside the device.

Figure 37.14 shows the IV characteristics from drift-diffusion and energy transport models and compares them with Monte Carlo simulation results. For long-channel devices with $L_\mathrm{G} \approx 1\,\mu\mathrm{m}$, all models yield the same results (not shown here). At 250 nm (Fig. 37.14a), the models are still close. For submicron devices with $L_\mathrm{G} \approx 100\,\mathrm{nm}$ (Fig. 37.13b), the energy transport model is closer to Monte Carlo simulation results. For short-channel devices with $L_\mathrm{G} \approx 50\,\mathrm{nm}$ (Fig. 37.14c), the energy transport model overestimates the current. In Fig. 37.14d at a channel length of $L_\mathrm{G} \approx 25\,\mathrm{nm}$, the drift-diffusion is even better than the energy transport model.

To better understand this behavior, one may look at the distributed quantities inside the transistor, for instance, the velocity profile. Figure 37.15a shows the velocity profile for a channel length of 250 nm Fig. 37.15b, for 50 nm, and Fig. 37.15c for and 25 nm, respectively. While the velocity in

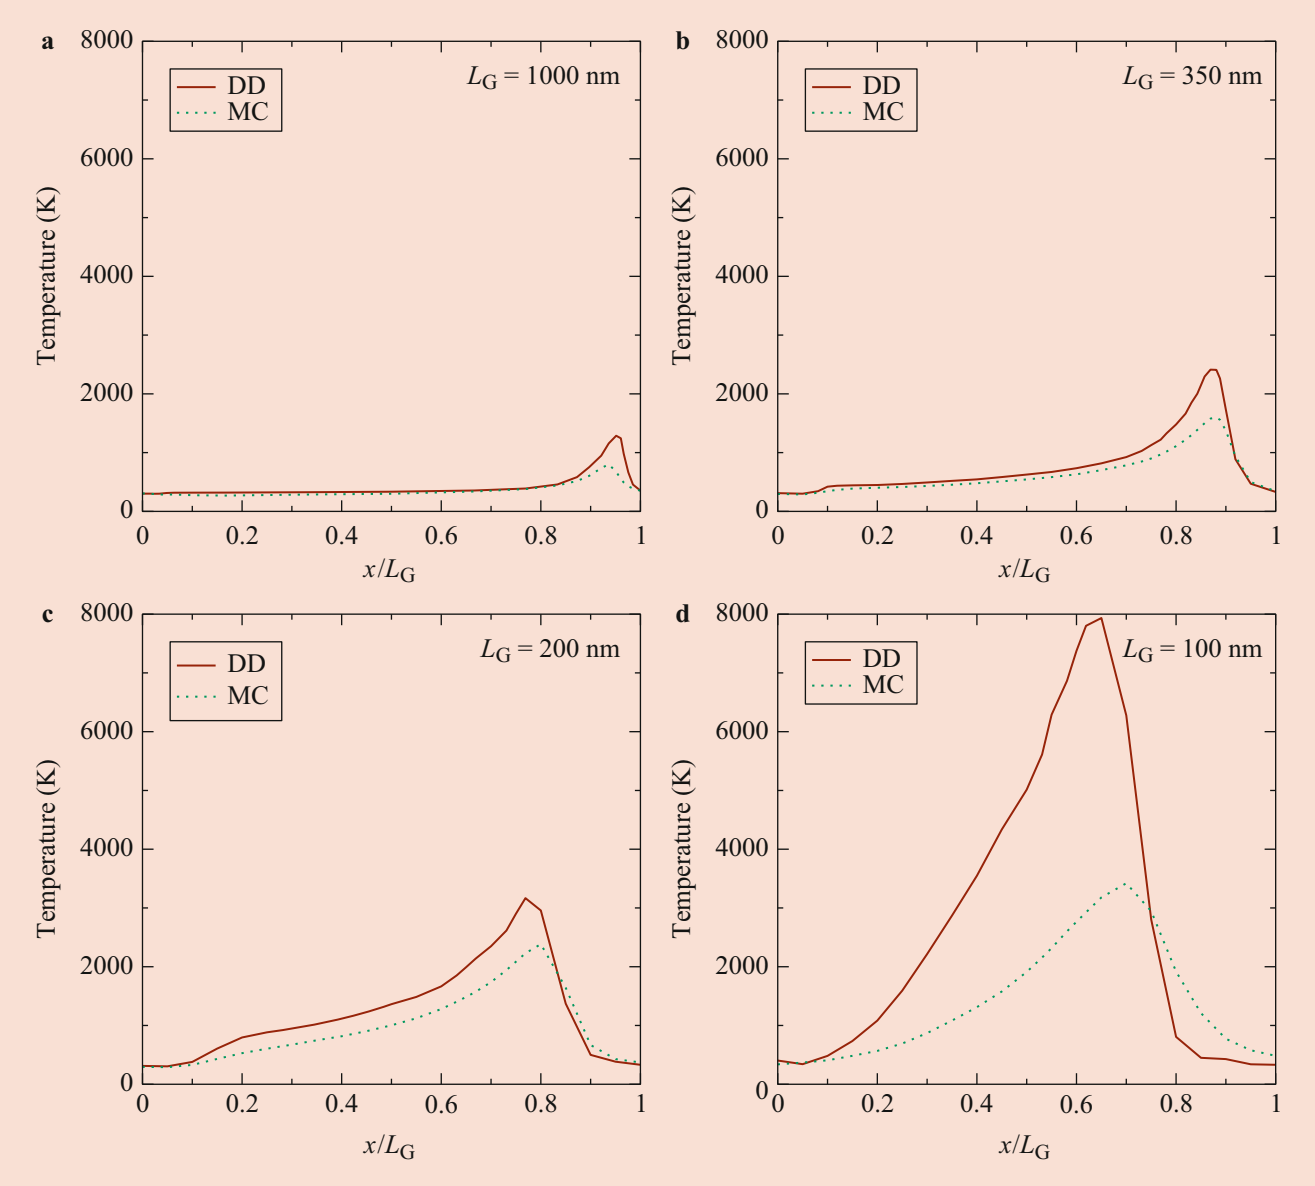

Fig. 37.12 Comparison of temperature approximated within the drift-diffusion model with Monte Carlo simulation results for MOSFETs with gate lengths of 1000 nm (**a**), 350 nm (**b**), 200 nm (**c**), and 100 nm (**d**). Drift-diffusion results provide a reasonable approximation till a gate length of 200 nm

the drift-diffusion model is always bounded, the Monte Carlo simulation results show a velocity overshoot. This is quite well matched in the energy transport model at 250 nm. However, at shorter-channel lengths, the velocity is overestimated in the energy transport model, and at 25 nm, the velocity profile of the energy transport model is far off from Monte Carlo simulation results.

Spurious Velocity Overshoot

Compared to drift-diffusion models, energy transport models have advantages concerning the modeling of velocity overshoot in the main channel region. However, when the electric field decreases rapidly, these models also tend to show a nonphysical (spurious) velocity overshoot. This is the case, for instance, at the end of the channel of a MOSFET. The same effect is more pronounced in n^+nn^+ test structures (see Sect. 37.8.1 for more simulation results). Models based on Bløtekjær's approach have been frequently associated with such nonplausible spikes in the velocity characteristics which do not occur in Monte Carlo simulations. Since the velocity overshoot at the end of the channel is not observed by Monte Carlo simulations, this effect is known as the spurious velocity overshoot (SVO) [81–83].

In [34], this spurious velocity overshoot is investigated using different mobility models. It is found that improved results are possible when proper mobility models are used.

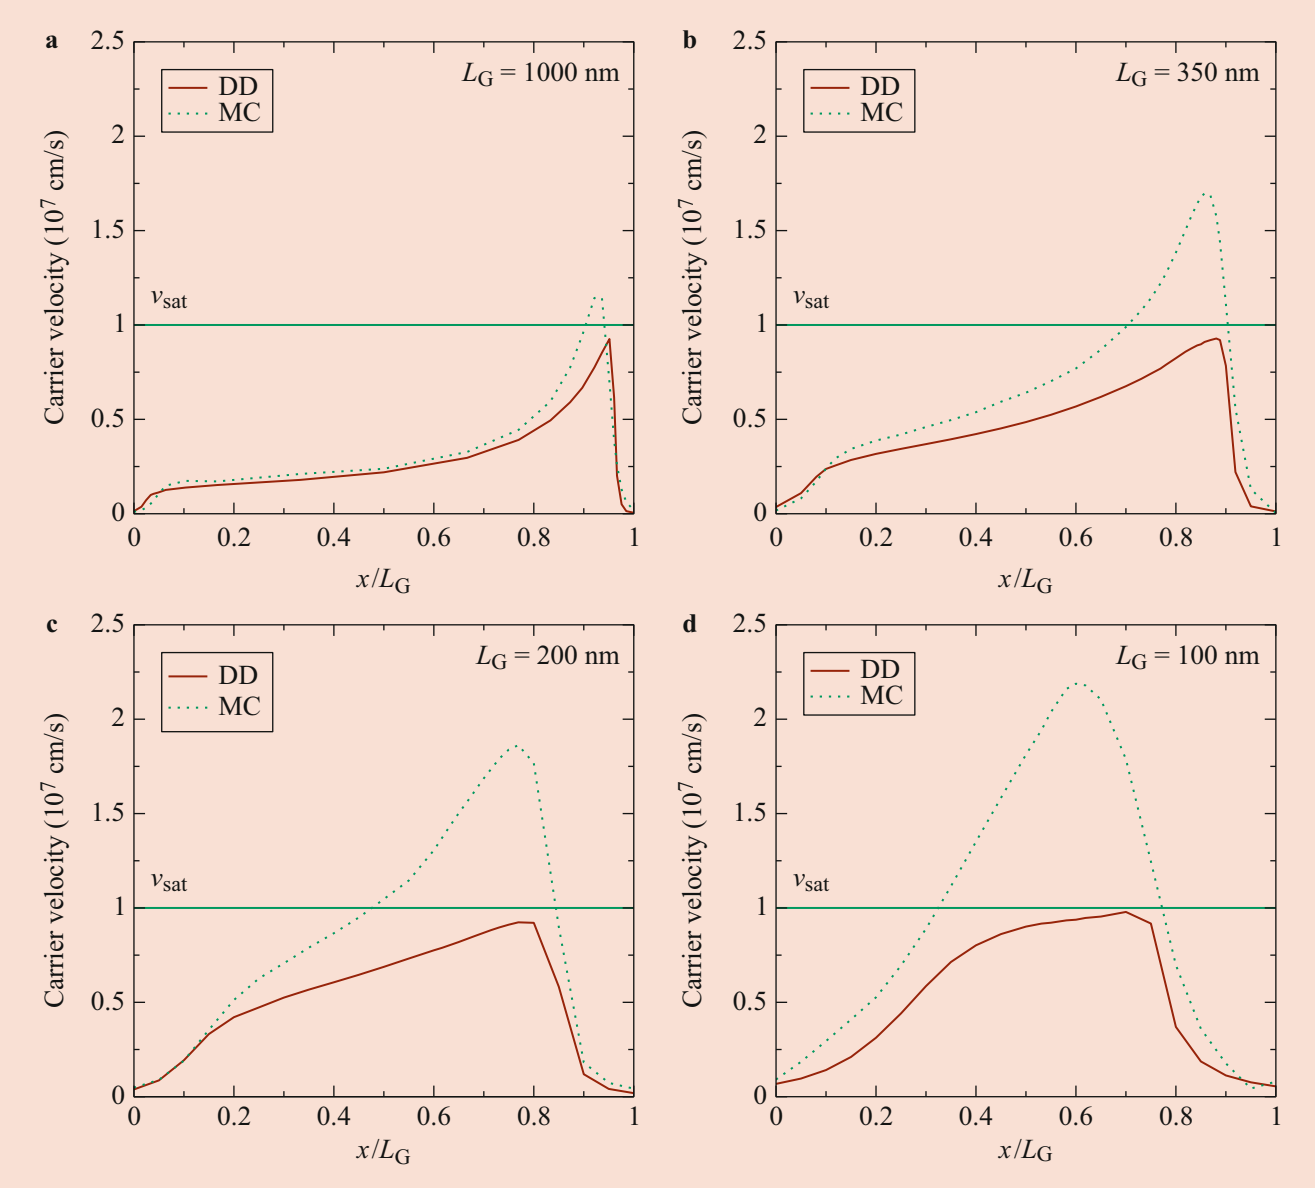

Fig. 37.13 Comparison of the velocity calculated by the drift-diffusion model with Monte Carlo simulation results for MOSFETs with varying gate lengths of 1000 nm (**a**), 350 nm (**b**), 200 nm (**c**), and 100 nm (**d**). At 350 nm and below, Monte Carlo simulation results show a velocity overshoot. Velocity in the drift-diffusion model stays bounded

For example, with Hänsch's mobility model (37.162), these spikes are strongly diminished but not completely removed. Unfortunately, Monte Carlo simulations show that (37.162) also overestimates the real velocity overshoot at the beginning of the channel.

37.7 Advanced Macroscopic Transport Models

As device geometries are further reduced without according reduction of the supply voltages, the electric fields occurring inside the devices increase rapidly. Furthermore, strong gradients in the electric field are observed. These highly inhomogeneous field distributions give rise to distribution functions which deviate significantly from the frequently assumed Maxwellian distribution.

37.7.1 Ansatz-Based Approaches

Various improved macroscopic transport models have been developed based on analytical descriptions of the distribution function, e.g., [84]. Unfortunately, the model from Liotta and Struchtrup [85] and the model from Nekovee [86], which are both discussed below, require a large number of moments, because the chosen ansatz functions converge slowly.

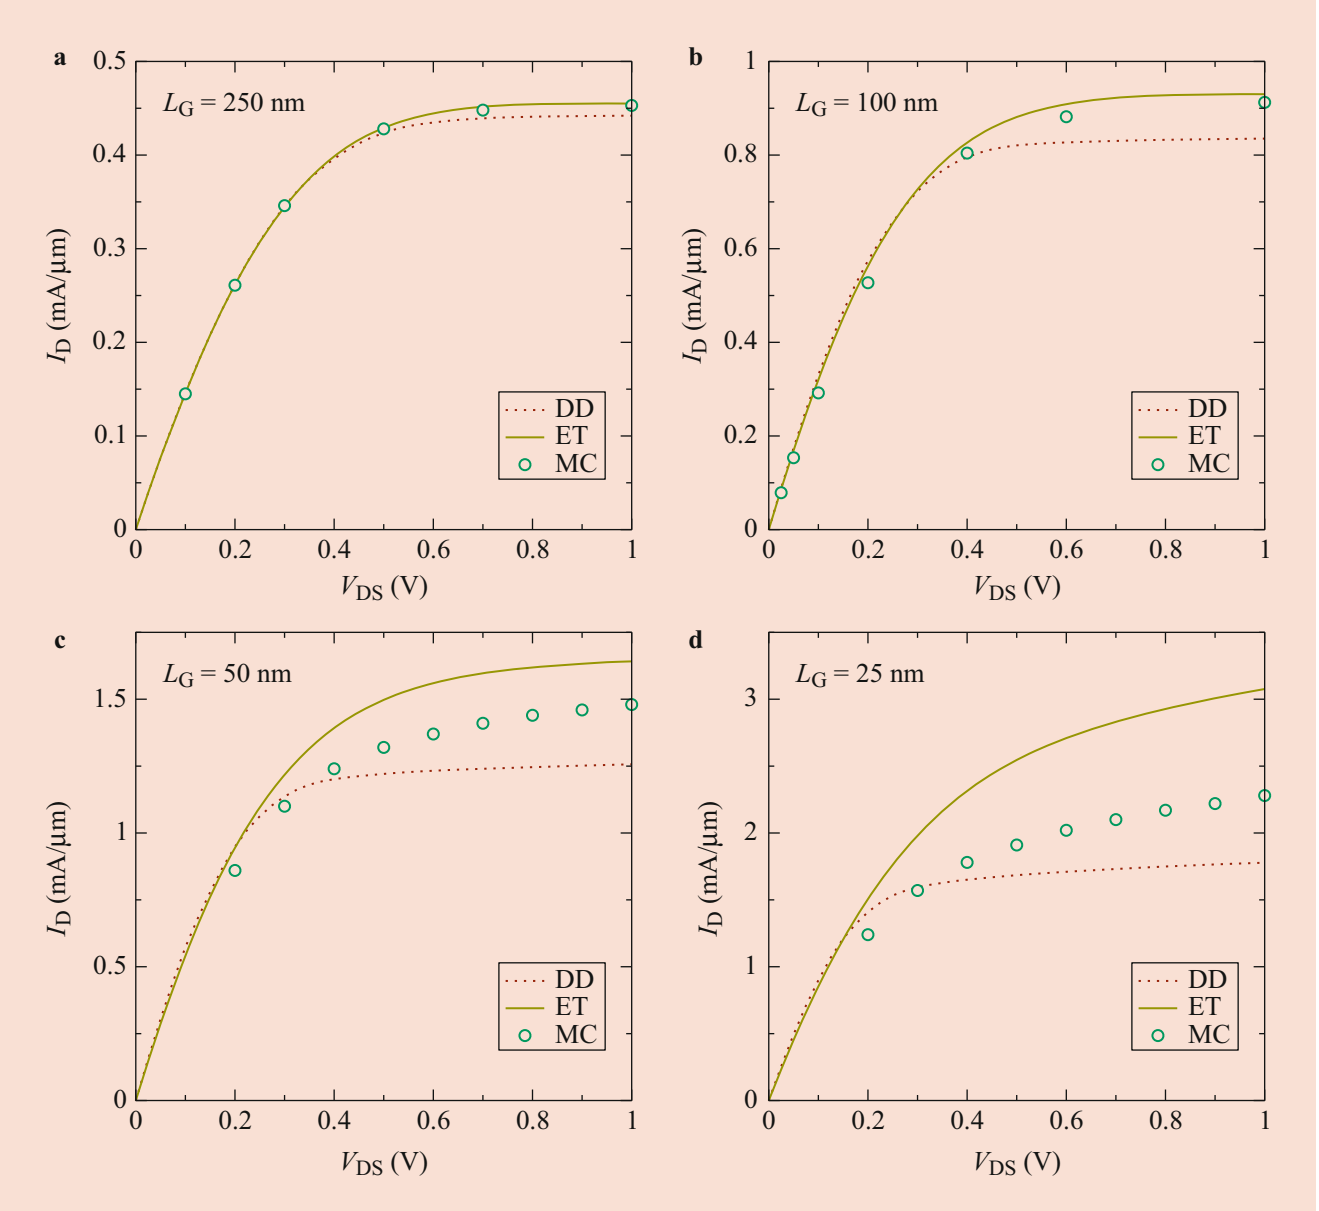

Fig. 37.14 Comparison of drain currents from the drift-diffusion and energy transport models with Monte Carlo simulation results for a doublegate MOSFET with a gate length of 250 nm (**a**), 100 nm (**b**), 50 nm (**c**), and 25 nm (**d**). The drift-diffusion model stays accurate down to a gate length of 250 nm. The energy transport model is accurate down to 100 nm

Liotta and Struchtrup [85] find that a hierarchy containing 12-moment equations is needed to reproduce simulation results obtained from an expansion in spherical harmonics. The proposed model uses an ansatz for the distribution function to calculate the closure relations which is less general than moment-based models with carefully derived closure relations.

A conclusion similar to Liotta and Struchtrup is drawn in [86] by Nekovee et al., who solve the Boltzmann equation using moment-based models. However, this "moment" model is based on an expression for the distribution function using a sum of Hermite polynomials multiplied by a Maxwellian shape. They find that the hierarchy of equations converges too slowly and the model fails to predict results for ballistic diodes. Instead of the moments, the parameters of the distribution function are considered in [86]. Hence, we feel that their conclusion is not applicable to moment-based models [10, 87].

Another approach [88–90] derives only the closure relations from an analytical distribution function model based on the maximum entropy principle. However, these models are difficult to handle numerically as they are hyperbolic.

An explicit ansatz for the distribution function can be avoided in the derivation of a higher-order moment-based

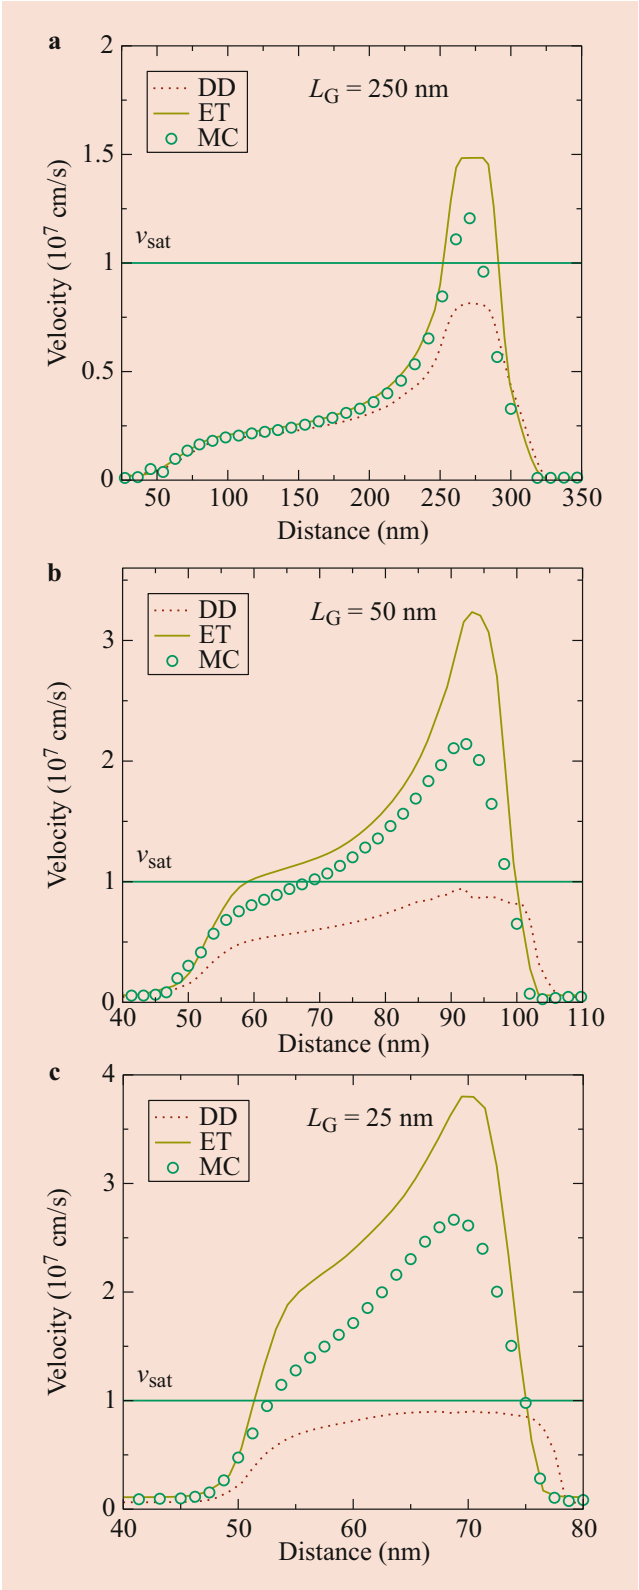

Fig. 37.15 Comparison of velocity profiles from a drift-diffusion and energy transport model with Monte Carlo simulation results for MOSFETs with varying gate lengths of 250 nm (**a**), 50 nm (**b**), and 25 nm (**c**). Down to 250 nm, the energy transport model matches the Monte Carlo simulation results quite well. At shorter gate lengths, the energy transport model overestimates the velocity

transport model. In particular, a macroscopic transport model has been proposed in [51] which considers the first six moments in the Boltzmann transport equation and closes the system using an empirical relation matched to Monte Carlo simulation results.

37.7.2 Higher-Order Moment Models

A natural extension of energy transport models which retains the basic structure of the equation system is to include higher-order moment equations. The only assumption made about the distribution function is the validity of the diffusion approximation in order to obtain a numerically tractable (parabolic) model [52]. Ignoring generation and recombination terms, the flux and balance equations of the six-moment model read for electrons:

$$\nabla \cdot \frac{\mathbf{J}}{q} = \partial_t n \tag{37.173}$$

$$\frac{\mathbf{J}}{q} = \frac{k_B}{q}\mu\left(\frac{\mathrm{q}}{k_B}\mathbf{E}\,n + \nabla(nT_n)\right) \tag{37.174}$$

$$\nabla \cdot \mathbf{S} = -\frac{3}{2}k_B\,\partial_t(nT_n) + \mathbf{E}\cdot\mathbf{J} - n\frac{3}{2}k_B\frac{T_n - T_L}{\tau_\varepsilon} \tag{37.175}$$

$$\mathbf{S} = -\frac{5}{2}\frac{k_B^2}{\mathrm{q}}\mu_S\left(\frac{\mathrm{q}}{k_B}\mathbf{E}\,n\,T_n + \nabla(n\,T_n^2\,\beta)\right) \tag{37.176}$$

$$\nabla \cdot \mathbf{K} = -\frac{15}{4}k_B^2\,\partial_t(n\,T_n^2\,\beta) - 2\,q\,\mathbf{E}\cdot\mathbf{S} - \frac{15}{4}k_B^2\,n\,\frac{T_n^2\,\beta - T_L^2}{\tau_\beta} \tag{37.177}$$

$$\mathbf{K} = -\frac{35}{4}\frac{k_B^3}{q}\mu_K\left(\frac{\mathrm{q}}{k_B}\mathbf{E}\,n\,T_n^2\,\beta + \nabla(n\,T_n^3\,\beta^3)\right) \tag{37.178}$$

The additional unknowns of the six-moment model are the kurtosis of the distribution function β and the kurtosis flux density $\mathbf{K}$, which are defined as

$$\beta = \frac{3}{5}\frac{\langle\mathcal{E}^2\rangle}{\langle\mathcal{E}\rangle^2} \quad \text{and} \quad \mathbf{K} = \langle\mathbf{v}\,\mathcal{E}^2\rangle. \tag{37.179}$$

This definition of the kurtosis is based on the diffusion approximation. The additional transport parameters are the kurtosis relaxation time τ_β and the kurtosis flux mobility μ_K. In terms of the kurtosis, the fourth-order moment is expressed as

$$\langle v^2 \boldsymbol{\mathcal{E}} \rangle = \frac{5{\cdot}3}{2} \frac{k_\mathrm{B}^2}{m} n T_\mathrm{n}^2 \beta. \tag{37.180}$$

In the six-moment model above, we have used an empirically found closure [51] for the sixth-order moment which depends on the third power of β:

$$\langle v^4 \boldsymbol{\mathcal{E}} \rangle = \frac{7 \cdot 5 \cdot 3}{2} \frac{k_\mathrm{B}^3}{m^2} n T_\mathrm{n}^3 \beta^3. \tag{37.181}$$

With this closure, the six-moment model is contained as a special case in the model hierarchy described by Jüngel in [13, p.187].

The first four equations are the same as for the energy transport model, except that the kurtosis β appears in the energy flux equation (37.176). As a consequence, the energy flux equation cannot be written in the form frequently used for energy transport models as proportional to the current density (cf. (37.156)) without producing additional terms. This modification makes the coupled equation system difficult to solve, and approximations have been used [51]. Note that the six-moment model reduces to a standard energy transport model when the equations containing $\mathbf{K}$ are dropped and a value of unity is assumed for β.

Discretization and numerical solution of the six-moment model are covered in [15]. A generalized Maxwellian closure for the sixth moment is proposed in [51], and a cumulant-based closure is discussed in [91, 92]. Correction terms for non-parabolicity are added to the six-moment model in [73, 74].

Properties of the Kurtosis

For a heated Maxwell distribution and parabolic bands, the kurtosis β_M is identical 1. Thus, a $\beta \neq 1$ quantifies the deviation from the heated Maxwellian shape. Note that a Maxwellian shape is never observed in Monte Carlo simulations, except for the contact regions where the carriers are still cold and the Pauli principle is neglected.

For the special case of a bulk semiconductor, the kurtosis can be expressed as a function of the carrier temperature. By considering the homogeneous six-moment model, the following expression is obtained [10]:

$$\beta_\mathrm{bulk}(T_\mathrm{n}) = \frac{T_\mathrm{L}^2}{T_\mathrm{n}^2} + 2 \frac{\tau_\beta}{\tau_\varepsilon} \frac{\mu_\mathrm{S}}{\mu_\mathrm{n}} \left(1 - \frac{T_\mathrm{L}}{T_\mathrm{n}}\right). \tag{37.182}$$

This is an analogy to the homogeneous energy transport equation used to estimate the carrier temperature from the electric field as discussed in Sect. 37.5.4. Since in inhomogeneous samples T_n already lags behind the field (for increasing $\mathbf{E}$), some nonlocality is also expected for beta, and an expression estimating β from T_n is preferable to one using $\mathbf{E}$. Figure 37.16a shows that the doping dependence

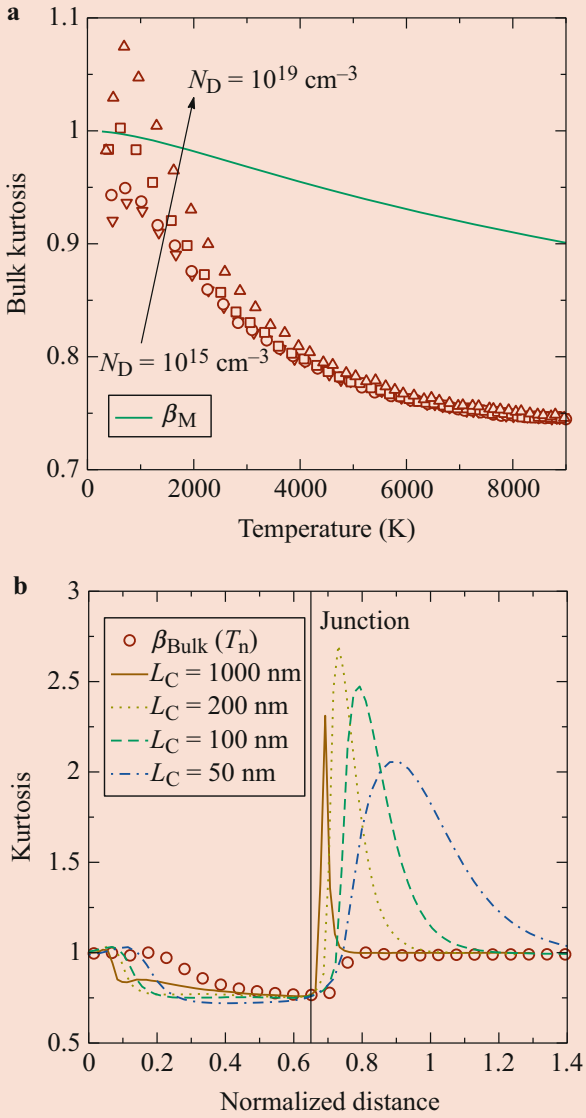

Fig. 37.16 The kurtosis for bulk (**a**) and for different n^+nn^+ test structures (**b**). Note the strong deviation from unity after the second junction

of the bulk kurtosis $\beta_\mathrm{bulk}(T_\mathrm{n})$ is only relevant at doping concentrations higher than 10^{16} cm^{-3} and for lower-carrier temperatures.

As shown in Fig. 37.16b, the kurtosis behaves quite differently in inhomogeneous samples than would be expected from the bulk relation $\beta_\mathrm{bulk}(T_\mathrm{n})$. While inside the channel β is typically below unity and reasonably close to the bulk relation, values larger than unity are observed at the end of the channel region. This deviation corresponds to the high-energy tail of the distribution function in Fig. 37.9. Typical values of the kurtosis β are in the range [0.75, 3] which indicates a strong deviation from a heated Maxwellian distribution.

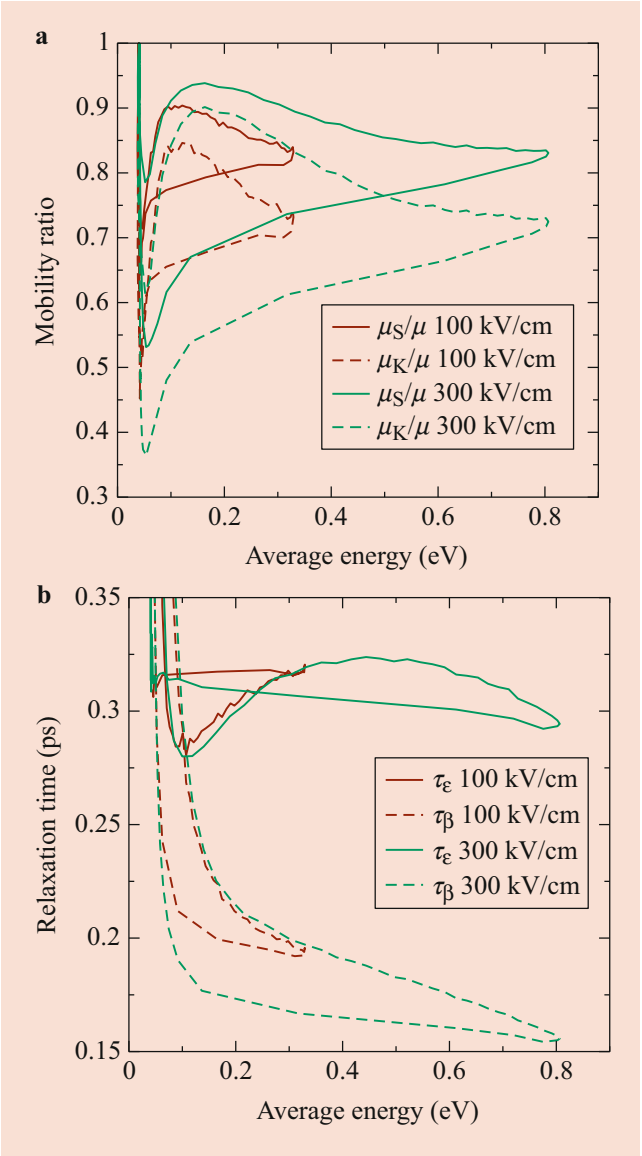

Fig. 37.17 (**a**) The ratio of the mobilities μ_S/μ and μ_K/μ for an n^+nn^+ test structure with $L_c = 200$ nm. (**b**) The energy and the kurtosis relaxation times $\tau_\mathcal{E}$ and τ_β

Modeling of the Transport Parameters

Modeling of the additional parameters μ_K and τ_β faces similar problems as discussed in Sect. 37.5.5. These parameters contain information on hot-carrier effects. Both parameters show a clear hysteresis when plotted over the average energy as shown in Fig. 37.17.

In the six-moment model, the interplay between the various parameters is highly complex and has a strong impact on the numerical stability of the whole transport model. Simple analytical models based on constant values as the ones used in [51] do not always deliver satisfactory results.

For an appropriate description of higher-order transport models, it is therefore important to model the transport parameters with as few simplifying assumptions as possible. To minimize uncertainties arising from this issue, all physical parameters might be extracted as a function of the doping concentration and the average energy from homogeneous Monte Carlo simulations. This is discussed below.

37.7.3 Table-Based Parameter Modeling

Modeling transport parameters like the mobilities μ, μ_S, and μ_K and the relaxation times $\tau_\mathcal{E}$ and τ_β is challenging, since they all depend on the actual shape of the distribution function, on the scattering rates, as well as on the band structure [74]. Having many adjustable parameters is an inconvenience inherent in many higher-order transport models based on analytical models for the mobilities and relaxation times [10]. In particular, a consistent comparison with Monte Carlo simulations is difficult, when the resulting transport models do not reproduce the Monte Carlo simulation results in the homogeneous case. For a meaningful comparison, the models should be consistent at least in the bulk case, which already is far from trivial.

In [93], a transport parameter model based on homogeneous fullband Monte Carlo tables has been introduced. By adjusting this method for the six-moment model, all higher-order transport parameters are extracted from bulk Monte Carlo simulations for different doping concentrations and for different driving forces. In the macroscopic models, the transport parameters are then considered as a function of doping and the average energy [73, 94]. In this way, the fullband structure of the material and scattering mechanisms such as phonon-induced scattering are inherently included in the model. Correction factors for non-parabolic band structures have also been obtained [74].

Since all model parameters are obtained from bulk Monte Carlo simulations, the transport models are free of fit parameters which leaves us with "no knobs to turn" [95]. Macroscopic models based on Monte Carlo simulation data improve on their counterpart models based on analytical models significantly, both in terms of numerical stability and in the agreement with Monte Carlo device simulations [74].

In Fig. 37.18, the extracted bulk mobility parameter set for higher-order macroscopic transport models is displayed. Here the carrier mobility μ (Fig. 37.18a) and higher-order mobilities μ_S (Fig. 37.18b) and μ_K (Fig. 37.18c) as a function of the electric field E_{abs} for different doping concentrations N_d are presented. As can be observed for each type of mobility, the values of the mobility are independent of the doping concentration for fields above 100 kV/cm, which is where $v = v_{sat}$ and $\mu = v_{sat}/E$. For low fields, the mobilities are much larger at low doping concentrations compared to high doping concentrations.

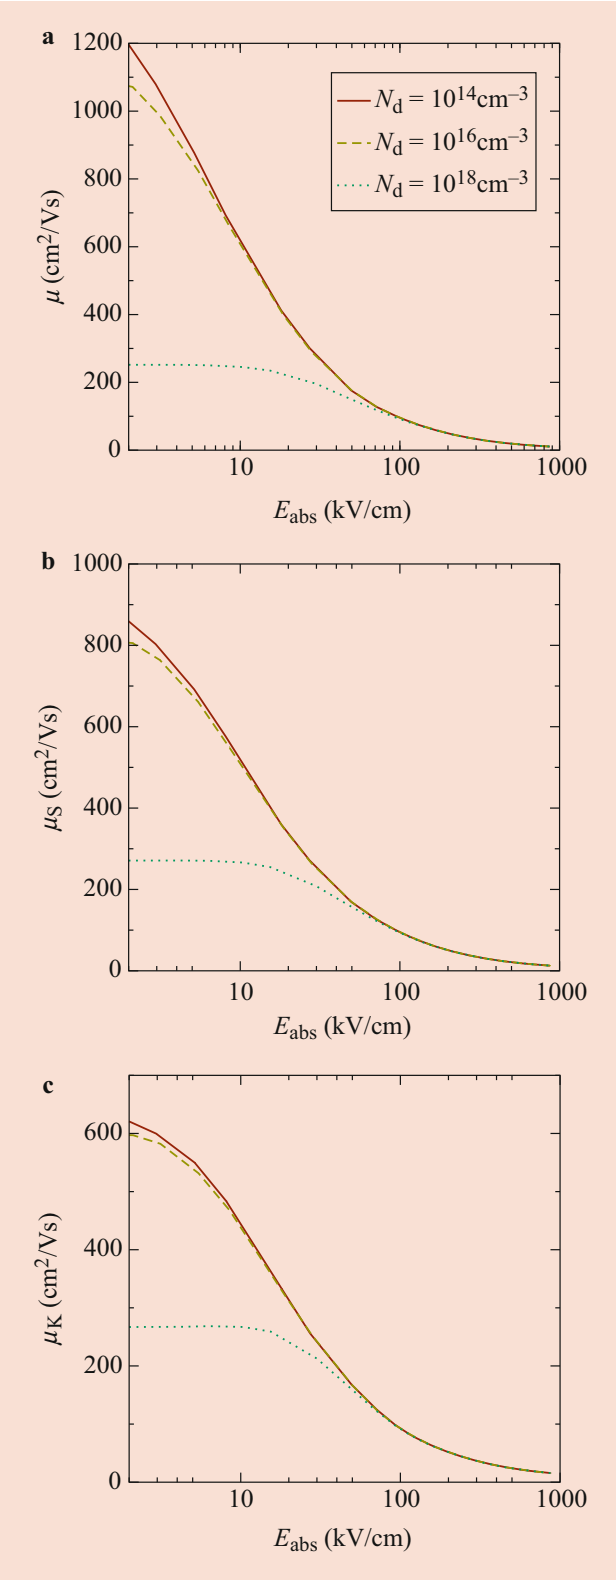

Fig. 37.18 Carrier mobility μ, (**a**) energy flux mobility μ_S, and (**b**) second-order energy flux mobility μ_K versus driving field for different doping concentrations. For fields higher than (**c**) 100 kV/cm, the mobilities are independent of the doping concentration. For low fields, the values of the mobilities are much larger at low doping than at high doping concentrations

The value of all three types of mobilities is comparable at high doping concentrations. For low doping concentrations and low fields, the energy flux mobility and the second-order flux mobility are smaller than the carrier mobility.

Figure 37.19 presents the relaxation times τ_ε and τ_β for different doping concentrations as a function of the kinetic energy of the carriers. As can be seen, for high energies, the relaxation times become doping-independent.

For a fixed energy, the Monte Carlo simulations predict lower relaxation times with higher N_d. In a certain field regime, where optical phonons can be neglected, the energy relaxation time τ_ε is approximately constant. However, for driving fields above 450 kV/cm, the energy relaxation time is no longer constant but decreases due to the increase of optical phonon scattering, which is an inelastic process.

The carrier velocity as a function of the lateral field and for different N_d is shown in Fig. 37.20. The saturation velocity of Si is reached at a driving field of 150 kV/cm.

In Fig. 37.21, the bulk carrier temperature as a function of the electric field calculated with the bulk fullband Monte Carlo method is presented. The quadratic dependence of the carrier temperature on the electric field (37.150) is a good approximation for fields lower than 200 kV/cm, while for fields up to 450 kV/cm a linear approximation

$$T_n = T_L + \tau_{const} \frac{2}{3} \frac{q}{k_B} v_{sat} E \,. \tag{37.183}$$

can be used assuming $\mu = v_{sat}/E$. However, for driving fields above 450 kV/cm, the linear approximation breaks down due to optical phonon scattering.

37.8 Applications

This section discusses applications of the six-moment model in the deca-nanometer regime. The channel length range of deca-nanometer devices is here defined approximately from 100 nm down to 20 nm.

In order to consider the high-field case as accurately as possible, a transport model based on fullband Monte Carlo tables is considered. The results of the Monte Carlo table-based higher-order transport models are benchmarked for n^+nn^+ test structures and double-gate MOSFETs against Monte Carlo simulations. Occasionally, the spherical harmonic expansion simulator is used as a reference, because the results are very close to those obtained by the Monte Carlo method, but the computational effort is considerably lower, particularly for rare events which determine, for example, the high-energy tail of the energy distribution function.

When the channel length is reduced to increase the operation speed and the number of components per chip, the so-called short-channel effects arise [96]. An adequate de-

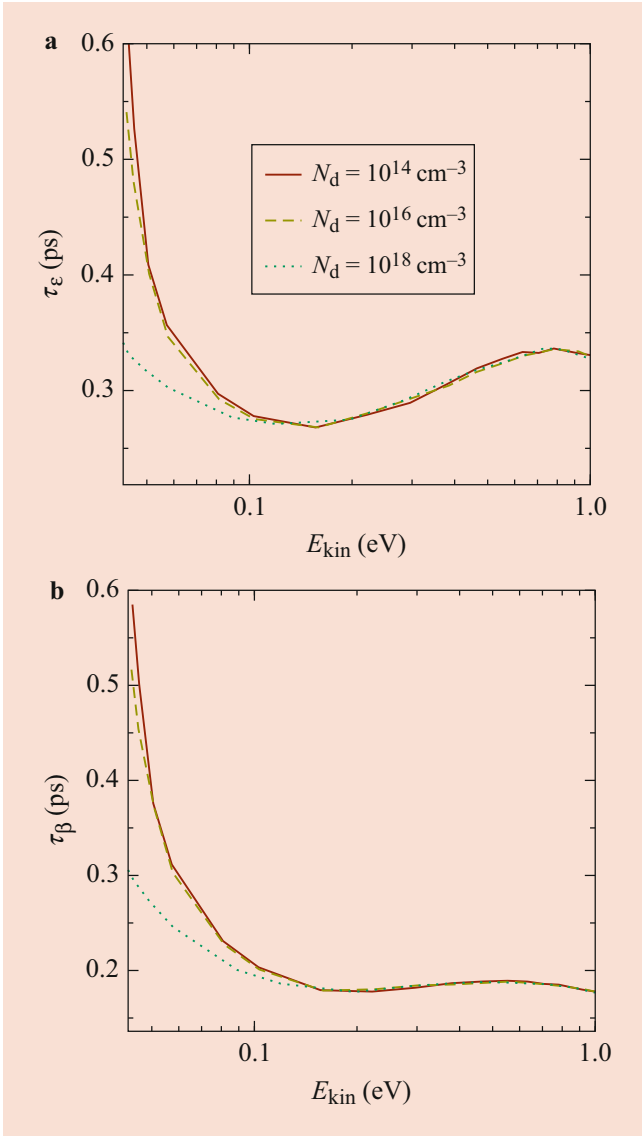

Fig. 37.19 Energy relaxation time $\tau_\mathcal{E}$ (**a**) and second-order energy relaxation time τ_β (**b**) extracted from bulk Monte Carlo simulations as a function of the kinetic energy for different bulk dopings. For very high energies, the relaxation times decrease due to the increase of optical phonon scattering

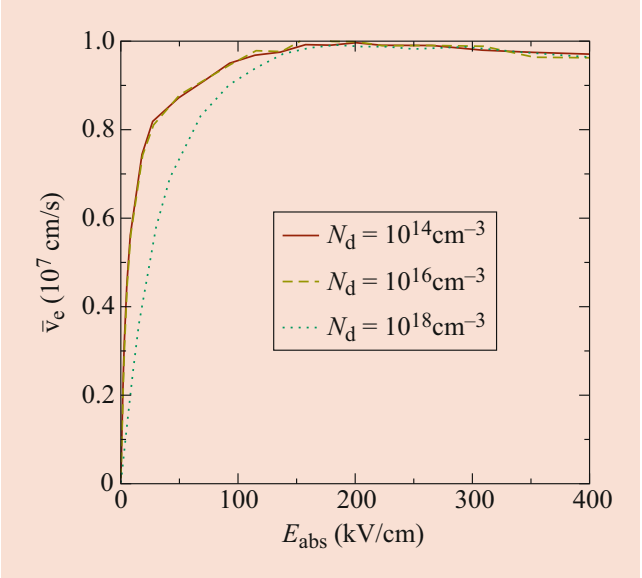

Fig. 37.20 Bulk velocity of electrons as a function of the driving field E_{abs} for a doping of 10^{14} cm^{-3}, 10^{16} cm^{-3}, and 10^{18} cm^{-3}. In the low-field regime, the electron velocity for high dopings is lower than the velocity of the low dopings, while the value of the velocity converges for high fields

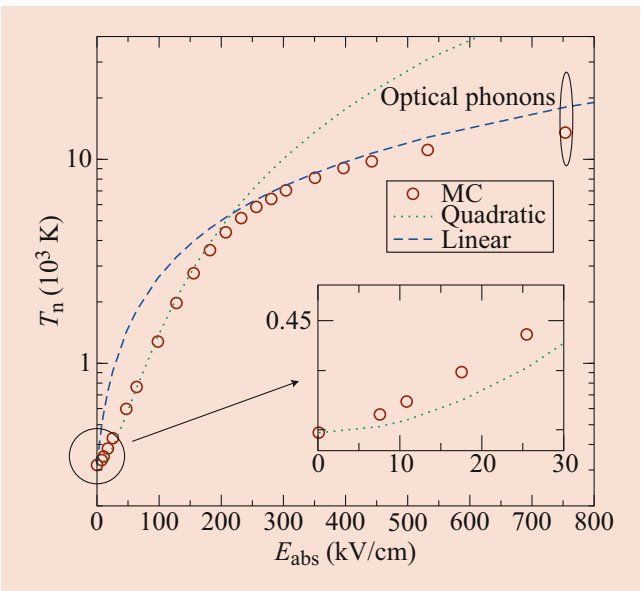

Fig. 37.21 Carrier temperature T_n as a function of the driving field in a homogeneous bulk simulation carried out with the fullband Monte Carlo method. For lower fields, the carrier temperature is a function of E^2, while for high fields, the temperature is closer to a linear dependence on the driving field

scription of these phenomena relies on a detailed description of the distribution function which is provided by the six-moment model [11, 74]. A variety of short-channel effects such as the velocity overshoot, the impact ionization, and the influence of hot electrons on the carrier distribution function are investigated.

37.8.1 n^+nn^+ Test Structures

We first investigate the validity of higher-order transport models on a series of the most popular test devices, one-dimensional n^+nn^+ structures. Due to the simplified one-dimensional structure and the requirement of only one carrier type, the influence of the various parameters on basic quantities like the velocity or the carrier temperature can be more easily separated and interpreted. However, as can be seen

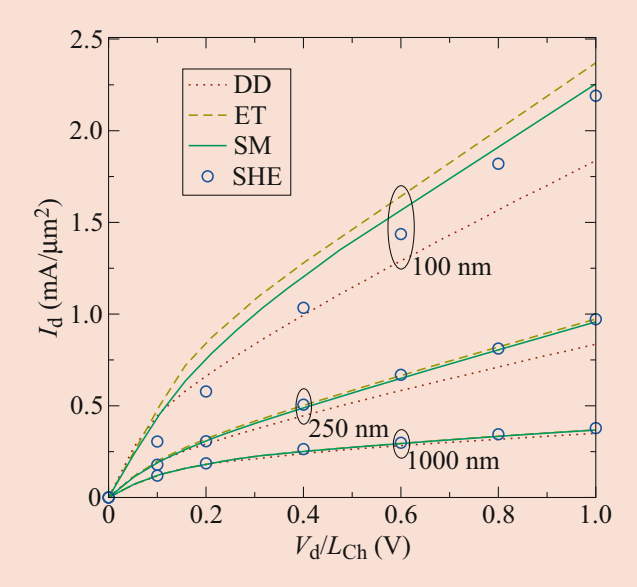

Fig. 37.22 Output currents for different n^+nn^+ structures calculated with DD, ET, and SM models. As a reference, spherical harmonic expansion simulations are used. For 1000 nm, all models predict the same current, while the DD model underestimates the current for a channel length of 100 nm

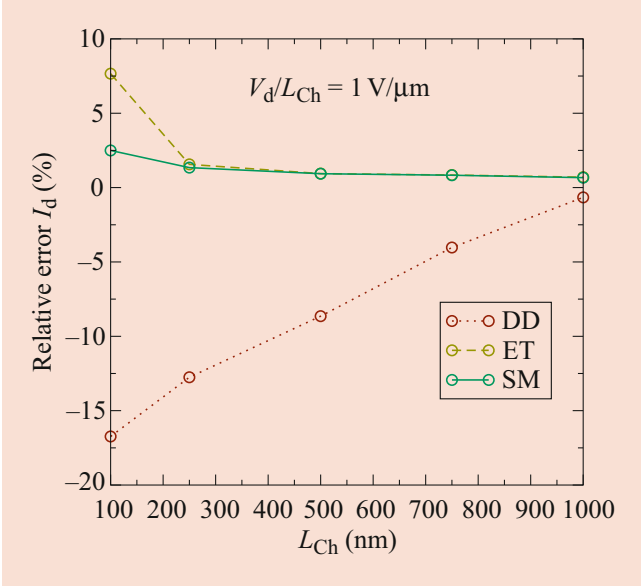

Fig. 37.23 Relative error of the current calculated with the DD, ET, and the SM model as a function of the channel length L_{Ch}. A voltage of 1 mV/nm × L_{Ch} has been applied. While the relative error in the ET and the SM model is always below 7.5%, the relative error in the DD model approaches 16% at a channel length of 100 nm

from the examples below, even for these simple structures, such an interpretation is far from trivial.

Model Check

As discussed in the previous sections, macroscopic transport models are based on many empirical assumptions. Hardly any of these can be justified theoretically below a channel-length of one micrometer. Hence, we choose 1000 nm as the calibration point, where all macroscopic transport models together with the spherical harmonic approach, which is the reference simulator here, should yield the same result.

Figure 37.22 shows the output currents of different n^+nn^+ structures for channel lengths of 100 nm, 250 nm, and 1000 nm calculated with the DD, ET, SM, and the spherical harmonic expansion model. For a channel length of 1000 nm, all models yield the same results with an error below 1% as can be observed in Fig. 37.23. While the error of the ET and SM model stays more or less constant below 2.5% for a channel length down to 250 nm, the error of the DD model continuously increases and reaches a value of −16% for a channel length of 100 nm. Therefore, simulating short-channel devices with the DD model gives only poor results. While the inaccuracy of the ET model starts to increase below 250 nm, the SM model still gives results very close to spherical harmonic expansion simulations.

Velocity Profile

In Fig. 37.24, the evolution of the velocity profile within several n^+nn^+ structures calculated with the DD, ET, SM, and the spherical harmonic expansion model as a reference is shown. The bias conditions were chosen in such a way to result in an electric field of 50 kV/cm in the middle of the intrinsic region (loosely referred to as channel region in the following) for each channel length. Overall, the SM model predicts a velocity profile closer to the spherical harmonic expansion data than the DD and the ET model. From this, we conclude that the closure relation of the SM model is improved compared to the ET model.

For long-channel devices, all models yield a similar velocity profile. For decreasing channel length below L_{Ch} = 250 nm, the spurious velocity overshoot in the ET model and the reduced one in the six-moment model are clearly visible. On the other hand, the DD model does not predict any velocity overshoot at all and stays always below the bulk saturation velocity v_{sat}.

In order to explain this effect, various theories have been put forward. Some authors have argued that there is a relation with non-parabolicity effects [97], whereas other theories relate it to the hysteresis in the mobility [98].

However, it was demonstrated in [99] that the SVO is caused by deficient models for the closure relation and the transport parameters. For higher-order transport models, the error in the SVO decreases. This can also be seen in Fig. 37.24 where the six-moment model is consistently better than the energy transport model.

Drain Current

The improved accuracy in the device characteristics obtained from higher-order moments is also reflected in the currents, which is demonstrated in Fig. 37.25. Here, the output characteristics of a 40 nm and 80 nm channel length n^+nn^+ structure calculated with the DD, ET, SM, and the reference spherical harmonic expansion model are shown.

While the relative error of the current calculated with the SM and the ET model stays small in long-channel devices (see Fig. 37.23), there is a significant deviation for short-channel devices as shown in Fig. 37.26. In the short-channel range, from 40 to 100 nm, the current calculated with the SM model is below an error of 10%. In contrast, at a channel length of 40 nm, the errors of the DD and the ET model are at −30% and 40%, respectively.

As has been pointed out, the ET model accurately describes current transport down to a channel length of about 80 nm, but a strong increase in the error of the current can be observed below 80 nm. Therefore, the ET model is a suitable transport model for devices down to 80 nm channel lengths

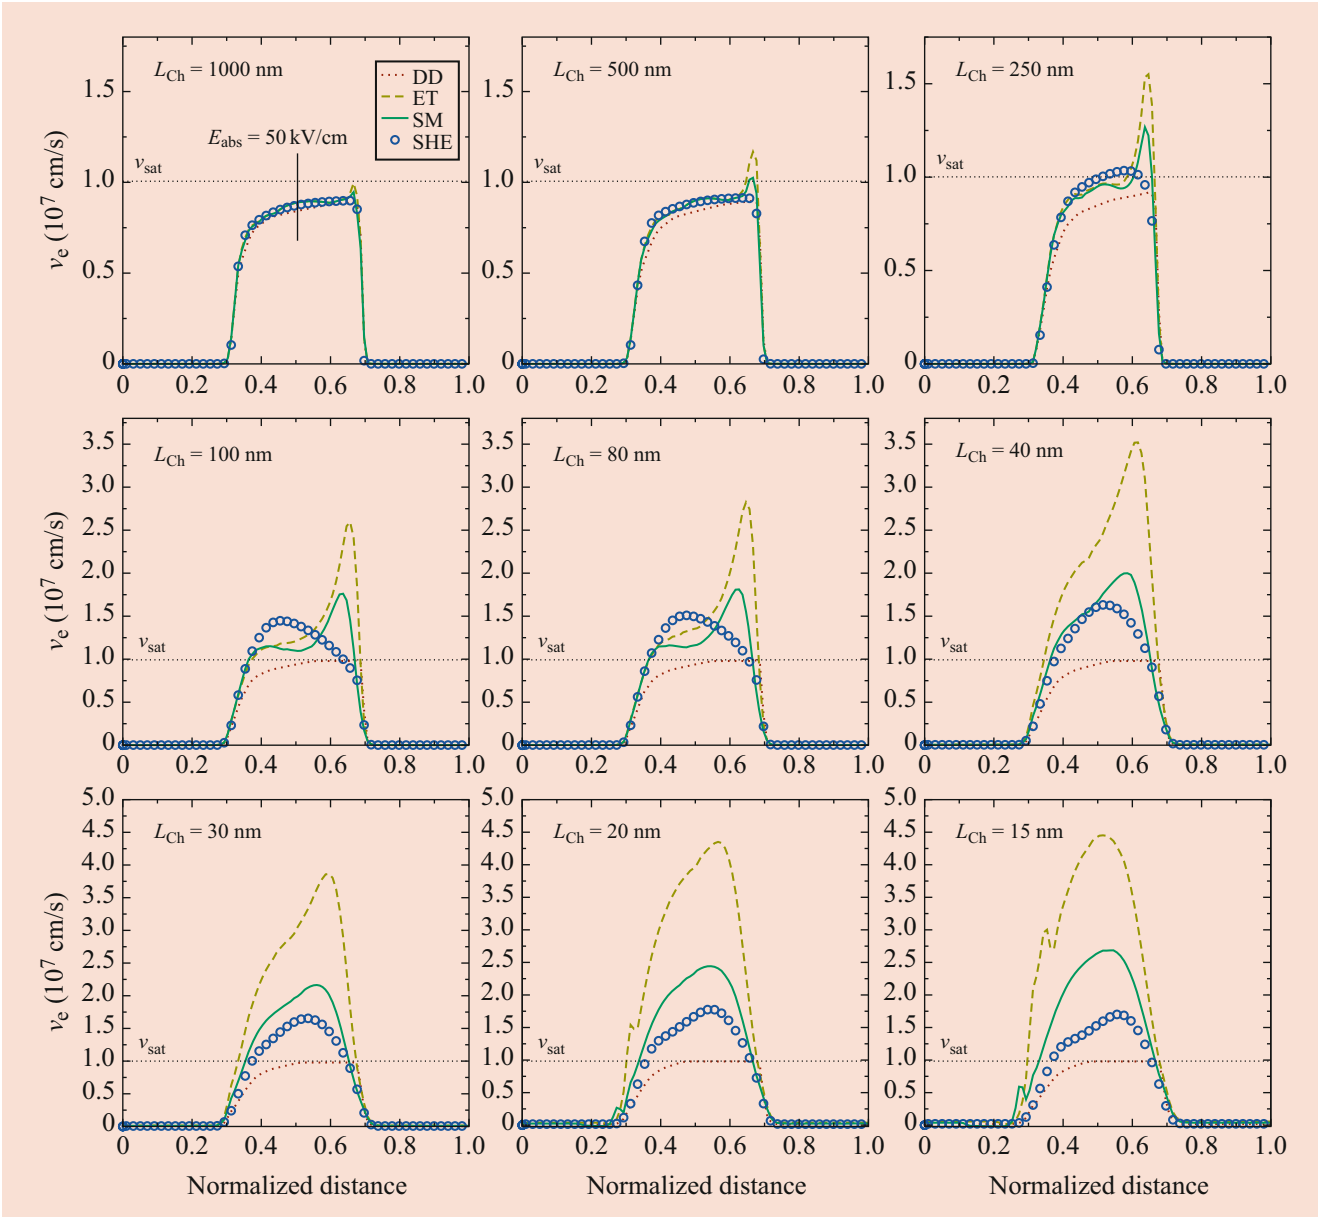

Fig. 37.24 Evolution of the carrier velocity profiles for decreasing channel lengths calculated with the DD, the ET, and the SM model. The velocities are compared to the results obtained from spherical harmonic expansion simulations. While the maximum velocity of the DD model is the saturation velocity v_{sat}, the spurious velocity overshoot at the end of the channel in the ET and the SM model is clearly visible. The velocity overshoot at the beginning of the channel can be quantitatively identified for devices smaller than 100 nm in the ET and the SM model

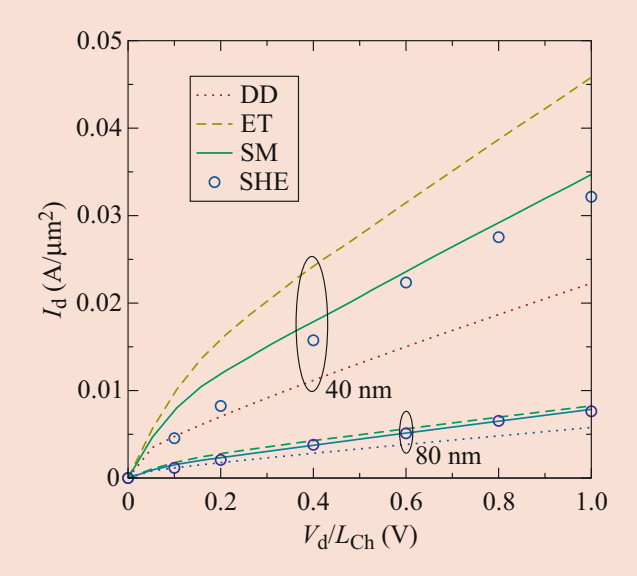

Fig. 37.25 Output currents of an 80 nm and a 40 nm channel length n^+nn^+ structure calculated with the DD, ET, SM, and spherical harmonic expansion model. The ET model overestimates the current at 40 nm, while the SM model yields the most accurate result

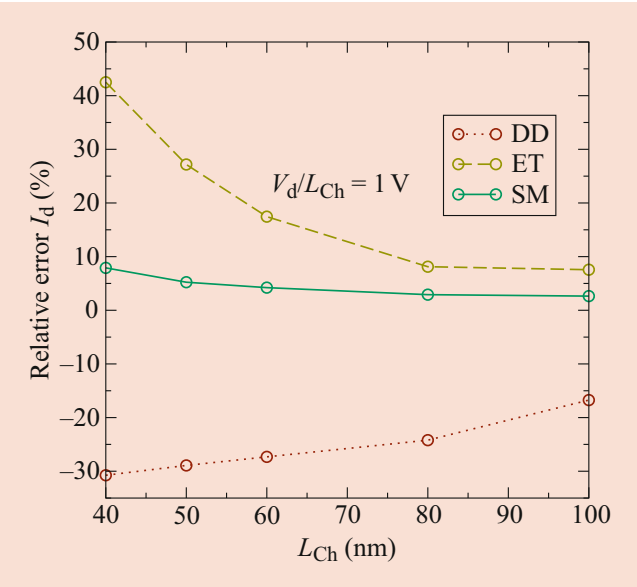

Fig. 37.26 Relative error in the current of the DD, the ET, and the SM model for an n^+nn^+ structure in the channel range from 100 nm down to 40 nm. At 40 nm the relative error of the SM model is below 6%, while the error of the DD and the ET model is at −30% and 40% respectively

only. For a channel length below 80 nm, the SM model appears to be the model of choice. One additional strength of the six-moment model is that it gives more information about the distribution function than the ET model.

37.8.2 A Double-Gate MOSFET

Previously, the transport models have been validated with n^+nn^+ structures. Although it has been frequently claimed that n^+nn^+ structures emulate the behavior of MOS transistors, the most important devices in silicon technology, this is only partly true.

Drain Current

In Fig. 37.27, we compare results from drift-diffusion, energy transport and six-moment model with Monte Carlo simulation results for double-gate MOSFETs. All models use consistent bulk parameters. For long-channel devices down to a gate length of 250 nm (Fig. 37.28a) all of the models yield consistent results for the drain current.

However, the DD model consistently underestimates the current, particularly in the saturation regime. The ET model starts to deviate from the Monte Carlo simulation data at 100 nm (Fig. 37.28b), while the SM model properly reflects the output characteristic down to 50 nm (Fig. 37.28c). For gate lengths below 50 nm, all macroscopic models fail to describe the reference current.

Velocity

For a detailed analysis, we make a comparison of distributed quantities. Among several quantities, we find that velocity profiles are the most critical. Getting the right velocity profiles is important for correct terminal currents. Velocity profiles are depicted in Fig. 37.28. As above, for 250 nm, all models give reasonable results (Fig. 37.28a). At 50 nm and below (Fig. 37.28b-c), the ET models overestimate the velocity. The results of the SM model stay closest to Monte Carlo simulations but is also off at 25 nm.

The energy transport models tend to overestimate the velocity overshoot and introduce a spurious velocity overshoot at the end of the channel region of n^+nn^+ structures. For MOS transistors, on the other hand, the SVO coincides with the velocity overshoot at the end of the channel and is therefore not explicitly visible.

Predictiveness

To compare the predictiveness of macroscopic models, we plot drain current and transit frequency as a function of the gate length in Fig. 37.29. In both figures, the error of the DD model is much higher. The six-moment model and the energy transport model show similar behavior. But the six-moment model is closer to the Monte Carlo simulation results as it utilizes more information about the distribution function.

Despite the apparent limitations, it is possible to use drift-diffusion transport models also for deca-nanometer devices [100, 101]. These drift-diffusion models use mobility models and saturation velocities which are inconsistent with bulk data [102] and can provide short-term fixes to available

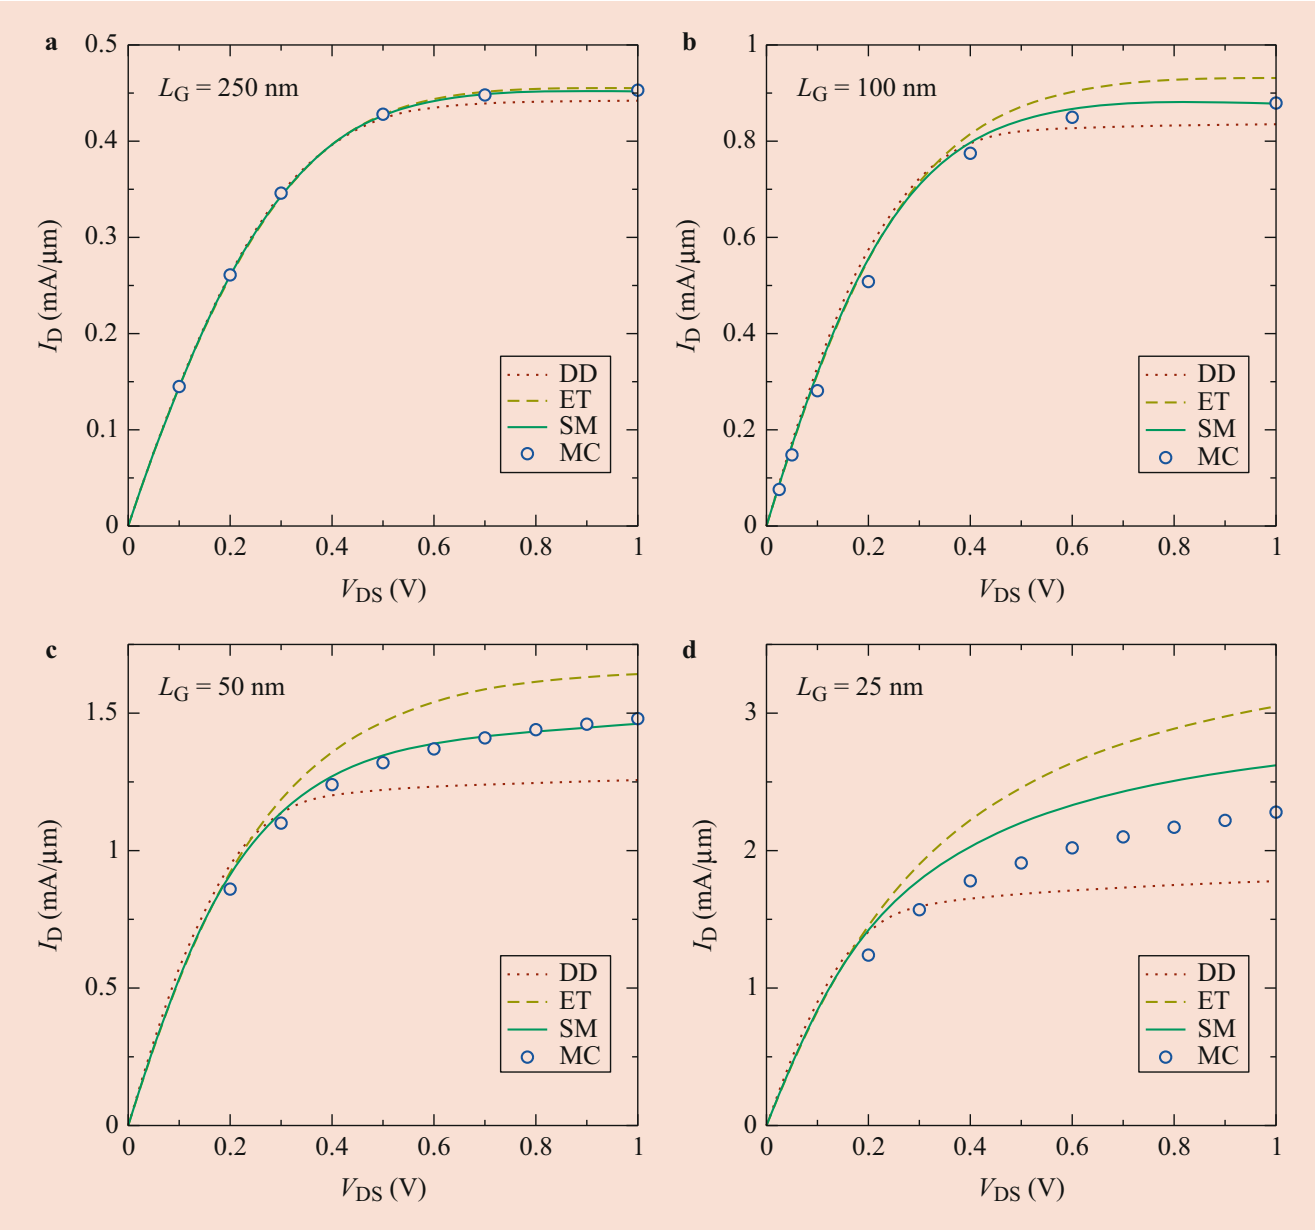

Fig. 37.27 Comparison of drain currents from the drift-diffusion, energy transport, and six-moment models with Monte Carlo simulation data for a double-gate MOSFET with varying gate lengths of 250 nm (**a**), 100 nm (**b**), 50 nm (**c**), and 25 nm (**d**). The six-moment model stays accurate down to a gate length of about 50 nm

models. This, obviously, is a fitting approach and has limited value for predictive simulations.

As a side note, we would like to mention that with shrinking device geometries quantum effects gain more importance and limit the validity of the BTE itself [103]. When the device dimensions are comparable to the carrier wave length, the carriers can no longer be treated as classical pointlike particles, and effects originating from the quantum mechanical nature of propagation begin to determine transport [104].

Numerical Properties

From a practical point of view, it has to be pointed out that convergence problems are an issue and inhibit the use of higher-order moment equations in everyday engineering applications. Unfortunately, simulation codes based on higher-order moment equations have never reached a robustness comparable to the drift-diffusion model. Several discretization schemes have been proposed [45], but no generally accepted discretization like the Scharfetter-Gummel scheme [7] for the drift-diffusion equations exists.

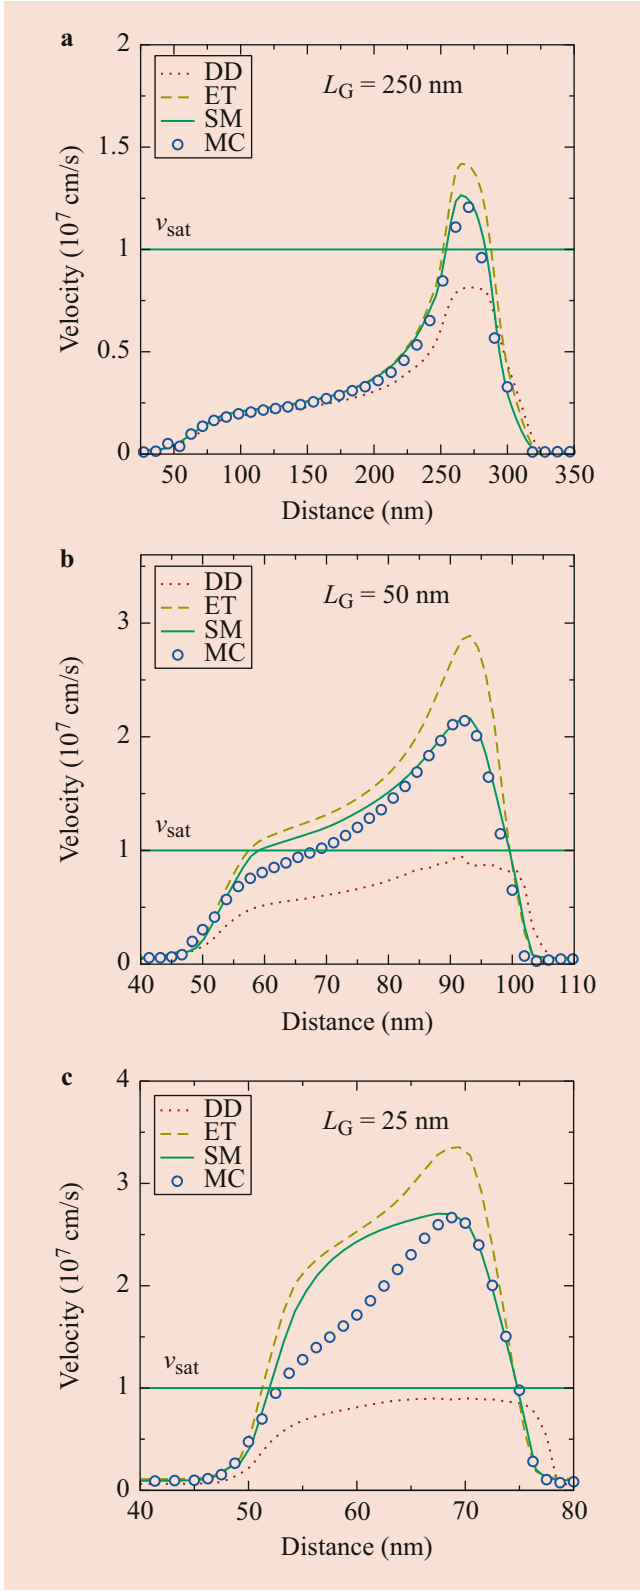

Fig. 37.28 Comparison of the velocity from the drift-diffusion, energy transport, and six-moment model with Monte Carlo simulation data for a double-gate MOSFET with gate length of 250 nm (**a**), 50 nm (**b**), and 25 nm (**c**). The spurious velocity overshoot is much less pronounced than for n^+nn^+ structures. The six-moment model stays closest to the Monte Carlo simulation results

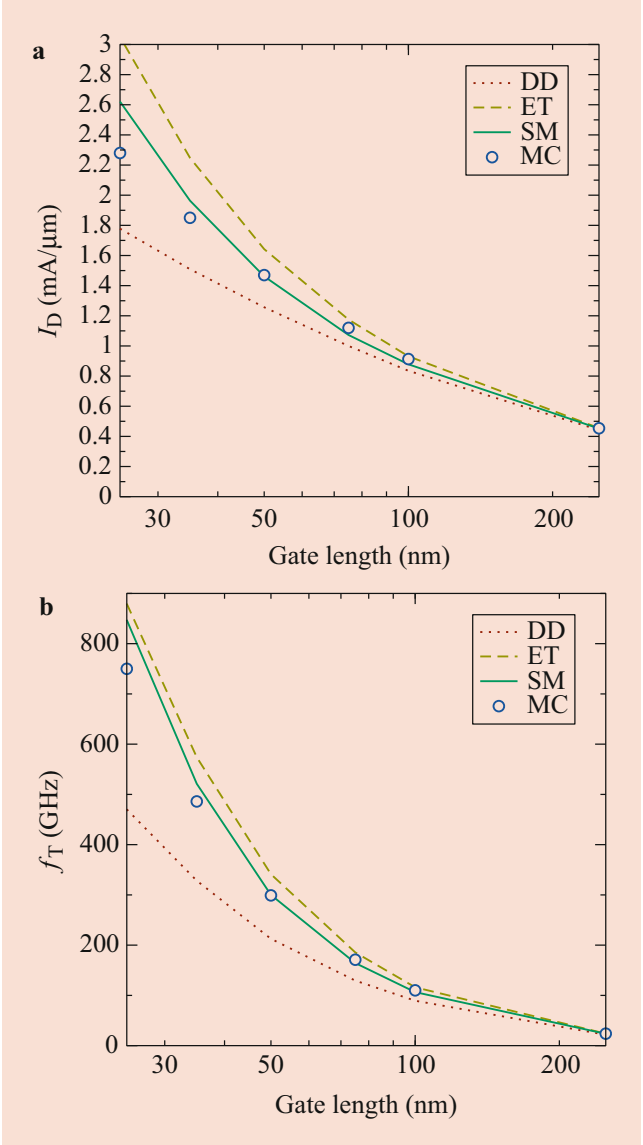

Fig. 37.29 Comparison of drain currents (**a**) and transit frequency (**b**) as a function of the gate length from the drift-diffusion, energy transport, and six-moment model with Monte Carlo simulation data for a double-gate MOSFET. The six-moment model is predictive down to 50 nm

37.8.3 Modeling of Hot-Carrier Effects

Hot carriers can lead to a number of interesting phenomena and are difficult to model in the drift-diffusion model, because too little information about the distribution function is available.

Within DD and ET, it is difficult to estimate the deviation of the energy distribution function from the Maxwellian shape. By contrast, the SM model provides the kurtosis, which has been shown to be crucial in that respect.

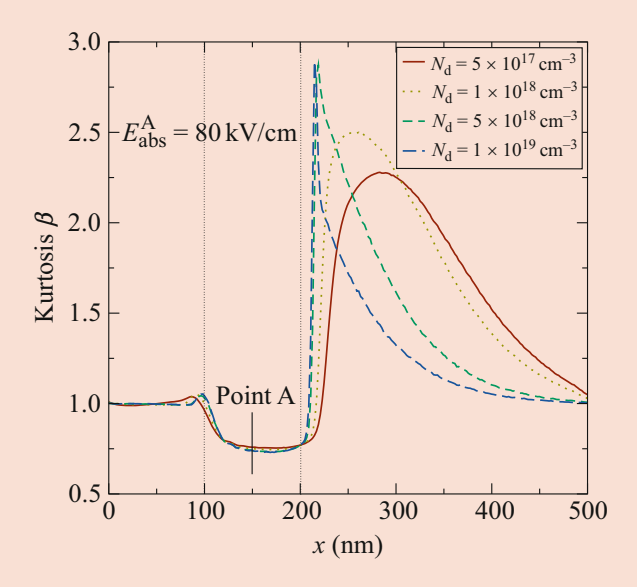

Fig. 37.30 Kurtosis calculated for different source and drain doping concentrations in an n^+nn^+ structure with a channel length of 100 nm. With increase in the doping concentrations, the peak of the kurtosis moves closer to the channel, as the cold carriers in the highly doped region strongly suppress the high-energy tail

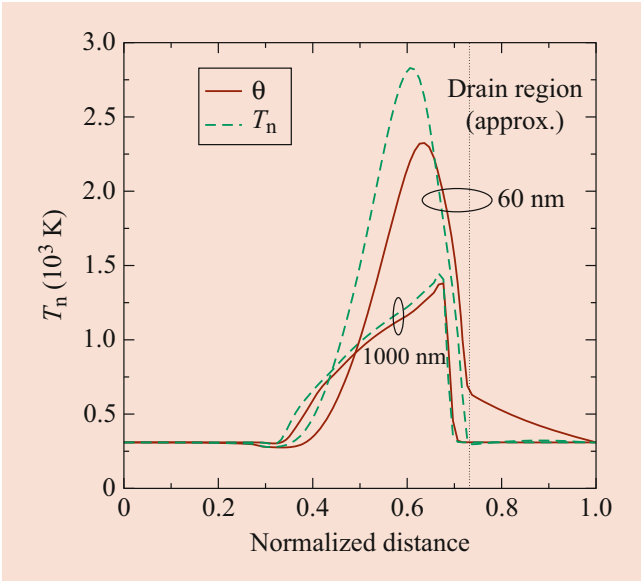

Fig. 37.31 Carrier temperature T_n together with the second-order temperature Θ for a 1000 nm and a 60 nm device. A bias leading to a maximum field of 50 kV/cm has been applied. While in the long-channel device a Maxwellian can be used, the high-energy tail in the short-channel device in the drain region increases

Kurtosis

As will be shown below, the kurtosis provides information to distinguish the channel region from the drain region [87]. The kurtosis of an n^+nn^+ structure with 100 nm channel length and a total length of 500 nm is visualized in Fig. 37.30 for different source and drain dopings. A constant channel doping of 10^{16} cm^{-3} is considered. As can be observed, for low doping, the maximum peak of the kurtosis is at 300 nm. For high doping, the maximum is at about 220 nm.

This can be explained as follows: Due to the higher concentration of cold electrons in the highly doped drain region, the relaxation of hot carriers is faster than in the low doped drain region. Hence, the maximum peak of β for the high doping concentration case is 25% higher than for low doping concentrations.

In Fig. 37.31, the second-order temperature Θ defined as

$$\Theta = \beta T_n \tag{37.184}$$

and the carrier temperature T_n are presented for a short- and a long-channel device. For the long-channel device, the hot distribution part can be neglected due to the small deviation of the second-order temperature Θ from T_n. Note that for cold carriers, where the energy distribution function follows a Maxwellian distribution for which $\beta = 1$, we also have $\Theta = T_n$.

Large field gradients strongly influence the kurtosis as shown in Fig. 37.32. Here, the kurtosis for fields of 5 kV/cm, 20 kV/cm, and 50 kV/cm for a 100 nm channel length structure is shown in the upper part of Fig. 37.32. The electric field has been calculated in the middle of the channel at Point A. As can be seen for a low field of 5 kV/cm, where the carrier temperature is low (see the lower part), a heated Maxwellian ($\beta_M = 1$) can be used, while for 20 kV/cm, an increase of the kurtosis at the beginning of the drain region is apparent. An overall significant increase of the kurtosis can be observed for high fields. As shown in the upper part of Fig. 37.32, the kurtosis starts to rise when the maximum of the carrier temperature decreases to the equilibrium value. This is the region where the hot electrons from the channel meet the large pool of cold electrons in the drain region, which quickly thermalizes the energy distribution function.

Velocity Overshoot

Within this work, the velocity overshoot has already been shown for n^+nn^+ test structures in Fig. 37.24 and for double-gate MOSFETs in Fig. 37.28. For a complete discussion, the velocity is given in Fig. 37.33 for the same type of structure which has been simulated in the previous figures. The ET transport model yields the same velocity profile in the low-field regime as the SM model, which is an indication that a Maxwellian is a good approximation at low fields. However, for high fields, the ET model overestimates the velocity profile of the DD and the SM model and exhibits a maximum at the end of the channel.

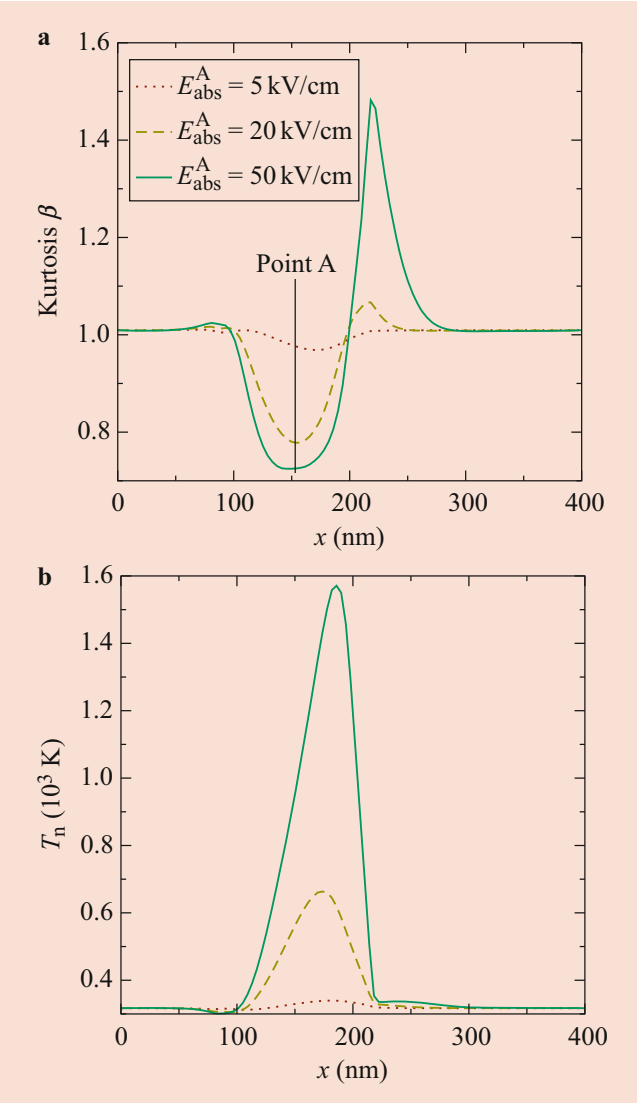

Fig. 37.32 Kurtosis β (**a**) and the carrier temperature (**b**) for electric fields of 5 kV/cm, 20 kV/cm, and 50 kV/cm through a 100 nm channel n^+nn^+ device (the value of the fields is calculated at Point A from Fig. 37.30). For high fields, the kurtosis increases at the beginning of the drain region, which means that the high-energy tail of the distribution function becomes very important. In the lower part of the figure, the carrier temperature profile for different electric fields is shown. The kurtosis exceeds unity in the region, where the carrier temperature drops down

Impact Ionization

Impact ionization due to high lateral fields occurs particularly in n-channel MOSFETs, because of the higher velocity of electrons compared to holes. The electrons in the conduction band collide with electrons in the valence band and generate electron-hole pairs. Hence, the probability of impact ionization for electrons in a strong field is determined by the probability that the electrons will acquire the ionization energy of the atoms from the field [105].

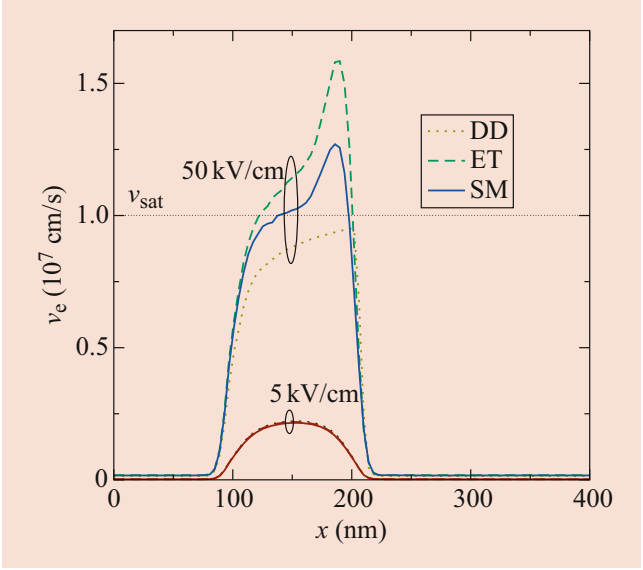

Fig. 37.33 The velocity profile for fields of 5 kV/cm and 50 kV/cm is shown for a MOSFET. For low fields, all models yield the same velocity profiles, which is an indication that the heated Maxwellian can be used. For high fields, a significant deviation of the velocity profiles can be observed

Figure 37.34 shows impact ionization rates of a 200 nm (Fig. 37.34a) and a 50 nm (Fig. 37.34b) channel device calculated with the DD, ET, and SM model and the Monte Carlo method. As can be observed, the impact ionization rate predicted by the SM model is closer to Monte Carlo simulation data than the ET and the DD model due to the better modeling of the distribution function in the SM model [106, 107].

Hot-Carrier Gate Currents

In the channel region of a MOSFET, the energy distribution deviates from the ideal shape implied by a heated Maxwellian. The carrier energy distribution influences tunneling processes which is important for modeling of gate leakage currents in turned-on devices. If a heated Maxwellian approximation is used for the description of hot-carrier tunneling, the gate current density is heavily overestimated. This effect is found to be especially pronounced for devices with short gate lengths. Some non-Maxwellian models are reviewed in [108], and it is found that a model which is based on the solution variables of a six-moment transport model accurately reproduces the Monte Carlo simulation results.

Hot-Carrier Degradation

Hot-carrier degradation is a major device reliability issue, particularly for MOSFETs. The degradation is commonly assumed to be driven by the generation of traps at or near the Si/SiO_2 interface.

Charge carriers in the channel can gain high kinetic energy and trigger the creation of defects at the Si/SiO_2 interface

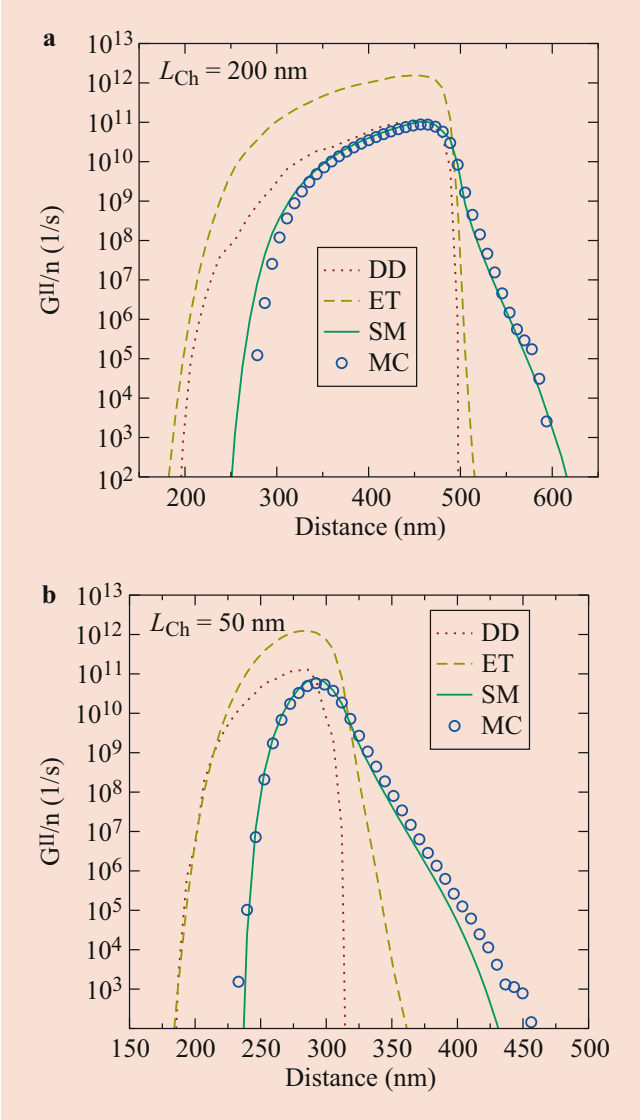

Fig. 37.34 The impact ionization rate calculated with Monte Carlo, the DD, ET, and the SM model for a 200 nm (**a**) and a 50 nm structure (**b**). Due to the better modeling of the distribution function in the SM model, the results are closer to the Monte Carlo simulation data than those of the DD and the ET model

[109, 110]. The driving force of this process is the energy deposited by charge carriers. For a proper physics-based description of this complex phenomenon, one again requires a detailed knowledge about the carrier transport in the targeted devices [111–116].

37.9 Summary and Conclusion

Macroscopic models for current transport in semiconductors can be formulated by following two approaches: phenomenologically, where the semiconductor equations are based on the laws of mass and energy conservation as well as the principles of irreversible thermodynamics, or systematically, where a set of equations is derived starting from the Boltzmann transport equation.

Transport models can be derived from the semiclassical Boltzmann equation using various methods. The method of moments can be considered the most general one as it does not require an explicit ansatz for the distribution function. Within the method of moments, the Boltzmann transport equation is multiplied with a polynomial weight function, and the whole equation is integrated over *k*-space. Each equation contains information about the next higher-order moment which yields an infinite number of coupled equations. To obtain a tractable equation set, this hierarchy has to be truncated at a certain order. The next higher-order moment has to be modeled as a function of the available lower-order moments which is referred to as the closure of the equation system.

When only the first two moments are considered, the drift-diffusion model is obtained, which is still predominantly used in engineering applications due to its simplicity and numerical stability. As the drift-diffusion model cannot capture nonlocal effects, which become increasingly important for miniaturized devices, its use becomes questionable. Therefore, higher-order equations have to be considered.

Inclusion of the first three or four moments of Boltzmann's equation results in hydrodynamic models which are, however, numerically too complicated to solve for everyday's use due to their hyperbolic nature. Within the framework of the diffusion approximation, the convective terms in the hydrodynamic models can be neglected, resulting in much simpler parabolic energy transport models, which are offered by the leading commercial device simulators in addition to the traditional drift-diffusion model.

A detailed study reveals some common problems observed in macroscopic transport models using only the first three or four moments. Most importantly, the energy distribution function is frequently modeled by a heated Maxwellian distribution. This distribution function model is then used to derive a closure relation. However, Monte Carlo simulations show that the energy distribution function is only poorly described by a heated Maxwellian distribution function, both for bulk and inhomogeneous devices. Another important issue is the modeling of the relaxation times and mobilities. Both quantities show a pronounced hysteresis when plotted over the average energy. This is insofar of importance as both quantities are often modeled as a single valued function of the average energy. A comparison with Monte Carlo simulation data reveals that this error in the mobilities and the error introduced in the closure relation cause a spurious overshoot in the velocity characteristics.

Based on the observations made during the evaluation of transport models including the first four moments of Boltzmann's transport equation, an extended model has been pro-

posed which includes the first six moments. The additional even order moment, the kurtosis of the distribution function, has been proven to be beneficial for device simulation and the modeling of hot-carrier effects.

Several interesting cases where the heated Maxwellian assumption introduces impermissibly large errors have been discussed, particularly impact ionization, hot-carrier gate currents, and hot-carrier degradation. Highly satisfactory results are obtained in all cases. The six-moment transport model, the six-moment impact ionization model, and the six-moment gate current model have been implemented in the device simulator MINIMOS-NT [117]. It has been demonstrated that the six-moment model can improve on the drift-diffusion and energy transport models and still has the advantage of vastly reduced numerical costs in relation to Monte Carlo simulations [11,74].

Acknowledgments Many of the results shown in the previous sections were computed with software developed by the Institute for Microelectronics at TU Wien in the course over many years. The authors are indebted to Andreas Gehring, Martin Wagner, Oliver Triebl, Thomas Windbacher, Prateek Sharma, Gerhard Rzepa, Stanislav Tyaginov, and Markus Kampl for their contributions to the development and implementation of the six-moment model or for applications thereof. We thank Viktor Sverdlov, Josef Weinbub, and especially Hans Kosina for numerous discussions during the preparation of this manuscript.

Special thanks go to Prof. David Esseni, who helped with Monte Carlo code and simulations. We are indebted to Prof. Christoph Jungemann who provided a spherical harmonic code and numerous fullband Monte Carlo simulation results.

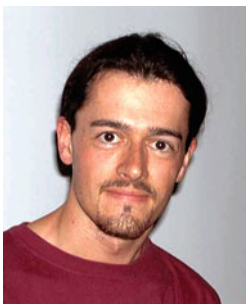
Johann Cervenka holds a Ph.D. degree in Electrical Engineering from TU Wien, Austria. He is a Senior Scientist at the Institute for Microelectronics, TU Wien. His research topics include the simulation of microelectronic devices and processes as well as algorithms for modeling quantum (Wigner) electron transport in nanostructures.

Robert Kosik holds an M.Sc. degree in Mathematics and a Ph.D. degree in Electrical Engineering from TU Wien, Austria. His research interests include partial differential equations for modeling of classical (Boltzmann) and quantum (Wigner) electron transport in microstructures and nanostructures, stochastic processes, probability theory, and uncertain reasoning in general.

Markus Jech received his M.Sc. degree in Physics and his Ph.D. degree in Electrical Engineering from the TU Wien, Austria, in 2014 and 2020, respectively. His research focuses on nonequilibrium reliability effects in transistors, such as hot-carrier degradation and its interplay with bias temperature instability, as well as on atomistic first principles modeling of defects and reactions of their formation.

Martin-Thomas Vasicek received his M.Sc. degree and his Ph.D. degree from TU Wien, Austria, in 2005 and 2009, respectively. His scientific interests include higher-order macroscopic transport models for advanced semiconductor devices.



Markus Gritsch studied Electrical Engineering at the TU Wien, Austria, and received his M.Sc. degree in 1999 and his Ph.D. degree in 2002. His scientific interests include circuit and device simulation, device modeling, and physical aspects in general.

Siegfried Selberherr is a Chair Professor at the TU Wien, Austria. With his research teams, he has published about 2000 manuscripts in journals, in books, and in proceedings, including 3 monographs and about 50 edited volumes. His research interests are modeling and simulation for nanoelectronic and microelectronic engineering. He has received numerous honors; he is a Fellow of the Institute of Electrical and Electronics Engineers, of the Academia Europaea, and of the European Academy of Sciences and Arts.

Tibor Grasser is a Professor of Microelectronic Reliability and an IEEE Fellow. He currently serves as an Associate Editor for the IEEE Transactions on Electron Devices following his assignment as Associate Editor for Microelectronics Reliability (Elsevier). His current research interests include theoretical modeling of performance aspects of 2D and 3D devices (charge trapping, reliability), starting from the ab initio level over more efficient quantum mechanical descriptions up to TCAD modeling. The models developed in his group have been made available in the most important commercial TCAD environments.

Abstract

This work focuses on some of the most relevant numerical issues in the solution of the drift-diffusion model for semiconductor devices. The drift-diffusion model consists of an elliptic and two parabolic partial differential equations which are nonlinearly coupled. A reliable numerical approximation of this model unavoidably leads to choose a suitable tessellation of the computational domain as well as specific solvers for linear and nonlinear systems of equations. These are the two main issues tackled in this work, after introducing a classical discretization of the drift-diffusion model based on finite elements. Numerical experiments are also provided to investigate the performances both of up-to-date and of advanced numerical procedures.

38.1 Introduction and Motivations

Partial differential equations (PDEs) can be used to model a wide variety of phenomena, ranging from sound propagation, heat transfer, diffusion processes, electrostatics, electrodynamics, fluid dynamics, elasticity, or quantum mechanics. A PDE model generally coincides with an equation (or with a system of equations) of the form

$$\mathcal{P}\left(x_1, \ldots, x_d, t, u, \frac{\partial u}{\partial t}, \frac{\partial u}{\partial x_1}, \ldots, \frac{\partial u}{\partial x_d}, \ldots, \frac{\partial^{k_t+k_1+\ldots+k_d} u}{\partial^{k_t} t\, \partial^{k_1} x_1 \cdots \partial^{k_d} x_d}, f\right) = 0, \tag{38.1}$$

with $\mathbf{x} = (x_1, \ldots, x_d)^{\mathrm{T}} \in \Omega \subset \mathbb{R}^d$ and $t \in I \subset \mathbb{R}$ the independent variables, $u = u(\mathbf{x}, t)$ the unknown function, f

the set of data, and where $\mathcal{P}$ mathematically translates the (mass, momentum, energy) conservation laws involved by the phenomenon at hand [1–3]. The law $\mathcal{P}$ is defined in the space-time domain $Q = \Omega \times I$, and it may be linear or nonlinear with respect to u and the involved derivatives, homogeneous or nonhomogeneous according to the presence or the absence of a source term feeding the system.

Model (38.1) has to be completed with initial and boundary conditions. Initial data specify the starting configuration of the modeled system. Boundary conditions constrain the problem evolution at the boundary, $\partial\Omega$, of the physical domain, by tuning, for instance, the value of the solution (Dirichlet conditions) or of the flux of the solution (Neumann conditions), or of a weighted combination of u and its flux (Robin conditions).

A classification at least for the second-order linear PDEs, which are the most frequently encountered in applications, is well-established. It is based on the *discriminant*, $\mathcal{D}$, of the differential operator, which combines the coefficients (here assumed constant) of the highest order derivatives, so that one can distinguish among elliptic ($\mathcal{D} < 0$), parabolic ($\mathcal{D} = 0$), and hyperbolic ($\mathcal{D} > 0$) PDEs. This classification gives an insight on the smoothness of the solution and on how it does depend on the initial and on the boundary conditions. In particular, when dealing with hyperbolic PDEs, the smoothness of the solution depends on the smoothness of the initial and of the boundary conditions (e.g., a discontinuity in the data propagates as a shock in the solution while, if the equation is nonlinear, shocks may occur even though the data are smooth). In contrast, the solution of an elliptic PDE is smooth although the initial and boundary conditions are rough. Parabolic PDEs are associated with time-dependent processes. Solutions are smooth in space but may exhibit singularities during the time window.

The modeling of the physical mechanisms occurring in modern semiconductor devices involves several aspects, such as the electrical transport, the thermal generation, mechanical stresses, the atomic migration, and chemical reactions. The most recurrent PDE problem to model the carrier transport in semiconductors is represented by the drift-diffusion model [4], which describes the electronic and the hole current flow in terms of a drift and a diffusion contribution. From a modeling viewpoint, the drift-diffusion equations coincide with an elliptic and two parabolic PDEs which are nonlinearly coupled and deserve an ad hoc theoretical as well as numerical investigation [5–7].

In practical problems, the integral to the PDE model (38.1) is generally not available, so that the solution u is approximated by numerical methods. The numerical solution of PDEs requires the replacement of the continuous differential equations with a discrete counterpart. This step is known as *discretization*. The specific features of the PDE affect the choice of the discretization. Essentially, we can distinguish between two main settings, namely, when the discretization takes place at discrete points or over discrete cells. The former approach coincides with a *finite difference* (FD) discretization (see, e.g., [8]), where the derivatives in the PDE are approximated at specific points by difference quotients obtained via the Taylor series expansion. The second approach considers the integral (weak) form of the PDE to represent the solution over discrete cells in terms of selected functions and then to integrate these functions analytically over the volume (*finite element* (FE) discretization, see, e.g., [9]), or to balance the fluxes through the cell sides (*finite volume* (FV) discretization, see, e.g., [10]). This chapter primarily focuses on the FE method. Independently of the adopted discretization, the key role to move from a continuous to a discrete setting is played by the generation of the computational mesh which provides a discrete representation of the physical domain Ω. Grid generation is the practice of creating a tessellation of a continuous geometric space into discrete cells [11–14]. The actual goal is to create a mesh that accurately describes the domain geometry and that, possibly, follows the main features of the solution, to better model the phenomenon under investigation. In particular, tessellations ensuring this last property are known as adapted meshes [11,12,15,16]. Ideally, the number of the cells should be the smallest possible to ensure a certain discretization accuracy and to make computations affordable. As an alternative, one could be interested in setting the number of mesh elements while maximizing the accuracy of the discretization. Generating a good computational grid becomes an important issue, especially in the presence of problems characterized by complex trends, such as singularities or boundary/internal layers, which pose additional challenges in the numerical solution. This is, for instance, the case of any semiconductor device. The presence of regions with a different type of doping requires ad hoc meshes to accurately describe the doping variation across the junctions. Moreover, the presence of material interfaces (e.g., between the silicon and the silicon oxide) or the use of polycrystalline materials induces complex physical mechanisms in correspondence with these interfaces that deserve to be carefully computed. This demands for meshes closely refined in such areas [17,18].

Concerning the time discretization, numerical methods can be divided into explicit and implicit algorithms. Among the most widely employed schemes, we mention the θ-method (which includes the well-known Euler and Crank-Nicolson algorithms), the backward differentiation formulas (BDF), and the Runge-Kutta schemes [19]. Implicit methods require an extra computation with respect to explicit schemes. However, for a wide class of problems (e.g., when dealing with stiff problems), explicit methods require impractical small time steps to ensure numerical stability, so that implicit schemes become the choice since allowing much

larger time steps [19]. Thus, the time partition is, in general, driven by stability considerations. Although less recurrent than the spatial one, adaptivity in time turns out to be a useful tool, especially when the modeled phenomena exhibit strong temporal heterogeneities. In semiconductor modeling, a standard approach to discretize the time dependence combines BDF schemes with the θ-method [20].

As the last step, the discretization of a model leads to solve a system of equations which may be linear or nonlinear according to the PDE involved and, in general, of large scale when tackling real-life problems. There exists a large variety of solvers for these systems. Among the most efficient linear solvers, we cite the preconditioned Krylov subspace methods [21]. Similar concepts can be used for nonlinear systems, where different nonlinear solvers can be combined to significantly improve the computational efficiency.

The chapter is organized as follows. Section 38.2 is devoted to the drift-diffusion model which is introduced both in the standard and in the scaled form. In Sect. 38.3 we introduce the Gummel map, which represents a very well-known tool to solve the drift-diffusion system. In particular, we provide the corresponding weak form and FE discretization, in order to obtain the algebraic counterpart of the Gummel map. Section 38.4 introduces the fully coupled Newton method which represents an alternative to the Gummel map to deal with the drift-diffusion model. The focus is mainly on the solvers to deal with the nonlinear systems characterizing such an approach. Sections 38.5 and 38.6 represent the core of the chapter. The former offers a rich survey about standard and advanced techniques for grid generation, by including examples of different types of meshes for a n-MOSFET semiconductor device. Section 38.6 focuses both on nonlinear and linear solvers to deal with the algebraic counterpart of the procedures in Sects. 38.2 and 38.4. Finally, the last Sect. 38.7 provides a numerical assessment of the methodological part when applied to a n-MOSFET device, with a specific attention to the role played by the selected computational grid and by the adopted solver in order to improve the accuracy and the efficiency of the simulations based on the drift-diffusion model.

38.2 Modeling Semiconductor Devices

In this section, we shortly review the drift-diffusion (DD) model, together with the associated initial and boundary conditions. For more details, we refer the reader, for instance, to [6,7].

The DD model is currently the most used approach to model the transport in semiconductors. DD equations were introduced by W. Van Roosbroeck in 1950 as a conservation system for electron and hole carriers, along with the electric field [4]. From a geometric viewpoint, a standard

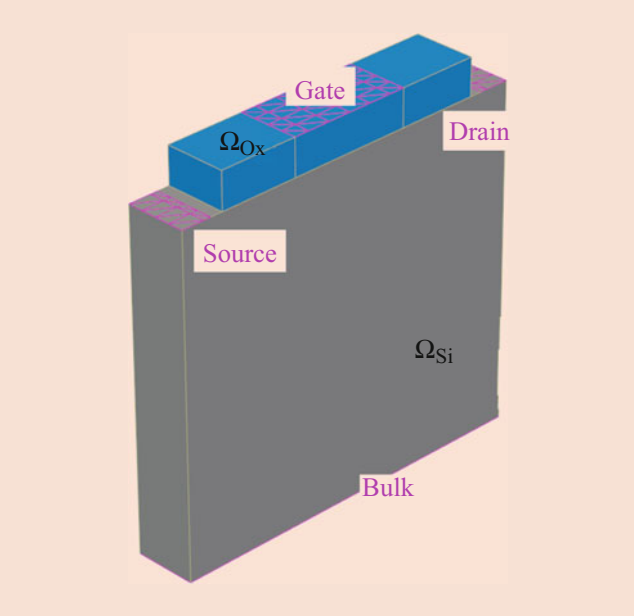

Fig. 38.1 Sketch of the geometry for a 3D MOSFET: the purple areas represent the electrical terminals (drain, source, gate, and bulk), where the boundary conditions of the DD system are assigned. Domains Ω_{Si} and Ω_{Ox}, of dimension $0.3 \times 0.05 \times 0.27\,\mu m^3$ and $0.22 \times 0.05 \times 0.01\,\mu m^3$, respectively, are highlighted

semiconductor device coincides with a bounded and simply connected domain $\Omega \subset \mathbb{R}^d$ ($d = 1, 2, 3$), which consists of a semiconductor part, Ω_{Si}, and, in the case of a metal-oxide-semiconductor (MOS), of a portion of thin oxide, Ω_{Ox}, which is adjacent to Ω_{Si}, so that $\bar{\Omega} = \bar{\Omega}_{Si} \cup \bar{\Omega}_{Ox}$ (see Fig. 38.1 for a sketch). The DD model is provided by the system

$$\begin{cases} \nabla \cdot \mathbf{D} = q(p - n + \bar{N}) \ \text{ with } \ \mathbf{D} = -\varepsilon \nabla\varphi = \varepsilon \mathbf{E} & \text{in } \mathbf{Q} \\ \dfrac{\partial n}{\partial t} - \dfrac{1}{q} \nabla \cdot \mathbf{J}_n = -R & \text{with } \ \mathbf{J}_n = q\mu_n n \mathbf{E} + qD_n \nabla n \ \text{ in } \mathbf{Q}_{Si} \\ \dfrac{\partial p}{\partial t} + \dfrac{1}{q} \nabla \cdot \mathbf{J}_p = -R & \text{with } \ \mathbf{J}_p = q\mu_p p \mathbf{E} - qD_p \nabla p \ \text{ in } \mathbf{Q}_{Si}, \end{cases} \tag{38.2}$$

whose unknowns coincide with the electrostatic potential, φ; the electron concentration, n; and the hole concentration, p, being $\mathbf{Q} = \Omega \times (0, t_f)$ and $\mathbf{Q}_{Si} = \Omega_{Si} \times (0, t_f)$, with t_f the final time of the considered time window. In particular, $\mathbf{D}$ models the electric displacement; $\mathbf{E}$ is the electric field; q is the positive electron charge; ε denotes the dielectric constant of the material; μ_n, μ_p and D_n, D_p are the mobilities and the diffusion coefficients of n and p, respectively; R is the net recombination/generation rate; $\bar{N} = N_D^+ - N_A^-$ is the net doping profile resulting from the sum of donors, N_D^+, and acceptors, N_A^-; $\mathbf{J}_n$ is the electron current density; and $\mathbf{J}_p$ is the hole current density.

Exploiting the explicit expression for $\mathbf{D}$, $\mathbf{J}_n$, and $\mathbf{J}_p$, we obtain a system of elliptic equations. In particular, the first

equation leads to the standard Poisson problem for the scalar variable φ, being

$$-\nabla\cdot(\varepsilon\nabla\varphi)=q(p-n+\bar{N})\ \text{ in } \mathbf{Q}. \tag{38.3}$$

The two remaining equations coincide with a nonlinear advection-diffusion-reaction model for n and p, respectively, and can be rewritten as

$$\begin{cases}\dfrac{\partial n}{\partial t}+\dfrac{1}{q}\nabla\cdot(q\mu_{\mathrm{n}}n\nabla\varphi-qD_{\mathrm{n}}\nabla n)=-\left(np-n_i^2\right)\mathcal{F}(n,p) & \text{in } \mathbf{Q}_{\mathrm{Si}}\\ \dfrac{\partial p}{\partial t}-\dfrac{1}{q}\nabla\cdot(q\mu_{\mathrm{p}}p\nabla\varphi+qD_{\mathrm{p}}\nabla p)=-\left(np-n_i^2\right)\mathcal{F}(n,p) & \text{in } \mathbf{Q}_{\mathrm{Si}}\end{cases} \tag{38.4}$$

with n_i the intrinsic concentration of the semiconductor material, representing the number of electrons and holes available for the electric conduction if $\bar{N}=0$ (see [22, Chapter 1]). For the rate R, we adopt the general form $(np-n_i^2)\mathcal{F}(n,p)$, which can model several recombination/generation mechanisms, by properly setting $\mathcal{F}$.

Concerning the boundary conditions completing the DD model, we have to distinguish between the Dirichlet, $\partial\Omega_{\mathrm{D}}$, and the Neumann, $\partial\Omega_{\mathrm{N}}$, portions of the boundary $\partial\Omega$ of Ω. With reference to the device in Fig. 38.1, $\partial\Omega_{\mathrm{D}}$ includes the MOSFET electrical terminals (drain, source, gate, and bulk) which are assumed to be ideal Ohmic contacts, while $\partial\Omega_{\mathrm{N}}$ coincides with the remaining portion of the boundary, i.e., $\partial\Omega_{\mathrm{N}}=\partial\Omega\setminus\partial\Omega_{\mathrm{D}}$. On $\partial\Omega_{\mathrm{D}}$, we assign nonhomogeneous data to all the unknowns, namely,

$$\varphi=\varphi_{\mathrm{D}},\quad n=n_{\mathrm{D}},\quad p=p_{\mathrm{D}}, \tag{38.5}$$

while we impose homogeneous data on $\partial\Omega_{\mathrm{N}}$ (i.e., we require that the fluxes of the electric field and of the current densities vanish across $\partial\Omega_{\mathrm{N}}$). To determine φ_{D}, n_{D}, and p_{D}, we enforce the thermodynamical equilibrium and charge neutrality conditions [22].

As far as the initial values is concerned, conditions $n=n_0$, $p=p_0$ are assigned consistently with the doping profile $\bar{N}$ and according to the Maxwell-Boltzmann distribution [22], whereas the initial value $\varphi=\varphi_0$ is obtained by prolongating the bias applied to the contacts into the whole domain (for more details, we refer to [5]).

Finally, we remark that the DD model actually consists of three nonlinear equations. Indeed, the electron and the hole concentrations are related to the potential φ via the Maxwell-Boltzmann statistics, being

$$n=n_i\exp\left(\frac{\varphi-\varphi_{\mathrm{n}}}{V_{\mathrm{th}}}\right),\quad p=n_i\exp\left(\frac{\varphi_{\mathrm{p}}-\varphi}{V_{\mathrm{th}}}\right), \tag{38.6}$$

where φ_{n} and φ_{p} are the electrochemical potentials and $V_{\mathrm{th}}=K_{\mathrm{B}}T/q$ is the thermal potential, with K_{B} the Boltzmann constant and T the device temperature. Thus, the Poisson equation (38.3) turns out to be nonlinear with respect to φ. In practice, the nonlinearity characterizing the DD model is tackled by resorting to two alternative strategies, i.e., the decoupling Gummel approach or the fully coupled Newton approach which will be tackled in Sects. 38.3 and 38.4, respectively.

38.2.1 The Scaled Dimensionless DD Model

Models (38.3) and (38.4) depend on quantities characterized by a different physical dimension. It is advisable to reformulate such a model in a dimensionless form, in order to reduce possible numerical oscillations (see Sect. 38.4). One possibility consists in scaling the potential by the thermal voltage, V_{th}; the concentration by the intrinsic concentration, n_i; and the length by the characteristic Debye length, $L_{\mathrm{D}}=\sqrt{\varepsilon V_{\mathrm{th}}/(qn_i)}$ [23]. Another option leads to scale the potential by the thermal voltage, V_{th}, the concentration by the maximum value of $\bar{N}$ over the whole domain, and the length by a characteristic device dimension [7, 24]. By adopting, for simplicity, the same notation for the unscaled and scaled unknowns, we can write the scaled dimensionless DD model as

$$\begin{cases}-\lambda^2\nabla\cdot(\varepsilon\nabla\varphi)=p-n+\bar{N} & \text{in } \mathbf{Q}\\ \dfrac{\partial n}{\partial t}+\nabla\cdot(\mu_{\mathrm{n}}(n\nabla\varphi-\nabla n))=-R & \text{in } \mathbf{Q}_{\mathrm{Si}}\\ \dfrac{\partial p}{\partial \hat{t}}-\nabla\cdot\left(\mu_{\mathrm{p}}(p\nabla\varphi+\nabla p)\right)=-R & \text{in } \mathbf{Q}_{\mathrm{Si}}\end{cases} \tag{38.7}$$

being

$$D=-\varepsilon\nabla\varphi,\ \mathbf{J}_{\mathrm{n}}=\mu_{\mathrm{n}}(-n\nabla\varphi+\nabla n),\ \mathbf{J}_{\mathrm{p}}=-\mu_{\mathrm{p}}(p\nabla\varphi+\nabla p) \tag{38.8}$$

and where λ^2 is a scalar depending on the adopted scaling. We refer to [25, p. 326] for a complete list of possible choices for the scaling factors. Clearly, the scaling has to be applied also to the boundary and to the initial conditions.

In the sequel, we will essentially refer to formulations (38.3) and (38.4), although in some context the dimensionless model plays a crucial role [26].

38.3 The Gummel Map

To simplify the discussion, we neglect the time dependence in (38.3) and (38.4). Actually, the Gummel map is an iterative algorithm originally proposed in [27] to solve this stationary problem, although it can be extended to a time-dependent setting in a straightforward way. The basic idea is to preserve the nonlinearity only for the Poisson equation (38.3), while linearizing the continuity equation for the electrons and for

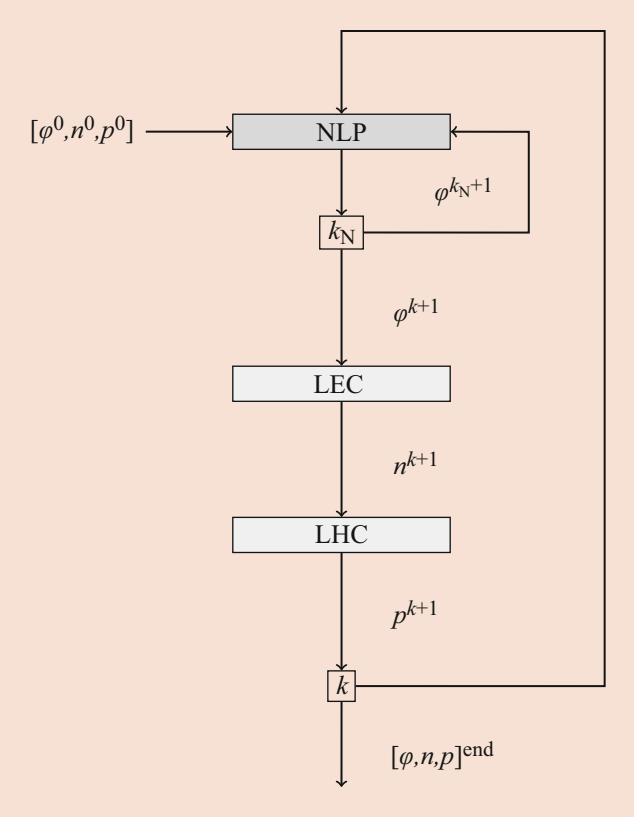

Fig. 38.2 Flowchart of the Gummel map

the holes. In particular, we tackle the nonlinearity in (38.3) by resorting to the standard Newton method (in this section, we limit to a plain use of this algorithm, while referring to Sect. 38.6.1 for all the details and for more sophisticated variants of it). The whole decoupling Gummel algorithm is outlined in Fig. 38.2, where NLP stands for nonlinear Poisson problem, whereas LEC and LHC denote the linearized electron and hole continuity equations. We distinguish between the Gummel iterations, identified by index k, and the Newton iterations, identified by index k_N.

At the generic iteration, $k+1$, of the Gummel map, first we approximate the electrostatic potential φ via φ^{k+1}, where φ^{k+1} denotes the value Newton algorithm converges to. In more detail, at the generic iteration, k_N+1, of the Newton method, we compute the approximation φ^{k_N+1} for φ^{k+1} such that

$$\varphi^{k_N+1} = \varphi^{k_N} + \delta\varphi^{k_N},$$

where the update $\delta\varphi^{k_N}$ is the solution to the problem

$$\begin{cases} \nabla\cdot(-\varepsilon\nabla\delta\varphi^{k_N}) + \sigma^{k_N}\delta\varphi^{k_N} = -f^{k_N} & \text{in } \Omega \\ \delta\varphi^{k_N} = 0 & \text{on } \partial\Omega_D \\ \varepsilon\nabla\delta\varphi^{k_N}\cdot\mathbf{n} = 0 & \text{on } \partial\Omega_N, \end{cases} \tag{38.9}$$

with $\mathbf{n}$ the unit outward normal vector to the boundary, and with

$$\sigma^{k_N} = \begin{cases} \dfrac{qn_i}{V_{th}}\left(\exp\left(\dfrac{\varphi_p-\varphi^{k_N}}{V_{th}}\right)+\exp\left(\dfrac{\varphi^{k_N}-\varphi_n}{V_{th}}\right)\right) & \text{in } \Omega_{Si} \\ 0 & \text{in } \Omega_{Ox} \end{cases} \tag{38.10}$$

and

$$f^{k_N} = \begin{cases} \nabla\cdot(-\varepsilon\nabla\varphi^{k_N}) - qn_i\left(\exp\left(\dfrac{\varphi_p-\varphi^{k_N}}{V_{th}}\right)-\exp\left(\dfrac{\varphi^{k_N}-\varphi_n}{V_{th}}\right)\right) - q\tilde{N} & \text{in } \Omega_{Si} \\ \nabla\cdot(-\varepsilon\nabla\varphi^{k_N}) & \text{in } \Omega_{Ox}. \end{cases}$$

Then, we linearize equations (38.4). With this aim, we replace φ with φ^{k+1}, and we compute the right-hand side of Eqs. $(38.4)_1$ and $(38.4)_2$, here denoted by R_n^{k+1} and R_p^{k+1}, respectively, as

$$\begin{aligned} R_n^{k+1} &= -\left(n^{k+1}p^k - n_i^2\right)F(n^k,p^k), \\ R_p^{k+1} &= -\left(n^k p^{k+1} - n_i^2\right)F(n^k,p^k). \end{aligned} \tag{38.11}$$

If other recombination/generation mechanisms are considered, the same type of linearization can be adopted in a straightforward way. Thus, we obtain LEC and LHC equations which read

$$\begin{cases} \nabla\cdot\left(q\mu_n^{k+1}n^{k+1}\nabla\varphi^{k+1} - qD_n^{k+1}\nabla n^{k+1}\right) = qR_n^{k+1} & \text{in } \Omega_{Si} \\ n^{k+1} = n_D & \text{on } \partial\Omega_{D,Si} \\ \nabla n^{k+1}\cdot\mathbf{n} = 0 & \text{on } \partial\Omega_{N,Si} \end{cases} \tag{38.12}$$

and

$$\begin{cases} -\nabla\cdot\left(q\mu_p^{k+1}p^{k+1}\nabla\varphi^{k+1} + qD_p^{k+1}\nabla p^{k+1}\right) = qR_p^{k+1} & \text{in } \Omega_{Si} \\ p^{k+1} = p_D & \text{on } \partial\Omega_{D,Si} \\ \nabla p^{k+1}\cdot\mathbf{n} = 0 & \text{on } \partial\Omega_{N,Si}, \end{cases} \tag{38.13}$$

respectively with $\partial\Omega_{D,Si} = \partial\Omega_D \cap \partial\Omega_{Si}$, $\partial\Omega_{N,Si} = \partial\Omega_N \cap \partial\Omega_{Si}$. Notice that the mobilities as well as the diffusion coefficients might depend on φ, n, and p, so that they have to be updated throughout Gummel iterations. The idea is to compute these quantities by exploiting the same linearization as in (38.11) in order to preserve the linearity of Eqs. (38.12) and (38.13).

Finally, problems (38.12) and (38.13) are solved with respect to the carrier densities, n^{k+1} and p^{k+1}, respectively, which are successively used to compute the quasi-Fermi potentials, φ_n and φ_p, in (38.10) via the formulas (38.6), before restarting the Gummel iterations.

Suitable stopping criteria clearly control both the Gummel and Newton loops. Standard choices are based on the residual (to stop NLP iterations) and on the increment (to stop LEC and LHC iterations). Moreover, we remark that the current definition of R_n^{k+1} and R_p^{k+1} in (38.11) allows us to solve LEC

and LHC problems in parallel, in the spirit of a Jacobi solver. As an alternative, one can modify the definition of R_{p}^{k+1} by replacing n^k with n^{k+1}, this leading to a sequential Gauss-Seidel-like solver.

38.3.1 Toward the Numerical Solution of the Gummel Map

The numerical solution of the Gummel map moves from the weak formulation of the corresponding differential problems and the associated well-posedness analysis. In the sequel, we adopt standard notation for the function spaces involved in this analysis [28]. For the sake of simplicity, we remove any dependence on the indices associated with the Gummel and Newton iterations throughout the whole section.

Let us first consider Eq. (38.9), whose weak form reads: find $\delta\varphi \in V = H^1_{0,\partial\Omega_{\mathrm{D}}}(\Omega)$ such that

$$a_{\mathrm{NLP}}(\delta\varphi, v) = F_{\mathrm{NLP}}(v) \quad \forall v \in V, \tag{38.14}$$

whose bilinear and linear forms, $a_{\mathrm{NLP}} : V \times V \to \mathbb{R}$ and $F_{\mathrm{NLP}} : V \to \mathbb{R}$, are defined by

$$\begin{aligned} a_{\mathrm{NLP}}(u, v) &= \int_\Omega \varepsilon \nabla u \cdot \nabla v \, \mathrm{d}\Omega + \int_\Omega \sigma u v \, \mathrm{d}\Omega, \\ F_{\mathrm{NLP}}(v) &= \int_\Omega -f v \, \mathrm{d}\Omega, \end{aligned} \tag{38.15}$$

respectively for any $u, v \in V$. The boundary conditions in (38.9) are exploited to choose space V and to erase the boundary contributions yielded by the integration by parts of the diffusive term.

The well-posedness of problem (38.14) is analyzed by resorting to the Lax-Milgram lemma [1, 28]. The continuity of $a_{\mathrm{NLP}}(\cdot,\cdot)$ is proved by combining Hölder with Cauchy-Schwarz inequalities and by exploiting the definition of the norm in V. This leads to the upper bound

$$\begin{aligned} \left|a_{\mathrm{NLP}}(u, v)\right| &\le \|\varepsilon\|_{L^\infty(\Omega)} \|\nabla u\|_{L^2(\Omega)} \|\nabla v\|_{L^2(\Omega)} \\ &\quad + \|\sigma\|_{L^\infty(\Omega)} \|u\|_{L^2(\Omega)} \|v\|_{L^2(\Omega)} \\ &\le \left[\|\varepsilon\|_{L^\infty(\Omega)} + \|\sigma\|_{L^\infty(\Omega)}\right] \|u\|_V \|v\|_V, \end{aligned} \tag{38.16}$$

after assuming $\varepsilon, \sigma \in L^\infty(\Omega)$, with $M = \|\varepsilon\|_{L^\infty(\Omega)} + \|\sigma\|_{L^\infty(\Omega)}$ the continuity constant of the bilinear form. (We can relax the regularity assumption on σ, by choosing $\sigma \in L^2(\Omega)$. By exploiting inequality $\|uv\|_{L^2(\Omega)} \le \|u\|_{L^4(\Omega)} \|v\|_{L^4(\Omega)}$ and the Sobolev immersion theorem, we have $\left|a_{\mathrm{NLP}}(u, v)\right| \le [\|\varepsilon\|_{L^\infty(\Omega)} + \|\sigma\|_{L^2(\Omega)}] \|u\|_V \|v\|_V$, i.e., the continuity property with $M = \|\varepsilon\|_{L^\infty(\Omega)} + \|\sigma\|_{L^2(\Omega)}$.) The coercivity of $a_{\mathrm{NLP}}(\cdot,\cdot)$ is guaranteed by requiring $\varepsilon(\mathbf{x}) \ge \varepsilon_{\mathrm{m}} > 0$ a.e. in Ω and $\sigma(\mathbf{x}) \ge 0$ a.e. in Ω, so that we have, for any $v \in V$,

$$a_{\mathrm{NLP}}(v, v) \ge \varepsilon_{\mathrm{m}} \left\|\nabla v\right\|^2_{L^2(\Omega)} \ge \frac{\varepsilon_{\mathrm{m}}}{1 + C_{\mathrm{P}}^2} \|v\|^2_V, \tag{38.17}$$

with $\alpha = \varepsilon_{\mathrm{m}}/(1 + C_{\mathrm{P}}^2)$ the coercivity constant of the bilinear form and where C_{P} denotes the Poincaré constant. Finally, the continuity of $F_{\mathrm{NLP}}(\cdot)$ is ensured by selecting $f \in L^2(\Omega)$. Indeed, the Cauchy-Schwarz inequality together with the definition of the norm in V leads to the bound

$$\left|F_{\mathrm{NLP}}(v)\right| \le \|f\|_{L^2(\Omega)} \|v\|_{L^2(\Omega)} \le \|f\|_{L^2(\Omega)} \|v\|_V \tag{38.18}$$

for any $v \in V$, so that $\tilde{C} = \|f\|_{L^2(\Omega)}$ represents the continuity constant for the linear form.

Now we consider Eq. (38.12). After simplifying q throughout all the terms, we rewrite the LEC problem as an advection-diffusion-reaction problem (in conservative form), namely, as

$$\begin{cases} -\nabla \cdot (D_{\mathrm{n}} \nabla n) + \nabla \cdot (\boldsymbol{\beta}_{\mathrm{n}} n) + \sigma_{\mathrm{n}} n = f_n & \text{in } \Omega_{\mathrm{Si}} \\ n = n_{\mathrm{D}} & \text{on } \partial\Omega_{\mathrm{D,Si}} \\ \nabla n \cdot \mathbf{n} = 0 & \text{on } \partial\Omega_{\mathrm{N,Si}} \end{cases} \tag{38.19}$$

with $\boldsymbol{\beta}_{\mathrm{n}} = \mu_{\mathrm{n}} \nabla\varphi$, $\sigma_{\mathrm{n}} = p\tilde{F}$, $f_{\mathrm{n}} = n_i^2 \tilde{F}$ and where we have denoted function $F(n^k, p^k)$ in (38.11) by $\tilde{F}$, made computable thanks to the performed linearization.

The weak form of the LEC equations is generally stated after rewriting (38.19) in terms of the so-called Slotboom variable [29]

$$u_n = n_i \exp\left(-\frac{\varphi_{\mathrm{n}}}{V_{\mathrm{th}}}\right), \tag{38.20}$$

so that n and u_n are related by

$$n = \exp\left(\frac{\varphi}{V_{\mathrm{th}}}\right) u_{\mathrm{n}}.$$

Notice that

$$\nabla u_{\mathrm{n}} = \exp\left(-\frac{\varphi}{V_{\mathrm{th}}}\right) \nabla n - \exp\left(-\frac{\varphi}{V_{\mathrm{th}}}\right) \frac{n}{V_{\mathrm{th}}} \nabla\varphi$$

and thanks to Einstein's relation, $D_{\mathrm{n}} = \mu_{\mathrm{n}} V_{\mathrm{th}}$. Thus, it follows

$$\begin{aligned} \nabla \cdot \left(-D_{\mathrm{n}} \exp\left(\frac{\varphi}{V_{\mathrm{th}}}\right) \nabla u_{\mathrm{n}}\right) &= \nabla \cdot (-D_{\mathrm{n}} \nabla n + \mu_{\mathrm{n}} n \nabla\varphi) \\ &= \nabla \cdot \left(-D_{\mathrm{n}} \nabla n + \boldsymbol{\beta}_{\mathrm{n}} n\right). \end{aligned}$$

Exploiting this relation in (38.19) and the boundary conditions for the potential on $\partial\Omega_{\mathrm{N}}$, we obtain

$$\begin{cases} \nabla \cdot \left(-D_{\mathrm{n}} \exp\left(\dfrac{\varphi}{V_{\mathrm{th}}}\right) \nabla u_{\mathrm{n}}\right) + \sigma_{\mathrm{n}} \exp\left(\dfrac{\varphi}{V_{\mathrm{th}}}\right) u_{\mathrm{n}} = f_{u_{\mathrm{n}}} & \text{in } \Omega_{\mathrm{Si}} \\ u_{\mathrm{n}} = n_{\mathrm{D}} \exp\left(-\dfrac{\varphi}{V_{\mathrm{th}}}\right) & \text{on } \partial\Omega_{\mathrm{D,Si}} \\ \nabla u_{\mathrm{n}} \cdot \mathbf{n} = 0 & \text{on } \partial\Omega_{\mathrm{N,Si}}, \end{cases} \tag{38.21}$$

where $f_{u_{\mathrm{n}}}$ coincides with function f_{n} in (38.19) properly rewritten in terms of the Slotboom variable.

To provide the weak form of Eq. (38.21), we pick the space $W = H^1_{0,\partial\Omega_{\mathrm{D,Si}}}(\Omega_{\mathrm{Si}})$, so that, we have: find $u_{\mathrm{n}} \in W$ such that

$$a_{\mathrm{LEC}}(u_{\mathrm{n}}, w) = F_{\mathrm{LEC}}(w) \quad \forall w \in W, \tag{38.22}$$

where the bilinear and linear forms, $a_{\mathrm{LEC}} : W \times W \to \mathbb{R}$ and $F_{\mathrm{LEC}} : W \to \mathbb{R}$, are defined by

$$\begin{aligned} a_{\mathrm{LEC}}(u, w) &= \int_{\Omega_{\mathrm{Si}}} D_{\mathrm{n}} \exp\left(\frac{\varphi}{V_{\mathrm{th}}}\right) \nabla u \cdot \nabla w \, d\Omega_{\mathrm{Si}} \\ &\quad + \int_{\Omega_{\mathrm{Si}}} \sigma_{\mathrm{n}} \exp\left(\frac{\varphi}{V_{\mathrm{th}}}\right) uw \, d\Omega_{\mathrm{Si}}, \\ F_{\mathrm{LEC}}(w) &= \int_{\Omega_{\mathrm{Si}}} f_{u_{\mathrm{n}}} w \, d\Omega_{\mathrm{Si}} - a_{\mathrm{LEC}}(R_{u_{\mathrm{n}}}, w), \end{aligned} \tag{38.23}$$

respectively for any $u, w \in W$, and where $R_{u_{\mathrm{n}}} \in H^1(\Omega_{\mathrm{Si}})$ denotes the lifting of the nonhomogeneous Dirichlet data in (38.21), so that, $R_{u_{\mathrm{n}}}\big|_{\partial\Omega_{\mathrm{D,Si}}} = n_{\mathrm{D}} \exp(-\varphi/V_{\mathrm{th}})$.

We exploit the Lax-Milgram lemma to investigate the well-posedness of problem (38.22). By adopting the notation $\gamma_{\mathrm{n}} = D_{\mathrm{n}} \exp(\varphi/V_{\mathrm{th}})$, $\delta_{\mathrm{n}} = \sigma_{\mathrm{n}} \exp(\varphi/V_{\mathrm{th}})$, we can repeat computations in (38.16) and (38.17), so that we can ensure the continuity and the coercivity of the bilinear form $a_{\mathrm{LEC}}(\cdot,\cdot)$ under the hypotheses $\gamma_{\mathrm{n}}, \delta_{\mathrm{n}} \in L^\infty(\Omega_{\mathrm{Si}})$, $\gamma_{\mathrm{n}}(\mathbf{x}) \geq \gamma_{\mathrm{n,m}} > 0$ a.e. in Ω_{Si}, $\delta_n(\mathbf{x}) \geq 0$ a.e. in Ω_{Si}, with $M_{\mathrm{n}} = \|\gamma_{\mathrm{n}}\|_{L^\infty(\Omega_{\mathrm{Si}})} + \|\delta_{\mathrm{n}}\|_{L^\infty(\Omega_{\mathrm{Si}})}$ and $\alpha_{\mathrm{n}} = \gamma_{\mathrm{n,m}}/(1 + C_{\mathrm{P}}^2)$ the continuity and coercivity constant, respectively. As far as the continuity of $F_{\mathrm{LEC}}(\cdot)$ is concerned, following (38.18) and by exploiting the continuity of $a_{\mathrm{LEC}}(\cdot,\cdot)$, we have

$$\left|F_{\mathrm{LEC}}(w)\right| \leq \|f_{u_{\mathrm{n}}}\|_{L^2(\Omega_{\mathrm{Si}})} \|w\|_W + M_{\mathrm{n}} \|R_{u_{\mathrm{n}}}\|_W \|w\|_W$$

for any $w \in W$, so that, for $f_{u_{\mathrm{n}}} \in L^2(\Omega_{\mathrm{Si}})$, we can guarantee the continuity of the linear form. The well-posedness of (38.22) thus follows.

Problem (38.13) can be addressed analogously to LEC equation, by introducing the corresponding Slotboom variable $u_{\mathrm{p}} = n_i \exp(\varphi_{\mathrm{p}}/V_{\mathrm{th}})$ [29]. This completes the well-posedness analysis for the weak form of the Gummel map.

38.3.2 The Discretization of the Gummel Map

To provide the discrete counterpart of the Gummel map, we have first to define a discretization $\mathcal{T}_h = \{K\}$ of the computational domain. The choice of $\mathcal{T}_h$ is not a trivial task, in particular when dealing with complex phenomena such as the modeling of semiconductor devices. For this reason, we devote the whole Sect. 38.5 to furnish some hints for the generation of a good computational mesh.

Concerning the adopted discretization scheme, we focus on a FE approach as implemented in [30], although instances of FV discretizations are available in commercial codes (e.g., in [26, 31]). To this aim, we introduce the discrete space,

$$X_h^1(\Omega) = \left\{v_h \in C^0(\bar{\Omega}) : v_h|_K \in \mathbb{P}_1(K), \forall K \in \mathcal{T}_h\right\},$$

of the continuous piecewise linear finite elements, associated with the tessellation $\mathcal{T}_h$. Thus, the discrete form of the nonlinear Poisson problem reads: find $\delta\varphi_h \in V_h$, with $V_h = V \cap X_h^1(\Omega)$, such that

$$a_{\mathrm{NLP}}(\delta\varphi_h, v_h) = F_{\mathrm{NLP}}(v_h) \quad \forall v_h \in V_h, \tag{38.24}$$

where the bilinear and linear forms, $a_{\mathrm{NLP}}(\cdot,\cdot)$ and $F_{\mathrm{NLP}}(\cdot)$, are defined exactly as in (38.15). We now introduce a Lagrangian basis, $\{\psi_j\}_{j=1}^{N_h}$, of the space V_h, with $N_h = \dim(V_h)$. This allows us to expand the discrete solution $\delta\varphi_h$ to (38.24) in terms of this basis as

$$\delta\varphi_h(\mathbf{x}) = \sum_{j=1}^{N_h} \delta\varphi_j \, \psi_j(\mathbf{x}), \tag{38.25}$$

and to pick the test function v_h in (38.24) as the generic basis function ψ_i, with $i = 1, \ldots, N_h$, so that we reduce the discrete problem (38.24) to the N_h identities

$$\sum_{j=1}^{N_h} \delta\varphi_j \, a_{\mathrm{NLP}}(\psi_j, \psi_i) = F_{\mathrm{NLP}}(\psi_i) \quad \text{with } i = 1, \ldots, N_h.$$

These relations identify the algebraic counterpart of the NLP problem, namely, the linear system

$$\mathbf{A}_{\mathrm{NLP}} \delta\boldsymbol{\varphi} = \mathbf{b}_{\mathrm{NLP}}, \tag{38.26}$$

where the stiffness matrix, $\mathbf{A}_{\mathrm{NLP}} \in \mathbb{R}^{N_h \times N_h}$, and the right-hand side, $\mathbf{b}_{\mathrm{NLP}} \in \mathbb{R}^{N_h}$, are defined by

$$[\mathbf{A}_{\mathrm{NLP}}]_{ij} = a_{\mathrm{NLP}}(\psi_j, \psi_i), \quad [\mathbf{b}_{\mathrm{NLP}}]_i = F_{\mathrm{NLP}}(\psi_i),$$

respectively, with $i, j = 1, \ldots, N_h$, while vector $\delta\boldsymbol{\varphi} \in \mathbb{R}^{N_h}$ collects the (unknown) coefficients $\{\delta\varphi_j\}_{j=1}^{N_h}$ characterizing the discrete solution $\delta\varphi_h$.

In a similar way, we introduce the discrete space $W_h = W \cap X_h^1(\Omega_{\rm Si})$, with basis $\{\theta_k\}_{k=1}^{M_h}$ and $M_h = \dim(W_h)$, where we look for an approximation

$$n_h(\mathbf{x}) = \sum_{k=1}^{M_h} n_k\, \theta_k(\mathbf{x})$$

of the electron concentration. This leads to solve the linear system

$$\mathbf{A}_{\rm LEC}\mathbf{N} = \mathbf{b}_{\rm LEC}, \tag{38.27}$$

with $\mathbf{A}_{\rm LEC} \in \mathbb{R}^{M_h \times M_h}$ and $[\mathbf{A}_{\rm LEC}]_{lk} = a_{\rm LEC}(\theta_k, \theta_l)$, $\mathbf{b}_{\rm LEC} \in \mathbb{R}^{M_h}$ and $[\mathbf{b}_{\rm LEC}]_l = F_{\rm NLP}(\theta_l)$, $\mathbf{N} \in \mathbb{R}^{M_h}$ and $[\mathbf{N}]_k = n_k$, for $l, k = 1, \ldots, M_h$, and where $a_{\rm LEC}(\cdot,\cdot)$ and $F_{\rm NLP}(\cdot)$ are defined as in (38.23).

Finally, the same procedure is applied to the hole concentration, p, to yield the associated linear system,

$$\mathbf{A}_{\rm LHC}\mathbf{P} = \mathbf{b}_{\rm LHC}. \tag{38.28}$$

The solver adopted for systems (38.26), (38.26), and (38.28) has to be carefully chosen. We refer the reader to Sect. 38.6 for an overview on possible solvers.

Remark 38.1 The Slotboom variables play a crucial role when proving the well-posedness of the Gummel map, as checked in Sect. 38.3.1. Nevertheless, the practical implementation of the Gummel map moves from the linearized equations (38.12) and (38.13). These equations may be troublesome from a numerical viewpoint, due to the occurrence of spurious oscillations, in particular when the drift component is dominant. A possible remedy is represented by a (global) mesh refinement, although this choice generally leads to an unaffordable computational cost, especially for 3D simulations. As an alternative, one can resort to suitable stabilization schemes for the FE discretization, such as the upwind technique [32], the Scharfetter-Gummel method [33], or the edge-averaged FE (EAFE) approach [34]. The employment of ad hoc adapted meshes represents a third possible solution to numerical instabilities which still deserves to be properly investigated.

Remark 38.2 Gummel map is applied in a stationary setting. When dealing with an unsteady configuration, the NLP problem remains unchanged, while the linearized equations (38.12) and (38.13) are embedded into a time-advancing loop, after being properly modified to include the contributions due to the time discretization (we refer the interested reader to [5] for more details). In the context of semiconductor modeling, the approximation in time is generally performed via the TRBDF2 method [20], i.e., a composite scheme which combines the trapezoidal rule (TR) with the second-order backward difference formula (BDF2) in a two-step method, to contemporary benefit of the accuracy of TR and of the stability properties of the BDF2 scheme.

38.4 The Fully Coupled Newton Approach

This procedure represents an alternative to the Gummel map to tackle the DD model [35]. To simplify the discussion, we exemplify such an approach on the scaled system (38.7), after neglecting the time dependence analogously to what done in Sect. 38.3, so that we have

$$\begin{cases} \mathcal{F}_1(\varphi, n, p) = -\lambda^2 \nabla \cdot (\varepsilon \nabla \varphi) - p + n - \bar{N} = 0 & \text{in } \mathbf{Q} \\ \mathcal{F}_2(\varphi, n, p) = \nabla \cdot (\mu_n (n \nabla \varphi - \nabla n)) + R(\mathbf{E}, n, p) = 0 & \text{in } \mathbf{Q}_{\rm Si} \\ \mathcal{F}_3(\varphi, n, p) = -\nabla \cdot \big(\mu_p (p \nabla \varphi + \nabla p)\big) + R(\mathbf{E}, n, p) = 0 & \text{in } \mathbf{Q}_{\rm Si}, \end{cases} \tag{38.29}$$

where we have highlighted the dependence of the net recombination/generation rate term, R, on the electric field and on the electron and the hole concentrations. We rewrite (38.29) in a matrix form, as

$$\mathbf{F}(\mathbf{U}) = \mathbf{0}, \tag{38.30}$$

with $\mathbf{F}(\mathbf{U}) = [\mathcal{F}_1(\mathbf{U}), \mathcal{F}_2(\mathbf{U}), \mathcal{F}_3(\mathbf{U})]^{\rm T}$, $\mathbf{U} = [\varphi, n, p]^{\rm T}$ and $\mathbf{0} = [0, 0, 0]^{\rm T}$.

We resort to the standard Newton method to solve system (38.29). As remarked in Sect. 38.3, the Newton algorithm is here meant as a simple tool to manage the nonlinearity of the problem, while referring to Sect. 38.6.1 for details and improvements of the basic setting. The update of the generic $k_{\rm N}$ iteration is performed via the standard rule

$$\mathbf{U}^{(k_{\rm N}+1)} = \mathbf{U}^{(k_{\rm N})} + \delta\mathbf{U}^{(k_{\rm N})}, \tag{38.31}$$

with $\mathbf{U}^{(k_{\rm N})} = [\varphi^{(k_{\rm N})}, n^{(k_{\rm N})}, p^{(k_{\rm N})}]^{\rm T}$. The update $\delta\mathbf{U}^{(k_{\rm N})} = [\delta\varphi^{(k_{\rm N})}, \delta n^{(k_{\rm N})}, \delta p^{(k_{\rm N})}]^{\rm T}$ is the solution to the system

$$\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})\delta\mathbf{U}^{(k_{\rm N})} = -\mathbf{F}(\mathbf{U}^{(k_{\rm N})}) \tag{38.32}$$

with $\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})$ the Jacobian matrix associated with the $k_{\rm N}$-th iteration. The generic entry $[\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})]_{ij}$ of the Jacobian matrix coincides with the Frèchet derivative of the i-th row of $\mathbf{F}(\mathbf{U})$ with respect to the j-th variable in $\mathbf{U}$. For instance, the first row of $\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})$ involves the derivatives of $\mathcal{F}_1(\mathbf{U})$, being

$$[\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})]_{11} = \frac{\partial \mathcal{F}_1(\mathbf{U}^{(k_{\rm N})})}{\partial \varphi}\delta\varphi^{(k_{\rm N})} = -\lambda^2 \nabla \cdot \left(\varepsilon \nabla \delta\varphi^{(k_{\rm N})}\right),$$

$$[\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})]_{12} = \frac{\partial \mathcal{F}_1(\mathbf{U}^{(k_{\rm N})})}{\partial n}\delta n^{(k_{\rm N})} = \delta n^{(k_{\rm N})},$$

$$[\mathbf{F}'(\mathbf{U}^{(k_{\rm N})})]_{13} = \frac{\partial \mathcal{F}_1(\mathbf{U}^{(k_{\rm N})})}{\partial p}\delta p^{(k_{\rm N})} = -\delta p^{(k_{\rm N})}.$$

The dependence of the mobilities, μ_n, μ_p, and of the net recombination/generation rate term, R, on the unknowns φ, n, and p explicitly affects the definition of the Jacobian entries $[\mathbf{F}'(\mathbf{U}^{(k_N)})]_{ij}$, for $i = 2, 3$.

We proceed now by discretizing each block of the Jacobian matrix. Consistently with Sect. 38.3, we resort to a FE discretization. Thus, at the generic k_N-th iteration, we are led to solve the algebraic system

$$\begin{bmatrix} \mathbf{A}_{11}^{(k_N)} & \mathbf{A}_{12}^{(k_N)} & \mathbf{A}_{13}^{(k_N)} \\ \mathbf{A}_{21}^{(k_N)} & \mathbf{A}_{22}^{(k_N)} & \mathbf{A}_{23}^{(k_N)} \\ \mathbf{A}_{31}^{(k_N)} & \mathbf{A}_{32}^{(k_N)} & \mathbf{A}_{33}^{(k_N)} \end{bmatrix} \begin{bmatrix} \delta\varphi^{(k_N)} \\ \delta n^{(k_N)} \\ \delta p^{(k_N)} \end{bmatrix} = \begin{bmatrix} -\mathbf{F}_1(\mathbf{U}^{(k_N)}) \\ -\mathbf{F}_2(\mathbf{U}^{(k_N)}) \\ -\mathbf{F}_3(\mathbf{U}^{(k_N)}) \end{bmatrix}, \tag{38.33}$$

where $\mathbf{A}_{ij}^{(k_N)}$ is the matrix associated with the FE discretization of $[\mathbf{F}'(\mathbf{U}^{(k_N)})]_{ij}$, while $\mathbf{F}_i(\mathbf{U}^{(k_N)})$ denotes the discrete counterpart of $\mathcal{F}_i(\mathbf{U}^{(k_N)})$, for $i, j = 1, 2, 3$.

To simplify the computation, we consider a discretization of the domain Ω only, and we set to zero the values taken by n and p at the dofs in $\Omega \backslash \Omega_{Si}$. Thus, each block $\mathbf{A}_{ij}^{(k_N)}$ in (38.33) coincides with a matrix of order N_h, with N_h the dimension of the FE space employed to discretize the Poisson problem, consistently with the notation adopted in Sect. 38.3.2. Thus, the order of the system involved by the Newton iterations in the fully coupled approach is higher compared with the one used at the NLP step of the Gummel algorithm ($3N_h$ versus N_h), with a consequent larger demand in terms of computational burden.

The choice of the initial guess to start Newton iterations in (38.31) is far from being trivial. Very often, the Gummel map is employed for this purpose, in the spirit of a predictor-corrector technique [5]. The increment represents the criterion usually adopted to stop Newton algorithm (we refer to Sect. 38.6.1 for more details).

Moreover, we remark that the complex definition often assumed by mobilities μ_n and μ_p makes the Jacobian, in general, an ill-conditioned matrix. This demands to resort to suitable scaling and balancing techniques, in order to avoid possible problems related to the round-off error propagation.

Finally, considerations analogous to the ones in Remark 38.2 hold when generalizing the fully coupled approach to a time-dependent framework.

38.5 Grid Generation: The Basics

The choice of the computational mesh represents a challenging task. Actually, grid generation cannot be identified with a unique process for a fixed domain. In this direction, we quote the statement "Mesh is not a data but an unknown of the problem" which clearly frames the grid generation issue [36].

Given a domain Ω, the first step toward mesh generation consists in a suitable discretization of the boundary, $\partial\Omega$, of Ω. This process, known as *boundary rectification*, is straightforward in the presence of Cartesian geometries, while unavoidably introduces an error (known as geometric error) when dealing with domains characterized by a complex shape. Grid nodes are expected to sharply approximate the original geometry, so that boundary conditions can be accurately imposed.

Successively, the problem turns into the construction of a tessellation of the internal part, $\mathring{\Omega}$, of Ω. Given a polygonal domain $\Omega \subset \mathbb{R}^3$ (so that the geometric error is null), a grid (or a mesh or a tessellation), $\mathcal{T}_h = \{K\}$, of Ω is such that:

(H1) $\overline{\Omega} = \bigcup_{K \in \mathcal{T}_h} K$;

(H2) $\mathring{K} \neq \emptyset$, for any cell (or element) $K \in \mathcal{T}_h$;

(H3) $\mathring{K}_1 \cap \mathring{K}_2 = \emptyset$, for any cells $K_1, K_2 \in \mathcal{T}_h$ with $K_1 \neq K_2$,

$\overline{\omega}$ and $\mathring{\omega}$ denoting the closure and the internal part of the generic set ω, respectively. Moreover, a mesh satisfying the additional condition

(H4) if $\mathcal{I} = K_1 \cap K_2 \neq \emptyset$, then $\mathcal{I}$ coincides with a vertex, an edge or a face in $\mathcal{T}_h$, for any cells $K_1, K_2 \in \mathcal{T}_h$ with $K_1 \neq K_2$,

is classified as *conformal* mesh [28]. In the sequel, we focus on conformal tessellations of Ω. The *grid size* is identified by the number of cells (i.e., the mesh cardinality) or of cell vertices, while the *cell size* coincides with the maximum length of the cell edges. In particular, when dealing with standard finite elements, the size of the cell K coincides with the diameter $h_K = \max_{\mathbf{x},\mathbf{y} \in K} |\mathbf{x} - \mathbf{y}|$.

The adopted discretization as well as the PDE to be solved have a direct impact on the construction of the tessellation $\mathcal{T}_h$. Actually, the shape of the elements K depends on the adopted discretization, on the geometry of Ω and on the PDE at hand. In general, in a 3D setting, tetrahedra, hexahedra, or prisms are adopted. Historically, finite differences are associated with Cartesian grids, since such regular lattice structures allow one to easily identify the points to be used in the representation of derivatives. On the contrary, general pattern tessellations are well suited to fill arbitrarily shaped regions and are usually related to a FE discretization. More recently, polytopal meshes have been employed in several settings (see, e.g., [37]), this topic being beyond the goal of the present work.

Computational grids can be categorized driven by different criteria. In the sequel, we consider the standard classification into structured, unstructured, and hybrid meshes, before considering more sophisticated techniques to generate grids customized to the considered problem.

38.5.1 Structured Meshes

The basic difference between structured and unstructured meshes lies in the data structure which most appropriately describes the grid. In particular, in the structured case, the connectivity of the grid is implicitly taken into account, while for unstructured grids, it has to be explicitly described through an appropriate data structure (see Sect. 38.5.2). For instance, a structured 3D mesh of quadrilateral cells consists of a set of coordinates and connectivities that naturally map into the elements of a 3D matrix. Neighboring points in the mesh are associated with neighboring elements in the mesh matrix. Thus, a 3D array, $X(i, j, k)$, can be used to store the coordinates of the mesh vertices, indices i, j, and k describing the position of points along the x-, y-, and z-direction, respectively. The idea generalizes in a straightforward way to structured meshes with arbitrarily shaped cells.

Among structured grids, the simplest ones are the Cartesian meshes obtained by the intersection of the Cartesian coordinates in Ω and whose cells are rectangular parallelepipeds in 3D (or rectangles in 2D). The basic idea, characterizing all the structured mesh generation methods, starts from a partition of $\partial\Omega$, fitting the physical boundary of the domain the best way as possible, and successively extends the computational mesh from the boundary to the interior of Ω. Following [14,38,39], we can distinguish essentially among three different methods to generate the internal mesh:

(a) *Algebraic methods*: the interior points of the grid are computed through transfinite interpolation [40]. These methods are very simple. However, they can lead to a degenerate tessellation (with overlapped or reversed elements) when applied to complex geometries.
(b) *Differential methods*: these approaches are ideal to deal with domains characterized by arbitrary shapes. To generate the internal mesh in Ω, a partial differential equation problem is solved on a reference domain. Solution to this problem will be the vertex coordinates of the grid in Ω. In particular, elliptic equations are employed when these coordinates are specified on the whole boundary. Vice versa, when the coordinates are specified only on a part of $\partial\Omega$, parabolic or hyperbolic problems are solved. Elliptic equations are widely employed since they ensure several good properties to the grid (e.g., grid orthogonality close to the boundary, smoothness and equal spacing of the coordinate lines according to the boundary curvature, no propagation of boundary discontinuities inside Ω).
(c) *Variational methods*: the internal mesh generation is driven by the optimization of different grid properties (e.g., non-degeneracy, smoothness, uniformity, near-orthogonality) which are imposed through special functionals defined on a set of smooth discrete transformations. A compromise grid, with properties close the desired ones, is thus obtained for a suitable combination of these functionals.

As we will see in Sect. 38.5.5, alternative techniques can be used to generate structured grids, especially in the presence of complex problems, such as in the modeling of semiconductor devices.

38.5.2 Unstructured Meshes

Unstructured grids are considered as the most efficient solution to deal with realistic geometries and complex solution features. In such a case, points and connectivities do not have any global structure. On the one hand, this allows one to add and delete nodes and elements according to the geometry or the solution, making these meshes the ideal setting where to perform mesh adaptation. On the other hand, for any vertex in $\mathcal{T}_h$, the connection with other points must be defined explicitly via the connectivity matrix. Standard information provided by such an array are the number of vertices, the number of elements, the coordinates for each vertex, and the vertices identifying each cell, sometimes completed by data related to the boundary discretization (e.g., the number of the edges constituting $\partial\Omega$ together with the vertices associated with these edges). The connectivity matrix clearly plays a role when dealing with the numerical solution of PDEs, leading to an additional computational effort. Actually, numerical algorithms based on an unstructured grid topology are the most costly in terms of operations per time step and memory per grid point.

In contrast to the generation of structured grids, algorithms to build unstructured meshes are usually driven by geometric criteria. Among the most widespread techniques, we mention:

(d) *The octree approach*: spatial decomposition methods were applied to mesh generation about three decades ago [41]. An octree procedure (quadtree in 2D) yields a hierarchical tree structure which is used to simplify the geometry of the grid. First, Ω is enclosed in a bounding box (one cell, the root). The domain is then approximated with a union of disjoint, variably sized cells, representing a partition of the domain. In particular, each cell is analyzed and recursively subdivided so as to determine whether it conforms to a stopping criterion (e.g., based on the curvature of the domain or supplied by an error estimate). If not, it is subdivided into eight (four in 2D) cells of identical size. A covering up of a spatial region enclosing the root is thus obtained. Each cell is finally further decomposed into tetrahedra, leading to a suitable unstructured mesh of the domain Ω. The

main drawback of the octree approach is the inability to match a prescribed boundary discretization, the grid on the surface being identified by the intersection of the irregular volume cells with the surface itself.

(e) *The Delaunay criterion*: (The basic geometric concept behind this approach has been discussed already by Dirichlet in 1850 [42].) this approach connects a specified set of nodes to form tetrahedra so that the circumsphere through the four vertices of a tetrahedral cell does not contain any other point (in-sphere (in-circle in 2D) criterion). For a given set of points, there exists a unique Delaunay triangulation [43]. The main limit of this technique is that it does not preserve the boundary integrity. To recover such a property, improvements of the basic approach have been proposed, such as the constrained and the conforming Delaunay triangulations (see, e.g., [44, 45]).

(f) *The advancing front method*: this procedure does not exploit geometric criteria. The main idea is to construct the mesh, element by element, starting from an initial front which coincides with a discretization of the domain boundary. An entity of the front is selected and a mesh element is generated by connecting this entity to an existing or to a newly created point in order to form a new cell. For each new element, the front is updated so that it dynamically evolves. The process stops when the domain is entirely meshed [46, 47]. In general, the marching direction for the front takes into account the normals to the surface. Limits of advancing front methods include the selection of the front entity and of the marching step size and the capability to prevent the front from intersecting.

The techniques above are often combined to overcome, for instance, the limits exhibited by approaches (d)–(e) in managing surfaces and interfaces. A possibility is to resort to the advancing front on the external parts of the domain and to apply the Delaunay criterion to generate the internal mesh (see Sect. 38.5.5). Moreover, we remark that approaches (d)–(f) can be adopted to generate also structured meshes. Finally, it is very recurrent to apply, after generation, a smoothing of the unstructured mesh (e.g., by a Laplacian-type smoother) in order to enhance the quality of the mesh [11, 13, 14].

38.5.3 Hybrid Meshes

Hybrid meshes combine structured with unstructured grids [48, 49], meshes with elements characterized by a different shape (triangles/tetrahedra with squares/parallelepipeds), or grids generated via different approaches (e.g., by alternating an octree with a Delaunay criterion, see Sect. 38.5.5). This combination is meant to benefit of the good properties characterizing the different grid types, for instance, the computational efficiency of structured meshes and the geometric flexibility of unstructured tessellations. In general, the advantages of one approach are the disadvantages of the other one. Hybrid meshes find a large employment when dealing with phenomena where the presence of boundary layers demands for ad hoc meshes. This occurs, for instance, when modeling semiconductor devices in correspondence with Si/SiO2 interfaces [50–52], or high Reynolds number turbulent flows with immersed bodies in aero- and hydro-dynamics [53, 54]. In particular, when unstructured grids are used, boundary layers require very small spacing, resulting either in very long skewed cells or in a prohibitively large number of small cells. The practical solution implemented in a structured/unstructured hybrid mesh resorts to very thin structured grids along layers immersed into an unstructured grid. Anisotropic meshes represent an alternative smart solution to manage boundary or internal layers (see Remark 38.4).

38.5.4 Advanced Techniques: Mesh Adaptation

The choice of ad hoc meshes can significantly enhance the accuracy of the computed solution together with the computational cost and time, especially in the modeling of complex systems. The generation of tessellations customized to the problem at hand represents the main goal of mesh adaptation. The idea is to cluster the grid points in regions where solution exhibits a problematic trend, thus providing a local finer resolution. Actually, without grid clustering, some important features are missed, and the accuracy of the solution degrades. The benefit led by an adapted mesh can be in terms of accuracy, for a fixed size of the mesh, or vice versa, in terms of mesh size, for a desired accuracy on the discrete solution. The alternative to an adapted grid is a uniform refinement in the whole domain which, however, turns out to be very costly, especially for multidimensional computations.

Two are the main ingredients required to adapt a computational mesh, namely, an estimation for the discretization error to identify the regions where the mesh has to be modified and a procedure to modify the grid starting from this information. We will focus on these two topics in the next sections, separately.

Evaluation of the Discretization Error

Typically, the areas of the domain where a high resolution is demanded (e.g., the location of the junction breakdown in semiconductor simulations) are not known a priori. This issue is generally accomplished by defining an error quantifier for the problem at hand. There exists an extensive choice of criteria to quantify the discretization error in the different areas

of Ω, which are mainly categorized into heuristic information and rigorous mathematical tools. In the former case, we deal with an *error indicator*, $\boldsymbol{\mathcal{I}}$. Standard examples include the comparison between the computational stencils involved by the approximation of different order for the differential operators, the comparison of the same derivatives on different (finer and coarser) meshes, the Hessian or the gradient of the numerical solution, physical features (e.g., stagnation points, vortices, layers, carrier generation, and multiplication), or geometric information (e.g., corners, interfaces) relevant for the considered problem. More rigorous approaches lead to define an *error estimator*, $\boldsymbol{\mathcal{S}}$, which can be classified as a priori or a posteriori. The common goal is to provide a control for a certain norm, $\|\cdot\|_*$, of the discretization error.

To simplify the exposition, we denote the (weak) solution to the PDE problem of interest by u and the corresponding (e.g., FE) discretization by u_h. An estimator for the discretization error, $e_h = u - u_h$, takes the form

$$\|e_h\|_* \leq C\,\boldsymbol{\mathcal{S}} = C\left(\sum_{K\in\mathcal{T}_h} \eta_K^2\right)^{1/2}, \tag{38.34}$$

with $\boldsymbol{\mathcal{S}}$ and η_K the global and the local error estimator, respectively, and $C > 0$ a constant. In more detail, an a priori error analysis leads to a local estimator of the form

$$\eta_K = \eta_K(u, h_K) = h_K^{\alpha}\,\|u|_K\|_{\beta},$$

while, with an a posteriori error analysis, we have

$$\eta_K = \eta_K(u_h, h_K) = h_K^{\gamma}\,\|R(u_h|_K)\|_{\delta},$$

for certain powers, α and γ, of the cell diameter, h_K, and for suitable norms, $\|\cdot\|_{\beta}$ and $\|\cdot\|_{\delta}$, where $R(u_h|_K)$ denotes a quantity (e.g., the residual) depending on the discrete solution. The elementwise structure of the global estimator $\boldsymbol{\mathcal{S}}$ is crucial in order to localize the areas of the domain where the approximation has to be improved (i.e., the elements characterized by the highest estimated error) and vice versa. The same property is demanded for an error indicator.

A posteriori error estimators are directly computable in contrast to a priori estimates which, in general, require to replace u with a computable quantity, before being employed to drive mesh adaptation. Standard examples of a priori results are the interpolation and the convergence estimates. Concerning the a posteriori error estimators, they differ essentially for the controlled quantity and can be distinguished into the following categories [55–57]:

(g) *Residual-based error estimators*: the norm $\|\cdot\|_*$ in (38.34) coincides with the $H^1(\Omega)$- or with the $L^2(\Omega)$-norm, while the local estimator depends on the internal and on the boundary residuals associated with u_h in K. The main drawback for these estimators is that the constant C in (38.34) is, in general, not explicitly computable;

(h) *Goal-oriented error estimators*: the quantity controlled now coincides with an error functional, $J(u - u_h)$, where $J(\cdot)$ models a goal quantity of interest [56], for instance, the convective or diffusive flux across a portion of the boundary, the current density in a semiconductor device, the lift or the drag in fluid dynamic applications, pointwise values, and the stress of an elastic body. The control of $J(u)$ via the computable quantity $J(u_h)$ is achieved by solving an auxiliary problem, the dual problem, whose source term is strictly related to J. The extra computational cost associated with the dual problem (in particular, in an unsteady setting) represents the main limit of a goal-oriented approach;

(j) *Recovery-based error estimators*: these estimators are widely employed in practice because of the good properties they exhibit, e.g., the independence from the problem and from the adopted discretization, the computational cheapness, and the implementation easiness [58,59]. The $H^1(\Omega)$-seminorm replaces norm $\|\cdot\|_*$ in (38.34), whereas the local estimator coincides with the recovered error, $\|\nabla^* u_h - \nabla u_h\|^2_{L^2(K)}$, where $\nabla^* u_h$ denotes the recovered gradient, namely, an approximation for ∇u, in general, more accurate than the discrete gradient, ∇u_h [60]. The main weak point of these estimators is the limited theoretical investigation;

(k) *Local error estimators*: this analysis is based on the solution of local problems. The challenge is the choice of the corresponding boundary conditions [55].

The Adaptive Procedure

We exemplify a possible procedure to commute an error estimator $\boldsymbol{\mathcal{S}}$ (or, analogously, an error indicator, $\boldsymbol{\mathcal{I}}$) into an adapted mesh. Our goal is to ensure a user-defined accuracy, TOL, on the error (i.e., on the error estimator) so that $\|e_h\|_* \leq C\,\boldsymbol{\mathcal{S}} \leq$ TOL, and to equidistribute the error across the grid cells so that $\eta_K \leq \mathrm{TOL}/\#(\boldsymbol{\mathcal{T}}_h)$, with $\#(\boldsymbol{\mathcal{T}}_h)$ the mesh cardinality. At each step, $i \geq 0$, starting from a background grid, $\boldsymbol{\mathcal{T}}_h^{(0)}$:

1. We compute the discrete solution u_h and the corresponding error estimator $\boldsymbol{\mathcal{S}}$ on the actual mesh, $\boldsymbol{\mathcal{T}}_h^{(i)}$;
2. We identify the operations to be performed on $\boldsymbol{\mathcal{T}}_h^{(i)}$;
3. We generate the new mesh $\boldsymbol{\mathcal{T}}_h^{(i+1)}$.

Notice that the initial mesh cannot be too coarse, so that $\boldsymbol{\mathcal{S}}$ has enough information about the local accuracy of the current approximation. The stopping criterion for the adaptive

procedure coincides with the check on the accuracy to be equidistributed on the mesh, sometimes combined with additional controls (e.g., on the stagnation of mesh cardinality between consecutive adaptive loops [61]).

Let us focus now on step 2. We classify the possible different operations into three main classes:

(l) *Mesh refinement/coarsening*: all the cells K where the local error estimator is larger than a certain threshold, i.e., such that

$$\eta_K \geq \frac{C_1 \mathrm{TOL}}{\sqrt{\#(\mathcal{T}_h^{(i)})}}, \tag{38.35}$$

are marked for refinement. Vice versa, cells where the local error estimator is smaller than a certain threshold, i.e., such that

$$\eta_K < \frac{C_2 \mathrm{TOL}}{\sqrt{\#(\mathcal{T}_h^{(i)})}}, \tag{38.36}$$

are marked for coarsening. Inequalities (38.35) and (38.36) are meant to ensure the desired accuracy, TOL, together with the error equidistribution. Constants C_1 (>1) and C_2 (<1) confine mesh refinement and coarsening to the cells characterized by the largest and the smallest (estimated) error, respectively.

Elements marked for refinement are then subdivided into 2, 3, or 4 parts, according to a green, blue, or red refinement, respectively [57]. These techniques can be combined, depending on whether one is interested in conforming or non-conforming meshes.

Refinement of unstructured grids is readily implemented, whereas it is not so straightforward on structured grids, especially when dealing with conforming meshes. Indeed, the addition of new elements breaks the regular data structure characterizing structured meshes, due to the creation of vertices with a different number of connections to the neighboring points.When dealing with non-conforming structured meshes, hanging nodes are allowed during the refinement phase, and this requires modifications to the solver. Conversely, the addition of new cells in an unstructured mesh involves only a local reconnection of the elements, with a consequent update of the connectivity matrix, and the original solver can be preserved.

Unlike refinement, coarsening does not apply to a single cell. In particular, if all the cells belonging to the patch of elements, $\Delta_{\mathbf{v}} = \{K \in \mathcal{T}_h^{(i)} : K \ni \mathbf{v}\}$, associated with a node, $\mathbf{v}$, are marked for coarsening, vertex $\mathbf{v}$ is removed and the area covered by $\Delta_{\mathbf{v}}$ is remeshed.

From a practical point of view, an efficient adaptive procedure alternates mesh refinement and coarsening with regularization operations, such as edge swapping and node smoothing (see, e.g., [62]), to improve the mesh quality (see Remark 38.3);

(m) *Node movement*: the equidistribution of the desired accuracy is pursued through the migration of the mesh vertices from regions characterized by a small error to areas with a large error, so that the number of vertices remains fixed. Algorithms to move points are, in general, driven by a weight function which combines an error estimator with desired geometric properties (e.g., smoothness, orthogonality). Node movement can be applied both to structured and unstructured grids [15];

(n) *Remeshing*: a discrete function is derived from the error estimator/indicator computed on $\mathcal{T}_h^{(i)}$, to predict the element-size spacing $\mathcal{M}$ (i.e., the *metric* [12]), which identifies the new mesh $\mathcal{T}_h^{(i+1)}$. In more detail, function $\mathcal{M}$ is defined in Ω and specifies the size (for isotropic meshes) together with the directional features (for anisotropic meshes) that must be conformed to by the mesh elements (see Remark 38.4). In practice, metric $\mathcal{M}$ is assigned at the vertices of the background mesh, $\mathcal{T}_h^{(i)}$, to predict the new grid, $\mathcal{T}_h^{(i+1)}$. The derivation of $\mathcal{M}$ usually involves the resolution of local constrained optimization problems, thus leading to a computational overhead, especially for 3D configurations. However, impressive demonstrations of the effectiveness of remeshing are available in the literature, primarily on unstructured grids (see, for instance, [16,63,64]).

Mesh refinement/coarsening, node movement, and remeshing can be distinguished into global and local procedures. Remeshing is a global approach since, at each iteration, it reconstructs the whole mesh. On the contrary, mesh refinement/coarsening and node movement are local procedures, since they usually involve only a confined portion of the mesh. The adaptivity performed according to (l) and (n) is called *h-adaptivity*, while adaptivity driven by node movement (m) is called *r-adaptivity* (actually, there exists a third kind of adaptivity, the *p-adaptivity*, where the solution is improved by locally tuning the accuracy of the discretization scheme [65]).

The choice among the adaptive techniques in (l)–(n) is always affected by the available mesh generator. Mesh generators usually include local modification procedures, while only few provide metric-based routines. Finally, approaches (l)–(n) can be combined to maximize the benefits led by the individual procedures.

Remark 38.3 (Mesh Quality) There exist different ways to certify the quality of an adapted grid (see, e.g., [11,66,67]). A first possibility is to introduce geometric quantities which characterize the shape of the cells [68]. When dealing with a finite element approximation, a good mesh is the one which, for a certain mesh size, leads to the best possible numerical

accuracy or, vice versa, for a certain accuracy, minimizes the mesh cardinality. When dealing with an element-size spacing $\mathcal{M}$, the good quality of a mesh is ensured by making the length of each side in $\mathcal{T}_h^{(i+1)}$ the closest as possible to unit with respect to $\mathcal{M}$, since a triangle with unit edge lengths is necessarily a good quality triangle [12].

Remark 38.4 (Isotropic Versus Anisotropic Meshes) Meshes can be classified also into isotropic and anisotropic. In the former case, elements share the same length in all the directions and the cell diameter, h_K, is the only information demanded to characterize the grid. On the contrary, anisotropic meshes admit deformed cells, so that the elements are uniquely identified by supplying the shape and the orientation of K, in addition to the size h_K. The cell deformation can be quantified, for instance, through the aspect ratio (i.e., the ratio of the longest to shortest edge) or the angles between the cell edges, whereas the grid deformation is measured by the change rate of the geometric features across adjacent cells.

With reference to Sect. 38.5.2, Delaunay triangulations are, by construction, isotropic. The advancing front method can generate deformed elements, although of low quality. Actually, anisotropic meshes are generated via specific procedures, e.g., via a map that changes an isotropic reference cell into a distorted element in the physical space [69, 70]. The demand for extra information to characterize anisotropic meshes turns into a more involved error analysis as well as into a more complex definition of the metric $\mathcal{M}$. Moreover, stretched cells lead often to ill-conditioned systems, for instance, when dealing with a FE discretization (see [68]). Despite these drawbacks, anisotropic meshes have been successfully employed in several contexts. The computational advantages obtained by replacing isotropic with anisotropic meshes have been numerically checked, in particular when modeling phenomena with intrinsic directionalities (e.g., boundary or internal layers, shocks, stagnation points, vortices) such as in fluid dynamics, combustion, solid mechanics, and wave propagation [61, 63, 71–80].

38.5.5 Meshes for Semiconductor Devices

Three-dimensional mesh generation for semiconductor device simulations still leaves room for much innovation due to the complex phenomena often involved in such a modeling (e.g., silicon crystallization, ion precipitation, stoichiometry variation). Difficulties are experienced dealing with the boundaries and the interfaces (for instance, between semiconductor materials and dielectric or a cross p-n junction), in particular to strike a balance between a sharp fitting of these features and an optimal mesh density distribution [81].

Among the available techniques, we mention the Cartesian-based approach employed by the mesh generator OMEGA, which implements octree decomposition techniques, improved with the possibility to tessellate the Cartesian cells into Delaunay tetrahedra and more anisotropic cells [82].

Advancing front methods are sometimes used since they ensure good point placement properties. Indeed, elements are grown from the boundary so that they are well aligned with it. Some attempts are available in two dimensions [83–85], while it remains an issue how to effectively apply such methods to the complexity of a three-dimensional semiconductor device. An alternative approach in three dimensions is provided by hybrid meshes [50, 51]. In particular, we cite the hybrid mesh generator MESHise [52], which constitutes a further development of OMEGA.

Delaunay triangulations represent another viable choice for semiconductor simulations [86–89]. Also for this procedure, the most challenging context remains the three-dimensional case due to the difficulty in effectively integrating boundaries into a three-dimensional Delaunay mesh. Specific algorithms are demanded to generate an unstructured Delaunay mesh coherent with boundaries and interfaces, for instance, when dealing with an extremely thin oxide layer on top of a comparatively big silicon block.

Finally, some examples of adapted meshes for semiconductor devices are available in the literature, for Raviart-Thomas mixed finite elements [90] and in the context of a finite difference or a finite element discretization (see, e.g., [91–93]). Moreover, we refer to [94] for a first attempt of anisotropic mesh adaptation. Here, the authors apply the DD model to a p-n junction diode device and propose a goal-oriented error estimator to drive an anisotropic adaptation of the mesh via a metric-based procedure.

Among the mesh generators which are currently most widely employed in the modeling of semiconductor devices, we mention Gmsh, an open-source 3D finite element mesh generator with a built-in CAD engine and post-processor [95]; ViennaMesh, a mesh library which covers both mesh generation and adaptation in 2D and 3D [96]; Victory Mesh by Silvaco, to mesh and refine both existing and new 2D and 3D TCAD structures [97]; and Synopsys a tool suite which allows constructing device structures, meshing, simulation, visualization of electrical characteristics, plotting of various curves, and extraction of performance parameters [26]. In the examples provided below, we resort to the last mesh generator. This choice is motivated by the fact that Synopsys is one of the most widely used mesh suites for industrial applications. Moreover, it is compatible with the solver adopted in the numerical assessment (see Sect. 38.7).

Synopsys includes three mesh generators, i.e., Mesh, Noffset3D, and Sentaurus Mesh. In particular, we will employ Sentaurus Mesh to build an example of structured

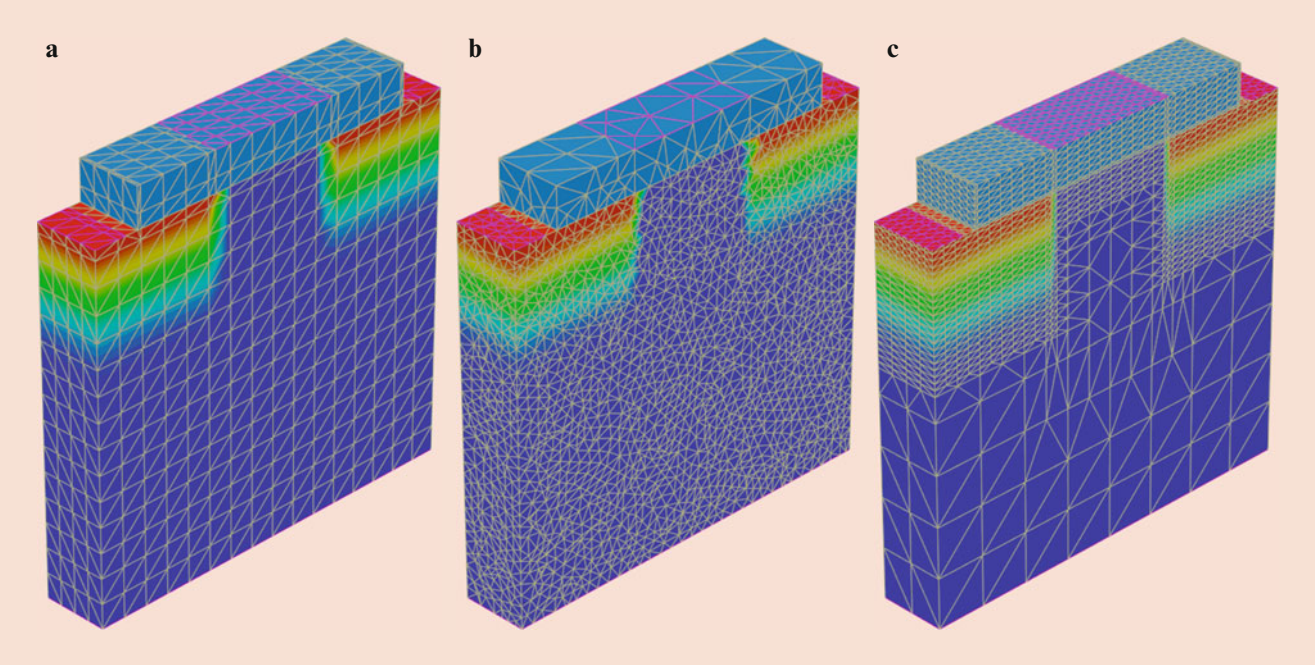

Fig. 38.3 n-MOSFET device: example of (**a**) structured, (**b**) unstructured, and (**c**) hybrid tetrahedral mesh (the colormap refers to the doping)

and hybrid mesh and Noffset3D to generate an unstructured grid. Sentaurus Mesh incorporates a tensor product mesh generator to produce hexahedral (or rectangular) elements and an axis-aligned grid generator where the octree (quadtree) technique is adopted to discretize the device domain via tetrahedra (triangles), in combination with the Delaunay criterion, which ensures high-quality conforming grids. Sentaurus Mesh performs also local mesh refinements, by using the doping or specific information prescribed by the user (see the example below). Noffset3D is a mesh generator that employs triangles and rectangles in 2D and tetrahedra in 3D to provide a fully unstructured tessellation of the computational domain. Noffset3D uses an advancing front method starting from specified surfaces and interfaces, to create anisotropic layers of elements, and fills the remainder of the domain with an isotropic mesh, by resorting to different meshing algorithms which can be arbitrarily selected by the user. Except for some special cases, the default series of algorithms produces very good results in terms of mesh quality. Moreover, meshes can be adapted to the geometry of a device by creating layers along certain interfaces or to suit other data such as refining p-n junctions.

Now, we focus on a specific semiconductor device, and we provide some examples of possible grids. We consider an n-type MOSFET (n-MOSFET), characterized by a constant p-type (Boron) channel doping of 10^{17} (cm^{-3}), and by symmetric source/drain junctions characterized by a Gaussian n-type (Arsenic) profile, with a peak value equal to 10^{18} (cm^3) at the top surface of Ω_{Si} (see Fig. 38.1 for a sketch). The gate is of n-type, with a thickness of 30 (nm) and a length of 100 (nm).

For this device, we show an example of structured mesh in Fig. 38.3a, which consists of 1560 vertices and 6600 cells. The grid has been generated with Sentaurus Mesh, which resorts to an octree recursive space decomposition technique to discretize the device domain. As previously remarked, methods devoted to unstructured meshes can be adopted also to generate structured tessellations.

For the same device, in Fig. 38.3b we show an example of unstructured mesh generated by Noffset3D. Two of the techniques in Sect. 38.5.2 are here combined to yield the desired grid, namely, the advancing front method to track the external surface and the interfaces and the Delaunay criterion to fill the internal part of the domain. The grid consists of 65,838 vertices and 12,240 tetrahedra.

Figure 38.3c shows an example of tetrahedral hybrid mesh for the n-MOSFET device, where hybrid is meant as a combination of different techniques to generate the tessellation of the domain. The grid consists of 30,866 vertices and 6442 elements. It has been generated with Sentaurus Mesh, which enriches the standard octree algorithm, here employed with two different step sizes, with a Delaunay criterion. The two different types of mesh can be easily distinguished in the hybrid grid.

It is also interesting to compare the three meshes in Fig. 38.3 in terms of vertices and elements.

We consider now the advanced techniques in Sect. 38.5.4. In Fig. 38.4, we provide two examples of adapted mesh for

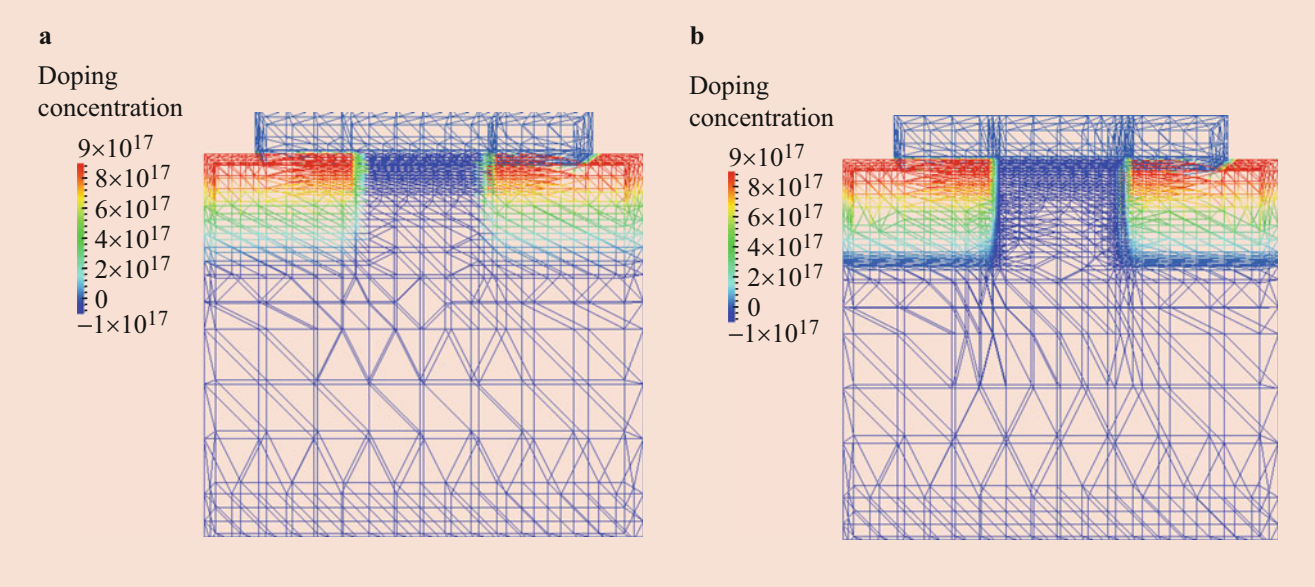

Fig. 38.4 n-MOSFET device: adapted mesh driven (**a**) by geometric and (**b**) by geometric plus physical information

the n-MOSFET device. The two grids are generated with Sentaurus Mesh, driven by heuristic considerations and by resorting to a mesh refinement/coarsening procedure. The mesh on the left consists of 2389 vertices and 10,284 cells. It has been obtained starting from the structured mesh in Fig. 38.3a and following a geometric indicator, namely, by refining the region under the channel where the inversion layer is induced by the bias applied to the gate. The mesh on the right, constituted by 4438 vertices and 19,888 tetrahedra, is obtained by enriching the geometric indicator with the value of the gradient of the doping profile. This allows us to better define the source and drain junctions inside the n-MOSFET bulk region. The twofold source of information driving mesh adaptation justifies the finer mesh, and it makes us expect a higher accuracy in terms of device modeling (see Sect. 38.7).

38.6 Algebraic Solvers

The numerical procedures introduced in the previous sections lead to solve both linear and nonlinear systems of equations. We discuss here suitable solvers for these systems, with a particular emphasis on a large-scale setting. In particular, to make the discussion more general, we do not confine the presentation to the specific systems associated with the DD model, and we consider a generic framework.

38.6.1 Nonlinear Solvers

Both the approaches in Sects. 38.3 and 38.4 involve the Newton algorithm to manage a nonlinearity. We generically denote a nonlinear system of equations by

$$F(\boldsymbol{U}) = \boldsymbol{0}, \tag{38.37}$$

with $F : \mathbb{R}^N \to \mathbb{R}^N$, $\boldsymbol{U} \in \mathbb{R}^N$, and $\boldsymbol{0} = [0, \ldots, 0]^{\mathrm{T}} \in \mathbb{R}^N$.

Several iterative procedures are available to solve system (38.37), which essentially differ for the linearized model employed at each iteration. Among the others, we mention Newton-based and quasi-Newton methods [98]. In the context of semiconductor modeling, it is common to resort to Newton-based schemes. The standard Newton method applied to (38.37) employs the linear model

$$F'(\boldsymbol{U}_{\mathtt{k}})(\boldsymbol{U} - \boldsymbol{U}_{\mathtt{k}}) + F(\boldsymbol{U}_{\mathtt{k}}) = 0, \tag{38.38}$$

with $\boldsymbol{U}_{\mathtt{k}}$ the $\mathtt{k}$-th iteration and with $F'(\boldsymbol{U}_{\mathtt{k}}) \in \mathbb{R}^{N\times N}$ the associated Jacobian matrix. The corresponding algorithm can be thus itemized:

Algorithm 38.1 Newton method

Input : $\boldsymbol{U}_0 \in \mathbb{R}^N$, $\mathtt{TOL} < 1$, $\mathtt{ESTIM}_0 > \mathtt{TOL}$, $\mathtt{kmax}$.

1: Set: $\mathtt{k} = 0$;
2: **while** $\mathtt{ESTIM}_{\mathtt{k}} > \mathtt{TOL}$ & $\mathtt{k} < \mathtt{kmax}$ **do**
3: Solve $F'(\boldsymbol{U}_{\mathtt{k}})\Delta\boldsymbol{U}_{\mathtt{k}} = -F(\boldsymbol{U}_{\mathtt{k}})$;
4: Compute $\boldsymbol{U}_{\mathtt{k}+1} = \boldsymbol{U}_{\mathtt{k}} + \Delta\boldsymbol{U}_{\mathtt{k}}$;
5: Compute $\mathtt{ESTIM}_{\mathtt{k}}$;
6: $\mathtt{k} = \mathtt{k}+1$;
7: **end while**

The termination of the iterative process is based on the estimator $\mathtt{ESTIM}_{\mathtt{k}}$ combined with a control on the maximum number, $\mathtt{kmax}$, of the iterations. The estimator typically coincides with the residual, $F(\boldsymbol{U}_{\mathtt{k}})$, and/or with the difference $\boldsymbol{U}_{\mathtt{k}+1} - \boldsymbol{U}_{\mathtt{k}}$ between two consecutive iterations. For instance, standard stopping criteria are

$$\|F(\boldsymbol{U}_{\mathtt{k}})\|_\infty \leq \tau_1 + \tau_2 \|F(\boldsymbol{U}_0)\|_\infty, \tag{38.39}$$

and

$$\|\boldsymbol{U}_{\mathtt{k}+1} - \boldsymbol{U}_{\mathtt{k}}\|_\infty \leq \tau_1 + \tau_2 \|\boldsymbol{U}_{\mathtt{k}}\|_\infty, \tag{38.40}$$

with $\|\cdot\|_\infty$ the infinite norm and where τ_1 and τ_2 are fixed tolerances on the absolute and on the relative error, respectively. The employment of the infinite norm is motivated by the large dimension of the vectors involved. Alternatively, if we resort to the Euclidean norm, it is advisable to properly scale the norms in (38.39) and (38.40) (e.g., by $1/\sqrt{N}$) and to rewrite the stopping criteria in terms of these scaled quantities.

Newton method is locally convergent, namely, the sequence $\{\boldsymbol{U}_{\mathtt{k}}\}$ converges to the solution $\boldsymbol{U}^*$ of (38.37) if the initial guess $\boldsymbol{U}_0$ is sufficiently close to such a solution. To enhance the convergence, Newton-based methods can be embedded into a *globalization* strategy, i.e., a procedure such that, for any initial value, either $\|F(\boldsymbol{U}_{\mathtt{k}})\|$ converges to zero or the iteration $\boldsymbol{U}_{\mathtt{k}}$ fails to converge and the ways which the sequence can fail to converge are well understood [99]. A possible globalization strategy is represented by a line search along the Newton step, $\Delta\boldsymbol{U}_{\mathtt{k}}$, leading to the so-called Damped Newton method (or Newton method with line search) [98–100]. This globalization strategy relies on the minimization problem

$$\min_{\mathbf{U}\in\mathbb{R}^N} \psi(\boldsymbol{U}) \quad \text{with } \psi(\boldsymbol{U}) = \|F(\boldsymbol{U})\|_2$$

and $\|\cdot\|_2$ the Euclidean norm and, given $\boldsymbol{U}_{\mathtt{k}}$ and $\Delta\boldsymbol{U}_{\mathtt{k}}$, computes the new iteration as

$$\boldsymbol{U}_{\mathtt{k}+1} = \boldsymbol{U}_{\mathtt{k}} + \lambda\, \Delta\boldsymbol{U}_{\mathtt{k}},$$

with $0 < \lambda \leq 1$ and $\psi(\boldsymbol{U}_{\mathtt{k}+1}) < \psi(\boldsymbol{U}_{\mathtt{k}})$. The existence of λ is guaranteed since the Newton step is a descent direction for ψ at $\boldsymbol{U}_{\mathtt{k}}$ (see [99, Proposition 3.3]). Typically, the step length λ is chosen via a backtracking approach. The idea is to start with $\lambda = 1$ and then to backtrack it, i.e., to reduce λ until $\|F\|_2$ is sufficiently reduced. A possible implementation of the damped Newton method is provided in the following

Algorithm 38.2 Damped Newton method

Input : $\boldsymbol{U}_0 \in \mathbb{R}^N$, $\mathtt{TOL} < 1$, $\mathtt{ESTIM}_0 > \mathtt{TOL}$, $\mathtt{kmax}$, α, $\sigma \in (0, 1)$

1: Set: $\mathtt{k} = 0$;
2: **while** $\mathtt{ESTIM}_{\mathtt{k}} > \mathtt{TOL}$ & $\mathtt{k} < \mathtt{kmax}$ **do**
3: Solve $F'(\boldsymbol{U}_{\mathtt{k}})\Delta\boldsymbol{U}_{\mathtt{k}} = -F(\boldsymbol{U}_{\mathtt{k}})$;
4: Set: $\lambda = 1$;
5: **while** $\|F(\boldsymbol{U}_{\mathtt{k}} + \lambda\, \Delta\boldsymbol{U}_{\mathtt{k}})\|_2 > (1 - \alpha\lambda)\|F(\boldsymbol{U}_{\mathtt{k}})\|_2$ **do**
6: Compute $\lambda = \sigma\lambda$;
7: **end while**
8: Compute $\boldsymbol{U}_{\mathtt{k}+1} = \boldsymbol{U}_{\mathtt{k}} + \lambda\Delta\boldsymbol{U}_{\mathtt{k}}$;
9: Compute $\mathtt{ESTIM}_{\mathtt{k}}$;
10: $\mathtt{k} = \mathtt{k}+1$;
11: **end while**

We remark that the backtracking phase (lines 5–6) has a finite termination [100]. Parameter α is known as Armijo constant, and it is usually set to 10^{-4}, while typical values for σ are 0.5 and 0.1 [99]. Concerning the choice of λ, the simple update in line 6 allows one to progressively reduce λ by a fixed factor. Alternatively, λ is selected by using a polynomial model for the scalar function $\psi(\boldsymbol{U}_{\mathtt{k}} + \lambda\Delta\boldsymbol{U}_{\mathtt{k}})$ and looking for the minimum of this polynomial as the next step length [99,100]. Finally, we cite the Bank-Rose strategy, where λ is first set to one and then updated as $\lambda = 1/(1 + \rho\|F(\boldsymbol{U}_{\mathtt{k}})\|_2)$, $\rho \geq 1$ being progressively increased to fulfill a sufficient reduction on ψ [101].

The main computational issue characterizing Newton method is represented by the solution, at each iteration, of the linear system in line 3 of both Algorithms 38.1 and 38.2. A direct solver is generally employed when dealing with small or medium size systems or with large dimension problems characterized by a sparse Jacobian matrix, whereas, in case of huge dimension systems, it is advisable to resort to an iterative linear solver. When the linear systems are solved approximately and in some unspecified manner, the resulting procedure is denoted by inexact Newton method [102], and it can be itemized as follows:

Algorithm 38.3 Inexact Newton method

Input : $\boldsymbol{U}_0 \in \mathbb{R}^N$, $\eta_{\max} \in (0, 1)$, $\mathtt{TOL} < 1$, $\mathtt{ESTIM}_0 > \mathtt{TOL}$, $\mathtt{kmax}$

1: Set: $\mathtt{k} = 0$;
2: **while** $\mathtt{ESTIM}_{\mathtt{k}} > \mathtt{TOL}$ & $\mathtt{k} < \mathtt{kmax}$ **do**
3: Choose $\eta_{\mathtt{k}} \in [0, \eta_{\max}]$;
4: Find $\Delta\boldsymbol{U}_{\mathtt{k}}$ such that $\|F(\boldsymbol{U}_{\mathtt{k}}) + F'(\boldsymbol{U}_{\mathtt{k}})\Delta\boldsymbol{U}_{\mathtt{k}}\|_2 \leq \eta_{\mathtt{k}}\|F(\boldsymbol{U}_{\mathtt{k}})\|_2$;
5: Compute $\boldsymbol{U}_{\mathtt{k}+1} = \boldsymbol{U}_{\mathtt{k}} + \Delta\boldsymbol{U}_{\mathtt{k}}$;
6: Compute $\mathtt{ESTIM}_{\mathtt{k}}$;
7: $\mathtt{k} = \mathtt{k}+1$;
8: **end while**

The so-called forcing term, $\eta_{\mathtt{k}}$, is employed to control the level of accuracy when solving the linear system (38.38), and it strongly influences the efficiency of the algorithm. If $\eta_{\mathtt{k}} = 0$ for all $\mathtt{k} \geq 0$, the inexact procedure reduces to the standard Newton method. Actually, the inexact Newton method is locally convergent [102]. In particular, if F' is Lipschitz continuous in a neighborhood of $\boldsymbol{U}^*$, $F'(\boldsymbol{U}^*)$ is nonsingular, $\boldsymbol{U}_0$ is sufficiently close to $\boldsymbol{U}^*$, and $\eta_{\mathtt{k}}$ is uniformly bounded away from one for any $\mathtt{k} \geq 0$ (i.e., $\eta_{\mathtt{k}} \leq \eta_{\max} < 1$, as in Algorithm 38.3), then the sequence $\{\boldsymbol{U}_{\mathtt{k}}\}$ converges linearly to $\boldsymbol{U}^*$ with respect to the norm $\|\cdot\|_*$, with $\|\mathbf{v}\|_* = \|F'(\boldsymbol{U}^*)\mathbf{v}\|$ for any $\mathbf{v} \in \mathbb{R}^N$ and with $\|\cdot\|$ a generic norm, i.e.,

$$\|\boldsymbol{U}_{\mathtt{k}\ +1} - \boldsymbol{U}^*\|_* \leq \nu\|\boldsymbol{U}_{\mathtt{k}} - \boldsymbol{U}^*\|_*$$

with $\nu \in (0, 1)$. If $\lim_{\mathtt{k}\to\infty} \eta_{\mathtt{k}} = 0$, then convergence is superlinear, i.e.,

$$\lim_{k\to\infty} \frac{\|\boldsymbol{U}_{k+1} - \boldsymbol{U}^*\|}{\|\boldsymbol{U}_k - \boldsymbol{U}^*\|} = 0.$$

Finally, if $\eta_k \leq \xi \|F(\boldsymbol{U}_k)\|^2$ for some $\xi > 0$, then convergence is quadratic, being

$$\|\boldsymbol{U}_{k+1} - \boldsymbol{U}^*\| \leq \tilde{\nu} \|\boldsymbol{U}_k - \boldsymbol{U}^*\|^2,$$

with $\tilde{\nu}$ a positive constant. Besides controlling local convergence rate, a proper choice of the forcing term avoids the so-called *oversolving* phenomenon. This means that system $F'(\boldsymbol{U}_k)\Delta\boldsymbol{U}_k = -F(\boldsymbol{U}_k)$ is approximately solved, with an accuracy that is far beyond what is needed to obtain a sufficient reduction in the norm of F. In particular, the computation of an accurate $\Delta\boldsymbol{U}_k$, when far from a solution, may yield either a marginal improvement or no progress toward an actual solution because of the significant mismatch between the linear model, $F(\boldsymbol{U}_k) + F'(\boldsymbol{U}_k)\Delta\boldsymbol{U}_k$, and the updated value, $F(\boldsymbol{U}_k + \Delta\boldsymbol{U}_k)$. Vice versa, a less accurate solution of system $F'(\boldsymbol{U}_k)\Delta\boldsymbol{U}_k = -F(\boldsymbol{U}_k)$ can be both more effective in reducing the norm of F and more convenient from a computational view point. Smart choices for the forcing term allows us to avoid oversolving in the early iteration phase and to achieve fast local convergence during the late iteration stage. Two choices that fulfill these requirements are provided in [103, 104]. Given $\eta_0 \in [0, 1)$ ($\eta_0 = 0.5$ is a standard default value), the first choice selects

$$\eta_k = \frac{\left|\|F(\boldsymbol{U}_k)\| - \|F(\boldsymbol{U}_{k-1}) + F'(\boldsymbol{U}_{k-1})\Delta\boldsymbol{U}_{k-1}\|\right|}{\|F(\boldsymbol{U}_{k-1})\|} \quad k \geq 1,$$

while the second choice leads us to pick

$$\eta_k = \frac{\|F(\boldsymbol{U}_k)\|}{\|F(\boldsymbol{U}_{k-1})\|} \quad k \geq 1.$$

Very frequently, Krylov subspace projection methods [21] are used as iterative linear solvers in inexact Newton methods, leading to the so-called Newton-Krylov algorithms [102, 104]. These methods, which will be discussed more in detail in Sect. 38.6.2, do not require the explicit computation of the Jacobian $F'(\boldsymbol{U}_k)$. On the contrary, they focus only on the "action" of $F'(\boldsymbol{U}_k)$ on a generic vector $\boldsymbol{V} \in \mathbb{R}^N$. In particular, if the nonzero entries of $F'(\boldsymbol{U}_k)$ are available, the product $F'(\boldsymbol{U}_k)\boldsymbol{V}$ can be computed analytically with a computational cost which depends on the sparsity of the Jacobian. Alternatively, product $F'(\boldsymbol{U}_k)\boldsymbol{V}$ is approximated by a finite difference scheme, i.e., as

$$F'(\boldsymbol{U}_k)\boldsymbol{V} \sim \frac{F(\boldsymbol{U}_k + \zeta\boldsymbol{V}) - F(\boldsymbol{U}_k)}{\zeta}, \tag{38.41}$$

with $\zeta > 0$ a properly selected scalar, this leading to a so-called "matrix-free" procedure [102, 104]. In this case, the cost for evaluating $F'(\boldsymbol{U}_k)\boldsymbol{V}$ reduces to a single function evaluation (i.e., $F(\boldsymbol{U}_k + \zeta\boldsymbol{V})$), $F(\boldsymbol{U}_k)$ being already available. The parameter ζ in (38.41) is commonly fixed as

$$\zeta = \begin{cases} \sqrt{\texttt{eps}}\,\dfrac{\|\boldsymbol{U}_k\|}{\|\boldsymbol{V}\|} & \text{if } \|\boldsymbol{U}_k\| \neq 0 \\ \sqrt{\texttt{eps}} & \text{otherwise,} \end{cases}$$

with `eps` the unit round-off. This choice, although heuristic, ensures a balance between floating point and truncation error [100, §5.4.4].

Globalization strategies consisting in a line search along the inexact Newton step, $\Delta\boldsymbol{U}_k$, have been widely investigated (see, e.g., [100, 103–106]), giving rise to the damped inexact Newton method (or inexact Newton method with line search). An effective implementation of the damped inexact Newton is provided in the following

Algorithm 38.4 Damped Inexact Newton method

Input : $\boldsymbol{U}_0 \in \mathbb{R}^N$, $\eta_{\max} \in (0, 1)$, `TOL` < 1, $\texttt{ESTIM}_0 >$ `TOL`, `kmax`, $\alpha, \sigma \in (0, 1)$

1: Set: `k = 0`;
2: **while** $\texttt{ESTIM}_k >$ `TOL` & `k` $<$ `kmax` **do**
3: Choose $\eta_k \in [0, \eta_{\max}]$;
4: Find $\Delta\boldsymbol{U}_k$ such that $\|F(\boldsymbol{U}_k) + F'(\boldsymbol{U}_k)\Delta\boldsymbol{U}_k\|_2 \leq \eta_k\|F(\boldsymbol{U}_k)\|_2$;
5: Set: $\lambda = 1$;
6: **while** $\|F(\boldsymbol{U}_k + \lambda\,\Delta\boldsymbol{U}_k)\|_2 > (1 - \alpha(1 - \eta_k))\|F(\boldsymbol{U}_k)\|_2$ **do**
7: Compute $\lambda = \sigma\lambda$;
8: Compute $\eta_k = 1 - \sigma(1 - \eta_k)$;
9: **end while**
10: Compute $\boldsymbol{U}_{k+1} = \boldsymbol{U}_k + \lambda\Delta\boldsymbol{U}_k$;
11: Compute $\texttt{ESTIM}_k$;
12: `k = k+1`;
13: **end while**

The backtracking phase (lines 6–8) has a finite termination [100]. It can be checked that the selected step, $\lambda\,\Delta\boldsymbol{U}_k$, coincides with an inexact Newton step corresponding to the forcing term $1 - \lambda(1 - \eta_k^*)$, with η_k^* the initial value of η_k (i.e., the forcing term selected in line 3). A typical value for α is 10^{-4} [99]. Concerning the choice of λ, the simple update in line 7 allows one to progressively reduce λ by a fixed factor, where typical values for σ are 0.5 and 0.1, as for Algorithm 38.2 [99]. As an alternative, λ is selected by using a polynomial model for the scalar function $\psi(\boldsymbol{U}_k + \lambda\Delta\boldsymbol{U}_k)$, and choosing the minimum of such a polynomial as the next step length [99, 100].

Finally, the Bank-Rose method can be adopted also in this case, by exploiting exactly what remarked for Algorithm 38.2 [101].

A Fortran implementation of the damped inexact Newton method based on Algorithm 38.4 and called NITSOL is pro-

posed in [104] and made freely accessible at the webpage https://users.wpi.edu/~walker/NITSOL/. This code can be easily employed as a template for a translation in other programming languages. Matlab codes for Newton method, inexact Newton method, and damped versions are accessible through the webpage https://ctk.math.ncsu.edu/newtony.html and are documented in [100].

38.6.2 Linear Solvers

Both the Gummel map and the fully coupled Newton approach involve the numerical solution of linear systems,

$$\mathbf{Az} = \mathbf{b}, \tag{38.42}$$

which are typically *sparse*. A rigorous definition of sparse matrix is not available. Informally, a sparse matrix is characterized by a sufficiently large number of zero entries such that this can be advantageously exploited [21, 107].

The efficient solution of sparse linear systems can be pursued by either direct or iterative methods. Direct methods for sparse linear systems overcome the drawback characterizing standard factorizations, i.e., the presence of entries that, during the factorization, change their value from zero to nonzero. This phenomenon is known as *fill-in*. A sparse factorization of matrix $\mathbf{A}$ consists of three steps [107]. The first one performs a reordering (with permutations of rows and/or columns) of $\mathbf{A}$ to reduce the fill-in induced by the factorization, with respect to the one associated with the original matrix. The reordering is driven by efficient heuristics, since minimizing the fill-in coincides with an NP-hard problem. Well-known ordering algorithms are provided by the approximate minimum degree, the Cuthill-McKee, and the column permutation methods [107]. The second step coincides with the LU factorization of the reordered matrix. Finally, the third step involves triangular solvers for sparse matrices.

The reordering of $\mathbf{A}$ can be performed without introducing instabilities in the associated LU factorization, as shown in [108]. In this case, it can be found a sparsity-preserving column permutation matrix, $\mathbf{Q}$, which reduces the fill-in induced by any row permutation associated with the *LU* factorization with partial pivoting of matrix $\mathbf{AQ}$. This finally yields the factorization $\mathbf{PAQ} = \mathbf{LU}$, where $\mathbf{P}$ is a permutation matrix selected independently of the sparsity, while $\mathbf{L}$ and $\mathbf{U}$ are a lower and an upper triangular matrix, respectively. This reordering is *symbolic*, namely, it is performed by using only the position of the nonzero entries of $\mathbf{A}$. Symbolic factorization is much more convenient in terms of time and memory than the numerical factorization. Actually, it can be reused for matrices characterized by the same sparsity pattern, such as those arising during Newton iterations and in the time stepping. In Sect. 38.7, we will provide some examples of reordering applied to the matrix yielded by the discretization of the drift-diffusion model for the MOS device in Fig. 38.1.

Concerning the softwares related to sparse direct solvers, we cite SUITESPARSE (`faculty.cse.tamu.edu/davis/suitesparse.html`.) and, specifically, function COLAMD. Both parallel and sequential implementations of sparse direct solvers are also available in the package MUMPS (http://mumps.enseeiht.fr/.) (MUltifrontal Massively Parallel Sparse solver) [109, 110] and PARDISO (https://www.pardiso-project.org/.) (PARallel DIrect sparse SOlver interface) [111, 112]. Finally, we point out that the MATLAB command\automatically resorts to linear solvers for sparse matrices if matrix $\mathbf{A}$ is allocated as a sparse array.

Krylov subspace methods constitute a class of very successful iterative algorithms for solving linear systems. As anticipated in the previous section, these methods require only the product of $\mathbf{A}$ times a vector. In the context of Newton-Krylov methods, *transpose-free* solvers are generally preferred. The reason is twofold. First of all, if the Jacobian is available, it is stored in a sparse compact format which allows one for an efficient row-column matrix-vector product. Secondly, if the Jacobian is not available, products involving the transpose of the Jacobian cannot be performed by resorting to finite difference schemes. Transpose-free methods commonly used are the GMRES (Generalized Minimal RESidual) [113], the BICGSTAB (Bi-Conjugate Gradient STABilized method) [114], and the TFQMR (Transpose-Free Quasi-Minimal Residual) [115] algorithms, although it is well-known that it is not possible to rank iterative solvers for non-symmetric linear systems [116].

GMRES is a breakdown-free iterative method suited to solve indefinite systems of linear equations [113]. When applied to system (38.42), given the initial guess $\mathbf{z}^0$, the m-th GMRES iteration, $\mathbf{z}^m$, with $m \geq 1$, solves the least-squares problem

$$\min_{\mathbf{z} \in \mathbf{z}^0 + K_m} \|\mathbf{Az} - \mathbf{b}\|_2, \tag{38.43}$$

where

$$K_m = \text{span}\left\{\boldsymbol{r}_{\text{k}}^0, \mathbf{A}\boldsymbol{r}_{\text{k}}^0, (\mathbf{A})^2\boldsymbol{r}_{\text{k}}^0, \ldots, (\mathbf{A})^{m-1}\boldsymbol{r}_{\text{k}}^0\right\}, \tag{38.44}$$

is the m-th Krylov subspace, and $\boldsymbol{r}_{\text{k}}^0 = (\mathbf{Az}^0 - \mathbf{b})$ is the initial linear residual. Ideally, the GMRES method finds the solution to the linear system in a number of iterations, at most, equal to the order of the system, since it minimizes the residual in increasing subspaces [113]. In practice, due to the accumulation of the rounding error, this is not the case and GMRES is implemented as an iterative algorithm and stopped when the residual becomes sufficiently small.

Using an orthonormal basis for the Krylov subspaces, K_m, the residual $\boldsymbol{r}_{\mathrm{k}}^m = \mathbf{A}\mathbf{z}^m - \mathbf{b}$ can be computed without deriving explicitly $\mathbf{z}^m$ [113].

Although from (38.43), the residual norm, $\|\boldsymbol{r}_{\mathrm{k}}^m\|$, is non-increasing with m, GMRES may stagnate, i.e., the residual norm may remain constant for a certain number of iterations [21]. Moreover, from a practical viewpoint, the basis of the Krylov subspaces has to be stored to perform GMRES iterations. This requirement becomes prohibitive when the order of the system is large. Typically a maximum value, ℓ, of GMRES iterations is fixed. If, after ℓ iterations, the desired accuracy is not reached, then GMRES is *restarted* with initial guess, $\mathbf{z}^0$, equal to $\mathbf{z}^\ell$. The convergence of such a procedure is not always guaranteed. Restarting may degrade performances but, in general, the idea works well in practice [113]. Small values of ℓ are usually chosen, such as $l = 10,\ 20,\ 50$. An alternative to restarted GMRES is represented by the QUASI-GMRES method [117].

BICGSTAB and TFQMR constitute useful alternatives to GMRES, since storage requirements do not increase during the successive iterations. Nevertheless, for these methods, the residual does not decrease monotonically and two matrix-vector products are required at each iteration. Although there does not exist a rigorous convergence theory for the BICGSTAB method, and the TFQMR algorithm may break down, both these procedures can be competitive with GMRES when matrix-vector products are cheap and GMRES convergence is slow.

Iterative methods may exhibit lack of robustness, unlike direct methods, or of efficiency [21, 118]. *Preconditioning* techniques can improve both these properties. They commute the original system into an equivalent one which turns out to be easier to solve via iterative methods. A preconditioner coincides with a non-singular matrix, $\mathbf{M}$, satisfying the following properties: it is, somehow, close to $\mathbf{A}$; solving linear systems with $\mathbf{M}$ as coefficient matrix is numerically affordable; the preconditioned system can be solved more efficiently (i.e., with a faster convergence) than the original one. Moreover, we remark that, if an effective preconditioner is available, the solution of the preconditioned system is less sensitive to the choice of the linear solver.

Now, if the preconditioner is applied on the left, the linear system in (38.42) becomes

$$\mathbf{M}^{-1}\mathbf{A}\mathbf{z} = \mathbf{M}^{-1}\mathbf{b}, \tag{38.45}$$

while, when it is applied on the right, we obtain

$$\mathbf{A}\mathbf{M}^{-1}\widetilde{\mathbf{z}} = \mathbf{b} \quad \text{with } \mathbf{z} = \mathbf{M}^{-1}\widetilde{\mathbf{z}}. \tag{38.46}$$

It follows that, if now we apply GMRES, in the former case we minimize the residual $\mathbf{M}^{-1}(\mathbf{A}\mathbf{z} - \mathbf{b})$, while, in the latter case, we minimize the residual associated with the original system. Thus, right preconditioning is often preferred to the left one since allowing to track, through the iterations, the residual we are interested in.

A common way to build the preconditioner $\mathbf{M}$ is to perform a threshold incomplete LU (ILUT) factorization of $\mathbf{A}$ [119]. ILUT factorization has sparse lower and upper triangular factors and is meant to approximate $\mathbf{A}$ at a low computational cost. One of the simplest ways to apply ILUT is to impose that factors $\mathbf{L}$ and $\mathbf{U}$ share the same sparsity pattern as $\mathbf{A}$. Nevertheless, the resulting incomplete factorization, named ILUT(0), is often a crude approximation to the original matrix. Alternatively, the incomplete factorization can be computed so that the entries smaller than a fixed tolerance are dropped from factors $\mathbf{L}$ and $\mathbf{U}$ during factorization. Clearly, the lower the tolerance, the more accurately the ILUT preconditioner approximates $\mathbf{A}$ as well as the denser the triangular factors become, thus increasing the computational effort of the direct triangular solvers [21].

38.7 The n-MOSFET Test Case

We numerically solve the drift-diffusion system (38.3)–(38.4) applied to the n-MOSFET device in Fig. 38.1 in a steady setting. In particular, we are interested in investigating the dependence of the transfer characteristics (i.e., the drain current as function of the gate voltage) on the adopted grid. For this purpose, we resort to the FEMOS-MP (Finite Element Modeling-Oriented Simulator for Multi-Physics simulations) platform [30, 120]. FEMOS-MP is a general-purpose modular code based on the Galerkin FE method to model complex interplaying multiphysics phenomena in semiconductor and biophysics, including both 2D and 3D geometric configurations.

To improve the mathematical and numerical description of the physics occurring in the n-MOSFET device, we consider the Shockley-Read-Hall (SRH) and the Auger mechanisms as the recombination/generation law on the right-hand side of (38.2) (for more details, we refer to [22]). Moreover, it is well-known that, in real semiconductors, the carrier bulk mobility exhibits a strong dependence on several mechanisms (e.g., the doping or the interface scattering). For this reason, we compute the carrier mobilities by considering the contribution of the doping (Masetti's model [121]) and of the electric field (Canali's model [122]), while neglecting the interface scattering and the short channel-related effects.

Due to the simplest choice allowed for the initial guess, we adopt the Gummel method in Sect. 38.3 as a decoupling scheme, while resorting to Algorithm 38.2 to solve the system associated with the nonlinear Poisson equation, as in [123]. Concerning the computational mesh, we identify $\mathcal{T}_h$ with the grids in Figs. 38.3 and 38.4, and we apply the EAFE discretization scheme (see Remark 38.1). Finally, we will

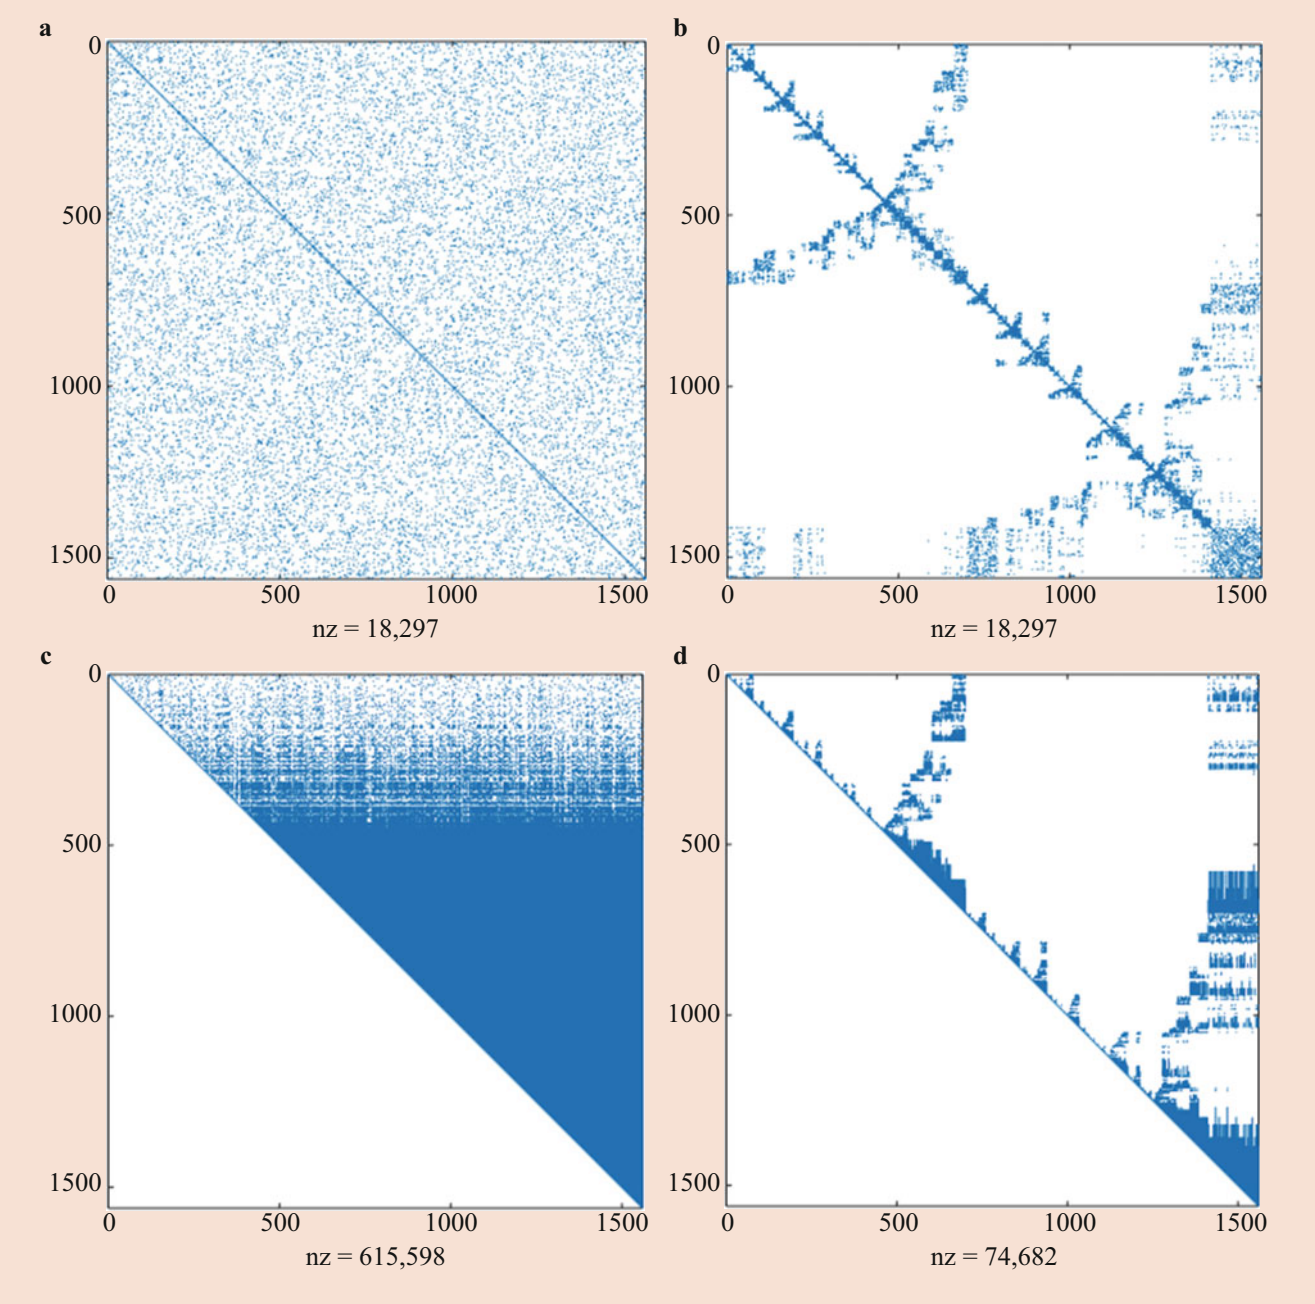

Fig. 38.5 Structured mesh: (**a**) sparsity pattern of matrix $\mathbf{A}_{\mathrm{NLP}}$ and (**b**) of the corresponding Cholesky factor, (**c**) before and (**d**) after the AMD reordering

compare the performances of some of the solvers available in FEMOS-MP to deal with systems (38.26)–(38.28).

38.7.1 Comparison of Sparse Solution Techniques

We focus here on the matrix associated with the FE discretization of the nonlinear Poisson equation (38.3) on the three meshes in Fig. 38.3.

In particular, in Figs. 38.5, 38.6, and 38.7a, we show the sparsity pattern of the matrix $\mathbf{A}_{\mathrm{NLP}}$ in (38.26), after the assignment of the boundary conditions and for the three choices of the grid, the number of nonzero entries being denoted by `nz`. The pattern associated with the structured mesh is very uniform, with a completely full diagonal. This is due to the fact that tetrahedra evenly cover the whole domain, without distinguishing any particular area from the others. On the contrary, the corresponding panels in Figs. 38.6 and 38.7 exhibit the presence of block substructures.

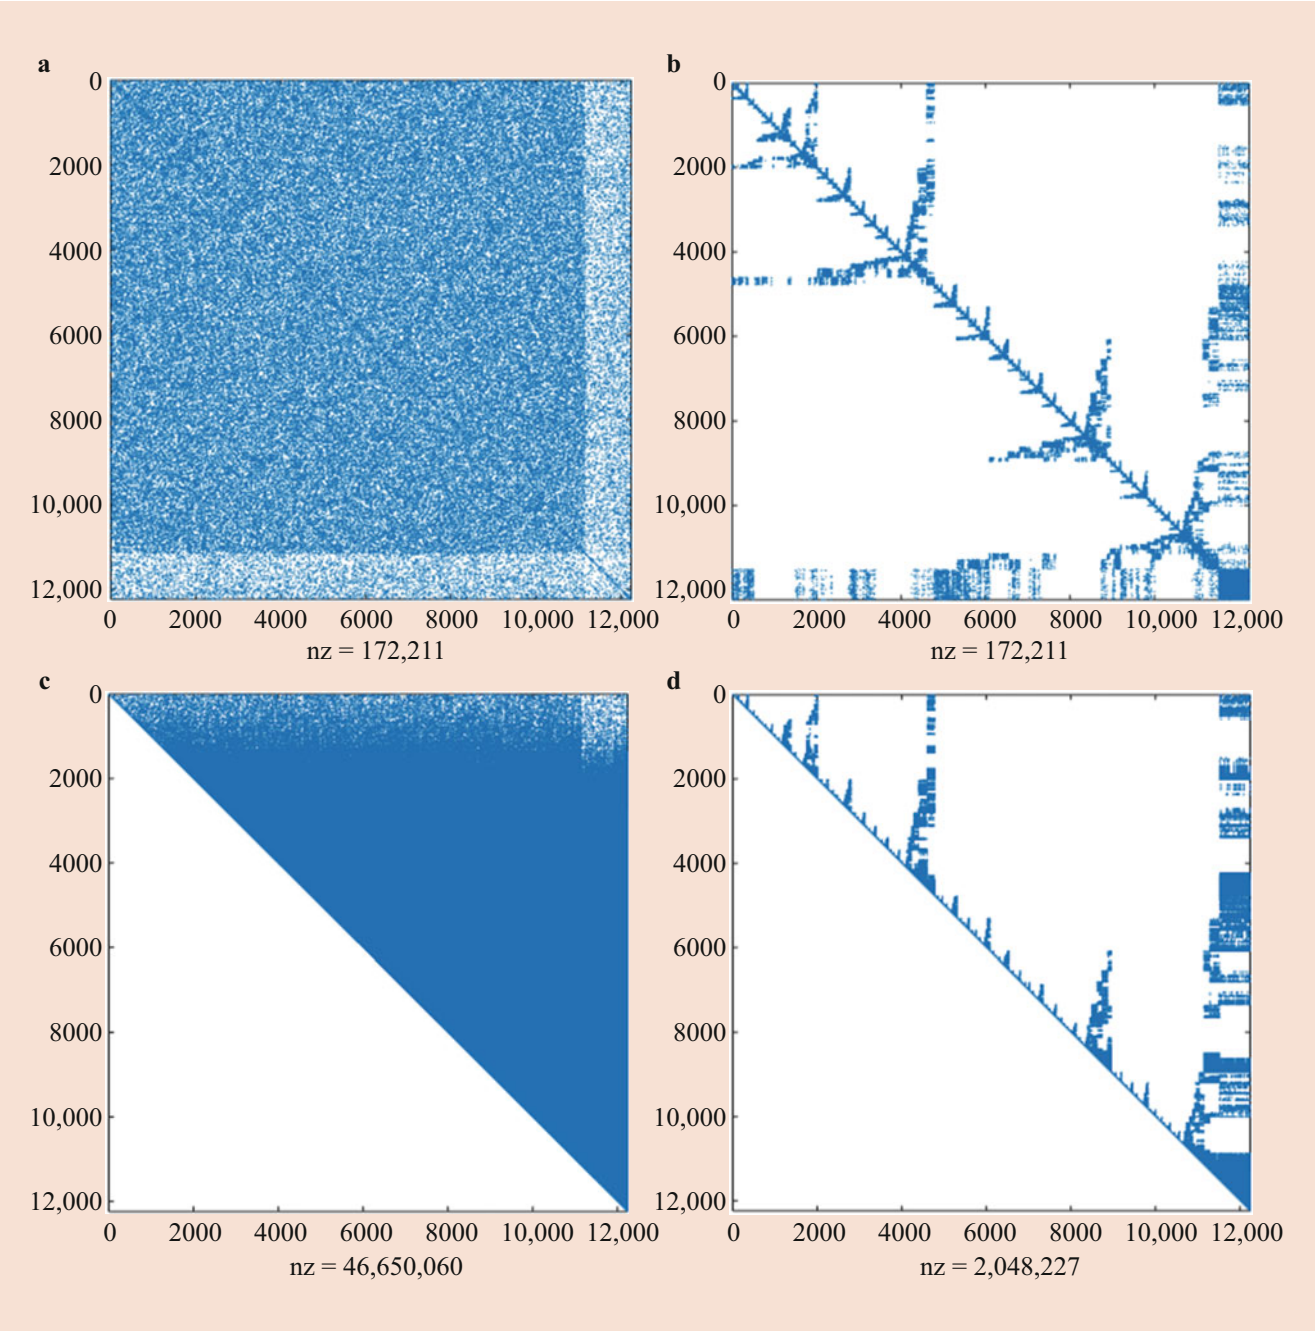

Fig. 38.6 Unstructured mesh: (**a**) sparsity pattern of matrix $\mathbf{A}_{\mathrm{NLP}}$ and (**b**) of the corresponding Cholesky factor, (**c**) before and (**d**) after the AMD reordering

The dimension, N_h, of matrix $\mathbf{A}_{\mathrm{NLP}}$ increases when moving from the structured ($N_h = 1580$) to the hybrid ($N_h = 6442$) and to the unstructured ($N_h = 12,240$) mesh, while the matrix density, identified by the ratio $\mathtt{nz}/N_h^2$, increases as expected, being $7 \cdot 10^{-3}$, $5 \cdot 10^{-4}$ and 10^{-3}, respectively.

To efficiently solve system (38.26) via a direct method, it is advisable to employ a reordering algorithm (see Sect. 38.6.2). Figures 38.5, 38.6, and 38.7b show how the sparsity pattern of matrix $\mathbf{A}_{\mathrm{NLP}}$ modifies after applying the `Matlab` function `AMD` which implements the approximate minimum degree (AMD) reordering [124]. In the same figures, we also provide the sparsity pattern for the Cholesky (upper triangular) factor, before (bottom left) and after (bottom right) the reordering. The effect of the reordering is evident both on the original matrix and the Cholesky factor. In particular, the difference in terms of the sparsity pattern among the three different meshes reduces after the reordering, independently of the value for N_h.

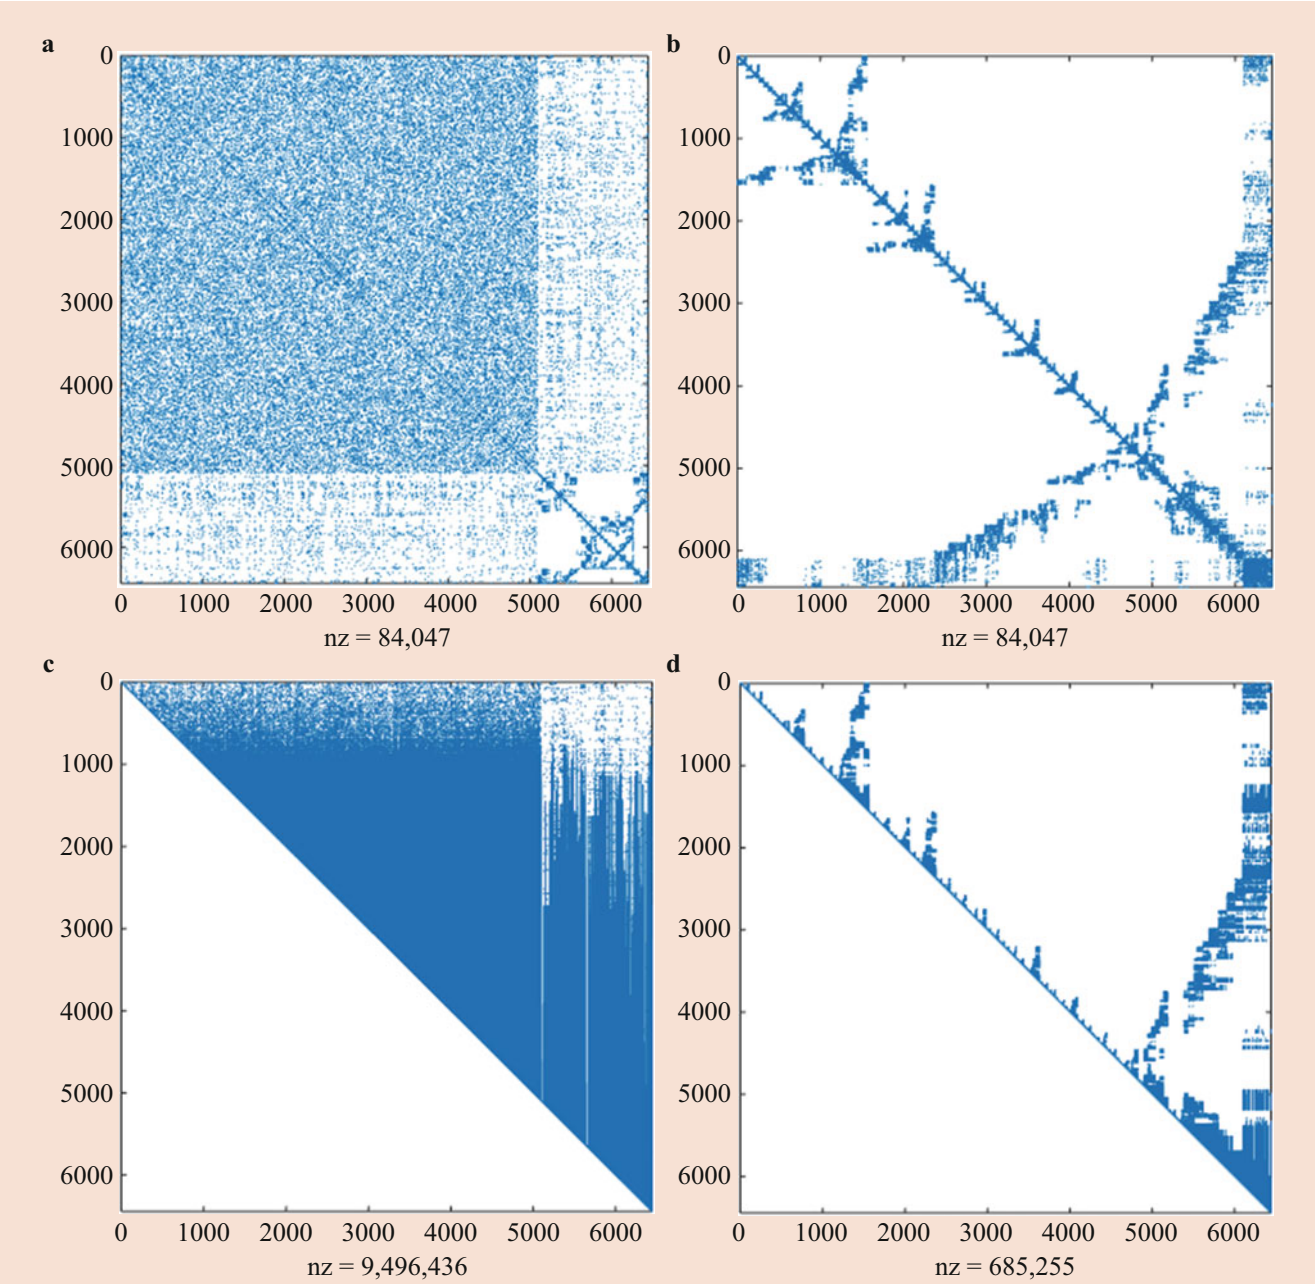

Fig. 38.7 Hybrid mesh: (**a**) sparsity pattern of matrix $\mathbf{A}_{\mathrm{NLP}}$ and (**b**) of the corresponding Cholesky factor, (**c**) before and (**d**) after the AMD reordering

In Table 38.1, we investigate the effectiveness of direct methods for sparse linear systems. We compare SUPERLU [125], MUMPS [109, 110], and UMFPACK [107] libraries in terms of CPU time (in seconds) (The computations have been run on a portable PC equipped with INTEL i5 processor 2.4 GHz and 8 GB of RAM.). In particular, we measure the time actually demanded by the solver, while neglecting the matrix assembling phase. All the libraries involved in this comparison employ LU-based factorizations combined with the AMD reordering. As an alternative, we resort to a SParse QR (SPQR) factorization [107]. Nevertheless, this turns out to be the most expensive algorithm both on the structured and unstructured grids and fails on the hybrid mesh. Actually, QR factorization efficiently works only for highly ill-conditioned systems. In all the other cases, the orthogonal matrix Q is characterized by many nonzero entries, thus becoming unpractical.

For the sake of comparison, in Table 38.1 we furnish also the CPU time associated with the BCG-NR [126] and the BCG-EIGEN [127] iterative methods that we run without

preconditioning and by adopting the default options. The performances of BCG-NR are fully comparable with the ones of MUMPS and UMFPACK. Nevertheless, to have reliable solutions, we have set a very high accuracy. Moreover, these methods are, in general, enriched by suitable preconditioners (see Sect. 38.6.2), whose choice, unfortunately, represents a problem-dependent issue.

Thus, to sum-up, we can state that LU-based direct solvers (enriched with reordering algorithms) represent the ideal tool to solve sparse systems, provided that memory requirements and CPU time remain contained. If this is not the case, we can resort to iterative methods, after an ad hoc selection of a preconditioner.

38.7.2 Numerical Assessment

We investigate here the electrical properties characterizing the discretization performed in the previous section, with a particular emphasis on the possible influence of the computational mesh. We adopt the MUMPS solver for all the assessments throughout performed.

Table 38.1 NLP system, CPU time [s]: comparison among solvers and for different meshes

Solver	Structured mesh	Unstructured mesh	Hybrid mesh
Superlu	$1.8573 \cdot 10^{-2}$	$1.6730 \cdot 10^{0}$	$2.6797 \cdot 10^{-1}$
mumps	$2.6008 \cdot 10^{-2}$	$5.2267 \cdot 10^{-1}$	$2.0729 \cdot 10^{-1}$
umfpack	$1.2558 \cdot 10^{-2}$	$4.6721 \cdot 10^{-1}$	$1.3596 \cdot 10^{-1}$
spqr	$3.5664 \cdot 10^{-2}$	$2.1753 \cdot 10^{0}$	FAILURE
bcg-nr	$2.2140 \cdot 10^{-2}$	$4.2618 \cdot 10^{-1}$	$1.5783 \cdot 10^{-1}$
bcg-eigen	$3.2930 \cdot 10^{-2}$	$1.1702 \cdot 10^{0}$	$3.3415 \cdot 10^{-1}$

In particular, Fig. 38.8a compares the n-MOSFET transfer characteristics, for the different computational meshes in Fig. 38.3. We observe a mismatch among the three curves when the gate voltage is low. This can be ascribed to the electron density, whose gradient strongly influences the drift-diffusion current. Figure 38.9 highlights the difference among the three meshes in terms of electron density concentration. In particular, the structured grid results in the highest current, i.e., in the highest electron concentration in the region under the gate. From a modeling viewpoint, the simulations associated with the unstructured and the hybrid grids better describe the electron generation in the region delimited by the source and the drain junctions. On the contrary, the employment of the structured mesh leads to an overestimation of this mechanism, due to the limited number of dofs in such a region.

Figure 38.8b shows the Id-Vg transfer curves associated with the adapted grids in Fig. 38.4. The characteristics are essentially overlapped, with a slight mismatch when the gate voltage is low, analogously to Fig. 38.8a. This very small difference does not allow to easily compare the two simulations in terms of electron density. In this case, it is more convenient to consider the SRH contribution (see Fig. 38.10, where higher SRH (red colors) mean higher recombination). It turns out that the SHR mechanism is correctly captured along the whole junction profile when employing the grid adapted via the geometric plus the physical criterion, whereas, in the purely geometric case, the profile exhibits some interruptions caused by the nonoptimal mesh. Thus, the choice of a computational mesh able to follow the features of the problem turns out to be crucial in terms of modeling accuracy (besides of convergence properties of the numerical algorithms).

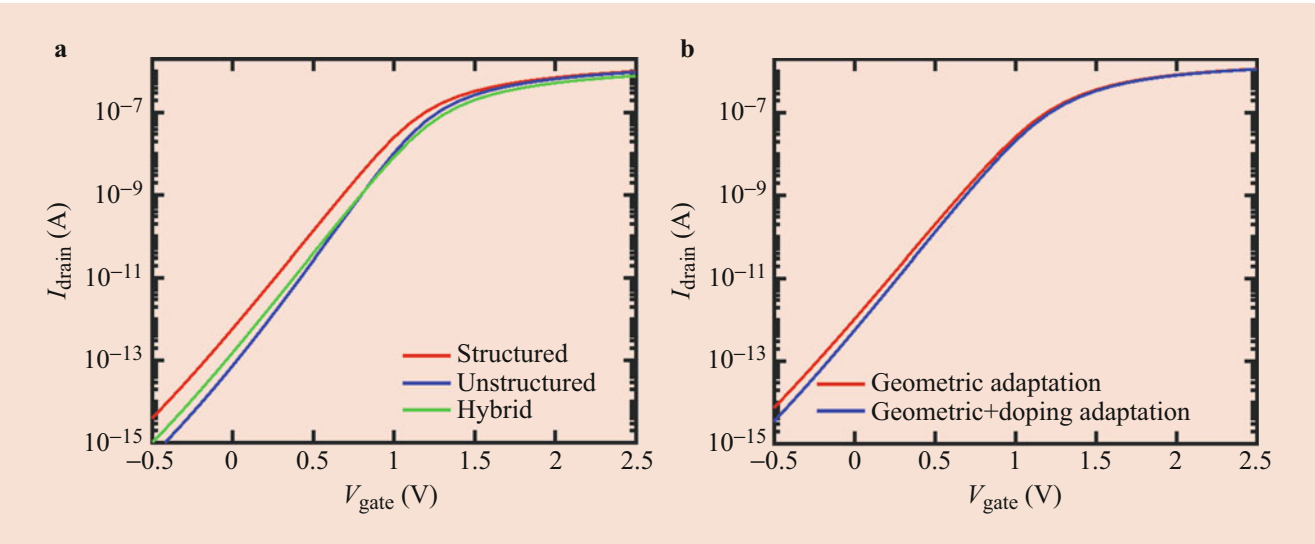

Fig. 38.8 n-MOSFET device: $I_d - V_g$ transfer characteristics in logarithmic scale for the grids in Fig. 38.3a and Fig. 38.4b

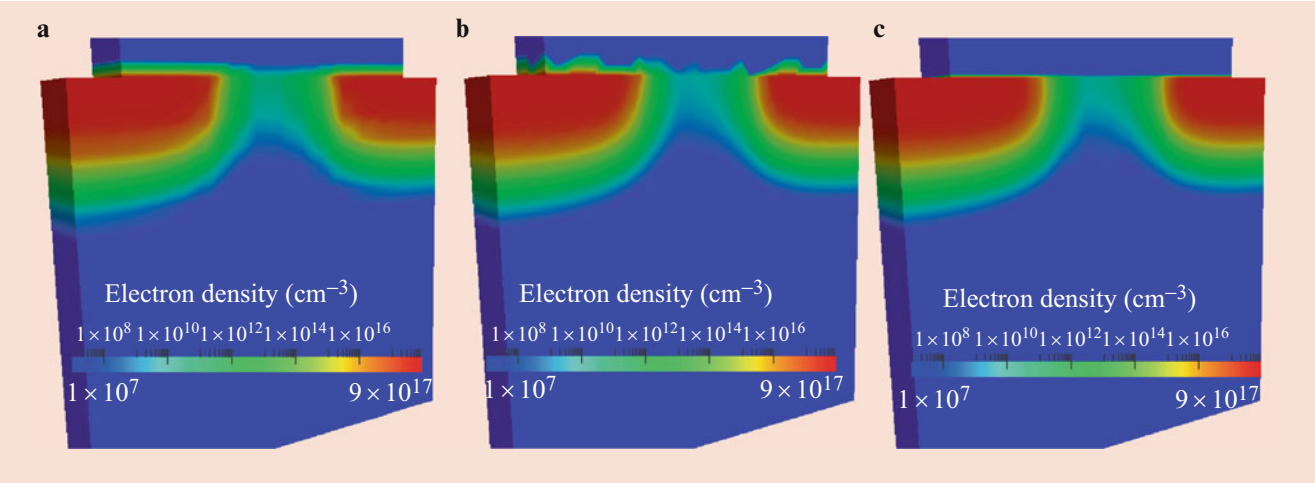

Fig. 38.9 n-MOSFET device: color plot of the electron density concentration at $V_{\text{Drain}} = 0.1$ (V) and $V_{\text{Gate}} = 0.0$ (V) on the (**a**) structured, (**b**) unstructured, and (**c**) hybrid mesh

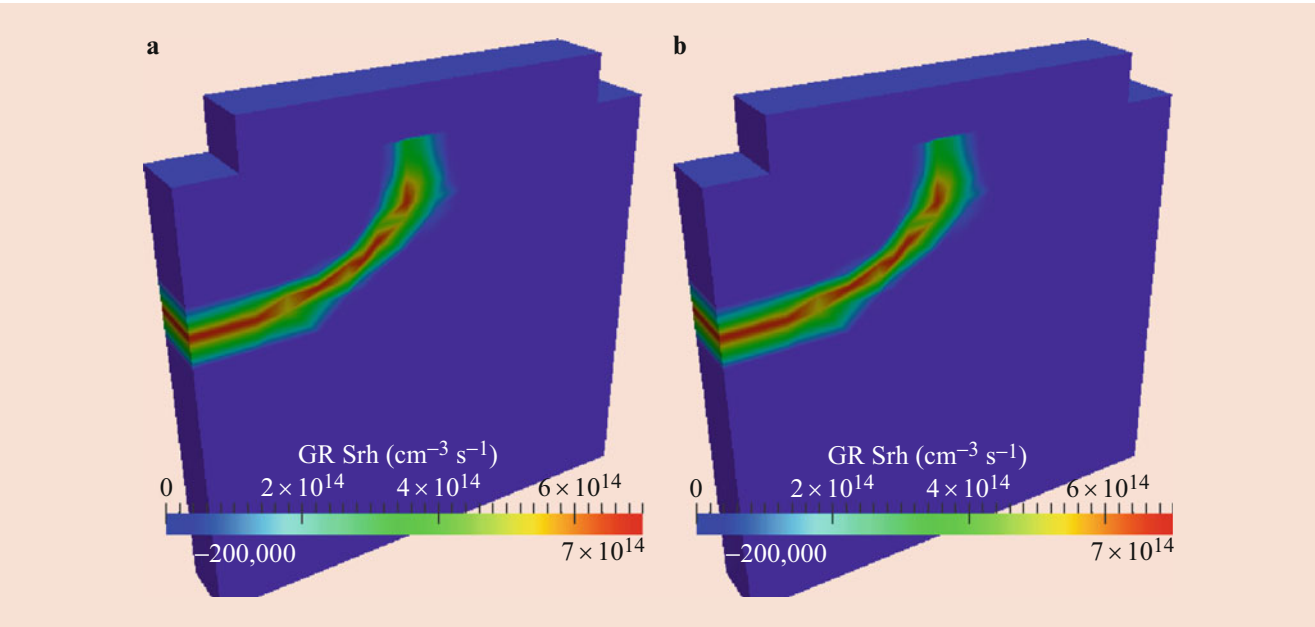

Fig. 38.10 n-MOSFET device: color plot of the SRH net production term at $V_{\text{Drain}} = 0.1$ (V) and $V_{\text{Gate}} = 0.0$ (V) on the (**a**) geometric and (**b**) geometric+doping adapted mesh

Aurelio Giancarlo Mauri is a lecturer fellowship at Politecnico di Milano for "Numerical Analysis" and "Computational Modeling for Electronics and Biomathematics." He is the author of FEMOS-MP (Finite Element Method Oriented Simulator for Multiphysics Problems), a C++ platform for modeling and simulation of complex systems. His scientific interests cover the multiphysics modeling of biologic and electronic systems.

Benedetta Morini graduated in Mathematics at the University of Firenze and obtained the PhD in Computational Mathematics at the University of Padova. She is Professor in the Department of Industrial Engineering at the University of Firenze. She serves as Associate Editor of *Numerical Algorithms*. Her scientific interests cover the development of numerical algorithms for continuous optimization and large-scale linear systems.

Simona Perotto is Associate Professor of Numerical Analysis in the Department of Mathematics of Politecnico di Milano. She got the Master degree in Mathematics from the University of Torino and PhD in Computational Mathematics and Operations Research from the University of Milano.

Her primary research fields cover anisotropic mesh adaptation and adaptive model reduction for Computational Fluid Dynamics problems.

Fiorella Sgallari is Professor of Numerical Analysis at the University of Bologna. She is a member of the Academy of Sciences of Bologna and author of more than 150 publications. She coordinated several national, international, and industrial research projects and was associate editor of international journals. Her research concerns PDE models and numerical methods for image processing and discrete ill-posed problems.

Abstract

By far, most numerical device simulations are still based on the drift-diffusion (DD) model, owing to its versatility, numerical efficiency, and robustness. However, the DD model is of limited physical accuracy for nanoscale devices and hot carrier effects. Advanced physical modeling in the regime of semi-classical transport must therefore be based on the Boltzmann transport equation (BTE), and the typical solution method for this equation is a Monte-Carlo (MC) algorithm owing to its small memory requirements. Unfortunately, this popular solution method makes the BTE model much less versatile than the DD approach, as, for example, no AC and noise analysis in the small-signal framework based on the Jacobian of the numerical model is available if the MC method is used. Moreover, evaluating the complete transport of carriers in a device by the BTE model is always several orders of magnitude less efficient in terms of CPU time than the application of the DD model. Thus, there is a clear demand to increase the versatility of the BTE model and to enhance the physical accuracy of the DD model without compromising its numerical efficiency and robustness. Solving the BTE model with the spherical harmonic expansion (SHE) method allows the calculation of the full Jacobian of the discrete system and to establish AC and noise analysis in the small-signal framework, thus making the BTE model much more versatile. Moreover, sequential and concurrent multi-scale methods using microscopic models such as the BTE model where necessary and macroscopic models such as the DD model otherwise are well suited to enhancing the physical accuracy of the DD model without compromising its efficiency and robustness. In addition, using the SHE method allows many of the discretization methods and principles previously developed for the DD model to be applied for the discretization of the BTE model. Therefore, a short overview of the historic development of discretization methods and principles, finally making the DD model as efficient and robust as it is today, is added as well.

whereas scattering rates and band structures are calculated by quantum mechanical methods [1]. The most fundamental transport equation in this framework is the BTE, which was derived by Ludwig Boltzmann to model the dynamics of an ideal gas, and was later applied to electrons and holes in semiconductors [2]. It describes the temporal evolution of the distribution function and the density in the single-particle phase space, which spans the real space and the k-space (KS) [3]. The BTE, which is an integro-differential equation, can be solved by the MC method, which is used to calculate hot-electron phenomena in the case of strong non-equilibrium [4–8]. Owing to its simplicity and low memory requirements, the stochastic MC algorithm is the method of choice for solving the BTE, and, for example, numerically calculated band structures (full bands) can be easily included [9–12]. It is inherently transient and in the case of the physical MC method electronic noise can be simulated [13]. On the other hand, the transient and stochastic nature of the MC technique can lead to problems. It is difficult to obtain very accurate solutions, because the variance of the estimated values is inversely proportional to the CPU time [14–17]. In the case of processes with very different time scales or rare events, CPU times might become too long to be feasible. This shows clearly that the numerical properties of the MC method are very different from the robust and versatile methods used in the case of other technology computer-aided design (TCAD) models (e.g., the drift-diffusion [DD] model), making the numerical effort needed for the TCAD models much less dependent on the bias conditions and the required numerical accuracy. Thus, alternative deterministic methods for the solution of the BTE were developed (e.g., [18–20]). The most important one is the spherical harmonics expansion (SHE) method, which has its origin in semi-analytical solutions of the BTE [21–23]. Application of this method to device simulation was only possible with the advent of large computer memories and the development of stable numerical algorithms [24]. Although SHE is numerically much more difficult to handle than the MC method, it has distinct advantages [25]. It can be solved directly for the stationary case, AC and noise simulations are possible in the small-signal framework in contrast to the MC method [26–28], and the numerical effort depends only weakly on bias conditions and the required numerical accuracy. The SHE approach can be easily extended in the case of lower-dimensional particle gases, which occur in systems that are confined perpendicular to the transport direction (e.g., inversion channel of a MOSFET). For example, in the case of a quasi-2D particle gas, instead of spherical coordinates, polar coordinates are used and the angular dependencies are expanded into a Fourier series (Fourier harmonic expansion) [29–31].

The models based on direct solutions of the BTE are not only used to simulate devices. As simpler lower-level transport models (e.g., DD and hydrodynamic (HD) models) can be derived from the BTE, their transport and noise parameters (mobilities, relaxation times, etc.) can be generated by bulk simulations with the BTE [12] (see also Sect. 39.3.1). In the case of new materials, it is often not possible to measure transport parameters for all material compositions in the design space and the more fundamental model can be used to generate the transport parameters. For example, in the case of strained SiGe, the transport and noise parameters for the HD and DD models were generated by solving the BTE for a large range of temperatures, Ge contents, doping concentrations, various strain configurations, and crystal orientations, and were stored in a table model [32]. In an investigation of the performance limits of SiGe heterojunction bipolar transistors (HBTs), BTE device simulations were even used to generate certain parameters of a compact model [33]. In addition, the models at the higher level are used to assess the accuracy of the models at a lower level by comparison of results for benchmark devices [12]. Moreover, hot carrier or tunneling-related effects can be modeled by higher-level models based on the results of lower-level models, thus improving the overall modeling accuracy without influencing the computational efficiency too much (see Sect. 39.3.2).

Despite its limited accuracy the DD model is still the numerical device model used most often for device simulations. This is largely because of the accurate, robust, versatile, and computationally efficient numerical methods that are applied for the simulations and which are very similar for the different DD simulation programs mostly applied today. The situation was very different when the solution methods for the DD model were developed about 50 years ago. In particular, many different discretization methods were applied in the beginning and it took about two decades to develop the method, which is still used today. As much can be learned from the historic development of the numerical DD model and the principles and insights leading to the advanced numerical device models used today, a brief outline is added at the end of this chapter.

39.2 The Spherical Harmonic Expansion Method for the Solution of the Boltzmann Transport Equation

39.2.1 The Boltzmann Transport Equation

The distribution function $f^{\nu}(\boldsymbol{r}, \boldsymbol{k}, t)$ is the density in the six-dimensional single-particle phase space of band or valley ν at position $\boldsymbol{r}$ and wave vector $\boldsymbol{k}$ at time t. The particle number in the infinitesimal volume $\mathrm{d}^3k\mathrm{d}^3r$ is given by [3, 34]

$$\mathrm{d}N^{\nu}(\boldsymbol{r}, \boldsymbol{k}, t) = \frac{2}{(2\pi)^3} f^{\nu}(\boldsymbol{r}, \boldsymbol{k}, t)\mathrm{d}^3r\mathrm{d}^3k \,. \tag{39.1}$$

The factor $2/(2\pi)^3$ takes into account spin degeneracy and the minimum phase space volume of a particle [2]. To reduce the notational clutter, only the case for electrons is discussed. With the distribution function and a microscopic quantity $X^\nu(\boldsymbol{k})$, a macroscopic density (generalized moment of the distribution function) can be calculated by integration over the KS

$$x(\boldsymbol{r},t) = \frac{2}{(2\pi)^3}\sum_\nu \int X^\nu(\boldsymbol{k}) f^\nu(\boldsymbol{r},\boldsymbol{k},t)\mathrm{d}^3k\,. \tag{39.2}$$

The sum runs over all valleys of the conduction bands. $X^\nu(\boldsymbol{k}) = 1$ yields the electron density

$$n(\boldsymbol{r},t) = \frac{2}{(2\pi)^3}\sum_\nu \int f^\nu(\boldsymbol{r},\boldsymbol{k},t)\mathrm{d}^3k\,. \tag{39.3}$$

The particle current density

$$\boldsymbol{j}(\boldsymbol{r},t) = \frac{2}{(2\pi)^3}\sum_\nu \int \boldsymbol{v}_\nu(\boldsymbol{k}) f^\nu(\boldsymbol{r},\boldsymbol{k},t)\mathrm{d}^3k \tag{39.4}$$

is obtained with the group velocity

$$\boldsymbol{v}_\nu(\boldsymbol{k}) = \frac{1}{\hbar}\nabla_{\boldsymbol{k}}\varepsilon_\nu(\boldsymbol{k})\,, \tag{39.5}$$

where $\varepsilon_\nu(\boldsymbol{k})$ is the band energy, which is assumed to be position independent, and $\hbar$ is the reduced Planck constant. The more general case of a position-dependent band structure is not discussed here and is described in Jungemann and Meinerzhagen [12, 30] and the references therein. If only the band or valley minima depend on the position, this dependence can be easily included by adding the corresponding potential energy to the quasi-stationary potential [12].

The distribution function is the solution of the BTE [8,34]

$$\left\{\frac{\partial}{\partial t} - \frac{e}{\hbar}\boldsymbol{E}\cdot\nabla_{\boldsymbol{k}} + \boldsymbol{v}\cdot\nabla_{\boldsymbol{r}}\right\} f = \mathcal{W}\,. \tag{39.6}$$

e is the magnitude of the electron charge and $\boldsymbol{E}(\boldsymbol{r},t)$ the electric field. The scattering integral

$$\begin{aligned}\mathcal{W}^\nu(\boldsymbol{r},\boldsymbol{k},t) = \frac{\Omega_{\mathrm{sys}}}{(2\pi)^3}\sum_\eta\sum_{\nu'}\int &\left[1 - f^\nu(\boldsymbol{r},\boldsymbol{k})\right] \\ &\times W_\eta^{\nu,\nu'}(\boldsymbol{r},\boldsymbol{k},\boldsymbol{k}') f^{\nu'}(\boldsymbol{r},\boldsymbol{k}') \\ &- \left[1 - f^{\nu'}(\boldsymbol{r},\boldsymbol{k}')\right] W_\eta^{\nu',\nu}(\boldsymbol{r},\boldsymbol{k}',\boldsymbol{k}) f^\nu(\boldsymbol{r},\boldsymbol{k})\,\mathrm{d}^3k'\end{aligned} \tag{39.7}$$

describes the scattering of particles into the state $\nu,\boldsymbol{k}$ and out of it. Ω_{sys} is the system volume and $W_\eta^{\nu,\nu'}(\boldsymbol{r},\boldsymbol{k},\boldsymbol{k}')$ the transition rate for scattering from state $\nu',\boldsymbol{k}'$ into $\nu,\boldsymbol{k}$ owing to scattering process η, of which the rate is calculated by Fermi's golden rule [2, 8].

The BTE is a partial differential equation that requires boundary conditions. At the surfaces of the semiconductor region, which belong to contacts, the distribution function of the inflowing particles is given by the equilibrium distribution function [35]. If $\boldsymbol{r}_i^{\mathrm{cont}}$ is a vector in the surface region of the ith contact and $\boldsymbol{n}$ a vector, which is normal to the surface and points into the semiconductor region, the condition

$$\boldsymbol{n}\left(\boldsymbol{r}_i^{\mathrm{cont}}\right)\cdot\boldsymbol{v}_\nu(\boldsymbol{k}_\nu) > 0 \tag{39.8}$$

selects all wave vectors, which represent states of inflowing particles. Only for these wave vectors is the distribution function given by the equilibrium distribution function, and the total flux through the boundary $\boldsymbol{n}\cdot\boldsymbol{J}$ is given by

$$\begin{aligned}&\boldsymbol{n}\left(\boldsymbol{r}_i^{\mathrm{cont}}\right)\cdot\boldsymbol{J}^\nu\left(\boldsymbol{r}_i^{\mathrm{cont}},\boldsymbol{k},t\right) \\ &\quad= \boldsymbol{v}_\nu(\boldsymbol{k}) f^\nu\left(\boldsymbol{r}_i^{\mathrm{cont}},\boldsymbol{k},t\right)\Theta\left[-\boldsymbol{n}\left(\boldsymbol{r}_i^{\mathrm{cont}}\right)\cdot\boldsymbol{v}_\nu(\boldsymbol{k})\right] \\ &\qquad+\boldsymbol{v}_\nu(\boldsymbol{k}) f^{\mathrm{eq},\nu}\left(\boldsymbol{r}_i^{\mathrm{cont}},\boldsymbol{k}\right)\Theta\left[\boldsymbol{n}\left(\boldsymbol{r}_i^{\mathrm{cont}}\right)\cdot\boldsymbol{v}_\nu(\boldsymbol{k})\right]\,.\end{aligned} \tag{39.9}$$

$\Theta(x)$ is the Heaviside function. The first part of the right-hand side (RHS) is the flux leaving the device, which depends on the distribution function within the device, and the second term describes the flux entering the device owing to a contact at equilibrium [30, 35]. At equilibrium the current density should be zero in the whole device and the Fermi levels of the distribution functions of the inflowing particles are chosen accordingly. On all other parts of the semiconductor surface, it is assumed that the particle flux through the surface is zero.

The electric field $\boldsymbol{E}(\boldsymbol{r},t)$ is the gradient of the quasi-stationary potential $\Psi(\boldsymbol{r},t)$

$$\boldsymbol{E} = -\nabla_{\boldsymbol{r}}\Psi\,, \tag{39.10}$$

which is the solution of the Poisson equation (PE) [36]

$$\nabla_{\boldsymbol{r}}\cdot\left[\kappa\nabla_{\boldsymbol{r}}\Psi\right] = -e\left(p - n + N_{\mathrm{D}} - N_{\mathrm{A}}\right)\,. \tag{39.11}$$

κ is the permittivity, p the hole density, N_{D} the donor concentration, and N_{A} the acceptor concentration. On all interfaces the potential and the normal electric flux density must be continuous. On contacts, Dirichlet boundary conditions are applied to the potential

$$\Psi = V_i + \Phi_{\mathrm{MS}}\,. \tag{39.12}$$

V_i is the bias applied to the ith contact and Φ_{MS} the metal–semiconductor work function difference [37]. On all other parts of the surface of the device, the component of the electric flux density perpendicular to the surface must vanish.

39.2.2 Spherical Harmonics Expansion

The phase space has six dimensions and is difficult to discretize directly. If the problem is translation-invariant in the real space for one or two dimensions, the dimensionality can be reduced accordingly. But even a problem with five or four dimensions requires a very large number of grid nodes. By expanding the angular dependence of the distribution function in the KS into a spherical harmonics series, the dimensionality can be reduced further [23, 38, 39]. In many cases this expansion converges rapidly and it can be truncated at a low order [39, 40].

A real spherical harmonic of degree $l \geq 0$ and order m with $-l \leq m \leq l$ is given by [41]

$$Y_{l,m}(\theta,\phi) = \begin{cases} c_{l,m} P_{l,m}(\cos\theta)\cos(m\phi) & \text{for } m \geq 0 \\ c_{l,m} P_{l,m}(\cos\theta)\sin(|m|\phi) & \text{for } m < 0 \end{cases} \tag{39.13}$$

with

$$c_{l,m} = \begin{cases} \sqrt{\frac{(2l+1)}{4\pi}} & \text{for } m = 0 \\ \sqrt{\frac{(2l+1)(l-|m|)!}{2\pi(l+|m|)!}} & \text{for } m \neq 0 \end{cases} . \tag{39.14}$$

The associated Legendre polynomial

$$P_{l,m}(x) = \left(1-x^2\right)^{\frac{m}{2}} \frac{\mathrm{d}^m}{\mathrm{d}x^m} P_l(x) \tag{39.15}$$

is related to the Legendre polynomial

$$P_l(x) = \frac{1}{2^l l!} \frac{\mathrm{d}^l}{\mathrm{d}x^l} \left(x^2-1\right)^l . \tag{39.16}$$

The first four spherical harmonics are

$$Y_{0,0} = \frac{1}{\sqrt{4\pi}} \tag{39.17}$$

$$Y_{1,1} = \sqrt{\frac{3}{4\pi}} \sin\theta\cos\phi \tag{39.18}$$

$$Y_{1,-1} = \sqrt{\frac{3}{4\pi}} \sin\theta\sin\phi \tag{39.19}$$

$$Y_{1,0} = \sqrt{\frac{3}{4\pi}} \cos\theta \tag{39.20}$$

The spherical harmonics form a complete set of orthonormal functions with respect to integration over the unit sphere

$$\oint Y_{l,m}(\theta,\phi) Y_{l',m'}(\theta,\phi)\mathrm{d}\Omega \tag{39.21}$$

$$\begin{aligned} &= \int_0^{2\pi}\int_0^{\pi} Y_{l,m}(\theta,\phi) Y_{l',m'}(\theta,\phi)\sin\theta \mathrm{d}\theta\mathrm{d}\phi \\ &= \delta_{l,l'}\delta_{m,m'} . \end{aligned}$$

$\delta_{i,j}$ is the Kronecker symbol.

A function that depends on the two angles of the spherical coordinates, can be projected onto spherical harmonics by

$$X_{l,m} = \oint X(\theta,\phi) Y_{l,m}(\theta,\phi)\mathrm{d}\Omega . \tag{39.22}$$

The corresponding SHE of the function is

$$\begin{aligned} X(\theta,\phi) &= \sum_{l=0}^{\infty}\sum_{m=-l}^{m=l} X_{l,m} Y_{l,m}(\theta,\phi) \\ &\approx \sum_{l=0}^{l_{\max}}\sum_{m=-l}^{m=l} X_{l,m} Y_{l,m}(\theta,\phi) , \end{aligned} \tag{39.23}$$

which is truncated at the maximum expansion order $l_{\max}$.

With $X(\theta,\phi) = Y_{l,m}(\theta,\phi) Y_{l',m'}(\theta,\phi)$ products of spherical harmonics can be expanded

$$a^{l,m}_{l',m',l'',m''} = \oint Y_{l,m} Y_{l',m'} Y_{l'',m''}\mathrm{d}\Omega . \tag{39.24}$$

The basis vector in radial direction of the KS can be expressed with spherical harmonics

$$\begin{aligned} \boldsymbol{e}_r(\theta,\phi) &= \begin{pmatrix} \sin\theta\cos\phi \\ \sin\theta\sin\phi \\ \cos\theta \end{pmatrix} \\ &= \sqrt{\frac{4\pi}{3}} \begin{pmatrix} Y_{1,1}(\theta,\phi) \\ Y_{1,-1}(\theta,\phi) \\ Y_{1,0}(\theta,\phi) \end{pmatrix} \end{aligned} \tag{39.25}$$

and its product with two spherical harmonics

$$\boldsymbol{a}^{l,m}_{l',m'} = \oint \boldsymbol{e}_r Y_{l,m} Y_{l',m'}\mathrm{d}\Omega = \boldsymbol{a}^{l',m'}_{l,m} \tag{39.26}$$

can be calculated by (39.24). The vector remains the same when the indices are interchanged. Another useful vector is obtained with the basis vectors in θ and ϕ directions

$$\boldsymbol{b}^{l,m}_{l',m'} = \oint \left(\boldsymbol{e}_\theta \frac{\partial Y_{l,m}}{\partial\theta} + \frac{\boldsymbol{e}_\phi}{\sin\theta} \frac{\partial Y_{l,m}}{\partial\phi} \right) Y_{l',m'}\mathrm{d}\Omega \tag{39.27}$$

with $\boldsymbol{b}^{0,0}_{l',m'} = 0$ for all l', m'. The two vectors satisfy [30]

$$2\boldsymbol{a}^{l,m}_{l',m'} = \boldsymbol{b}^{l,m}_{l',m'} + \boldsymbol{b}^{l',m'}_{l,m} . \tag{39.28}$$

Both vectors vanish for $|l - l'| \neq 1$. Thus, an even l couples only to an odd l' and vice versa.

For the boundary conditions of the BTE on contacts (39.10), two more expressions are required [30]:

$$D^{l,m}_{l',m'} = \oint \boldsymbol{e}_r \cdot \boldsymbol{n} \Theta(-\boldsymbol{e}_r \cdot \boldsymbol{n}) Y_{l,m} Y_{l',m'} \mathrm{d}\Omega$$
$$E^{l,m}_{l',m'} = \oint \boldsymbol{e}_r \cdot \boldsymbol{n} \Theta(\boldsymbol{e}_r \cdot \boldsymbol{n}) Y_{l,m} Y_{l',m'} \mathrm{d}\Omega \,. \quad (39.29)$$

$\boldsymbol{n}$ is a unit vector, which is perpendicular to the contact surface and points into the device.

For the sake of simplicity and legibility, it is assumed that the band structure is isotropic and depends only on the magnitude of the wave vector, where some full-band effects are included [42]:

$$\varepsilon_\nu(\boldsymbol{k}) = \varepsilon_\nu(k) \,. \quad (39.30)$$

Ellipsoidal valleys can be easily transformed into isotropic valleys by the Herring–Vogt transformation [43]. (The general case of full bands is discussed in Kosina et al., Jungemann et al., and Hong et al. [30, 40, 44, 45].) Assuming a monotonic relationship between the magnitude of the wave vector and the energy, a unique inversion of the relation is possible:

$$\boldsymbol{k} = \boldsymbol{k}_\nu(\varepsilon, \theta, \phi) = k_\nu(\varepsilon) \boldsymbol{e}_r(\theta, \phi) \quad (39.31)$$

and the energy can be used as a coordinate instead of the magnitude of the wave vector, where the two angles remain the same [44].

The distribution function is projected on the spherical equi-energy surfaces onto spherical harmonics [40]:

$$Z_\nu(\varepsilon) f^\nu_{l,m}(\boldsymbol{r}, \varepsilon, t) \quad (39.32)$$
$$= \frac{2}{(2\pi)^3} \int \delta(\varepsilon - \varepsilon_\nu(k)) Y_{l,m}(\theta, \phi) f^\nu(\boldsymbol{r}, \boldsymbol{k}, t) \mathrm{d}^3 k$$
$$= Z_\nu(\varepsilon) \oint Y_{l,m}(\theta, \phi) f^\nu(\boldsymbol{r}, \boldsymbol{k}_\nu(\varepsilon, \theta, \phi), t) \mathrm{d}\Omega$$

with the reduced density of states

$$Z_\nu(\varepsilon) = \frac{2}{(2\pi)^3} k^2_\nu(\varepsilon) \frac{\mathrm{d}k_\nu(\varepsilon)}{\mathrm{d}\varepsilon} \,. \quad (39.33)$$

This definition does not contain the usual integration over the unit sphere and is therefore smaller by a factor of 4π. The distribution function defined over the six-dimensional phase space is thus replaced by a generalized energy distribution function $Z_\nu(\varepsilon) f^\nu_{l,m}(\boldsymbol{r}, \varepsilon, t)$, which is defined over a four-dimensional space of energy and position and which has a finite number of components.

The macroscopic densities (39.2) are given with the energy distribution function by

$$x(\boldsymbol{r}, t) = \sum_{\nu,l,m} \int_0^\infty X^\nu_{l,m}(\varepsilon) Z_\nu(\varepsilon) f^\nu_{l,m}(\boldsymbol{r}, \varepsilon, t) \mathrm{d}\varepsilon \,. \quad (39.34)$$

The electron density is obtained with $X = 1 = \sqrt{4\pi} Y_{0,0}$ and $X_{l,m} = \sqrt{4\pi} \delta_{l,0} \delta_{m,0}$:

$$n(\boldsymbol{r}, t) = \sqrt{4\pi} \sum_\nu \int_0^\infty Z_\nu(\varepsilon) f^\nu_{0,0}(\boldsymbol{r}, \varepsilon, t) \mathrm{d}\varepsilon \quad (39.35)$$

and depends only on the lowest order of the distribution function, whereas the current density obtained with $X = \boldsymbol{v} = v\boldsymbol{e}_r$ involves only the first-order distribution functions:

$$\boldsymbol{j}(\boldsymbol{r}, t) = \sqrt{\frac{4\pi}{3}} \quad (39.36)$$
$$\times \sum_\nu \int_0^\infty v_\nu(\varepsilon) Z_\nu(\varepsilon) \begin{pmatrix} f^\nu_{1,1}(\boldsymbol{r}, \varepsilon, t) \\ f^\nu_{1,-1}(\boldsymbol{r}, \varepsilon, t) \\ f^\nu_{1,0}(\boldsymbol{r}, \varepsilon, t) \end{pmatrix} \mathrm{d}\varepsilon \,.$$

This is because of the assumption of a spherical band structure [40, 42].

The BTE is projected in a similar fashion

$$\frac{2}{(2\pi)^3} \int \delta(\varepsilon - \varepsilon_\nu(k)) Y_{l,m}(\theta, \phi) \{\mathrm{BTE}\} \mathrm{d}^3 k \,, \quad (39.37)$$

where arguments are suppressed as far as possible to improve legibility. The first term on the left-hand side (LHS) of Eq. (39.6) is given by

$$\frac{2}{(2\pi)^3} \int \delta(\varepsilon - \varepsilon_\nu(k)) Y_{l,m} \frac{\partial f^\nu}{\partial t} \mathrm{d}^3 k = \frac{\partial Z_\nu f^\nu_{l,m}}{\partial t} \,. \quad (39.38)$$

Integration by parts yields for the second term of the BTE

$$\frac{2}{(2\pi)^3} \int \delta(\varepsilon - \varepsilon_\nu(k)) Y_{l,m} \frac{e}{\hbar} \boldsymbol{E} \cdot \nabla_{\boldsymbol{k}} f^\nu \mathrm{d}^3 k$$
$$= e\boldsymbol{E} \cdot \oint \left[\frac{\partial \boldsymbol{v}_\nu Z_\nu f^\nu}{\partial \varepsilon} Y_{l,m} \right.$$
$$\left. - \frac{Z_\nu}{\hbar k_\nu} \left(\boldsymbol{e}_\theta \frac{\partial Y_{l,m}}{\partial \theta} + \frac{\boldsymbol{e}_\phi}{\sin\theta} \frac{\partial Y_{l,m}}{\partial \phi} \right) f^\nu \right] \mathrm{d}\Omega$$
$$= e \frac{\partial \boldsymbol{E} \cdot \boldsymbol{J}^\nu_{l,m}}{\partial \varepsilon} - \Gamma^\nu_{l,m} \quad (39.39)$$

with

$$\boldsymbol{J}^\nu_{l,m}(\varepsilon) = v_\nu(\varepsilon) Z_\nu(\varepsilon) \sum_{l',m'} \boldsymbol{a}^{l,m}_{l',m'} f^\nu_{l',m'}(\varepsilon) \quad (39.40)$$

and

$$\Gamma^{\nu}_{l,m}(\varepsilon) = \frac{e\boldsymbol{E}Z_{\nu}(\varepsilon)}{\hbar k_{\nu}(\varepsilon)} \cdot \sum_{l',m'} \boldsymbol{b}^{l,m}_{l',m'} f^{\nu}_{l',m'}(\varepsilon) \; . \tag{39.41}$$

The third term can be calculated along similar lines:

$$\frac{2}{(2\pi)^3} \int \delta\left(\varepsilon - \varepsilon_{\nu}(k)\right) Y_{l,m} \boldsymbol{v}_{\nu} \cdot \nabla_{\boldsymbol{r}} f^{\nu} \mathrm{d}^3 k = \nabla_{\boldsymbol{r}} \cdot \boldsymbol{J}^{\nu}_{l,m}. \tag{39.42}$$

For the scattering integral it is assumed in this chapter that the transition rate depends only on the scattering angle and not on all angles of the initial and final states. In addition, the energy transfer should be constant. This is the case, for example, for the scattering processes presented in Brunetti et al. [46] for silicon, which are widely used. The general case is discussed in Hong et al. [30]. With these assumptions the transition rate can be simplified:

$$\begin{aligned} W^{\nu,\nu'}(\boldsymbol{r},\boldsymbol{k},\boldsymbol{k}') = \frac{1}{\Omega_{\mathrm{sys}}} c^{\nu,\nu'}_{\eta}\left(\boldsymbol{r}, \varepsilon_{\nu}(\boldsymbol{k}), \cos\angle(\boldsymbol{k},\boldsymbol{k}')\right) \\ \times \delta(\varepsilon_{\nu}(\boldsymbol{k}) - \varepsilon_{\nu'}(\boldsymbol{k}') - \hbar\omega_{\eta}) \end{aligned} \tag{39.43}$$

where $\hbar\omega_{\eta}$ is the constant energy transfer of the ηth scattering process. The cosine of the scattering angle is given by

$$\begin{aligned} \cos\angle(\boldsymbol{k},\boldsymbol{k}') &= \boldsymbol{e}_r(\theta,\phi) \cdot \boldsymbol{e}_r(\theta',\phi') \\ &= \cos\theta\cos\theta' + \sin\theta\sin\theta'\cos(\phi-\phi') \; . \end{aligned} \tag{39.44}$$

With the addition theorem, the transition rate can be expressed by products of spherical harmonics [47]:

$$\begin{aligned} &c^{\nu,\nu'}_{\eta}\left(\boldsymbol{r}, \varepsilon_{\nu}(\boldsymbol{k}), \cos\angle(\boldsymbol{k},\boldsymbol{k}')\right) \\ &= \sum_{l=0}^{\infty} c^{\nu,\nu'}_{\eta,l}\left(\boldsymbol{r}, \varepsilon_{\nu}(\boldsymbol{k})\right) \sum_{m=-l}^{m=l} Y_{l,m}(\theta,\phi) Y_{l,m}(\theta',\phi') \end{aligned} \tag{39.45}$$

and

$$c^{\nu,\nu'}_{\eta,l}(\boldsymbol{r},\varepsilon) = 2\pi \int_{-1}^{1} P_l(x) c^{\nu,\nu'}_{\eta}(\boldsymbol{r},\varepsilon,x)\,\mathrm{d}x \tag{39.46}$$

is given by a projection onto Legendre polynomials.

The scattering integral is split into in- and out-scattering:

$$\mathcal{W}^{\nu}(\boldsymbol{r},\boldsymbol{k},t) = \mathcal{W}^{\mathrm{in},\nu}(\boldsymbol{r},\boldsymbol{k},t) - \mathcal{W}^{\mathrm{out},\nu}(\boldsymbol{r},\boldsymbol{k},t) \; . \tag{39.47}$$

Projection of in-scattering yields

$$\begin{aligned} \mathcal{W}^{\mathrm{in},\nu}_{l,m}(\boldsymbol{r},\varepsilon,t) = \sum_{\eta,\nu'} \Big[Z_{\nu}(\varepsilon) c^{\nu,\nu'}_{\eta,l}(\boldsymbol{r},\varepsilon) \\ \times Z_{\nu'}(\varepsilon - \hbar\omega_{\eta}) f^{\nu'}_{l,m}\left(\boldsymbol{r}, \varepsilon - \hbar\omega_{\eta}, t\right) \Big] \; , \end{aligned} \tag{39.48}$$

and for out-scattering the result is

$$\begin{aligned} \mathcal{W}^{\mathrm{out},\nu}_{l,m}(\boldsymbol{r},\varepsilon,t) &= \sum_{\eta,\nu'} \Big[Z_{\nu'}(\varepsilon + \hbar\omega_{\eta}) \\ &\quad \times c^{\nu',\nu}_{\eta,0}\left(\boldsymbol{r}, \varepsilon + \hbar\omega_{\eta}\right) Z_{\nu}(\varepsilon) \Big] f^{\nu}_{l,m}(\boldsymbol{r},\varepsilon,t) \\ &= S_{\nu}(\boldsymbol{r},\varepsilon) Z_{\nu}(\varepsilon) f^{\nu}_{l,m}(\boldsymbol{r},\varepsilon,t) \; , \end{aligned} \tag{39.49}$$

where the Pauli principle has been neglected for the sake of brevity. Inclusion of the Pauli principle is described in Hong et al. [30]. Scattering into and out of traps (e.g., Shockley–Read–Hall recombination) can be easily included in this formalism and is described in Jungemann, Piazza et al., and Rupp et al. [25, 48, 49].

The combination of all terms yields balance equations for the energy distribution function $Z_{\nu}(\varepsilon) f^{\nu}_{l,m}(\boldsymbol{r},\varepsilon,t)$:

$$\begin{aligned} \frac{\partial Z_{\nu} f^{\nu}_{l,m}}{\partial t} - e\boldsymbol{E} \cdot \frac{\partial \boldsymbol{J}^{\nu}_{l,m}}{\partial \varepsilon} + \Gamma^{\nu}_{l,m} \\ + \nabla_{\boldsymbol{r}} \cdot \boldsymbol{J}^{\nu}_{l,m} + S_{\nu} Z_{\nu} f^{\nu}_{l,m} = \mathcal{W}^{\mathrm{in},\nu}_{l,m} \; , \end{aligned} \tag{39.50}$$

where the different spherical harmonics couple owing to the sums in Eqs. (39.40) and (39.41) of the free-streaming operator, whereas the scattering integral does not lead to coupling because the Pauli principle was neglected.

The balance equations contain derivatives with respect to energy and position, which makes it difficult to stabilize the equations in the case of a device simulation. Different methods have been proposed (e.g., [39, 40]) and the most successful stabilization is based on a transformation onto the total energy (H-transform) [23, 24].

$$H_{\nu}(\boldsymbol{k},\boldsymbol{r},t) = \varepsilon_{\nu}(\boldsymbol{k}) - e\Psi(\boldsymbol{r},t) \; . \tag{39.51}$$

It changes the gradient with respect to position in the real space:

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{J}(\boldsymbol{r},\varepsilon) = \nabla_{\boldsymbol{r}} \cdot \boldsymbol{J}(\boldsymbol{r},H) - e\nabla_{\boldsymbol{r}}\Psi \cdot \frac{\partial \boldsymbol{J}(\boldsymbol{r},H)}{\partial H} \tag{39.52}$$

and the time derivative [31]

$$\frac{\partial f(\varepsilon,t)}{\partial t} = \frac{\partial f(H,t)}{\partial t} - e\frac{\partial \Psi}{\partial t}\frac{\partial f(H,t)}{\partial H} \; . \tag{39.53}$$

This makes it possible to remove the derivative with respect to energy in the balance equations:

$$\begin{aligned} \frac{\partial Z_{\nu} f^{\nu}_{l,m}}{\partial t} - e\frac{\partial \Psi}{\partial t}\frac{\partial Z_{\nu} f^{\nu}_{l,m}}{\partial H} + \Gamma^{\nu}_{l,m} \\ + \nabla_{\boldsymbol{r}} \cdot \boldsymbol{J}^{\nu}_{l,m} + S_{\nu} Z_{\nu} f^{\nu}_{l,m} = \mathcal{W}^{\mathrm{in},\nu}_{l,m} \end{aligned} \tag{39.54}$$

at the cost of a new time derivative. All quantities now depend via $f^{\nu}_{l,m}(\boldsymbol{r}, H, t)$ on the total energy H, which is the new independent variable. In the case of a stationary system, the first two terms vanish and the free-streaming operator contains only a derivative with respect to position. The free-streaming term can be transformed with

$$\frac{\mathrm{d}v_\nu Z_\nu}{\mathrm{d}\varepsilon} = \frac{2Z_\nu}{\hbar k_\nu} \tag{39.55}$$

and (39.28) into

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{J}^{\nu}_{l,m} + \Gamma^{\nu}_{l,m} = v_\nu Z_\nu \sum_{l',m'} \boldsymbol{a}^{l',m'}_{l,m} \cdot \nabla_{\boldsymbol{r}} f^{\nu}_{l',m'} \tag{39.56}$$
$$- \frac{e\boldsymbol{E}Z_\nu}{\hbar k_\nu} \cdot \sum_{l',m'} \boldsymbol{b}^{l',m'}_{l,m} f^{\nu}_{l',m'} \; .$$

The formula on the LHS is used in the case of an even l and the RHS in the case of an odd l [45]. This maximizes the dissipation of entropy [30], which means that the system of balance equations derived from the BTE is well posed [50].

The boundary conditions on the contacts describe the flux flowing into the device through the surface area of the contacts. Projection of (39.10) yields for the flux density at the contact

$$\boldsymbol{n} \cdot \boldsymbol{J}^{\nu}_{l,m} = v_\nu Z_\nu \sum_{l',m'} D^{l,m}_{l',m'}(\boldsymbol{n}) f^{\nu}_{l',m'} \tag{39.57}$$
$$+ v_\nu Z_\nu E^{l,m}_{0,0}(\boldsymbol{n}) f^{\mathrm{eq},\nu}_{0,0} \; .$$

As the unit vector $\boldsymbol{n}$, which is perpendicular to the surface, depends on the position on the surface, the coefficients $D^{l,m}_{l',m'}$ and $E^{l,m}_{0,0}$ have to be evaluated for the local $\boldsymbol{n}$.

The balance equations are mapped onto a grid in real and H space by the finite volume method (box integration) [51] (see also Sect. 39.4). This is described in detail in Hong et al. [30] and not repeated here. The SHE is terminated at a maximum order to obtain a system of equations with a finite size. The truncation error depends on the problem that is simulated and can be easily estimated by running simulations with different maximum expansion orders. In the case of quasi-ballistic transport, a rather high number of spherical harmonics is required, whereas strong scattering leads to a low value. As scattering depends on energy and the electric field on position, the necessary expansion order varies over phase space. In Rupp et al. [25] an adaptive scheme is presented, which minimizes the number of variables in the system by a truncation order that depends on the position in phase space.

The solution of the BTE must always be non-negative ($f^{\nu}(\boldsymbol{r}, \boldsymbol{k}, t) \geq 0$) and certain properties of the balance equations should reflect this. Owing to projection onto spherical harmonics, of which only the lowest order is non-negative, only the zeroth-order component of the distribution function $f^{\nu}_{0,0}(\boldsymbol{r}, H, t)$ has this property. The solution of the balance equations should also have this property. This is shown in Hong and Jungemann and Hong et al. [30,52] for the stationary case, an expansion up to the first order in spherical harmonics, and velocity randomizing scattering ($c^{\nu,\nu'}_{\eta,l}(\boldsymbol{r}, \varepsilon) = 0$ for $l > 0$). It turns out that this property, which is only shown for a first-order expansion, also improves the stability in the case of a higher-order expansion as shown by numerical experiments. On the other hand, certain important inelastic scattering processes (e.g., polar optical phonon scattering) are not velocity randomizing, and in this case it is no longer guaranteed that the zeroth-order SHE component is non-negative resulting in a less robust system of equations.

In contrast to the MC method, the SHE approach can be solved directly for the stationary case. The usual TCAD approaches (e.g., Gummel loop and Newton–Raphson iteration (see also Sect. 39.4) can be used to obtain a self-consistent solution of the BTE and PE. As the Jacobian matrix is available, extension to small-signal and noise analysis is straightforward [27,28,30], if the time derivative in (39.53) is treated as described in Ruić and Jungemann [31].

39.2.3 Results

Simulation results are presented for a homogeneous GaAs bulk system (0D real space), a silicon N^+NN^+ structure (1D real space), and a SiGe HBT (2D real space).

GaAs Bulk

Bulk simulations are used to investigate transport and noise properties of materials and to generate parameters for moments-based models (see also Sect. 39.3.1). In this case, a system homogeneous in the real space is assumed, with a constant electron density and electric field. The H-transform is not necessary in this case and a staggered grid in energy is used [40].

As an example, GaAs is investigated and the model is based on a band structure with three valley types (Γ, L, and X) with nonparabolic analytical dispersion relations and scattering by phonons, including polar optical ones, whereas impurity scattering is neglected, assuming a low donor concentration [53]. In Fig. 39.1 the total energy distribution function summed over all valleys

$$Zf(\varepsilon) = \sum_{\nu} Z_\nu(\varepsilon) f^{\nu}_{0,0}(\varepsilon) \tag{39.58}$$

is shown. The two humps in the energy distribution functions are due to the L and X valleys, which begin at higher energies

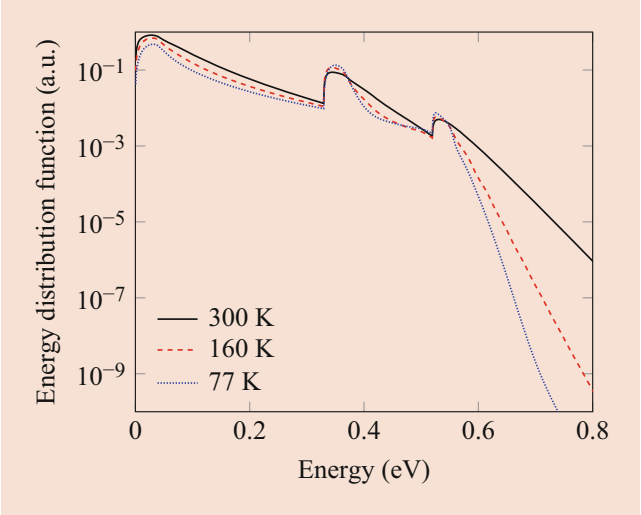

Fig. 39.1 Energy distribution function for GaAs at 77 K, 160 K, and 300 K and an electric field of 3 kV/cm

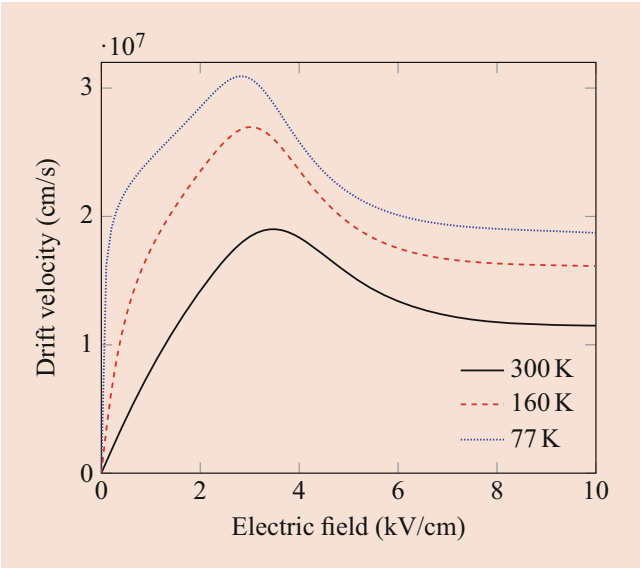

Fig. 39.2 Absolute value of the drift velocity in GaAs at different temperatures

than the Γ valley (0.33 eV and 0.52 eV respectively). The results show that with SHE, low values of the distribution function can be easily simulated, in contrast to MC.

In Fig. 39.2 the drift velocity is shown for GaAs in the limit of a low donor concentration. The drift velocity shows the usual stationary velocity overshoot due to transfer of electrons from the Γ valley into the L valleys (see Fig. 39.1), which have a higher mass [54].

A big advantage of the SHE method is that it can be easily extended to the case of small-signal analysis. With SHE the small-signal BTE can even be solved for plane waves as required for the analysis of plasma oscillations [55]. The small-signal distribution function is assumed to be harmonic in its dependence on time and position

$$\delta f^{\nu}(\boldsymbol{r},\boldsymbol{k},t) = \mathrm{Re}\left\{\underline{f}^{\nu}(\underline{\boldsymbol{q}},\boldsymbol{k},\underline{\omega})\exp\left(\mathrm{j}\underline{\omega}t - \mathrm{j}\underline{\boldsymbol{q}}\cdot\boldsymbol{r}\right)\right\} \quad (39.59)$$

$\underline{\omega}$ is the complex angular frequency, $\underline{\boldsymbol{q}}$ the complex wave vector, and $\underline{f}$ the phasor of the distribution function. Similar expressions are used for all other time- and position-dependent quantities. Under bulk conditions the small-signal BTE is given by

$$\left\{\mathrm{j}\underline{\omega} - \frac{e}{\hbar}\boldsymbol{E}_{\mathrm{DC}}\cdot\nabla_{\boldsymbol{k}} - \mathrm{j}\underline{\boldsymbol{q}}\cdot\boldsymbol{v}\right\}\underline{f} - \mathcal{W}\{\underline{f}\} \quad (39.60)$$
$$= \frac{e}{\hbar}\underline{\boldsymbol{E}}\cdot\nabla_{\boldsymbol{k}} f_{\mathrm{DC}}\,,$$

where $\boldsymbol{E}_{\mathrm{DC}}$ is the stationary electric field, f_{DC} the solution of the stationary BTE, and $\underline{\boldsymbol{E}}$ the phasor of the small-signal electric field. As the scattering integral is linear, the distribution function can be replaced by its phasor without any additional changes. The small-signal BTE can be projected onto spherical harmonics in the same way as the BTE. For the sake of simplicity it is assumed that the electric field and the wave vector are parallel:

$$\boldsymbol{E}_{\mathrm{DC}} = E_{\mathrm{DC}}\boldsymbol{n}\,,\quad \underline{\boldsymbol{E}} = \underline{E}\boldsymbol{n}\,,\quad \underline{\boldsymbol{q}} = \underline{q}\boldsymbol{n}\,. \quad (39.61)$$

In this case, the small-signal current is parallel to the electric field and a scalar small-signal mobility can be defined by

$$\underline{j} = en_{\mathrm{DC}}\underline{\mu}(\underline{\omega},\underline{q})\underline{E}\,. \quad (39.62)$$

This mobility definition corresponds at zero frequency and wave number to $\underline{\mu}(0,0) = -\mathrm{d}v/\mathrm{d}E$. In Fig. 39.3 the small-signal mobility is shown as a function of the real frequency and zero wave number at three electric fields and room temperature. For zero electric field the mobility can be described by a simple model with a single pole:

$$\underline{\mu}(\omega,0) \approx \frac{\underline{\mu}(0,0)}{1+\mathrm{j}\omega\tau_v}\,, \quad (39.63)$$

where τ_v is the macroscopic relaxation time of velocity. At higher electric fields transport is much more complex owing to the involvement of the different valleys and can no longer be described by a single pole. For an electric field of 3.47 kV/cm, the velocity peaks at room temperature (Fig. 39.2) and the small-signal mobility at zero frequency vanishes. At 5 kV/cm the derivative of the velocity-field relation is negative and the mobility is negative as well at zero frequency. This negative real part of the mobility could lead to instabilities (e.g., Gunn oscillations [56]). The

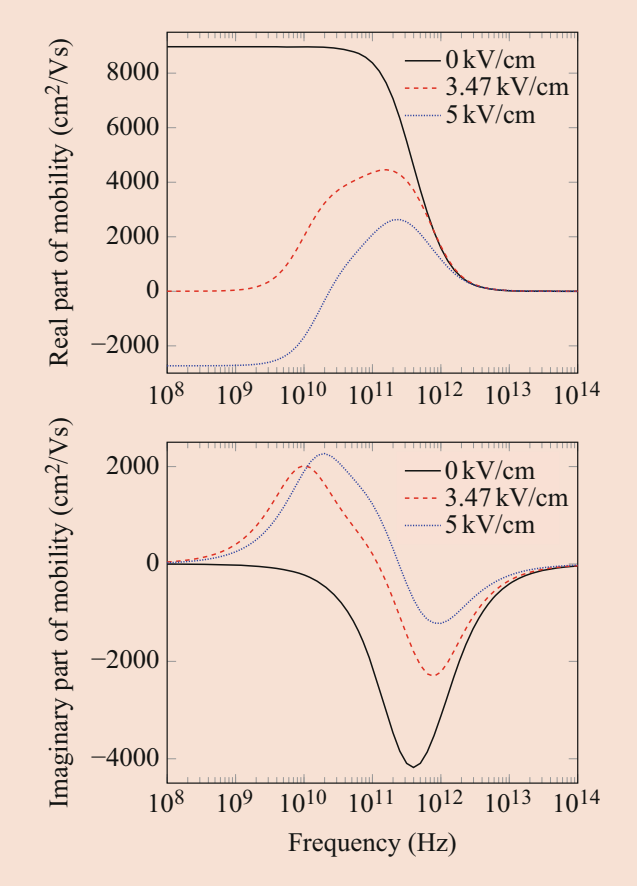

Fig. 39.3 Small-signal mobility for zero wave number ($q = 0$) and three electric fields at 300 K

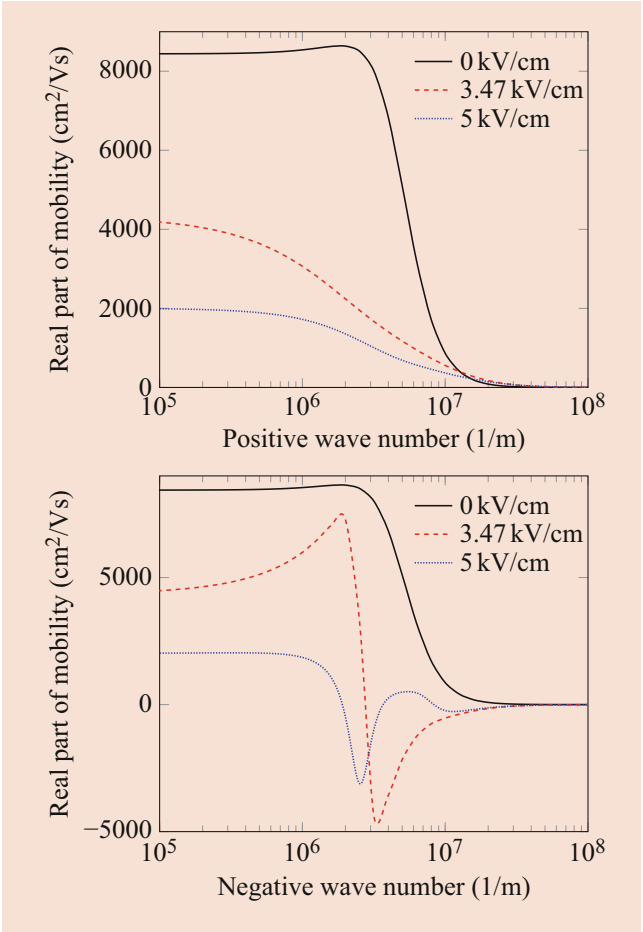

Fig. 39.4 Small-signal mobility for a frequency of 94 GHz and three electric fields at 300 K (upper graph, upstream; lower graph, downstream)

results clearly show that it is possible to cover the full range of technically relevant frequencies with SHE without any problems. Even zero frequency is feasible and very slow processes (e.g., deep traps) can be investigated [48,49].

In the case of a nonzero wave number, the mobility depends on the direction of the plasma wave. As electrons move into the negative direction of the electric field, a wave with a negative wave number travels into the same direction as the electrons, which is called "downstream." In the case of a positive wave number, it is "upstream." In Fig. 39.4 both cases are shown for a real frequency of 94 GHz and the real part of the mobility as a function of the wave number is different for positive and negative values. Only in the case of zero electric field, for which there is no electron flow, is the same result obtained. In the downstream case, negative real parts occur for nonzero electric field. This difference in the up- and downstream cases might induce instabilities in gated 2D plasmas with asymmetric boundary conditions [57]. In this case, both the frequency and the wave number are complex, which is extremely difficult to handle by the MC method and has not yet been attempted. This possibility of investigating the small-signal behavior in the complex frequency domain makes SHE the ideal tool for studying instabilities [58].

N^+NN^+ Structure

Transport in a silicon N^+NN^+ structure is investigated, where the six lowest minima of the conduction band (valleys) are considered by an analytical nonparabolic band structure and the phonon scattering processes described in Brunetti et al. [46] are included in the simulations. Scattering by ionized impurities is accounted for by the model presented in Brookes [59], where the scattering rate is modified in such a way that the measured mobility is reproduced at high donor concentrations [12].

In Fig. 39.5 the donor profile of the N^+NN^+ structure is shown, together with the electron density and potential at a bias of 0.5 V and room temperature. The donor concentration in the region between 200 and 300 nm is negligible and the contact regions are 200 nm long to ensure that the boundary conditions of the BTE have no impact

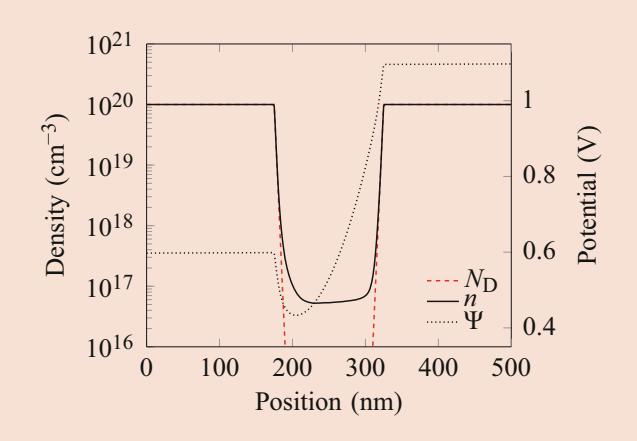

Fig. 39.5 Donor profile, electron density, and potential for the N^+NN^+ structure at a bias of 0.5 V

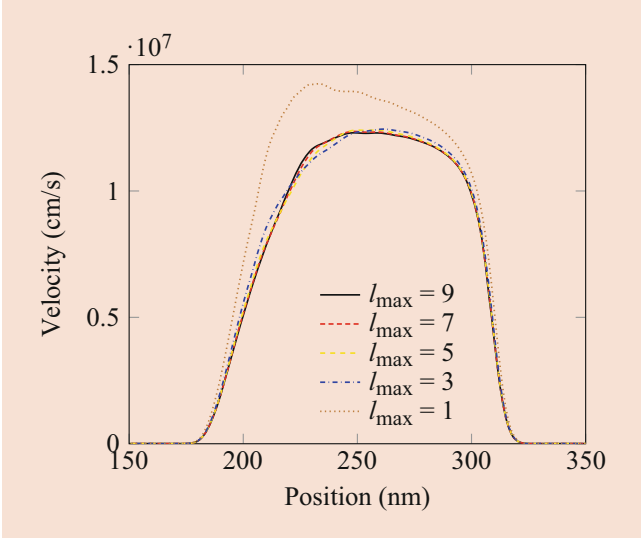

Fig. 39.6 Electron velocity for the N^+NN^+ structure at a bias of 0.5 V for different maximum expansion orders

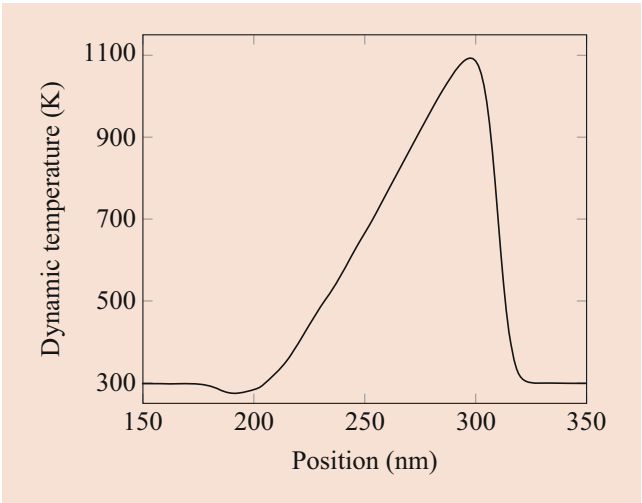

Fig. 39.7 Dynamic temperature for the N^+NN^+ structure at a bias of 0.5 V and a temperature of 300 K

on the results. An equidistant grid of 1.25 nm is used in the one-dimensional real space, and the energy grid has a fixed spacing of 5.17 meV and spans 1.24 eV. As transport in the ⟨100⟩ direction is simulated, two different sets of valleys (four degenerate valleys with the transverse mass in transport direction and two with the longitudinal ones) are considered. Owing to rotational symmetry with respect to the transport direction, only spherical harmonics with $m = 0$ are considered. For a SHE up to seventh order this results in 770,321 variables (401 grid nodes times 240 points in energy times 2 valley types times $(7+1)/2$ spherical harmonics plus 401 points for potential) and the CPU time is about 4000 s on a single core of a current processor. The simulation was started with a potential obtained by a DD model, and five Newton steps without any damping were sufficient to reduce the change in potential to 10^{-13} V. This small value shows that the combined BTE and PE are well-conditioned in this case.

The number of variables is proportional to the maximum expansion order and it should be as small as possible to save CPU time. In Fig. 39.6 the drift velocity is shown for different maximum orders of the SHE. The SHE clearly converges in this case and is by no means inferior to the MC method with respect to solving the BTE. Although an expansion up to first order introduces a large error, a third order seems to be sufficiently accurate compared with a ninth-order SHE. The error in current is for the third-order SHE 5.94%. To reduce this error below 1%, a seventh-order expansion is necessary (0.46%). The CPU efficiency of the SHE approach is much better than that of the MC method, even if the error due to the discrete energy grid is taken into account [48]. This is especially the case for internal variables (density, drift velocity, etc.). The high doping concentrations near the contacts do not lead to problems, in contrast to the MC method and no artificial heating of the particle gas is observed in Fig. 39.7, where the dynamic temperature is shown, which equals the lattice temperature near the contacts. The SHE simulations resolve without any problems in the electron gas cooling, when the electrons diffuse against the electric field before they pass the potential barrier at position 205 nm (see Fig. 39.5).

Transport models derived from the BTE by projection on moments of the distribution function require transport parameters. As an example the most basic transport parameters, the local mobility and diffusion constant, are discussed. With the microscopic relaxation time $\tau_\nu(\boldsymbol{k})$, which is the solution of the following integral equation [12, 60, 61]

$$\boldsymbol{v}_\nu(\boldsymbol{k}) = \frac{\Omega_{\mathrm{sys}}}{(2\pi)^3} \sum_\eta \sum_{\nu'} \int W_\eta^{\nu,\nu'}(\boldsymbol{r}, \boldsymbol{k}, \boldsymbol{k}') \times \left[\tau_\nu(\boldsymbol{k})\boldsymbol{v}_\nu(\boldsymbol{k}) - \tau_{\nu'}(\boldsymbol{k}')\boldsymbol{v}_{\nu'}(\boldsymbol{k}')\right] \mathrm{d}^3k' \,, \quad (39.64)$$

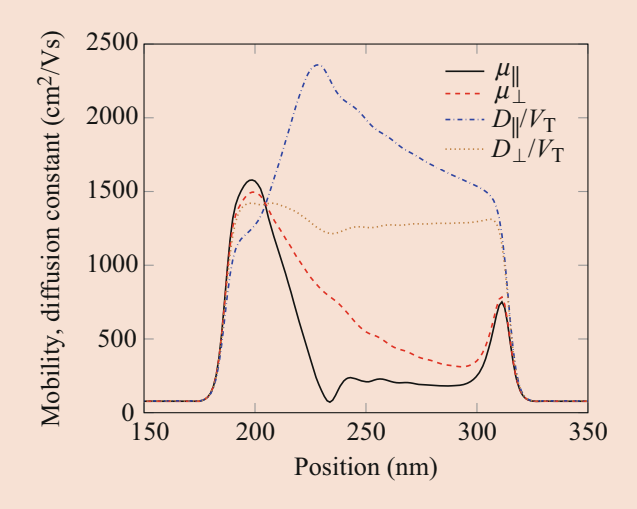

Fig. 39.8 Longitudinal and transverse mobilities and diffusion constants for the N^+NN^+ structure at a bias of 0.5 V and a temperature of 300 K. The diffusion constants are divided by the thermal voltage $V_T = 25.85\,\text{mV}$

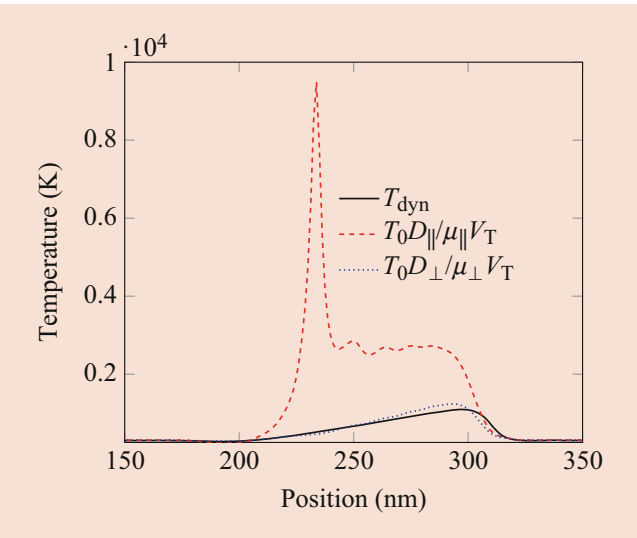

Fig. 39.9 Temperatures derived from the Einstein relation and the dynamic temperature for the N^+NN^+ structure at a bias of 0.5 V and a temperature of 300 K

the local mobility tensor can be exactly calculated:

$$\hat{\mu}(\boldsymbol{r},t) = \frac{1}{n(\boldsymbol{r},t)}\frac{2}{(2\pi)^3}\frac{e}{\hbar} \times \sum_\nu \int \nabla_{\boldsymbol{k}}\left[\tau_\nu(\boldsymbol{k})\boldsymbol{v}_\nu^{\mathrm{T}}(\boldsymbol{k})\right] f^\nu(\boldsymbol{r},\boldsymbol{k},t)\mathrm{d}^3k. \quad (39.65)$$

The diffusion tensor is obtained by

$$\hat{D}(\boldsymbol{r},t) = \frac{1}{n(\boldsymbol{r},t)}\frac{2}{(2\pi)^3} \times \sum_\nu \int \tau_\nu(\boldsymbol{k})\boldsymbol{v}_\nu(\boldsymbol{k})\boldsymbol{v}_\nu^{\mathrm{T}}(\boldsymbol{k}) f^\nu(\boldsymbol{r},\boldsymbol{k},t)\mathrm{d}^3k\,. \quad (39.66)$$

Both tensors are symmetric and in this one-dimensional case they have only two distinct elements, the longitudinal component for transport parallel to the transport direction and the transverse component for the perpendicular directions. They are shown in Fig. 39.8. In the regions with a very high electron density transport is close to equilibrium, the transport parameters are isotropic, and the Einstein relation between the diffusion constant and mobility holds. When the doping concentration drops, the mobilities and diffusion constants increase because of the reduced ionized impurity scattering. In the adjacent region with low electron density, the particle gas is in a strong non-equilibrium state and transport becomes anisotropic. Furthermore, the Einstein relation fails for longitudinal transport and the temperature defined by $D_\parallel/\mu_\parallel$ is very different from the dynamic temperature (Fig. 39.9), whereas for the transverse direction the Einstein relation roughly holds. In addition, the distribution function deviates very much from the simple form assumed to calculate the closure relation of the moments-based equations (e.g., drifted and heated Maxwellian), as shown in Fig. 39.10. Although near the left contact at 50 nm the energy distribution function is given by a Boltzmann distribution, it is very different at the position where the longitudinal temperature peaks (234 nm). At the peak of the dynamic temperature (297 nm), the distribution is very broad. Nevertheless, at high energies (>0.4 eV) the distribution function approaches the slope of the equilibrium distribution function and the distribution cannot be characterized by a single temperature. In the right contact region at 325 nm, the usual combination of a distribution of many cold electrons and a few hot ones is found.

The distribution of the electrons over the valleys is shown in Fig. 39.11. At equilibrium, each valley contains a fraction of 1/6 of all particles. When the electrons get hot, the energy gain in the valleys with the transverse mass parallel to the electric field is larger owing to the lower mass in this direction and the electrons scatter into the other valley type reducing the occupancy of these valleys. The mean free path of the electrons

$$\lambda(\boldsymbol{r},t) = \frac{1}{n(\boldsymbol{r},t)}\frac{2}{(2\pi)^3} \times \sum_\nu \int \tau_\nu(\boldsymbol{k})\,|\boldsymbol{v}_\nu(\boldsymbol{k})|\, f^\nu(\boldsymbol{r},\boldsymbol{k},t)\mathrm{d}^3k \quad (39.67)$$

must be small compared with the device dimensions for moments-based models to work. Owing to the strong scatter-

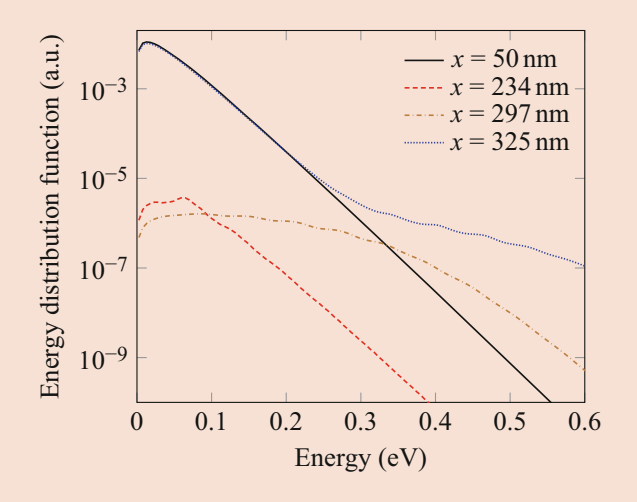

Fig. 39.10 Energy distribution function $Z_\nu(\varepsilon) f^\nu_{0,0}(\boldsymbol{r}, \varepsilon)$ for the valleys with longitudinal mass parallel to the transport direction for the N^+NN^+ structure at a bias of 0.5 V and a temperature of 300 K

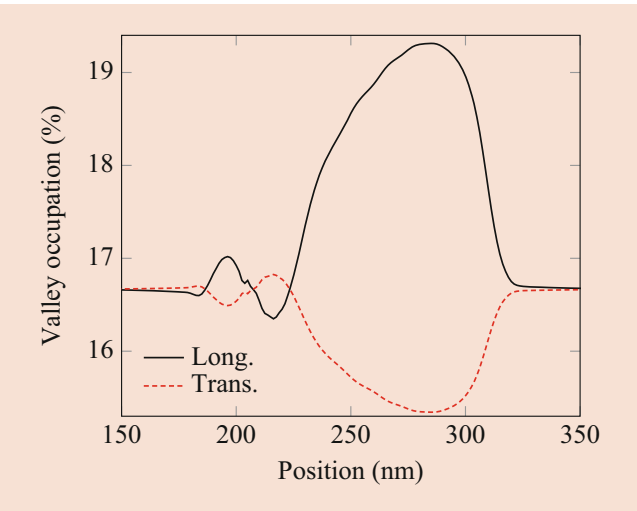

Fig. 39.11 Fraction of electrons in the valleys with longitudinal mass parallel to the transport direction and for the transverse direction for the N^+NN^+ structure at a bias of 0.5 V and a temperature of 300 K

ing by ionized impurities, this is the case near the contacts, but in the region with the low donor concentration, the mean free path becomes very large and of the same order as the length of the region. These results clearly show why it is difficult to model transport in nanoscale devices by moments-based models (Fig. 39.12).

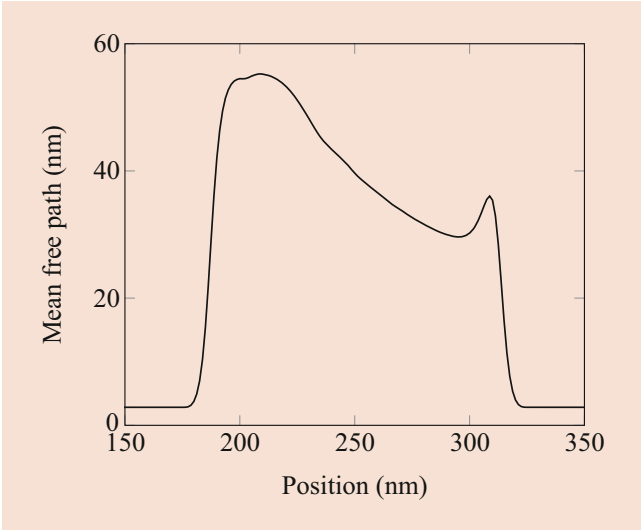

Fig. 39.12 Mean free path for the N^+NN^+ structure at a bias of 0.5 V and a temperature of 300 K

SiGe HBT

SiGe HBTs are a cost-efficient alternative to III–V transistors, which can be fabricated by silicon technologies and even integrated into CMOS circuits [62]. The fastest SiGe HBTs have cutoff and maximum oscillation frequencies above 500 GHz [63]. In Fig. 39.13 the doping and Ge profiles of an ultimate SiGe HBT are shown [33]. A corresponding symmetric 2D CBEBC structure with an emitter window of 50 nm in width is simulated at room temperature and self-heating effects are neglected [64]. The metallurgical base is about 7 nm thick and the peak acceptor concentration is $2.4 \cdot 10^{20}/\mathrm{cm}^3$. The Ge profile increases linearly from the emitter to the base to avoid an abrupt barrier in the out-of-plane valleys of the conduction band [30]. The peak Ge content is 30%. The 2D device structure is discretized by a non-uniform grid with 149 grid nodes in the vertical direction and 20 in the lateral direction. Owing to the assumption of translational invariance in the third dimension, only spherical harmonics with a non-negative m have to be considered in the fifth-order SHE. Three different sets of valleys are included in the simulation for the conduction band, whereas holes are simulated by a DD model. Scattering by phonons, ionized impurities, alloy fluctuations, and impact ionization are included in the simulations [30]. The BTE for electrons, the DD model for holes, and the PE are solved self-consistently by the Newton–Raphson method.

The Gummel plot of the transistor is shown in Fig. 39.14. Currents can be calculated over more than 12 orders of magnitude by SHE. The current gain is above 100 for base/emitter voltages below 0.95 V, at which the cutoff frequency peaks ($V_{\mathrm{CE}} = 1.0\,\mathrm{V}$). With SHE the ideality factor of the collector current can be calculated at a fixed collector/emitter bias by

$$n_{I_\mathrm{C}} = \frac{I_\mathrm{C}}{Y_{\mathrm{CB}}(0) V_\mathrm{T}} \,. \tag{39.68}$$

$Y_{\mathrm{CB}}(0) = \partial I_\mathrm{C}/\partial V_{\mathrm{BE}}$ is the collector/base admittance at zero frequency. At low base/emitter bias, the ideality factor is not

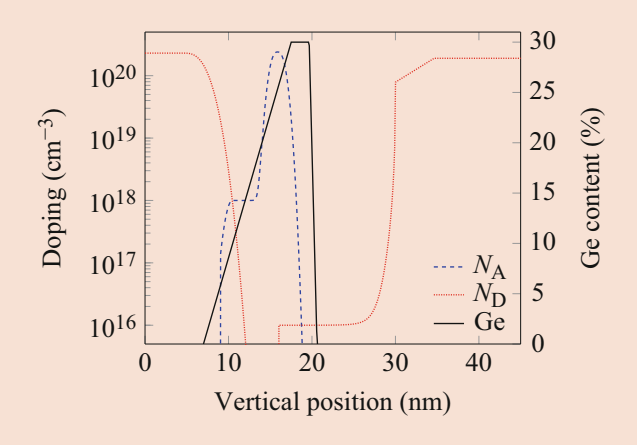

Fig. 39.13 Donor, acceptor, and Ge profiles along the vertical symmetry line of the SiGe HBT

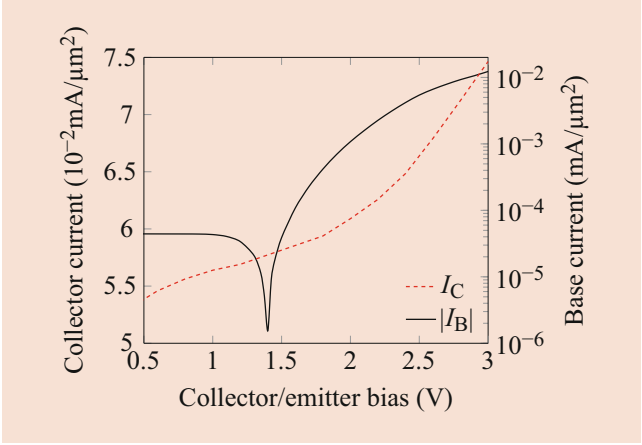

Fig. 39.15 Collector and base currents of the SiGe HBT at a base/emitter bias of 0.7 V

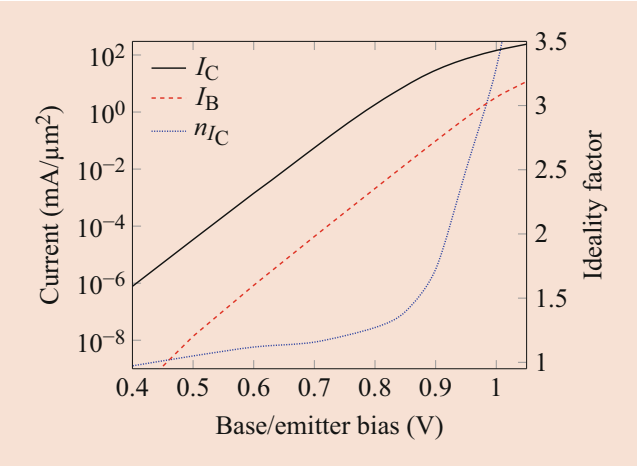

Fig. 39.14 Collector and base currents of the SiGe HBT at a collector/emitter bias of 1.0 V and the ideality factor

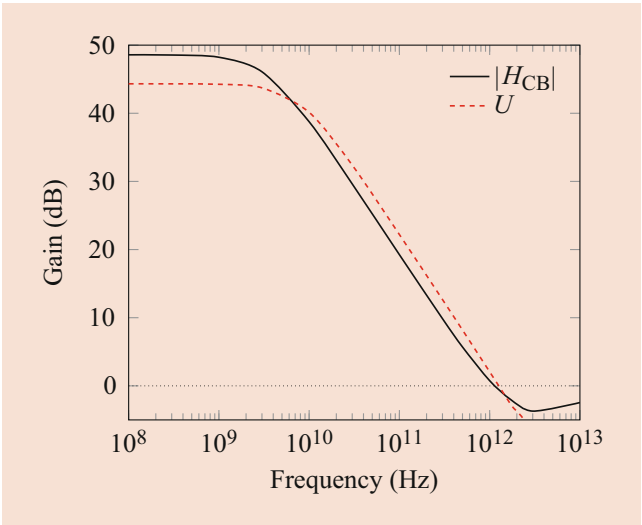

Fig. 39.16 Small-signal current gain (H_{CB}) and unilateral gain (U) at $V_{CE} = 1.0\,V$, $V_{BE} = 0.88\,V$

constant owing to the position-dependent band structure [65]. This quantity is very difficult to calculate using the MC method. Stochastic heating will lead to a reduced slope of the collector current and the stochastic error will make it very difficult to calculate the derivative at the required low current levels.

The collector and base currents at a base/emitter bias of 0.7 V are shown in Fig. 39.15 as a function of the collector/emitter voltage. The base current is positive up to $V_{CE} = 1.4\,V$ and then negative owing to the generation of holes by impact ionization. The collector/emitter breakdown voltage is defined as the bias for which the base current vanishes. In this case the breakdown voltage is $BV_{CE0} = 1.4\,V$, which is rather low and due to the thin low-doped collector. A thicker low-doped collector would increase the breakdown voltage at the cost of a lower cutoff frequency. The corresponding increase in the collector current due to feedback from the base current can lead to instability and is a major concern for the design of the safe operating area. The early voltage calculated at $V_{CE} = 1.0\,V$, $V_{BE} = 0.7\,V$ is $V_A = 16.7\,V$.

The cutoff frequency is defined as the frequency for which the magnitude of the small-signal current gain at a short-circuited output becomes one. In the common-emitter configuration, the small-signal gain is given by the hybrid parameter H_{CB}, which is shown in Fig. 39.16. At sufficiently high frequencies the gain drops with 20 dB/dec and the cutoff frequency can be estimated by extrapolation from its value at 300 GHz. Similarly, the maximum oscillation frequency can be calculated by extrapolation of the unilateral power gain. By this procedure, the cumbersome search for the frequency at which unit gain is obtained is avoided. The cutoff and maximum oscillation frequencies are shown in Fig. 39.17.

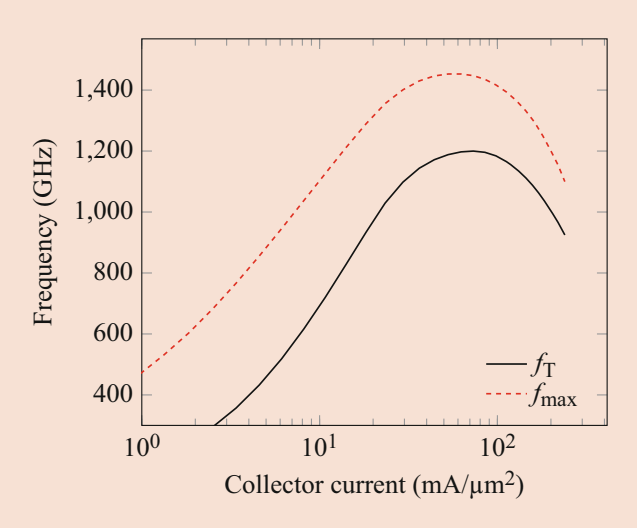

Fig. 39.17 Cutoff and maximum oscillation frequencies at $V_{CE} = 1.0\,V$

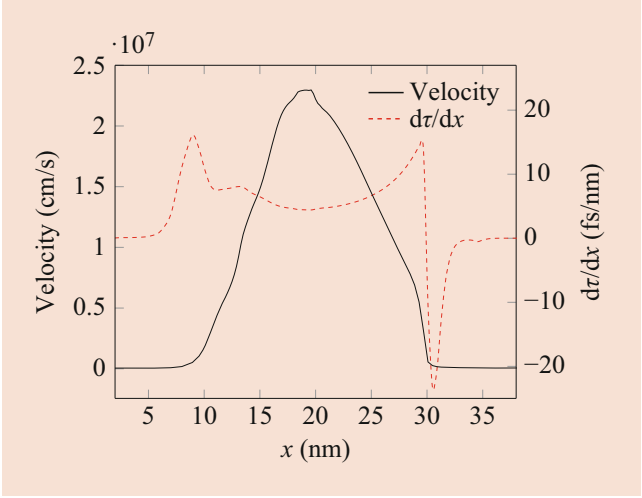

Fig. 39.18 Electron drift velocity and local contribution to the transit time ($d\tau/dx$) at $V_{CE} = 1.0\,V$, $V_{BE} = 0.885\,V$

The cutoff frequency peaks at 1.2 THz ($V_{BE} = 0.95\,V$) and the maximum frequency of oscillation at 1.45 THz.

The SHE approach allows the internal distributions to be investigated, and the drift velocity of the electrons is shown in Fig. 39.18. A strong velocity overshoot in the base of more than 100% is observed. This means that the thin base layer does not contribute much to the electron transit time of the device, which can be defined in the quasi-stationary limit and is inversely proportional to the cutoff frequency [66,67]. The local contribution to the transit time by the electrons is low in the base owing to the high velocity (Fig. 39.18) and the biggest contribution is due to the emitter/base space charge region. The large values at the junction between the low- and high-doped collector regions cancel to a certain degree. Thus, with SHE it is possible to get a detailed understanding of the processes that limit the speed of the transistor.

39.3 Multi-Scale Modeling

Multi-scale modeling is a vast field and remains very large, even if only applications for semiconductor devices are considered. Moreover, it is a scientific discipline with very fuzzy boundaries. Therefore, it is impossible to cite and describe all the methods that may fit within this framework. Consequently, this chapter relies mostly on the authors' experience and concentrates on methods that at least in the authors' opinion deserve to be named multi-scale models for semiconductor devices and which the authors helped to develop, at least to some extent. Concerning the defining terms in the field of multi-scale models, please refer to Weinan [68].

39.3.1 Sequential Multi-Scale Modeling

Sequential multi-scale modeling, as described in Weinan [68], typically starts with multi-scale analysis, which establishes a firm link between the models on the more microscopic scale, such as the BTE, and the models on the more macroscopic scale, such as the DD and HD equations. A typical example of a sequential multi-scale analysis is given below. At first, balance equations resulting from the BTE are derived, and HD and DD models are subsequently developed based on these balance equations. In this chapter, only the principles of such a derivation shall be shown. Therefore, the derivation is restricted to the case of electrons with a position-independent band structure. A generalization to the case of position-dependent band structures can be found in Jungemann and Meinerzhagen [12].

Balance Equations

Balance equations describe the behavior of macroscopic quantities $x(\boldsymbol{r}, t)$ as introduced in (39.2), which are averages over the KS, such as the electron density (39.3) or electron particle current density (39.4) [3,69–71]. These macroscopic quantities are closely related to expectation values introduced by the following equation for a scalar microscopic quantity X^ν:

$$x(\boldsymbol{r}, t) = n(\boldsymbol{r}, t)\,\langle X\rangle_{\boldsymbol{k}}\,(\boldsymbol{r}, t)\,, \tag{39.69}$$

where $n(\boldsymbol{r}, t)$ is the electron density and the subscript of the expectation value $\langle..\rangle_{\boldsymbol{k}}$ indicates that it is calculated over the KS (including the sum over the conduction bands). These expectation values are normalized because $\langle 1\rangle_{\boldsymbol{k}} = 1$. In the following the arguments ν, $\boldsymbol{r}$, $\boldsymbol{k}$, and t will be dropped as far as possible. In general, the current density $\boldsymbol{j}_X$ corresponding to the macroscopic quantity x reads

$$\boldsymbol{j}_X = n \langle X \boldsymbol{v} \rangle_{\boldsymbol{k}} \ , \tag{39.70}$$

where the microscopic quantity $\boldsymbol{v}_\nu$ is the group velocity, as introduced in (39.5). The balance equation for a given scalar microscopic quantity X^ν is obtained by integrating the BTE (39.6) multiplied by the microscopic quantity X^ν over the KS, as is done in (39.2) for X^ν alone. The first term on the left-hand side of the BTE (39.6) yields

$$\frac{2}{(2\pi)^3} \sum_\nu \int X^\nu(\boldsymbol{k}) \frac{\partial f^\nu(\boldsymbol{r}, \boldsymbol{k}, t)}{\partial t} \mathrm{d}^3 k = \frac{\partial x}{\partial t} \ . \tag{39.71}$$

The second term on the left-hand side is reformulated by the divergence theorem of Gauss based on the assumption that the distribution function is so small at the boundary of the KS that the integral along the boundary can be neglected:

$$\begin{aligned} &- \frac{2}{(2\pi)^3} \sum_\nu \int X^\nu(\boldsymbol{k}) \boldsymbol{E}(\boldsymbol{r}, t) \cdot \frac{e}{\hbar} \nabla_{\boldsymbol{k}} f^\nu(\boldsymbol{r}, \boldsymbol{k}, t) \mathrm{d}^3 k \\ &\quad = n \left\langle \boldsymbol{E} \cdot \frac{e}{\hbar} \nabla_{\boldsymbol{k}} X \right\rangle_{\boldsymbol{k}} \ . \end{aligned} \tag{39.72}$$

The last term on the left-hand side yields

$$\frac{2}{(2\pi)^3} \sum_\nu \int X^\nu(\boldsymbol{k}) \boldsymbol{v}_\nu(\boldsymbol{k}) \cdot \nabla_{\boldsymbol{r}} f^\nu(\vec{r}, \vec{k}, t) \mathrm{d}^3 k \ = \ \nabla_{\boldsymbol{r}} \cdot \boldsymbol{j}_X \ . \tag{39.73}$$

For the scattering integral on the right-hand side, the Pauli exclusion principle is neglected, resulting in

$$\begin{aligned} &\frac{2}{(2\pi)^3} \sum_\nu \int X^\nu(\boldsymbol{k}) \frac{\Omega_{\mathrm{sys}}}{(2\pi)^3} \\ &\quad \sum_\eta \sum_{\nu'} \int \left(W_\eta^{\nu,\nu'}(\boldsymbol{r}, \boldsymbol{k}, \boldsymbol{k}', t) f^{\nu'}(\boldsymbol{r}, \boldsymbol{k}', t) \right. \\ &\quad \left. - W_\eta^{\nu',\nu}(\boldsymbol{r}, \boldsymbol{k}', \boldsymbol{k}, t) f^{\nu}(\boldsymbol{r}, \boldsymbol{k}, t) \right) \mathrm{d}^3 k' \mathrm{d}^3 k \\ &= -n \left\langle \frac{\Omega_{\mathrm{sys}}}{(2\pi)^3} \sum_\eta \sum_{\nu'} \int W_\eta^{\nu',\nu}(\boldsymbol{r}, \boldsymbol{k}', \boldsymbol{k}, t) \left(X^\nu(\boldsymbol{k}) - X^{\nu'}(\boldsymbol{k}') \right) \mathrm{d}^3 k' \right\rangle_{\boldsymbol{k}} \ . \end{aligned} \tag{39.74}$$

With the abbreviation

$$S\{X\} = \frac{\Omega_{\mathrm{sys}}}{(2\pi)^3} \sum_\eta \sum_{\nu'} \int W_\eta^{\nu',\nu}(\boldsymbol{r}, \boldsymbol{k}', \boldsymbol{k}, t) \left(X^\nu(\boldsymbol{k}) - X^{\nu'}(\boldsymbol{k}') \right) \mathrm{d}^3 k' \tag{39.75}$$

the final balance equation is obtained:

$$\frac{\partial x}{\partial t} + n \boldsymbol{E} \cdot \left\langle \frac{e}{\hbar} \nabla_{\boldsymbol{k}} X \right\rangle_{\boldsymbol{k}} + \nabla_{\boldsymbol{r}} \cdot \boldsymbol{j}_X = -n \langle S\{X\} \rangle_{\boldsymbol{k}} \ . \tag{39.76}$$

Each balance equation of the type (39.76) not only contains the density $x(\boldsymbol{r}, t)$ but also the corresponding current density $\boldsymbol{j}_X(\boldsymbol{r}, t)$. Moreover, for an exact calculation of the expectation values the complete knowledge of the distribution function is typically required. Therefore, it is not possible to derive a finite set of balance equations with the property of having a unique solution without introducing further simplifying assumptions. In particular, the exact calculation of the expectation of the collision integral requires the full information of the distribution function. In the case of certain balance equations, the latter problem can be circumvented with the microscopic relaxation time [69]. However, for the general case, the macroscopic relaxation time approximation has to be used:

$$\langle S\{X\} \rangle_{\boldsymbol{k}} \approx \frac{\langle X \rangle_{\boldsymbol{k}} - \langle X \rangle_{\boldsymbol{k}}^{\mathrm{eq}}}{\tau_X} \ , \tag{39.77}$$

where $\langle \rangle_{\boldsymbol{k}}^{\mathrm{eq}}$ is the expectation in the case of thermodynamic equilibrium. The collision integral and the above approximation both vanish at thermodynamic equilibrium. Therefore, without further restrictions concerning the macroscopic relaxation time τ_X, the above equation could even be exact. The approximation is introduced by the fact that the macroscopic relaxation times are assumed to be functions of a finite set of macroscopic densities only [71].

Hierarchical Hydrodynamic Model

The solution of the BTE is very CPU intensive, irrespective of the solution algorithm (MC or SHE) used. Therefore, less accurate but more CPU-efficient numerical models based on balance equations have been developed. The most widely used models of this type are the DD and the hydrodynamic (HD) models [37,69–79]. Both models are derived by applying different degrees of approximation to balance equations of the type (39.76). Owing to the integration over the $\boldsymbol{k}$-space, the dimensionality of the problem is reduced and the CPU efficiency improves by orders of magnitude. For the HD model, four different balance equations are considered, which result from the four microscopic quantities 1, $\boldsymbol{v}$, ε, and $\varepsilon \boldsymbol{v}$, and relate on the macroscopic level to the electron density, electron particle current density, electron energy density, and the electron energy current density:

$$n = n \langle 1 \rangle_{\boldsymbol{k}} \ , \tag{39.78}$$

$$\boldsymbol{j}_{\mathrm{n}} = n \langle \boldsymbol{v} \rangle_{\boldsymbol{k}} \ , \tag{39.79}$$

$$w_{\mathrm{n}} = n \langle \varepsilon \rangle_{\boldsymbol{k}} \ , \tag{39.80}$$

$$\boldsymbol{s}_{\mathrm{n}} = n \langle \varepsilon \boldsymbol{v} \rangle_{\boldsymbol{k}} \ . \tag{39.81}$$

Such a reduced set of equations still enables the simulation of nonlocal effects, such as the velocity overshoot, that have a strong impact on the behavior of modern devices with

nanometer dimensions. The remaining model derivation presented in this section leads to the generalized HD model and follows closely the arguments outlined in [71]. First, the HD model for electrons is derived and then the results for the hole model are added. With Eq. (39.76) and $X = 1$ the electron continuity equation is obtained without approximations:

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{j}_{\mathrm{n}} + \frac{\partial n}{\partial t} = 0 \,. \tag{39.82}$$

Here, generation-recombination processes are neglected for the sake of brevity.

The balance equation for the electron particle current density is derived with the macroscopic relaxation time approximation (39.77) and by choosing $X = v_x$, $X = v_y$, and $X = v_z$, where v_x, v_y, and v_z are the components of $\boldsymbol{v}$ in a Cartesian coordinate system. Combining the resulting three scalar equations into one vector equation yields the balance equation for the current density

$$\frac{\partial \boldsymbol{j}_{\mathrm{n}}}{\partial t} + e\, n \left\langle \hat{m}^{-1} \right\rangle_{\boldsymbol{k}} \boldsymbol{E} + \left(\nabla_{\boldsymbol{r}}^{\mathrm{T}} \left[n \left\langle \boldsymbol{v} \boldsymbol{v}^{\mathrm{T}} \right\rangle_{\boldsymbol{k}} \right] \right)^{\mathrm{T}} = -\frac{\boldsymbol{j}_{\mathrm{n}}}{\tau_{j_{\mathrm{n}}}}, \tag{39.83}$$

where the inverse mass tensor is given by

$$\hat{m}_{\nu}^{-1}(\boldsymbol{k}) = \frac{1}{\hbar^2} \nabla_{\boldsymbol{k}} \nabla_{\boldsymbol{k}}^{\mathrm{T}} \varepsilon_{\nu}(\boldsymbol{k}) \,. \tag{39.84}$$

The last balance equation contains two tensor quantities, which are replaced by scalar approximations.

$$\left\langle \hat{m}^{-1} \right\rangle_{\boldsymbol{k}} \approx \frac{\mathrm{Tr} \left\langle \hat{m}^{-1} \right\rangle_{\boldsymbol{k}}}{3} \hat{I} \,, \tag{39.85}$$

$$\left\langle \boldsymbol{v} \boldsymbol{v}^{\mathrm{T}} \right\rangle_{\boldsymbol{k}} \approx \frac{\left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}}}{3} \hat{I} \,, \tag{39.86}$$

where $\hat{I}$ is the unity tensor. Owing to the symmetry properties of the dispersion relations and the distribution function for situations close to thermodynamic equilibrium, these approximations are nearly exact close to equilibrium for typical semiconductor materials such as unstrained silicon. Moreover, the dynamic electron temperature $T_{\mathrm{n}}^{\star}$ is introduced by

$$\frac{3}{2} k_{\mathrm{B}} T_{\mathrm{n}}^{\star} = \frac{1}{2} m_{\mathrm{n}}^{\star} \left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}} \,, \tag{39.87}$$

where the mass $m_{\mathrm{n}}^{\star}$ is calculated for thermodynamic equilibrium

$$\frac{1}{m_{\mathrm{n}}^{\star}} = \frac{\left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}}^{\mathrm{eq}}}{3 k_{\mathrm{B}} T_0} \,, \tag{39.88}$$

and T_0 is the lattice temperature. Thus, under equilibrium conditions the dynamic temperature equals the lattice temperature. In addition, the approximation of the inverse mass tensor is absorbed by the introduction of a new relaxation time $\tau_{j_{\mathrm{n}}}^{*}$:

$$\frac{\mathrm{Tr} \left\langle \hat{m}^{-1} \right\rangle_{\boldsymbol{k}}}{3} \tau_{j_{\mathrm{n}}} = \frac{\tau_{j_{\mathrm{n}}}^{*}}{m_{\mathrm{n}}^{\star}}. \tag{39.89}$$

With these approximations, the final current balance equation is obtained:

$$\boldsymbol{j}_{\mathrm{n}} + \tau_{j_{\mathrm{n}}} \frac{\partial \boldsymbol{j}_{\mathrm{n}}}{\partial t} = -n \frac{e\, \tau_{j_{\mathrm{n}}}^{*}}{m_{\mathrm{n}}^{\star}} \boldsymbol{E} - \frac{\tau_{j_{\mathrm{n}}}}{m_{\mathrm{n}}^{\star}} \nabla_{\boldsymbol{r}} \left(n k_{\mathrm{B}} T_n^{\star} \right) . \tag{39.90}$$

Thus, the diffusion constant is given by a generalized Einstein relation [71]:

$$D = \frac{\tau_{j_{\mathrm{n}}} k_{\mathrm{B}} T_{\mathrm{n}}^{\star}}{m_{\mathrm{n}}^{\star}} = \underbrace{\frac{e \tau_{j_{\mathrm{n}}}^{*}}{m_{\mathrm{n}}^{\star}}}_{=\mu} \frac{\tau_{j_{\mathrm{n}}}}{\tau_{j_{\mathrm{n}}}^{*}} \underbrace{\frac{k_{\mathrm{B}} T_{\mathrm{n}}^{\star}}{e}}_{=V_{T_{\mathrm{n}}^{\star}}} = \mu V_{T_{\mathrm{n}}^{\star}} \frac{\tau_{j_{\mathrm{n}}}}{\tau_{j_{\mathrm{n}}}^{*}}, \tag{39.91}$$

where the thermal voltage is evaluated with the dynamic temperature of the particle gas instead of the lattice temperature. At equilibrium, the generalized Einstein relation reduces to the standard one.

The balance equation for the electron energy density results with $X = \varepsilon$

$$\frac{\partial w_{\mathrm{n}}}{\partial t} + e\, \boldsymbol{j}_{\mathrm{n}} \cdot \boldsymbol{E} + \nabla_{\boldsymbol{r}} \cdot \boldsymbol{s}_n = -n \frac{\langle \varepsilon \rangle - \langle \varepsilon \rangle^{\mathrm{eq}}}{\tau_{w_n}} \,. \tag{39.92}$$

Considering the relation between the expectation value $\langle \varepsilon \rangle$ and the dynamic temperature by introducing the new energy relaxation time $\tau_{w_{\mathrm{n}}}^{\star}$

$$\frac{\langle \varepsilon \rangle - \langle \varepsilon \rangle^{\mathrm{eq}}}{\tau_{w_{\mathrm{n}}}} = \frac{3 k_{\mathrm{B}}}{2} \frac{T_{\mathrm{n}}^{\star} - T_0}{\tau_{w_{\mathrm{n}}}^{\star}} \tag{39.93}$$

the final equation reads

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{s}_{\mathrm{n}} + \frac{\partial w_{\mathrm{n}}}{\partial t} = -e\, \boldsymbol{j}_{\mathrm{n}} \cdot \boldsymbol{E} - n \frac{3 k_{\mathrm{B}}}{2} \frac{T_{\mathrm{n}}^{\star} - T_0}{\tau_{w_{\mathrm{n}}}^{\star}} \,. \tag{39.94}$$

The balance equation for the energy current density results from the three scalar balance equations for $X = \varepsilon v_x$, $X = \varepsilon v_y$, and $X = \varepsilon v_z$, which combined yield the vector balance equation :

$$\begin{aligned} \frac{\partial \boldsymbol{s}_{\mathrm{n}}}{\partial t} &+ e\, n \left\langle \hat{m}^{-1} \varepsilon + \boldsymbol{v} \boldsymbol{v}^{\mathrm{T}} \right\rangle_{\boldsymbol{k}} \boldsymbol{E} \\ &+ \left(\nabla_{\boldsymbol{r}}^{\mathrm{T}} \left[n \left\langle \varepsilon \boldsymbol{v} \boldsymbol{v}^{\mathrm{T}} \right\rangle_{\boldsymbol{k}} \right] \right)^{\mathrm{T}} = -\frac{\boldsymbol{s}_{\mathrm{n}}}{\tau_{\boldsymbol{s}_{\mathrm{n}}}} \,. \end{aligned} \tag{39.95}$$

The first tensor quantity in the equation above is again approximated in such a manner that close to equilibrium, and for typical unstrained semiconductors such as silicon the approximation is well justified:

$$\left\langle \hat{m}^{-1}\varepsilon + \boldsymbol{v}\boldsymbol{v}^{\mathrm{T}} \right\rangle_{\boldsymbol{k}} \approx \left[\frac{\mathrm{Tr}\left\langle \varepsilon\, \hat{m}^{-1} \right\rangle_{\boldsymbol{k}}}{3} + \frac{\left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}}}{3} \right] \hat{I}\,. \tag{39.96}$$

Moreover, this approximation is simplified by the introduction of the additional relaxation time $\tau^*_{s_\mathrm{n}}$.

$$\left[\frac{\mathrm{Tr}\left\langle \varepsilon\, \hat{m}^{-1} \right\rangle_{\boldsymbol{k}}}{3} + \frac{\left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}}}{3} \right] \tau_{s_\mathrm{n}} = \frac{5}{6} \left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}} .\tau^*_{s_\mathrm{n}} \tag{39.97}$$

The second tensor quantity in (39.95) is of the highest order, and a stronger approximation, which relates this term to the lower-order quantity $\left\langle \boldsymbol{v}^2 \right\rangle_{\boldsymbol{k}}$, is applied to close the set of equations.

$$\left\langle \varepsilon \boldsymbol{v}\boldsymbol{v}^{\mathrm{T}} \right\rangle_{\boldsymbol{k}} \approx \frac{5\left\langle \boldsymbol{v}^2 \right\rangle^2_{\boldsymbol{k}}}{6\mathrm{Tr}\left\langle \hat{m}^{-1} \right\rangle_{\boldsymbol{k}}} \hat{I}\,. \tag{39.98}$$

The approximation above is exact for a Maxwell–Boltzmann distribution function in conjunction with a parabolic band structure. Also, the gradient of the expected value of the inverse mass is neglected:

$$\nabla_{\boldsymbol{r}} \frac{1}{\mathrm{Tr}\left\langle \hat{m}^{-1} \right\rangle_{\boldsymbol{k}}} \approx 0\,. \tag{39.99}$$

The evaluation of the relaxation times has finally revealed [71] that the following simplifying assumption is well justified:

$$\tau^*_{s_\mathrm{n}} \approx \tau_{s_\mathrm{n}} \tag{39.100}$$

In summary, these approximations result in the final equation for the energy current density:

$$\begin{aligned} \boldsymbol{s}_\mathrm{n} + \tau^*_{s_\mathrm{n}} \frac{\partial \boldsymbol{s}_\mathrm{n}}{\partial t} &= -e\, n \frac{5 k_\mathrm{B} T^\star_\mathrm{n} \tau^*_{s_\mathrm{n}}}{2 m^\star_\mathrm{n}} \boldsymbol{E} \\ &\quad - \frac{5\tau^*_{s_\mathrm{n}} \tau_{j_\mathrm{n}}}{2 m^\star_\mathrm{n} \tau^*_{j_\mathrm{n}}} \nabla_{\boldsymbol{r}} \left[n \left(k_\mathrm{B} T^\star_\mathrm{n} \right)^2 \right]\,. \end{aligned} \tag{39.101}$$

Equations (39.90), (39.94), and (39.101) contain first-order derivatives with respect to time. Considering these derivatives leads to a strong influence of plasma oscillations with frequencies in the THz regime on the transient response of the final device model. This makes the initial value problem very stiff and creates a large amount of unnecessary numerical effort. However, plasma oscillations are not important for most applications. Therefore, these time derivatives are typically neglected. As a consequence, plasma oscillations are suppressed, and as the relaxation times are typically smaller than 1 ps, this approximation is considered to be valid as long as only time constants much larger than 1 ps are relevant for the application under consideration. Moreover, the interband transition of carriers has been neglected so far. These transitions are typically related to processes such as Shockley–Read–Hall recombination, Auger recombination, impact ionization, or band-to-band tunneling (BBT) [37]. These processes are typically considered only in the continuity equations for electrons and holes by a generation term G. Taking this into account, the final equation set of the generalized HD model reads as follows for electrons:

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{j}_\mathrm{n} + \frac{\partial n}{\partial t} = G\,, \tag{39.102}$$

$$\boldsymbol{j}_\mathrm{n} = -e\, n \frac{\tau^*_{j_\mathrm{n}}}{m^\star_\mathrm{n}} \boldsymbol{E} - \frac{\tau_{j_\mathrm{n}}}{m^\star_\mathrm{n}} \nabla_{\boldsymbol{r}} \left[n k_\mathrm{B} T^\star_\mathrm{n} \right]\,, \tag{39.103}$$

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{s}_\mathrm{n} = -e \boldsymbol{j}_\mathrm{n} \cdot \boldsymbol{E} - n \frac{3 k_\mathrm{B}}{2} \frac{T^\star_\mathrm{n} - T_0}{\tau^\star_{w_\mathrm{n}}}\,, \tag{39.104}$$

$$\boldsymbol{s}_\mathrm{n} = -e\, n \frac{5 k_\mathrm{B} T^\star_\mathrm{n} \tau^*_{s_\mathrm{n}}}{2 m^\star_\mathrm{n}} \boldsymbol{E} - \frac{5\tau^*_{s_\mathrm{n}} \tau_{j_\mathrm{n}}}{2 m^\star_\mathrm{n} \tau^*_{j_\mathrm{n}}} \nabla_{\boldsymbol{r}} \left[n \left(k_\mathrm{B} T^\star_\mathrm{n} \right)^2 \right]\,. \tag{39.105}$$

With the same chain of arguments as above, the following equation set of the generalized HD model for holes can be derived as well:

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{j}_\mathrm{p} + \frac{\partial p}{\partial t} = G\,, \tag{39.106}$$

$$\boldsymbol{j}_\mathrm{p} = e\, p \frac{\tau^*_{j_\mathrm{p}}}{m^\star_\mathrm{p}} \boldsymbol{E} - \frac{\tau_{j_\mathrm{p}}}{m^\star_\mathrm{p}} \nabla_{\boldsymbol{r}} \left[p k_\mathrm{B} T^\star_\mathrm{p} \right]\,, \tag{39.107}$$

$$\nabla_{\boldsymbol{r}} \cdot \boldsymbol{s}_\mathrm{p} = e \boldsymbol{j}_\mathrm{p} \cdot \boldsymbol{E} - p \frac{3 k_\mathrm{B}}{2} \frac{T^\star_\mathrm{p} - T_0}{\tau^\star_{w_\mathrm{p}}}\,, \tag{39.108}$$

$$\boldsymbol{s}_\mathrm{p} = e\, p \frac{5 k_\mathrm{B} T^\star_\mathrm{p} \tau^*_{s_\mathrm{p}}}{2 m^\star_\mathrm{p}} \boldsymbol{E} - \frac{5\tau^*_{s_\mathrm{p}} \tau_{j_\mathrm{p}}}{2 m^\star_\mathrm{p} \tau^*_{j_\mathrm{p}}} \nabla_{\boldsymbol{r}} \left[p \left(k_\mathrm{B} T^\star_\mathrm{p} \right)^2 \right]\,. \tag{39.109}$$

The particle and energy current densities are eliminated from the HD model by inserting Eqs. (39.107), (39.109), (39.103), and (39.105) into Eqs. (39.106), (39.108), (39.102), and (39.104). Including PE (39.11) and keeping in mind (39.10), five equations remain for the unknown variables p, $T^\star_\mathrm{p}$, n, $T^\star_\mathrm{n}$, and Ψ. These are

$$(39.106) + (39.107) \;\rightarrow F_{\dot{\mathrm{p}}}(p, T^\star_\mathrm{p}, n, T^\star_\mathrm{n}, \Psi) + \frac{\partial p}{\partial t} = 0\,, \tag{39.110}$$

$$(39.108) + (39.107) + (39.109) \rightarrow F_{\dot{w}_\mathrm{p}}(p, T^\star_\mathrm{p}, n, T^\star_\mathrm{n}, \Psi) = 0\,, \tag{39.111}$$

$$(39.102) + (39.103) \;\rightarrow F_{\dot{\mathrm{n}}}(p, T^\star_\mathrm{p}, n, T^\star_\mathrm{n}, \Psi) + \frac{\partial n}{\partial t} = 0\,, \tag{39.112}$$

$$(39.104) + (39.103) + (39.105) \rightarrow F_{\dot{w}_\mathrm{n}}(p, T^\star_\mathrm{p}, n, T^\star_\mathrm{n}, \Psi) = 0\,, \tag{39.113}$$

$$(39.11) \;\rightarrow F_\Psi(p, n, \Psi) = 0\,, \tag{39.114}$$

where F_α with $\alpha = \dot{p}, \dot{w}_\mathrm{p}, \dot{n}, \dot{w}_\mathrm{n}, \Psi$ are abbreviations including all relevant terms besides the derivatives in time. The final set of Eqs. (39.110)–(39.114) contains four macroscopic relaxation times for holes ($\tau^*_{j_\mathrm{p}}$, τ_{j_p}, $\tau^\star_{w_\mathrm{p}}$, $\tau^*_{s_\mathrm{p}}$) and four for electrons ($\tau^*_{j_\mathrm{n}}$, τ_{j_n}, $\tau^\star_{w_\mathrm{n}}$, $\tau^*_{s_\mathrm{n}}$).

In order to generate a sequential multi-scale model, the assumption is introduced that these relaxation times depend only locally on the hole or electron dynamic temperature respectively for a predefined lattice temperature and doping level. This assumption allows a precalculation of these parameters under homogeneous bulk conditions with a given lattice temperature, a constant doping level, and a constant electric field $\boldsymbol{E}$ by SHE or single-particle MC simulations. Combining (39.79)–(39.81), (39.89), (39.103)–(39.105) and introducing the simplifications resulting from the assumption of homogeneous material and electric field yield

$$\tau^*_{j_\mathrm{n}} = \frac{m^\star_\mathrm{n} \langle \boldsymbol{v} \rangle_\mathrm{hom} \cdot \boldsymbol{E}}{e\boldsymbol{E}^2}\,, \tag{39.115}$$

$$\tau_{j_\mathrm{n}} = \frac{3\tau^*_{j_\mathrm{n}}}{m^\star_\mathrm{n} \mathrm{Tr} \langle \hat{m}^{-1} \rangle_\mathrm{hom}}\,, \tag{39.116}$$

$$\tau^\star_{w_\mathrm{n}} = \frac{3k_\mathrm{B}(T^\star_\mathrm{n} - T_0)}{2e \langle \boldsymbol{v} \rangle_\mathrm{hom} \cdot \boldsymbol{E}}\,, \tag{39.117}$$

$$\tau^*_{s_\mathrm{n}} = \frac{2m^\star_\mathrm{n} \langle \varepsilon \boldsymbol{v} \rangle_\mathrm{hom} \cdot \boldsymbol{E}}{5ek_\mathrm{B}T^\star_\mathrm{n}\boldsymbol{E}^2}\,. \tag{39.118}$$

Please note that the dynamic temperature corresponding to a given homogeneous bulk condition with a constant electric field $\boldsymbol{E}$ is calculated following (39.87) by

$$T^\star_\mathrm{n} = \frac{m^\star_\mathrm{n}}{3k_\mathrm{B}} \langle \boldsymbol{v}^2 \rangle_\mathrm{hom}\,. \tag{39.119}$$

Similar equations can be derived for holes. Please note that for unstrained silicon close to room temperature, the dependence of the above transport parameters and carrier temperatures on the orientation of the electric field is weak and can safely be neglected [80]. However, for other situations, especially strained semiconductor materials that show a non-isotropic transport behavior even close to equilibrium, it is advisable to choose the field orientation for the calculation of the transport parameters that best reflects the predominant transport direction in the device problem that should be simulated at least as long as scalar transport parameters should still be used [81]. For further details about the efficient evaluation of the relaxation times, please refer to Jungemann and Meinerzhagen [12].

The transport parameters are precalculated and stored together with the dynamic temperature in lookup tables as a function of discrete values of the electric field, doping, and lattice temperature. For device simulations they are interpolated with appropriate methods [81], and the relation between the carrier temperature and the modulus of the electric field (39.119) is applied to evaluate the correct parameter values for the device simulation based on the local carrier temperatures in the device simulator. The application of this table model-based sequential multi-scale approach does not impair the CPU efficiency of the HD model compared with models based on analytical expressions for the transport parameters.

Metal–semiconductor contacts typically have a highly doped semiconductor layer underneath the metal layer. This contact situation is typically modeled by the ideal ohmic contact model assuming charge neutrality in the highly doped semiconductor region and a local quasi-thermodynamic equilibrium between the metal and the highly doped semiconductor region. In order to understand this contact model properly, the relation between the carrier densities and the electrostatic potential at thermodynamic equilibrium must be reviewed first. At equilibrium the distribution function is given by the Fermi distribution function, which is known as soon as the temperature T_0 and the Fermi energy $E_{\mathrm{F},0}$ are given. Both quantities do not depend on the space coordinate. Assuming that the Fermi distribution function can be well approximated by the Boltzmann distribution function for the calculation of the carrier densities, these densities are given by Madelung [2]

$$n(\boldsymbol{r}) = N_\mathrm{C} \exp\left(-\frac{E_\mathrm{C} - e\Psi(\boldsymbol{r}) - E_{\mathrm{F},0}}{k_\mathrm{B}T_0}\right)\,, \tag{39.120}$$

$$p(\boldsymbol{r}) = N_\mathrm{V} \exp\left(\frac{E_\mathrm{V} - e\Psi(\boldsymbol{r}) - E_{\mathrm{F},0}}{k_\mathrm{B}T_0}\right)\,.$$

E_C and E_V are the energy levels of the conduction band and the valance band edges for vanishing electrostatic potential respectively. Moreover, the effective density of state N_C is given by

$$N_\mathrm{C} = \int_0^\infty D(\epsilon) \exp\left(-\frac{\epsilon}{k_\mathrm{B}T_0}\right) \mathrm{d}\epsilon\,, \tag{39.121}$$

where the density of states function $D(\epsilon)$ for the conduction bands is given by

$$D(\epsilon) = \sum_\nu \frac{2}{(2\pi)^3} \int_{\varepsilon_\nu(\boldsymbol{k})=\epsilon} \frac{\mathrm{d}^2k}{|\nabla_{\boldsymbol{k}}\varepsilon_\nu(\boldsymbol{k})|}\,. \tag{39.122}$$

The sum in the above equation extends over all conduction bands ν specified by the dispersion relations $\varepsilon_\nu(\boldsymbol{k})$ already introduced in (39.5) and the integral is a surface integral over all states $\boldsymbol{k}$ within the conduction band ν, having a band energy $\varepsilon_\nu(\boldsymbol{k}) = \epsilon$. Analog equations hold for N_V and

the valence bands. For the densities at equilibrium given in (39.120)

$$n(\boldsymbol{r})p(\boldsymbol{r}) = n_i^2 = N_\mathrm{C}N_\mathrm{V}\exp\left(\frac{E_\mathrm{V}-E_\mathrm{C}}{k_\mathrm{B}T_0}\right) \tag{39.123}$$

holds and this defines the intrinsic density n_i. Introducing the Fermi potential Φ by

$$-e\Phi = E_{\mathrm{F},0} - E_{\mathrm{F},i}\,, \tag{39.124}$$

where $E_{\mathrm{F},i}$ does not depend on $\boldsymbol{r}$ and is given by

$$E_{\mathrm{F},i} = \frac{1}{2}\left(E_\mathrm{V} + E_\mathrm{C} + k_\mathrm{B}T_0\,\ln\frac{N_\mathrm{V}}{N_\mathrm{C}}\right)\,, \tag{39.125}$$

yields the following more symmetric representation for the densities at equilibrium:

$$\begin{aligned} n(\boldsymbol{r}) &= n_i\,\exp\left(\frac{\Phi-\Psi(\boldsymbol{r})}{V_{T_0}}\right)\,,\\ p(\boldsymbol{r}) &= n_i\,\exp\left(\frac{\Psi(\boldsymbol{r})-\Phi}{V_{T_0}}\right)\,. \end{aligned} \tag{39.126}$$

Here, V_{T_0} is the thermal voltage for T_0 as defined already in (39.91) in an analog manner for $T_\mathrm{n}^\star$. Owing to the local quasi-thermodynamic equilibrium between the metal and the highly doped semiconductor region, it can be assumed that both regions share the common temperature T_0 and a common Fermi potential Φ_M that is independent of $\boldsymbol{r}$ in the contact region. Moreover, assuming charge neutrality means

$$p - n + N_\mathrm{D} - N_\mathrm{A} = 0\,, \tag{39.127}$$

where N_D and N_A are the densities of ionized donator and acceptor atoms. Using the last equation, (39.126) and $\Phi = \Phi_\mathrm{M}$ finally yield the boundary conditions of an ideal ohmic contact for the electrostatic potential

$$\Psi = \Phi_\mathrm{M} + V_{T_0}\,\sinh^{-1}\left(\frac{N_\mathrm{D}-N_\mathrm{A}}{n_\mathrm{i}}\right)\,, \tag{39.128}$$

the particle densities

$$p = -\frac{N_\mathrm{D}-N_\mathrm{A}}{2} + \sqrt{\left(\frac{N_\mathrm{D}-N_\mathrm{A}}{2}\right)^2 + n_\mathrm{i}^2}\,, \tag{39.129}$$

$$n = \frac{N_\mathrm{D}-N_\mathrm{A}}{2} + \sqrt{\left(\frac{N_\mathrm{D}-N_\mathrm{A}}{2}\right)^2 + n_\mathrm{i}^2}\,, \tag{39.130}$$

and the temperatures

$$T_\mathrm{p}^\star = T_0\,, \tag{39.131}$$

$$T_\mathrm{n}^\star = T_0\,. \tag{39.132}$$

The Fermi potentials at the metal contacts are typically specified by setting $\Phi_\mathrm{M} = 0\,\mathrm{V}$ at one reference contact and by applying voltages between this reference contact and the other contacts.

On all other surfaces, Neumann-type boundary conditions are typically applied for the electric field, the particle current, and energy current densities. For more information about boundary conditions, and in particular, for a more realistic boundary condition for minority carriers at ohmic contacts, please refer, for example, to Engl et al. [75].

Hierarchical Drift-Diffusion Model

The DD model is obtained by applying the following additional approximations to the HD model:

$$\tau_{j_\mathrm{n}} \approx \tau_{j_\mathrm{n}}^*\,, \tag{39.133}$$

$$T_\mathrm{n}^\star \approx T_0\,, \tag{39.134}$$

which imply the classical Einstein relation

$$D = V_{T_0}\mu\,. \tag{39.135}$$

Equation (39.90) now reads

$$\boldsymbol{j}_\mathrm{n} + \tau_{j_\mathrm{n}}^*\frac{\partial \boldsymbol{j}_\mathrm{n}}{\partial t} = -en\frac{\tau_{j_\mathrm{n}}^*}{m_\mathrm{n}^\star}\boldsymbol{E} - \frac{k_\mathrm{B}T_0\tau_{j_\mathrm{n}}^*}{m_\mathrm{n}^\star}\nabla_{\boldsymbol{r}} n\,, \tag{39.136}$$

and Eqs. (39.94) and (39.101) can be dropped, because the particle gas temperature is assumed to be equal to the lattice temperature. The final DD model for holes and electrons is obtained, neglecting again the derivative in time in the balance equations for the current densities

$$\nabla_{\boldsymbol{r}}\cdot\boldsymbol{j}_\mathrm{p} + \frac{\partial p}{\partial t} = G\,, \tag{39.137}$$

$$\boldsymbol{j}_\mathrm{p} = e\,p\frac{\tau_{j_\mathrm{p}}^*}{m_\mathrm{p}^\star}\boldsymbol{E} - \frac{k_\mathrm{B}T_0\tau_{j_\mathrm{p}}^*}{m_\mathrm{p}^\star}\nabla_{\boldsymbol{r}} p\,, \tag{39.138}$$

$$\nabla_{\boldsymbol{r}}\cdot\boldsymbol{j}_\mathrm{n} + \frac{\partial n}{\partial t} = G\,, \tag{39.139}$$

$$\boldsymbol{j}_\mathrm{n} = -e\,n\frac{\tau_{j_\mathrm{n}}^*}{m_\mathrm{n}^\star}\boldsymbol{E} - \frac{k_\mathrm{B}T_0\tau_{j_\mathrm{n}}^*}{m_\mathrm{n}^\star}\nabla_{\boldsymbol{r}} n\,. \tag{39.140}$$

The boundary conditions for the electrostatic potential, the particle densities, the electric field, and the particle current densities are the same as for the HD model.

Quasi-Fermi potentials Φ_p and Φ_n for holes and electrons can be defined by the relations

$$p = n_\mathrm{i} \exp\left(\frac{\Phi_\mathrm{p} - \Psi}{V_\mathrm{T}}\right) \tag{39.141}$$

and

$$n = n_\mathrm{i} \exp\left(\frac{\Psi - \Phi_\mathrm{n}}{V_\mathrm{T}}\right), \tag{39.142}$$

where n_i is the intrinsic particle density. This definition of the quasi-Fermi potentials is consistent with (39.126). This implies that in regions where the carrier distribution is close to equilibrium, these quasi-Fermi potentials still have a thermodynamic relevance. With these quasi-Fermi potentials the current continuity equations read

$$\boldsymbol{j}_\mathrm{p} = -p\frac{e\,\tau^*_{j_\mathrm{p}}}{m^\star_\mathrm{p}}\nabla_{\boldsymbol{r}}\Phi_\mathrm{p} = -p\mu_\mathrm{p}\nabla_{\boldsymbol{r}}\Phi_\mathrm{p} \tag{39.143}$$

and

$$\boldsymbol{j}_\mathrm{n} = n\frac{e\,\tau^*_{j_\mathrm{n}}}{m^\star_\mathrm{n}}\nabla_{\boldsymbol{r}}\Phi_\mathrm{n} = n\mu_\mathrm{n}\nabla_{\boldsymbol{r}}\Phi_\mathrm{n}. \tag{39.144}$$

Thus, the driving force is given by the gradient of the quasi-Fermi potential, of which the modulus $|\nabla_{\boldsymbol{r}}\Phi|$ is used to parameterize the mobility in order to account for non-equilibrium effects such as velocity saturation in the DD model [37, 75]. Moreover, under homogeneous material and field conditions

$$|\nabla_{\boldsymbol{r}}\Phi|_\mathrm{hom} = E \tag{39.145}$$

holds. This allows a sequential multi-scale DD model to be established by using the same transport parameter table as for the HD equation, by evaluating τ^*_j based on the local gradient of the quasi-Fermi potential and (39.145). Using this approach with an identical transport parameter table for the HD and DD models guarantees that the HD and DD models yield the same results as the BTE, which has been applied for calculating the transport parameter table, under homogeneous material and field conditions.

The balance equations of the current densities (39.138) and (39.140) are eliminated from the DD model similar to the HD case, and the final DD model for the variables p, n, and Ψ reads

$$(39.137) + (39.138) \;\rightarrow F_\mathrm{\dot{p}}(p, n, \Psi) + \frac{\partial p}{\partial t} = 0\,, \tag{39.146}$$

$$(39.139) + (39.140) \;\rightarrow F_\mathrm{\dot{n}}(p, n, \Psi) + \frac{\partial n}{\partial t} = 0\,, \tag{39.147}$$

$$(39.11) \;\rightarrow F_\Psi(p, n, \Psi) = 0\,. \tag{39.148}$$

The sequential multi-scale method just demonstrated for the case of silicon can be extended to other semiconductor materials such as SiGe and devices with heterojunctions such as SiGe HBTs [82]. The results for electron or hole transport resulting from the BTE and hierarchical HD and DD transport equations are identical for homogeneous material and field conditions. Thus, these models are ideally suited to study of the modeling differences at the level of inhomogeneous devices owing to the simplifying assumptions introduced for deriving the HD and DD equations. Therefore, these hierarchical models have been applied in [71, 83] to examine the accuracy of the DD and HD models for MOS transistors with nanometer dimensions and in [84] for advanced SiGe HBTs. Moreover, the sequential multi-scale methods have been extended to the efficient modeling of noise, where the noise in the HD and DD models is traced back to the microscopic scattering processes of the BTE [12, 32, 85]. In Jungemann et al. [86] it is verified that this approach to modeling noise yields excellent results for modern MOS transistors. Moreover, in the same paper it was also shown that the drain current noise in n-channel MOS transistors is predominantly due to the rather cool electrons near the source and not to the hot electrons near the drain, as was previously thought.

39.3.2 Concurrent Multi-Scale Modeling

Sequential multi-scale modeling typically tries to enhance the solution accuracy of macroscopic models (e.g., HD and DD models) by calculating transport parameters such as relaxation times or noise models sequentially in a preprocessing step based on models that consider effects on a more microscopic scale such as the BTE. However, there are many cases for which such a method is not applicable or just too much effort owing to the large amount of different cases that need to be considered in the preprocessor and stored in tables. In the case of semiconductor transport, such cases are typically related to an improved modeling of carrier generation or recombination both in the bulk or at the interfaces. Although the Shockley–Read–Hall and Auger recombinations can be well modeled based on the local quantities available in an HD and DD simulator such as the carrier densities or the electric field, local models for hot carrier or tunneling-related processes such as impact ionization (II), oxide injection, and BBT, tend to be very poor, especially for devices with submicron dimensions. These effects depend in a strongly nonlocal manner on the space-dependent solution variables of the HD and DD models and typically require for really accurate modeling details that can only be provided by models that access the microscopic scale, such as the BTE or Schrödinger's equation. In order to enhance the accuracy of the computationally efficient DD and HD models, this missing information related to nonlocal and/or microscopic effects is provided on-the-fly and incorporated in real time into the DD and HD simulations. Therefore, such methods are typically addressed as concurrent multi-scale

models [68]. Very often the additional information concerning nonlocal and/or microscopic effects is only needed in a very restricted region of the total simulation domain, so that concurrent multi-scale models can be very efficient.

William Shockley [87] showed that with his rather simple lucky electron ansatz, a wide variety of hot carrier-related experiments can be explained. This means that under favorable circumstances this simple model can provide useful quantitative information about the energy distribution function, which is normally only available after the solution of the BTE, already based on DD or HD models. This makes the lucky electron ansatz very interesting for concurrent multi-scale modeling. At the time of Shockley's publications, device dimensions were still so large that quantities such as densities and fields could typically be assumed to be spatially homogeneous and of only one-dimensional orientation for interpreting experiments. Therefore, as device dimensions shrank and these assumptions were no longer valid, it remained unclear how to generalize the lucky electron ansatz for inhomogeneous and multi-dimensional situations. For example, field lines of the electrostatic field and current lines of the electric current densities coincide for 1D but typically not for 2D or 3D situations. The solution to this problem became apparent when Tak Ning and coworkers showed that their experimental data of optical enhanced hot-electron injection could be nicely interpreted by a nonlocal lucky electron ansatz [88]. Based on the results of this paper, a new concurrent multi-scale model for impact ionization and oxide injection in silicon n-channel MOSFETs was developed consisting of a HD model [79] and a field line-based lucky electron model that exploited both the spatial electron density and the electrostatic potential distributions resulting from the HD model in a nonlocal manner [89, 90]. With only three different constants (one for each experiment), it is demonstrated in Meinerzhagen and Meinerzhagen and Engl [89, 90] that substrate current, drain-induced oxide injection, and optically triggered oxide injection can be modeled accurately by this new model in a consistent manner for many different devices and bias conditions. Moreover, it is demonstrated that the application of the HD model is mandatory for this success. None of the models published before typically combining a DD diffusion model and a nonlocal lucky electron ansatz based on current lines [91,92] could demonstrate a comparable predictive capability. The concurrent multi-scale hot-electron model first presented in Meinerzhagen and Meinerzhagen and Engl [89, 90] is therefore well suited to the modeling of flash memory devices, as demonstrated in Hagenbeck et al. [93]. Later the nonlocal lucky electron model for II in silicon was improved by replacing the hard threshold energy for impact ionization of the original model by a soft threshold model based on an energy-dependent impact ionization probability derived from full-band data [94, 95]. Moreover, a soft threshold model for the impact ionization triggered by holes was provided as well. The predictive capability of this improved model for substrate current simulations is verified in Jungemann et al. [96, 97] for a wide variety of different NMOS transistors and bias conditions. First, the nonlocal models for hot carrier effects were used in a postprocessing step [89, 90], but with a sufficiently smooth implementation of these models, a self-consistent solution is possible as well. Owing to the nonlocal nature of the lucky electron ansatz, a complete consideration of these models in the Jacobian matrices generates a large amount of additional entries typically changing the properties of the Jacobian matrices completely. Therefore, these nonlocal models are often embedded in the nonlinear relaxation schemes (e.g., [98]) updating the generation term G within every nonlinear iteration without generating Jacobian entries. The convergence of these iteration schemes may be slow if impact ionization dominates, but it is typically reliable enough to estimate the solution accuracy [99] and to simulate even the breakdown characteristic of a bipolar transistor with open base [100]. The nonlocal soft threshold model for impact ionization is used by many device simulation groups worldwide and is available in commercial TCAD tools [101].

In order to profit from the wealth of hot carrier-related information inherent to the energy distribution function, which results from the solution of the BTE, the classical DD and HD device models have also been directly coupled with the BTE resulting in another concurrent multi-scale model. In the beginning, the BTE was typically solved using the MC method and thus this new method is mostly addressed as non-self-consistent MC simulation (NSC-MC, [12]). The spatial distribution of the electrostatic potential is given for this method, mostly resulting from a DD or HD model. The NSC-MC method for hot carrier simulations was first described in Sangiorgi et al. and Higman et al. [102, 103]. In order to enhance the efficiency of this simulation method, the solution region of the BTE is typically substantially smaller than the solution region of the DD or HD models. The carriers within the MC simulation are injected at some part of the boundary of the MC simulation region or inside the simulation region based on information from the HD or DD simulations and absorbed at other parts of the boundary as described, for example, in Sangiorgi et al., Higman et al., and Jungemann and Meinerzhagen [12, 102, 103] and for the NAND-Flash memory simulation presented later in this section. The injection method depends on the purpose of the MC simulation and may require a profound understanding of the device behavior, as will be explained as well later in this section. The NSC-MC method was first verified for hot carrier effects in Sangiorgi et al. and Higman et al. [102, 103] and later on a much broader experimental basis for substrate current calculations in Bude and Mastrapasqua and Jungemann et al. [96, 104]. Moreover, in Jungemann et al. [96] it is shown that the NSC-MC method is predictive, as it does not require any calibration

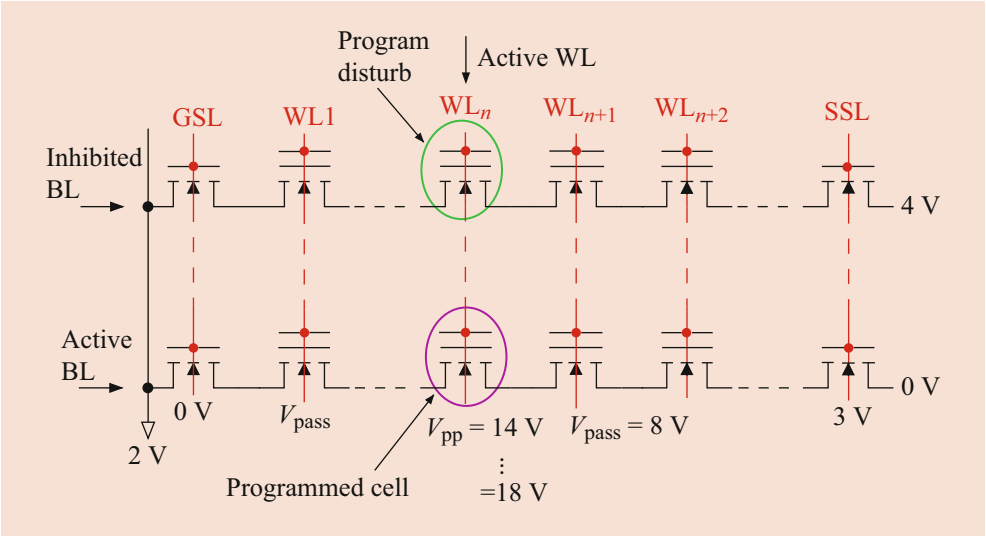

Fig. 39.19 Schematic of NAND strings with bias conditions during programming and the location of the program disturb

on the device level for modeling substrate currents with high accuracy over a wide range of devices and bias conditions. In addition it is shown in Jungemann et al. [96] that NSC-MC simulations are two to three orders of magnitude more efficient for substrate current calculations than self-consistent MC simulations, without compromising accuracy. The NSC-MC method presented in Jungemann et al. [96] is verified for an even wider variety of different MOSFETs in Jungemann et al. [97]. Thus, it can be concluded that the NSC-MC method is well suited to modeling hot carrier effects and this will be confirmed in Sect. 39.3.2. Although used for this purpose in a number of publications (e.g., Cheng et al. [105]), the NSC-MC method is not well suited to simulating drain currents and drain current noise. This is carefully examined and shown in Jungemann and Meinerzhagen [12, 106].

Probably the first nonlocal model for BBT in silicon MOSFETs and bipolar transistors was published and verified in Bergner et al. and Schwerin et al. [107–109]. The model describes the tunneling probabilities in a nonlocal manner based on the spatial distribution of the electrostatic potential following the early work of Keldysh. Provided that the nonlocal tunneling models are implemented in a sufficiently smooth manner, self-consistent simulations with these nonlocal models are possible [110]. Similar to the nonlocal II models described above, the easiest way to yield self-consistent simulations is to embed these models in one of the nonlinear relaxation schemes for DD or HD equations and to update the generation term G within each nonlinear iteration based on the nonlocal model. Again the convergence of these iteration schemes may be slow if the tunnel effect dominates, but it is typically reliable enough to estimate the solution accuracy [99]. In Carrillo-Nunez et al. [111] a nonlocal band-to-band tunnel model for heterostructure tunnel-FETs was developed and verified by simulation based on a full-band and atomistic quantum transport simulator. Meanwhile, a variety of different nonlocal tunneling models can be used, even in commercial TCAD tools [101].

Concurrent Multi-Scale Simulation of Program Disturb in NAND-Flash Memories

In this chapter it is shown that even very difficult problems can be simulated accurately and efficiently by a concurrent multi-scale model. Such a problem is the program disturb in NAND flash memory technologies. Program disturb is one effect that may ultimately limit the scalability of these technologies [112].

For the application of a concurrent multi-scale model, it is important to clearly understand the physical origin of this problem. Therefore, the effect itself is explained first. The results outlined in this section have been previously published in Nguyen et al. and Kuligt et al. [110, 113].

In Fig. 39.19 the scheme of a NAND memory block is shown, including all relevant bias voltages applied during the programming mode. The memory block consists of a number of bit line (BL) strings. Each string is composed of a number of memory cells and two select transistors at each end of the string. All cells and transistors in a BL string are of NMOS type and electrically connected by sharing common source/drain regions. The control gates of the memory cells are accessed by word lines (WLs) and the gates of the select transistors are accessed by the ground select line (GSL) and the string select line (SSL) respectively. The programming of the memory cell selected by the active WL and the active BL is intended. However, cells in other BLs sharing the active WL may also change their stored charge owing to the high programming voltage V_{pp} of the active WL. In order to inhibit programming in the non-active BLs, the string of memory cells in these lines is first isolated by switching the select

transistors connected to the SSL in these BLs into the off-state. This is achieved by applying a bias of 3 V to the SSL and a bias of 4 V to the source/drain regions of these select transistors that are accessible at the boundary of the memory block. Please note that during programming, because of the voltages applied, all select transistors connected to the GSL operate in the off-state and all memory cells operate in the on-state. Moreover, the select transistor connected to the SSL in the active BL operates in the on-state, as its contact accessible at the boundary is grounded, causing the electrostatic potential within the channels of the memory cells within the active BL to remain close to 0 V too. The undesired programming of a memory cell in an inhibited non-active BL is referred to as program disturb and depends strongly on the voltage V_{pass} applied to all nonactive WLs. This voltage increases (boosts) the channel potential in the inhibited BLs during programming owing to the capacitive coupling of the gate electrodes and the isolated electron charges in the inhibited BLs. As a consequence, the programming of the memory cells by electron injection is strongly reduced in the inhibited BLs. Program disturb is typically strongly enhanced for the memory cells neighboring the select transistors and depends critically on the distance between the memory cell and the closest select transistor (SL-WL separation) [114]. In Lee et al. [114] this enhanced program disturb is explained by BBT, which occurs in inhibited lines for programming bias conditions predominantly close to the silicon surface near the select transistors with the lower gate bias provided by the GSL. This BBT generates electrons and in Lee et al. [114] the enhanced program disturb is explained by the subset of these electrons that get hot enough to overcome the oxide barrier and increase the electron injection responsible for the programming of the cells. However, by far the most important reason for the enhanced program disturb is not mentioned in Lee et al. [114] and this is because of the holes that are generated by BBT. Owing to the large potential difference between the channel and the substrate in the inhibited BLs resulting from the boosting by V_{pass}, these holes generated close to the silicon/oxide interface are accelerated toward the substrate. Close to the bottom boundary of the substrate space charge region, the accelerated holes cause impact ionization (II). The electrons generated by this II are accelerated toward the silicon surface, and because of the same large potential difference, they can easily gain enough energy to overcome the oxide barrier leading to a significant increase in electron injection. Because the enhanced program disturb is clearly caused by hot electrons, it cannot be described by the program disturb model published in Torsi et al. [112], as this model neglects hot-electron injection.

Below, the feasibility, accuracy, and predictive capability of a new concurrent multi-scale simulation model for program disturb in general, and the enhanced disturb close to the select transistors in particular, are demonstrated by means of a comprehensive experimental verification. The disturb mechanism is investigated using a 48-nm TANOS 32-bit NAND string architecture as an example.

For the simulation a simplified 2D TANOS NAND string is considered consisting of the ground select, string select, and three WL cell transistors with lateral dimensions typical for a 48-nm NAND technology. The simulated structure is shown in Fig. 39.20. Program disturb is most pronounced for inhibited WL1 cells when the WL1 bias is equal to the programming voltage. Therefore, this situation is chosen for the simulation. Complete programming pulses of 20 µs in length are simulated by the transient DD simulator GALENE III [85], including self-consistently the nonlocal models for BBT [109] and II [94] for the electron and holes mentioned before. As all transistors in the string are either in the deep subthreshold or linear region, there is no difference if the DD or the HD model is used for simulating impact ionization. Therefore, the more CPU-efficient DD model is used for the simulation. The programming and inhibit pulses applied to the WLs have a trapezoidal shape with a length of about 22 µs and a maximum applied voltage of V_{pp} and V_{pass} respectively. The dominant mechanism allowing electrons to leak from the isolated inversion layer in the inhibited cell transistors is clearly BBT. Therefore, spatial distributions of electrostatic potential and the BBT generation rate for holes resulting from the transient DD simulations are transferred to the full-band Monte-Carlo (MC) simulator ELWOMIS [12] at equidistant time sampling points (every 2.5 µs in this example). Based on very CPU-time-efficient post-processor frozen-field MC simulations [12] using the BBT rate distribution for carrier injection and considering hole and electron-initiated II [12] in the full-band simulator, the energy distribution function for electrons is evaluated at the Si surface. The coupling of the DD and MC simulators is similar to the methods published in [115] and [96]. For every time step of the MC simulator, holes are injected into the MC simulation region and the total charge of the injected holes is equal to the integral of the BBT generation rate over the MC simulation region times the time step. The spatial injection probability density is given by the spatial BBT generation rate divided by the total integrated rate. The state of the injected hole in k-space is randomly chosen with a Maxwell–Boltzmann distribution. The carriers are reflected at the silicon/oxide boundary and removed out of the simulation at all other boundaries. The MC simulation region is selected large enough so that most hot carriers are included. The stochastic error control described in [12] is applied to control the numerical effort of the MC simulations. The oxide injection current density is calculated based on the energy distribution function resulting from the MC simulation underneath the WLs at the silicon/oxide interface. To calculate this current density both tunneling and direct over-the-barrier mechanisms are considered [1]. For this

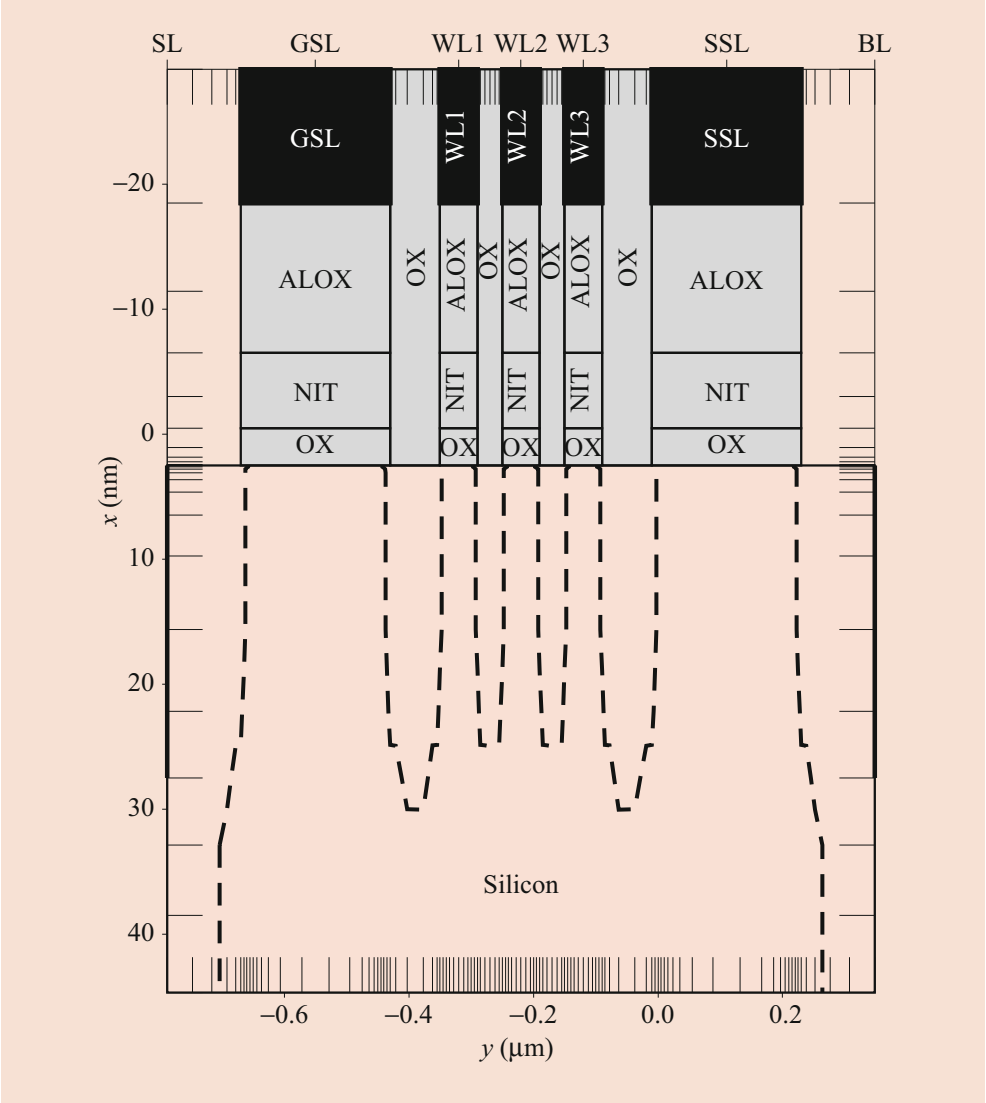

Fig. 39.20 Simplified 2D NAND string used in the simulations

example the latter mechanism was dominant. It is assumed that all injected electrons are finally trapped in the nitride layer. The injected charge per sampling time point or MC simulation is calculated as the injection current for each cell times the sampling time interval times the number of programming pulses NP for which the charge injection is calculated using the same transient DD simulation. After NP pulses, the injected charge, which is the sum over the injected charges per MC simulation (8 in this example), is fed back to the DD simulator by adding it to the charge considered in the nitride regions of the cells, and the DD and MC simulations are continued with the updated charge within the nitride layer. None of the physical models used in the simulations has been fitted or calibrated for these program disturb simulations. The model parameters applied have been either taken from the literature [12] or in the case of the BBT model have been extracted long ago based on experimental data from much older standard MOS technologies.

Figure 39.21 shows typical transient DD results for the surface potential in the middle of the channels of the cell transistors WL1–WL3 for 80 and 140 nm GSL-WL1 separation respectively. The decay of the potential after the initial programming pulse ramp-up is predominantly due to the BBT leakage current.

Figure 39.22 shows typical spatial BBT and II rate distributions from GALENE III and ELWOMIS respectively in an inhibited line for a typical programming situation in the middle of a programming pulse. Please note the much higher hole-initiated II rate for the small GSL-WL1 separation. The simulation time depends linearly on the number of DD and MC simulations necessary for an accurate simulation of the threshold voltage versus programming time characteristics.

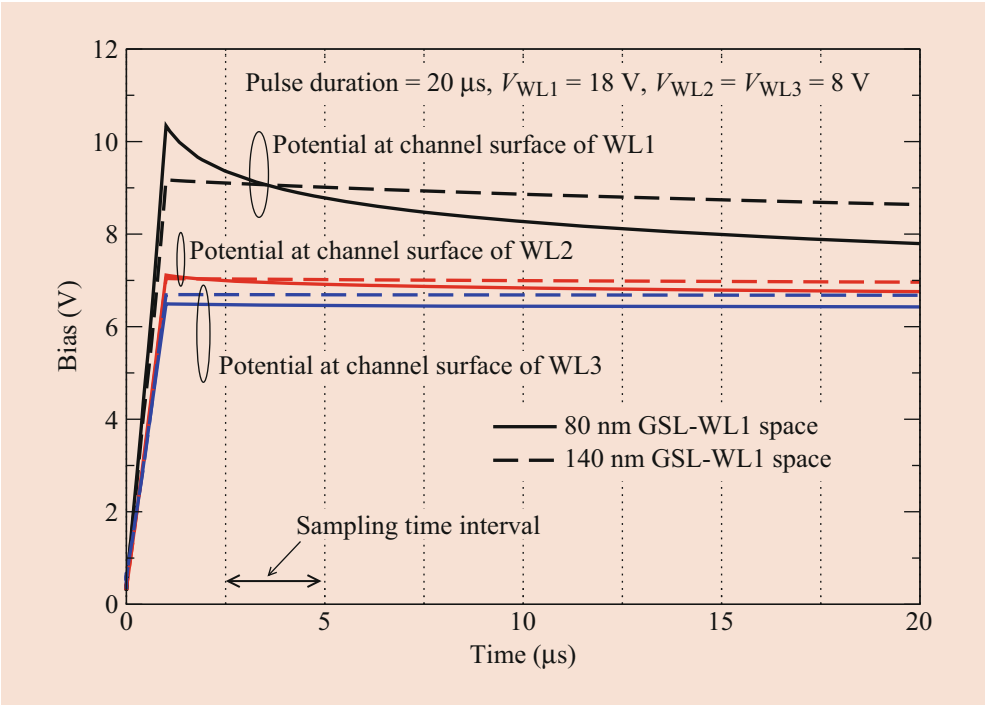

Fig. 39.21 Transient simulation results for the surface potential in the middle of the channel of the different cells for 80 nm and 140 nm GSLWL1 separation. The time sampling points for the MC simulations are marked by the dotted vertical lines

Figure 39.23 demonstrates that an update of the stored charge after NP = 5 pulses (or a total programming time increment of 0.1 ms) is sufficient to get accurate results. For NP = 5 the simulated threshold voltage increment versus programming time characteristics is shown in Fig. 39.24 for the inhibited WL1 cells, all programming voltages, and the most critical GSL-WL1 separation. Please note the large influence of the programming voltage on the program disturb. Figures 39.25, 39.26, 39.27, and 39.28 show a comparison between the simulated (big dots) and measured threshold voltages in the inhibited WL1 cells as a function of programming voltage for all four considered GSL-WL1 separations after a total programming time of 2 ms (100 pulses). The drawn lines in these figures represent the distribution of 15 measured samples. The horizontal lines indicate from bottom to top the minimum, quartile $Q_{0.25}$, median, quartile $Q_{0.75}$, and maximum of the distribution. Taking into consideration the complicated physics of program disturb, the simplified 2D structure used in the simulations and the fact that none of the physical models has been calibrated for these simulations, the agreement between the simulated and measured threshold voltage shifts is very impressive. The important influence of programming voltage and GSL-WL1 separation on WL1 threshold voltage is accurately represented by the new simulation model. This proves that the most important physical mechanisms governing program disturb are well represented by the simulation model in a predictive manner. Compared with the measured characteristics, the simulated threshold voltages increase somewhat faster with increasing programming voltage. This is most probably due to the neglect of charge leakage from the nitride layer between programming pulses in the simulations.

The demonstrated comprehensive comparison between simulation and experiment shows that the dependence of program disturb on WL-SL separation and programming voltage can be accurately described by a concurrent multi-scale model without fitting any model parameters.

39.4 Numerical Solution of the Drift-Diffusion Model: Some Historical Remarks

In the following, the development of the numerical solution methods for the DD equations will be reviewed, as much can be learned from this development for comparable tasks in the future. Aspects covered well in the literature will be only briefly mentioned by citing the appropriate references. Other aspects that are very important as well but rarely mentioned in the literature or even nearly forgotten today will be highlighted. In particular, the aspect of preserving the inherent "stability" of the underlying differential equations in terms of monotonicity properties during the discretization process will be carefully examined. The general flow of arguments presented here follows closely those outlined in Meinerzhagen [116]. Several details have also been previ-

ously published in Engl et al. and Bank et al. [75,117]. Some hints concerning the HD model will be given at the end.

As the potentials Φ_n and Φ_p cover a much smaller range of numerical values than do the densities n, p, intermediate and final solutions of the DD system of equations are typically saved by storing Ψ, Φ_n, and Φ_p instead of Ψ, n, and p. Moreover, formulating the DD equations in the new set of variables makes it much easier to introduce the solution algorithms that are typically applied. Substituting p and n in the time-independent version of (39.146)–(39.148) by (39.141) and (39.142) and using the alternative expressions for the particle current densities (39.143) and (39.144) result in the following alternative forms of the stationary DD equations:

$$TP(\Psi, \Phi_p, \Phi_n) := -\nabla_{\boldsymbol{r}} \cdot [\kappa \nabla_{\boldsymbol{r}} \Psi]$$

$$+ e\left(n_i\left(\exp\left(\frac{\Psi - \Phi_n}{V_T}\right) - \exp\left(\frac{\Phi_p - \Psi}{V_T}\right)\right) - N_D + N_A\right) = 0 \qquad (39.149)$$

$$TH(\Psi, \Phi_p, \Phi_n) \qquad (39.150)$$

$$:= -\nabla_{\boldsymbol{r}} \cdot \left(n_i \exp\left(\frac{\Phi_p - \Psi}{V_T}\right) \mu_p \nabla_{\boldsymbol{r}} \Phi_p\right) - G$$

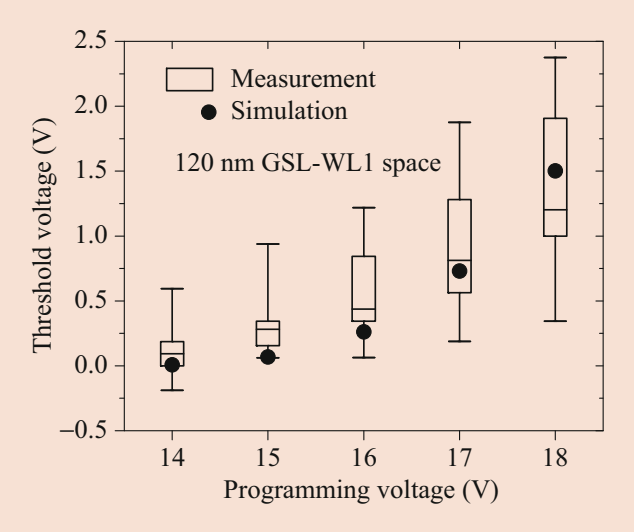

Fig. 39.27 Threshold voltage as a function of programming voltage after a total programming time of 2 ms for 120-nm GSL-WL1 separation; comparison of simulation and measurement

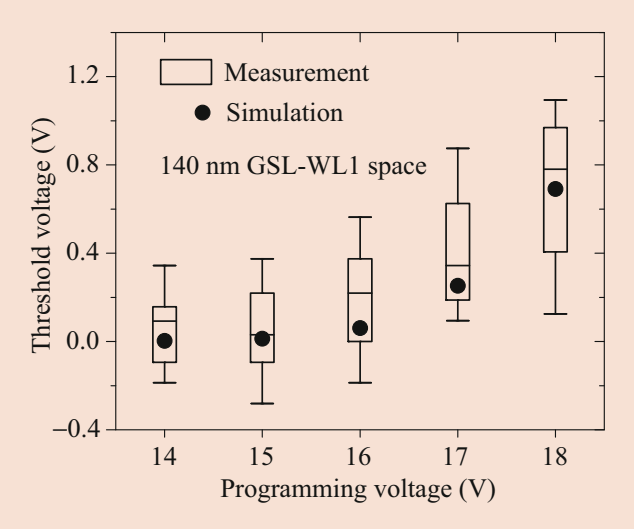

Fig. 39.28 Threshold voltage as a function of programming voltage after a total programming time of 2 ms for 140-nm GSL-WL1 separation; comparison of simulation and measurement

$$
\begin{aligned}
&= -\nabla_{\boldsymbol{r}} \cdot \left(n_{\mathrm{i}} \exp\left(\frac{-\Psi}{V_{\mathrm{T}}}\right) V_{\mathrm{T}} \mu_{\mathrm{p}} \nabla_{\boldsymbol{r}} \exp\left(\frac{\Phi_{\mathrm{p}}}{V_{\mathrm{T}}}\right)\right) - G \\
&=: \hat{TH}\left(\Psi, \exp\left(\frac{\Phi_{\mathrm{p}}}{V_{\mathrm{T}}}\right), \Phi_{\mathrm{n}}\right) = 0
\end{aligned}
$$

$$
\begin{aligned}
&TE(\Psi, \Phi_{\mathrm{p}}, \Phi_{\mathrm{n}}) \qquad (39.151) \\
&:= -\nabla_{\boldsymbol{r}} \cdot \left(n_{\mathrm{i}} \exp\left(\frac{\Psi - \Phi_{\mathrm{n}}}{V_{\mathrm{T}}}\right) \mu_{\mathrm{n}} \nabla_{\boldsymbol{r}} \Phi_{\mathrm{n}}\right) + G \\
&= +\nabla_{\boldsymbol{r}} \cdot \left(n_{\mathrm{i}} \exp\left(\frac{\Psi}{V_{\mathrm{T}}}\right) V_{\mathrm{T}} \mu_{\mathrm{n}} \nabla_{\boldsymbol{r}} \exp\left(\frac{-\Phi_{\mathrm{n}}}{V_{\mathrm{T}}}\right)\right) + G \\
&=: -\hat{TE}\left(\Psi, \Phi_{\mathrm{p}}, \exp\left(\frac{-\Phi_{\mathrm{n}}}{V_{\mathrm{T}}}\right)\right) = 0 \,.
\end{aligned}
$$

The boundary conditions remain unchanged, which means that at ideal ohmic contacts $\Phi_{\mathrm{p}} = \Phi_{\mathrm{n}} = \Phi_{\mathrm{M}}$ hold. It can be shown that the above system of differential equations has a unique solution provided a number of reasonable assumptions are fulfilled, especially for the generation term G. Please refer to Ladyshenskaya and Uraltseva [118] for a general theory and to Mock and Seidmann [119, 120] for special results concerning the DD set of equations. Moreover, there is an important property that deserves special attention.

I. All above operators TP - TE are in divergence from and result in important conservation laws if integrated over a finite volume and after the application of the divergence theorem.

For example, integrating $TE + TH$ over the simulation domain results in Kirchhoff's law for the stationary terminal currents of the device under consideration. If a numerical device model is used inside a circuit simulator, it is absolutely mandatory that this law is exactly reproduced by the numerical model. Therefore, it is very important to maintain the validity of such conservation laws in some sense during the discretization process.

The most important solution algorithm for the DD system is an iterative method often addressed as Gummel's nonlinear relaxation method [121]. Assuming that the result Ψ_k, $\Phi_{\mathrm{p},k}$, $\Phi_{\mathrm{n},k}$ after iteration k is known, this method evaluates the new approximate solution after iteration $k+1$ by solving the three boundary value problems (39.149)–(39.151) successively as follows:

$$
\begin{aligned}
TP(\Psi_{k+1}, \Phi_{\mathrm{p},k}, \Phi_{\mathrm{n},k}) &= 0 \,, \qquad (39.152) \\
TH(\Psi_{k+1}, \Phi_{\mathrm{p},k+1}, \Phi_{\mathrm{n},k}) &= 0 \,, \\
TE(\Psi_{k+1}, \Phi_{\mathrm{p},k+1}, \Phi_{\mathrm{n},k+1}) &= 0
\end{aligned}
$$

For the above partial differential equations, it is always assumed that the variable with the highest number of derivatives in the equation is updated and the other variables are kept unchanged. The individual nonlinear equations in (39.152) are typically solved by Newton's method, which converges very fast and robust, even for bad initial solutions, if the underlying equation is nearly linear. Therefore, Newton's method is typically applied for the operators $\hat{TH}$ and $\hat{TE}$ defined in (39.150) and (39.151) and not for the operators TH and TE, as $\hat{TH}$ and $\hat{TE}$ are nearly linear in the new variables:

$$
\zeta_{\mathrm{p}} := \exp\left(\frac{\Phi_{\mathrm{p}}}{V_{\mathrm{T}}}\right) \,, \quad \zeta_{\mathrm{n}} := \exp\left(\frac{-\Phi_{\mathrm{n}}}{V_{\mathrm{T}}}\right) \,, \qquad (39.153)
$$

provided that carrier generation G has no dominant influence. These new variables are often addressed as Slotboom variables because they were first introduced in Slotboom [122] and the advantages they have for generating "stable" discretization schemes were probably mentioned in Slotboom [123] for the first time. Nevertheless, it is still possible to calculate the Newton updates based on the numerically more convenient Jacobians TH and TE and the variables Φ_p and Φ_n. The only modification necessary for performing the Newton iterations for the more linear operators is to modify the Newton update itself as shown below for the hole continuity equation and the solution variable before ($\Phi_{p,b}$) and after ($\Phi_{p,a}$) one Newton step.

$$\Phi_{p,a} = \Phi_{p,b} + \delta\Phi_p \;\rightarrow \qquad (39.154)$$
$$\Phi_{p,a} = \Phi_{p,b} + V_T \ln\left(1 + \frac{\delta\Phi_p}{V_T}\right)$$

$\delta\Phi_p$ is the Newton update calculated using the Jacobian of TH for the variable ϕ_p. For a general report on using alternative solution variables for enhancing convergence, please refer to Bach et al. [124].

In order to understand which criteria in addition to the mandatory consistency criterion should be considered for the discretization of the continuous operators TP, TH and TE, it is very useful to look at the Jacobians of TP, $\hat{T}H$, and $\hat{T}E$, which are necessary for performing Gummel's nonlinear relaxation method based on Newton's method. These Jacobians are typically evaluated for some existing intermediate solution Ψ_b, $\Phi_{p,b}$, and $\Phi_{n,b}$, and operate on the functions $\delta\Psi$, $\delta\zeta_p$, and $\delta\zeta_n$. If in addition for the calculation of the Jacobians the dependence of the mobilities on the solution variables is neglected, these Jacobians have the following form:

$$\frac{\partial}{\partial\Psi} TP(\Psi_b, \Phi_{p,b}, \Phi_{n,b})[\delta\Psi] := -\nabla_{\boldsymbol{r}} \cdot [\kappa\nabla_{\boldsymbol{r}}\delta\Psi] \qquad (39.155)$$
$$+e\left(n_i\left(\exp\left(\frac{\Psi_b - \Phi_{n,b}}{V_T}\right) + \exp\left(\frac{\Phi_{p,b} - \Psi_b}{V_T}\right)\right)\right)\delta\Psi$$

$$\frac{\partial}{\partial\zeta_p}\hat{T}H(\Psi_b, \zeta_{p,b}, \Phi_{n,b})[\delta\zeta_p] \qquad (39.156)$$
$$:= -\nabla_{\boldsymbol{r}} \cdot \left(n_i \exp\left(\frac{-\Psi_b}{V_T}\right) V_T\mu_{p,b}\nabla_{\boldsymbol{r}}\delta\zeta_p\right)$$
$$-\frac{\partial}{\partial\zeta_p}G(\Psi_b, \zeta_{p,b}, \zeta_{n,b})\delta\zeta_p$$

$$\frac{\partial}{\partial\zeta_n}\hat{T}E(\Psi_b, \Phi_{p,b}, \zeta_{p,n})[\delta\zeta_n] \qquad (39.157)$$
$$:= -\nabla_{\boldsymbol{r}} \cdot \left(n_i \exp\left(\frac{\Psi_b}{V_T}\right) V_T\mu_{n,b}\nabla_{\boldsymbol{r}}\delta\zeta_n\right)$$
$$-\frac{\partial}{\partial\zeta_n}G(\Psi_b, \zeta_{p,b}, \zeta_{n,b})\delta\zeta_n.$$

All above partial derivatives with respect to solution variables are assumed to be Frećhet derivatives on suitable function spaces [125]. If only direct recombination and Shockley–Read–Hall recombination [37] are considered for the Frećhet derivative of the carrier generation G

$$-\frac{\partial}{\partial\zeta_p}G(\Psi_b, \zeta_{p,b}, \zeta_{n,b}) > 0 \qquad (39.158)$$
$$-\frac{\partial}{\partial\zeta_n}G(\Psi_b, \zeta_{p,b}, \zeta_{n,b}) > 0$$

holds. With this additional condition, all Jacobians (39.155)–(39.157) have important properties that again deserve special attention. They are:

II. Self-adjoint
III. Positive definite
IV. Of monotone type

if appropriate boundary conditions are assumed for the function spaces considered [125]. In particular, property IV is very important, as it means that for all these Jacobians monotonicity theorems hold [125, chapter 23.5], which restrict, for example, the possible form of the update functions $\delta\Psi$, $\delta\zeta_p$, and $\delta\zeta_n$ during the Newton iterations required for Gummel's nonlinear relaxation method very much and enhance the robustness and convergence properties of this solution method decisively.

The mathematical properties of the model after discretization should be as similar as possible to the properties of the continuous model! If this is fulfilled, the discrete model is an analogon of the continuous model, even if only coarse grids can be afforded, which is typically the case. This property is very important for the discretization error control on coarse grids. Therefore, discretization methods that are able to conserve conditions I–IV in some discrete sense are preferred.

The first 2D DD simulations used a rectangular solution domain and tensor product grids [123, 126] so that standard finite difference discretization methods for tensor product grids could be applied, which conserved most of the conditions mentioned above. However, many device cross sections were not rectangular, so that at least at the beginning of multi-dimensional numerical semiconductor device modeling, many groups developed discretization methods (see Barnes and Lomax, Buturla et al., Hachtel et al., Bank et al., Bürgler et al., and Mole [117, 127–132] and citations therein) for nonrectangular solution domains based on the

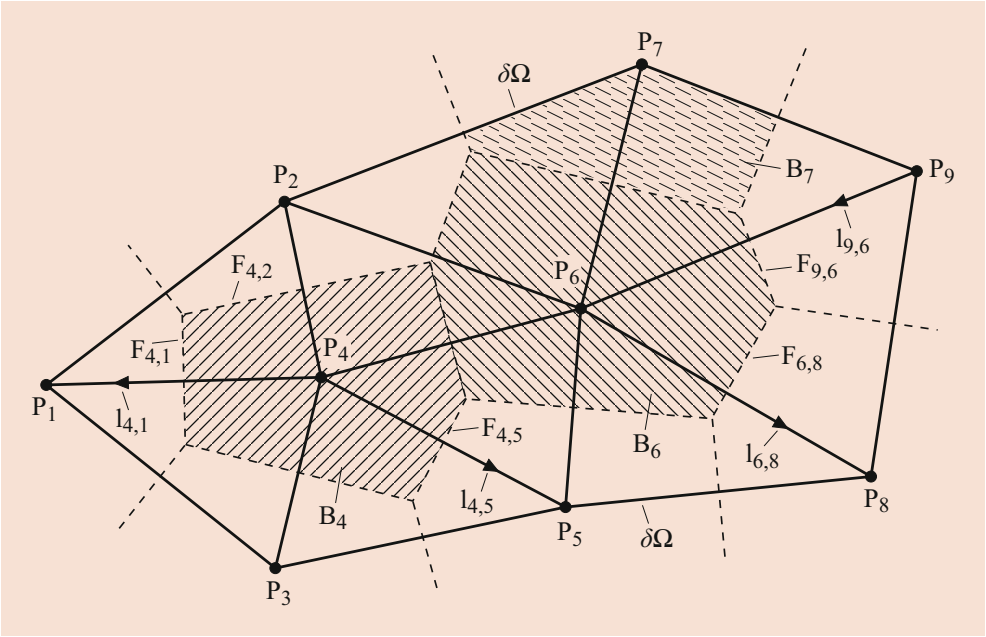

Fig. 39.29 Voronoi diagram (dashed lines) and Delaunay tessellation (thick drawn lines) for a 2D example with nine grid points

finite element approach [133], but it turned out that general finite element methods typically have problems conserving conditions I–IV [117, 128, 134, 135]. Finally, even for solution domains with complicated polygonal boundaries that cannot be discretized efficiently by a tensor product grid, the method of choice used today by the vast majority of DD and HD simulators is a straightforward generalization of the integration method published in Varga [51, chapter 6] for 2D tensor product grids. This method is able to conserve conditions I–IV, as will be shown below. This generalization for 2D problems was already briefly mentioned in Varga [51] using the early work of MacNeal [136] as a guideline. This general method is addressed as box integration method in Engl et al. [75] and as box method in Bank et al. [117] and today often named finite volume method [137]. An especially well-documented example of this historical development from the application of general finite element methods to the final exclusive application of the finite volume method is the development of numerical device modeling codes at IBM research. There, two groups independently developed two general numerical device modeling codes: one group with a clear focus on the application of general finite element methods [129,130,134] and the other group shifting more and more from hybrid finite element/finite volume discretization methods to the exclusive application of the finite volume method [128,138]. Both codes were developed over a decade until the beginning of the 1980s. Ten years later the finite element code development is no longer mentioned at all in a comprehensive review paper about TCAD development at IBM with more than 200 citations [139].

Possibly the first mathematical analysis of the general box integration method for the DD model in 3D is attributed to Sever [140]. The box integration method can be interpreted as a finite element method [117], but the grid elements for this method (e.g., triangles) cannot be considered as the basis from which the discretization method proceeds, as is the case for a general finite element method [133], but instead the elements are constructed in a unique way based on the predefined grid points. The method is based on the construction of two dual grids: the Voronoi diagram and the Delaunay tessellation. The early work of two Russian mathematicians M.G. Voronoi [141] and B.N. Delone [142] is typically cited in this context but the method in 2D is even older and has been rediscovered various times. Figure 39.29 is used to explain the basic principles of this method. The n grid points P_k ($n = 9$ in this example) with the coordinates $\boldsymbol{r}_k$ are considered as given. In a first step for each point with index k, its Voronoi volume V_k is constructed as the set of all points in space that are closer to P_k than to any other grid point.

$$V_k := \left\{\boldsymbol{r} | \parallel \boldsymbol{r} - \boldsymbol{r}_k \parallel \leq \parallel \boldsymbol{r} - \boldsymbol{r}_j \parallel, j = 1, \ldots, n, j \neq k\right\} \tag{39.159}$$

Moreover, for each grid point P_k its environment S_k is defined by

$$S_k := \left\{j | \mathcal{M}(V_k \cap V_j) \neq 0, j = 1, \ldots, n, j \neq k\right\}. \tag{39.160}$$

$\mathcal{M}$ indicates the 1D Lebesgue measure $\mathcal{M}_1$ for 2D problems and the 2D Lebesgue measure $\mathcal{M}_2$ for 3D problems. With this environment, the boundary of V_k is given by

$$\delta V_k := \bigcup_{j \in S_k} (V_k \cap V_j). \tag{39.161}$$

The union of all Voronoi volume boundaries defines the Voronoi diagram. Based on this diagram the dual grid structure of the Delaunay grid is defined by defining the set of edges D for this grid by the straight lines $l_{i,k}$ between the points P_i and P_k for which $\mathcal{M}(V_k \cap V_i) \neq 0$ and i and k vary between 1 and n with $i \neq k$. Please note that the $l_{i,k}$ are oriented curves starting at P_i and ending at P_k. If only the edges of the Delaunay grid without orientation are important, $l_{i,k}$ and $l_{k,i}$ can be considered equal. The typical elements in such a Delaunay grid are triangles for 2D problems and tetrahedra for 3D problems. But 2D and 3D rectangular tensor product grids are special cases for this method and fit perfectly into this framework. The DD and HD problems are typically formulated as boundary value problems on some finite region Ω, and in order to incorporate Neumann-type boundary conditions into the framework of box integration in a natural manner, the boundary $\delta\Omega$ is typically assumed to be composed of edges (faces in 3D) of the Delaunay grid elements. In the given example in Fig. 39.29 $\delta\Omega$ is the closed polygonal line composed of $l_{1,3}$, $l_{3,5}$, $l_{5,8}$, $l_{8,9}$, $l_{9,7}$, $l_{7,2}$, and $l_{2,1}$, and Ω is the interior of this closed polygonal line. The Voronoi volumes for the grid points on $\delta\Omega$ are typically unbounded, but for box integration, bounded boxes are mandatory. This leads to the following definitions:

$$B_k = V_k \cap (\Omega \cup \delta\Omega) \tag{39.162}$$

$$F_{k,j} = \delta V_k \cap \delta V_j \cap \Omega \tag{39.163}$$

Clearly, $\mathcal{M}(F_{k,j}) \geq 0$ and $F_{k,j}$ is only relevant if $l_{k,j}$ is part of the Delaunay grid. If no additional constraints are fulfilled, it can happen that $\mathcal{M}(F_{k,j}) = 0$ for some edge of the Delaunay grid. This is typically not good for the consistency of the discretization method and mostly avoided by constructing the grid in such a manner that, for 2D problems such as the given example, the Delaunay triangles that have some common boundary edge with $\delta\Omega$ have all their interior angles smaller than 90 degrees. Such triangles are called acute or non-obtuse. See, for example, Baker et al. [143], for algorithms generating grids in such a manner. If this additional condition is fulfilled, $\mathcal{M}(F_{k,j}) > 0$ for all edges of the Delaunay grid holds and only the boxes B_k of grid points on the boundary $\delta\Omega$ share some boundary with $\delta\Omega$ such as B_7 for the given example. Similar additional conditions with comparable consequences are considered for 3D problems as well [140]. For the box integration process presented here, it is not necessary for all triangles to be non-obtuse for preserving condition **IV**, but for finite element discretization schemes, this condition must be fulfilled [117, 143].

The boundary value problems TP, $\hat{T}H$, and $\hat{T}E$ defined in (39.149)–(39.151) and considered as individual problems that are solved separately have the following common form:

$$-\nabla_{\boldsymbol{r}} \cdot (a(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u) \nabla_{\boldsymbol{r}} u) + f(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u) = 0 \tag{39.164}$$

where $u(\boldsymbol{r})$ is the solution variable. Therefore, u is either Ψ or ζ_{p} or ζ_{n}. Moreover, $a(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u) > 0$ always holds. The dependence of a and f on $\nabla_{\boldsymbol{r}} u$ and u considers the typical physical models for the mobilities and the generation rate and their dependence on the solution variables [37]. The first step always performed for the box method is to integrate (39.164) over the box B_k for each grid point P_k, which is not determined by a Dirichlet boundary condition. Moreover, the divergence theorem is used to transform the suitable parts of the integral over B_k into integrals over δB_k. This yields:

$$-\sum_{j \in S_k} \int_{F_{k,j}} a(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u)(\nabla_{\boldsymbol{r}} u \cdot \boldsymbol{v}_{k,j}) \, \mathrm{d}F + \int_{B_k} f(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u) \, \mathrm{d}V = 0. \tag{39.165}$$

$\boldsymbol{v}_{k,j}$ is a unit vector that has the same orientation as $l_{k,j}$. The above formulation is for the 3D case, where the first integrals integrate fluxes over an area and the remaining part is a volume integral. In the 2D case, the first integrals are line integrals and the second part is an area integral. If $\mathcal{M}(B_k \cap \delta\Omega) \neq 0$, it can typically be assumed that for this part of the boundary $(B_k \cap \delta\Omega)$, a Neumann-type boundary condition holds such that the flux through this part of the boundary is zero. This applies for instance to B_7 in the example, if for P_7 no Dirichlet boundary condition is given. It is clear that

$$\int_{F_{k,j}} a(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u)(\nabla_{\boldsymbol{r}} u \cdot \boldsymbol{v}_{k,j}) \, \mathrm{d}F = -\int_{F_{j,k}} a(\boldsymbol{r}, \nabla_{\boldsymbol{r}} u, u)(\nabla_{\boldsymbol{r}} u \cdot \boldsymbol{v}_{j,k}) \, \mathrm{d}F \,, \tag{39.166}$$

where the first integral is related to P_k and the box integration over B_k, whereas the second integral is related to the point P_j and the box integration over B_j. During the discretization process the integrals in (39.165) are typically approximated independently by difference approximations and quadrature rules such that a consistent discrete approximation is generated. For conserving property **I** it is important that (39.166) holds exactly after discretization. If this is the case the discretized formulas for two points P_j and P_k with $k \in S_j$ (such as P_4 and P_6 in the example) can be summed, leading to an expression where the sum of the

discretized integrals over B_k and B_j is represented by the discretized flux integrals over the boundary of $B_k \cup B_j$, which is $\left((\cup_{i\in S_k} F_{k,i}) \cup (\cup_{i\in S_j} F_{j,i}) \cup ((B_k \cup B_j) \cap \delta\Omega)\right) \backslash F_{k,j}$. The resulting expression can be interpreted as a discrete version of the divergence theorem for $B_k \cup B_j$ and its boundary. If the discretized problem is solved exactly, this discretized version of the integral theorem holds exactly and does not depend on any discretization error. Relations of this kind are very helpful for checking the global numerical accuracy and the consistent calculation of, for instance, terminal currents.

In order to study how to preserve properties **II**–**IV** during the discretization process, Eq. (39.164) is simplified again by neglecting the dependence of a on the solution variable u and considering only the dependence of direct and SRH generation on the solution variable. Thus, (39.164) simplifies to

$$-\nabla_{\boldsymbol{r}} \cdot (a(\boldsymbol{r})\nabla_{\boldsymbol{r}} u) + f(\boldsymbol{r}, u) = 0 \tag{39.167}$$

and $\frac{\partial}{\partial u} f(\boldsymbol{r}, u) > 0$ always holds. If the discretization preserves property **I**, the discretized integral over $F_{k,j}$ in (39.165) can be considered as a function $\mathcal{F}(l_{k,j})$. This implies that $\mathcal{F}$ also depends on everything clearly connected to $l_{k,j}$ such as P_k and P_j. As (39.166) shall be preserved $\mathcal{F}(l_{k,j}) = -\mathcal{F}(-l_{k,j}) = -\mathcal{F}(l_{j,k})$ must hold. Let us assume that the discrete solution is represented by a vector $\boldsymbol{u}$ with n entries u_j and each u_j is the discrete approximation of the function u at the point P_j. The Jacobian of the equation system after discretization should be self-adjoint (symmetric). This requires the condition $\frac{\partial}{\partial u_j}\mathcal{F}(l_{k,j}) = \frac{\partial}{\partial u_k}\mathcal{F}(l_{j,k})$. There are not too many alternatives left if these above two conditions must be fulfilled simultaneously. One discretization formula, for which both conditions hold, is

$$\mathcal{F}(l_{k,j}) = -\frac{\mathcal{M}(F_{k,j})}{\mathcal{M}_1(l_{k,j})}\overline{a}(l_{k,j})(u_j - u_k). \tag{39.168}$$

Here, $\overline{a}(l_{k,j})$ is a suitable mean value of $a(\boldsymbol{r})$ that can be considered as a function of $l_{k,j}$ and for which $\overline{a}(l_{k,j}) = \overline{a}(l_{j,k}) > 0$ must be satisfied. If in addition the integral over the box B_k in (39.165) is discretized using the simplest quadrature formula

$$\int_{B_k} f(\boldsymbol{r}, u)\,\mathrm{d}V \approx \mathcal{V}(B_k) f(\boldsymbol{r}_k, u_k), \tag{39.169}$$

the strict diagonal dominance of the Jacobian matrix of the discrete system is guaranteed as well. $\mathcal{V}$ indicates the 2D Lebesgue measure for 2D problems and the 3D Lebesgue measure for 3D problems. So far, only the discretization for all points that are not given by a Dirichlet boundary condition has been studied. The set of indices of these points should be given by S_B. Moreover, S_D contains all indices of points that are given by a Dirichlet condition. The Jacobian entries for the latter points are simply 1 for the main diagonal and 0 for the other entries. In summary, the Jacobian of the discretized boundary value problem (39.167) is strictly diagonal dominant, all main diagonal elements are strictly positive, and all other elements are negative or zero. Such matrices are positive definite and M-matrices as well, which means that their inverse matrix has only elements that are positive or zero [51]. These properties are very beneficial for a large number of solution algorithms solving linear equations involving matrices. The convergence of iterative methods such as the Jacobi or Gauss–Seidel methods is guaranteed [51], semi-iterative methods such as conjugated gradient algorithms work well [144], and even Gaussian elimination profits, because a pivot element search is not necessary and the accumulation of the rounding error during elimination is well controlled. Finally, and probably most importantly, the discrete system introduced above is of the monotone type, which means that important stability inequalities can even be derived for the maximum norm, which is the most important norm for practical applications. For example, in Samarskij [145, chapter 4.2.2] the following is proven. If for all $k \in S_\mathrm{B}$

$$\sum_{j\in S_k} -\frac{\mathcal{M}(F_{k,j})}{\mathcal{M}_1(l_{k,j})}\overline{a}(l_{k,j})(\delta u_j - \delta u_k) + \mathcal{V}(B_k)\frac{\partial}{\partial u} f(\boldsymbol{r}_k, u_{k,b})\delta u_k = R_k \tag{39.170}$$

and $\delta u_k = b_k$ for all $k \in S_\mathrm{D}$, then the following stability inequality holds for the discrete solution:

$$\max_{1\le k\le n} |\delta u_k| \le \max_{k\in S_\mathrm{D}} |b_k| + \max_{k\in S_\mathrm{B}} \frac{|R_k|}{\mathcal{V}(B_k)\frac{\partial}{\partial u} f(\boldsymbol{r}_k, u_{k,b})} \tag{39.171}$$

This inequality is directly applicable for the estimation of the maximum Newton correction if the Jacobian on the left-hand side of (39.170) is used to solve the discretized nonlinear problem (39.167) by Newton's method. Moreover, such stability inequalities are very useful for evaluating upper bounds for the discretization error, even for the nonlinear problem (39.167). In Rafferty et al. [135] an excellent example is given demonstrating clearly how bad the discretization error is controlled if the off-diagonal elements of the Jacobian of the discretized electron continuity equation have both signs. Moreover, it is also shown in Rafferty et al. [135] for the same problem that the discrete solution becomes much more accurate and very well controlled by the applied voltages if all off-diagonal elements of the Jacobian always become negative or zero after a modification of the grid. The underlying reason is not as falsely stated in Bürgler et al. [131] that the original grid had one obtuse triangle but

that the original grid was not the Delaunay grid constructed on the basis of the Voronoi diagram, whereas the modified grid is the Delaunay grid. As already pointed out earlier, a Delaunay grid may contain obtuse triangles!

Another advantage of the discretization scheme presented above is that it allows a straightforward incorporation of the Scharfetter–Gummel discretization formula for the balance equations, which was originally developed for rectangular grids [75, 117, 146]. The application of this discretization formula is mandatory for achieving accurate simulation results on coarse grids. For general finite element schemes, it is typically very difficult to incorporate this formula, but for the scheme described above, it is easily done by choosing $\overline{a}(l_{k,j})$ as follows:

For holes:

$$\overline{a}(l_{k,j}) = n_{\mathrm{i}}\overline{\mu_{\mathrm{p}}}(l_{k,j})V_{\mathrm{T}}\frac{\Psi_j - \Psi_k}{\exp\left(\frac{\Psi_j}{V_{\mathrm{T}}}\right) - \exp\left(\frac{\Psi_k}{V_{\mathrm{T}}}\right)}. \quad (39.172)$$

For electrons:

$$\overline{a}(l_{k,j}) = n_{\mathrm{i}}\overline{\mu_{\mathrm{n}}}(l_{k,j})V_{\mathrm{T}}\frac{\Psi_k - \Psi_j}{\exp\left(\frac{-\Psi_j}{V_{\mathrm{T}}}\right) - \exp\left(\frac{-\Psi_k}{V_{\mathrm{T}}}\right)}. \quad (39.173)$$

$\overline{\mu_{\mathrm{n,p}}}(l_{k,j})$ are appropriate mean values of the mobilities that can be regarded as a function of the edge $l_{k,j}$. Results concerning the consistency and convergence of the discretization scheme described above for the balance equations can be found in Sever [140].

Gummel's nonlinear relaxation method (39.152), performed in such a manner that the relevant discrete Jacobian matrices fulfill conditions **II**–**IV**, which typically means that derivatives with respect to the solution variables are neglected for the mobilities and impact ionization, nearly always converges even for very bad initial solutions. One of the rare counterexamples is given in Bach et al. [124]. The convergence is typically slow for high current applications, but is very predictable; thus, the solution accuracy can be estimated very reliably during the iteration process [99]. This allows to switch to more coupled methods, like a simultaneous Newton method, as soon as the numerical solution accuracy is so high that the simultaneous Newton method is within the range where it converges quadratically. Of course, after switching all derivatives should be considered in the Jacobian matrix of the fully simultaneous Newton method. The availability of this combination of solution methods for the DD model featuring high robustness even for bad initial solution and high accuracy at the same time is possibly one reason why the DD model is still the numerical device model that is applied by far the most, even for nanoscale devices, where its physical accuracy is certainly questionable [83]. The above comments concerning the beneficial effect on robustness of neglecting the derivatives of the mobilities and impact ionization also apply to other nonlinear relaxation methods [124, 147] and are even valid for the fully coupled Newton method outside the range of quadratic convergence.

It is rather straightforward to extend the box integration method, including a Scharfetter–Gummel-type discretization for the energy flux densities to the HD model [79]. A nonlinear relaxation method with convergence properties that are coparable to Gummel's method has been published in Meinerzhagen et al. [98] and evaluated in Apanovich et al. [148] for the HD model. For this method and the numerical solution algorithms of the HD model in general, convergence robustness also increases significantly if certain derivatives with respect to mobilities and impact ionization are turned off in order to enhance the "stability" of the discretized equations.

39.5 Conclusion

The SHE method for the solution of the BTE is presented. This method enhances the applicability and versatility of the BTE model very much compared with typical MC solutions. This is shown in three examples: the calculation of plasma waves in GaAs bulk material, the detailed investigation of strong non-equilibrium transport in a one-dimensional nanoscale silicon N^+NN^+ structure, and the calculation of small-signal high-frequency figures of merit such as the maximum frequency of oscillation for an ultimately scaled silicon germanium heterojunction bipolar transistor. Sequential multi-scale DD and HD transport models for silicon are derived from the BTE. Owing to this derivation, called multi-scale analysis, it is possible to calculate the transport and noise parameters for these DD and HD models based on the solution of the BTE model under homogeneous material and field conditions in a consistent manner. Thus, the accuracy of the computationally more efficient DD and HD models is significantly enhanced. This is of paricular importance as it is typically impossible to evaluate the full set of transport and noise parameters experimentally. The historical development of the DD or the HD model-based concurrent multi-scale models for the efficient and accurate modeling of hot carrier or BBT effects is outlined. Moreover, it is demonstrated that the program disturb effect in modern NAND-Flash memories can be modeled accurately and efficiently using a concurrent multi-scale model based on the DD model, a nonlocal BBT model, and a post-processor MC model for modeling hot electrons and holes. Finally, based on the historic development of the spatial discretization of the DD model, it is shown how important it is for the control of the discretization error on coarse grids to preserve the monotonicity properties of the underlying partial differential equations in the final discretized model. The authors believe that this observation

should serve as a guideline for the development of discretization methods for transport models in the future.

The authors would like to apologize to all whose work deserves to be mentioned in this chapter but has not been included.

Acknowledgments The authors gratefully acknowledge discussions with Rainer Thoma (IBM), Sung-Min Hong (GIST), and Mikhail Isaackowitsch Vexler (Ioffe).

Bernd Meinerzhagen is Full Professor and Head of the Institute for Electron Devices and Circuits at the Technical University Braunschweig, Braunschweig, Germany. He received the Dipl.-Ing. degree in Electrical Engineering, the Dipl.-Math. degree in Mathematics, the Dr.-Ing. degree in Electrical Engineering, and the "venia legendi," all from the RWTH Aachen (Aachen University of Technology), Aachen, Germany, in 1977, 1981, 1985, and 1995 respectively. From 1978 to 1986, he worked mainly on the development of numerical device modeling codes as a Research and Teaching Assistant at the RWTH Aachen. In 1986, he joined AT&T Bell Laboratories, Allentown, PA, USA, as a Member of Technical Staff, where he developed advanced numerical models for MOS substrate and gate currents. From 1988 to 1995 he was the Head of the Research and Development Group for Silicon technology modeling and simulation (TCAD) at the RWTH Aachen, and he continued this research as Professor at the University of Bremen, Bremen, Germany, between 1995 and 2003. His research interests are focused on the physics, characterization, modeling and design of Si/SiGe integrated devices and circuits and on the mathematical foundations of electrical engineering. Prof. Meinerzhagen has coauthored a book, several book chapters and more than 300 papers published in international journals and conference proceedings and has been a Technical Program Committee member of IEDM, ESSDERC, SISPAD, IWCE, and other conferences.

Christoph Jungemann received the PhD degree in Electrical Engineering from RWTH Aachen University, Aachen, Germany. After working at Fujitsu Ltd., Kawasaki, Japan; the University of Bremen, Bremen, Germany; Stanford University, Stanford, CA, USA; and the Braunschweig University of Technology, Braunschweig, Germany, he became a Professor of microelectronics with Bundeswehr University Munich, Neubiberg, Germany, in 2006. Since 2011, he has held the chair of electromagnetic theory with RWTH Aachen University. His research interests are in the area of numerical device simulation.

Abstract

The chapter addresses the issue of transport models applied to the amorphous chalcogenides which, in the last decades, have acquired importance in the design and manufacture of solid-state memories. After an introductory part where the main properties of the materials are outlined, ab initio atomistic, and semiclassical computational approaches for the study of the atomic structure and the features of electronic states of chalcogenides are briefly illustrated. This part is concluded by a description of the resistance-drift phenomenon and of how the simulation approaches contributed to the comprehension of the underlying physics.

The successive section summarizes a variety of physical models and numerical methods useful for describing charge transport in the materials. The issue is developed in the two subsequent sections, dealing with microscopic and macroscopic models, respectively. The first section of the pair addresses the trap-limited transport model in the hydrodynamic form and discusses a 3D network of randomly placed traps. Specific issues, like detrapping due to electron-electron interaction and the probability of inter-trap transitions, are addressed here. Finally, ab initio quantum models for ultrascaled devices are illustrated.

The last section deals with measuring schemes for the negative-slope branch of the $I(V)$ characteristic of the amorphous chalcogenide and with a method suitable for describing the instability due to this branch; the section is concluded by a macroscopic thermal analysis of a PCM. A brief outline of open problems and challenges in modeling transport in amorphous chalcogenides closes the chapter.

40.1 Amorphous Semiconductors

Even though the majority of conventional electronic and optical devices exploit the physical properties of semiconductor materials in their crystalline form, amorphous semiconductors, like amorphous Silicon (a-Si) and related materials, together with chalcogenide alloys, have also been variously employed, albeit to a lesser extent, in technological applications, like solar cells, thin-film transistors, light sensors, and optical memory devices, just to quote some examples [1–5]. A recent compact and clear review on the fundamental concepts about structural, optical, and electrical properties of amorphous semiconductors is found in [6].

The first relevant scientific and technological focus was on light-induced phenomena, in particular the dark conductivity and photoconductivity in the a-Si:H material: both properties exhibit a decrease of their values after long illumination of band-gap light [3]. These effects have been studied in view of the associated performance degradation of the optoelectronic devices based on these materials. Details about the use of amorphous semiconductor materials for the realization of solar cells and sensors are found in [4] and, in this book, in Chaps. ▶ 19 by S. Goodnick and C. Honsberg, and ▶ 21 by J. Li and M. Östling. Furthermore, the tunable optical properties of a class of chalcogenide alloys, ranging over several orders of magnitude from the amorphous to the crystalline phase, gave impulse to the industrial exploitation, that is today a mature technology, for rewritable optical data storage and display devices [7]. In the last years, chalcogenide-based photonics has emerged as a new research topic, where the extremely efficient switching of chalcogenide phase-change materials under short optical pulses is exploited to implement light engineering. The interested reader can refer to [7] and references therein for a recent review on the subject.

As for the electrical properties of amorphous semiconductors, the pioneer literature published from the 1960s to mid-1980s established that both band and hopping conduction contribute to determine the material response to an external bias. The temperature dependence of the Ohmic conductivity σ is the "fingerprint" of the prevalent effect:

$$\sigma \propto \exp\left(-\frac{E_a}{kT}\right) \tag{40.1}$$

for band conduction in undoped amorphous semiconductors (with E_a the activation energy, k the Boltzmann constant, T the temperature), and

$$\sigma \propto \exp\left(-\frac{B}{T^{1/4}}\right) \tag{40.2}$$

for (nearest-neighbor and variable-range) hopping, with B a coupling parameter [1]. The former mechanism dominates at room temperature; the latter prevails at low temperature.

A renewed interest of the scientific community and the electronic industries on the extremely tunable nonequilibrium electrical properties of chalcogenides has been observed in the last 20 years, due to the foreseen range of applications [8–11]. This strong focus on the topic brought about a wide-range exploration of possible materials to be employed, an increasing control of the growing techniques, and a decrease in the dimensions of the material layers. Some performance limitations of the experimental characterization equipments have been overcome in order to meet the new issues brought about by this quickly expanding field; new alloys were grown, and their properties were tailored for specific purposes; thinner active regions were considered to the purpose of improving the device performances. The increasingly important role of metallic contacts has been explored down to the atomic level, in order to define the miniaturization limit at which the functionality of the devices is still preserved.

Innovative device architectures based on these materials, both in the amorphous and crystalline phase, have been proposed for memory elements, and their scaling to the nanometer range opened the way to the realization of 2D and 3D arrays with potentially new fields of application [12]. The process technology involved in the realization of these devices is extensively described in [8] and, in this book, in Chap. ▶ 2 by P. Fantini et al.; an overview of phase-change memory device physics can be found in [13], while new possible applications of chalcogenide-based memory devices are found in [12].

Another emerging field where chalcogenide materials are foreseen to play a relevant role is neuromorphic computing. Here, chalcogenides are employed to design memristive devices, i.e., devices that integrate memory and elaboration functions. The subject is treated in detail in this book in Chap. ▶ 32 by D. Ielmini. This topic is still rapidly evolving and is, so far, the most innovative and "trendy" one as for architecture design and modeling.

The impressive scientific and technological driving force described above brought about new challenges in the field of material and device modeling. Many different approaches have been adopted, ranging from compact models down to atomistic simulations. On the basis of the arguments discussed above, the present chapter will review the modeling approaches applicable to the analysis of the electrical properties of amorphous chalcogenides for device applications. The same approaches can be applied to the study of other amorphous semiconductors that share similar structural properties and electronic states.

Generally speaking, while a deep theoretical understanding of the most fundamental aspects related to electronic states and charge-transport properties of crystalline semiconductors and devices has been reached, many open issues still remain about the same topics as far as amorphous semiconductors are concerned, despite the huge amount of experimental and theoretical literature of the last years.

As for all amorphous materials, the electronic properties of amorphous semiconductors are difficult to study with the experimental techniques commonly applied to crystalline materials, since broken symmetries in the atom distribution of the disordered network make the spectral lines to broaden. For the same reasons, mathematical and numerical modeling of the atomic arrangement and of the electronic states, at the basis of any transport approach, is a formidable task also for amorphous chalcogenides; among several issues under debate, we quote two very basic questions, still open: (1) to what extent the "extended" band states influence the transport process in the amorphous phase? and (2) what is the microscopic origin of the trapping and recombination centers?

Focusing now on the charge-transport issues, the peculiar effects characterizing the amorphous phase of most chalcogenides can be summarized as follows:

(a) The $I(V)$ characteristic exhibits a linear dependence near the origin, followed by an exponential behavior.
(b) At a threshold field, mainly determined by the type of chalcogenide at hand, a sudden increase in conductivity (often of several orders of magnitude) sets in, while the material is still in the amorphous phase. The phenomenon is called "OTS".
(c) The transition from low- to high-conductivity state is an ultrafast phenomenon, taking place in the picosecond/-subpicosecond timescale.
(d) If, after the OTS, the external bias is reduced below a given value called *holding voltage*, in absence of memory switching, the amorphous chalcogenide returns to the initial conductivity state.
(e) The OTS behavior is maintained when the amorphous chalcogenide cell geometry is scaled down to the nanometer size.
(f) A slow increase of the electrical resistance of the amorphous phase with time (referred to as *resistance drift*) is observed for most amorphous chalcogenides.

Point (b) above is by far the most relevant one for the applications. The process described in it is referred to, in the literature, as "Ovonic threshold switching" or "OTS," and the $I(V)$ characteristic becomes S-shaped (equivalently, the $V(I)$ characteristic is N-shaped). In many cases, OTS is followed by a phase change to a crystalline state. Since such a transformation is exploited in the phase-change memory (PCM) technology, this second change is sometimes called "memory threshold switching" or "MTS." In some cases, instead, OTS is not followed by a phase change; however, when phase change occurs, it is favored by OTS, since the increase in conduction increases the Joule power absorbed by the material, thus favoring the temperature rise necessary for the phase change. When chalcogenide materials are used as PCM, the amorphous-to-crystal transition induced by a suitable electric pulse is called *set*; the opposite transition is called *reset*.

It must be remarked that OTS may occur or not, depending on the details of the carrier energy states within the specific amorphous material. The physical origin of the electrical bistability observed in some amorphous semiconductors is still a matter of debate, as discussed in this chapter and its references. However, no matter what the invoked explanation is (viz., electrical, thermal, or electrothermal, as extensively discussed in the chapter), in all cases the effect is strictly related to the extended and/or localized distribution of the electronic states in the amorphous material. Chalcogenides seem to possess two "key" ingredients, namely, a wide band gap and a distribution of more or less localized states in the band gap. To clarify this point, Buscemi et al. [14] analyzed the abovementioned bistability by an analytical approach; they found that the electric snapback may occur only when the energy separation between the electron localized and free states is larger than $4\,k\,T_\circ$, where k is the Boltzmann constant and $T_\circ$ the lattice temperature. This clarifies why bistability is generally not observed in the most popular elemental and compound semiconductors, where a high density of localized states deep in the gap is not present.

A recent concise review on the measured transport properties, their technological relevance, and the physical effects possibly influencing transport in chalcogenides is found in [15]. Extensive experimental investigations produced an impressive amount of data for a large number of chalcogenide alloys that have been used to test and validate the simulation models.

The contents of the chapter are organized as follows. In Sect. 40.2 we present a short review of the most relevant theoretical concepts and computational approaches about the atomic structure and electronic states of the amorphous chalcogenides, selected from about 20 years of advanced basic and applied research. In Sect. 40.3 and in the following ones, we present an overview of the physical models and the numerical approaches proposed by the scientific community to study the transport properties of amorphous chalcogenide materials and devices, ranging from the microscopic transport models, including atomistic ab initio simulations (Sect. 40.4), to macroscopic models solved by finite-element numerical techniques (Sect. 40.5). The theoretical predictions will be validated against experimental results for state-of-the-art devices. A number of still open questions

on the fundamental physics at the origin of the electrical performances of amorphous chalcogenides, along with some future trends for the modeling methodologies, will be drawn in Sect. 40.6, based on the present research achievements.

40.2 Atomic Structure and Electronic States

Understanding the atomic structure and the distribution of electronic states of amorphous chalcogenide materials is of fundamental importance for any study of charge transport and for device applications. In fact, the knowledge of the atomic structure is crucial for understanding, and possibly tailoring, the phase change and the consequent memory switching of chalcogenides; in turn, the distribution of the electronic states crucially influences the charge-transport properties of the amorphous phase, in particular the OTS phenomenon.

In the following sections, the two topics will be briefly reviewed on the basis of the most recent theoretical, experimental, and computational achievements appeared in the literature, with the purpose of providing the reader with the basic concepts used to discuss transport features of amorphous chalcogenides in the rest of the chapter.

40.2.1 Atomic Structure of Amorphous and Crystalline Chalcogenides

Owing to the lack of long-range order, the structure of amorphous materials is usually studied in terms of short- and medium-range properties. Statistical quantities, such as form factors, correlation functions, and coordination numbers, contribute to the identification of some characteristic units or building blocks which describe the short-range structural properties of the amorphous phase. From the experimental side, the above properties can be studied by means of neutron scattering, Raman scattering, X-ray diffraction (XRD), far IR absorption, photoemission, or extended X-ray absorption fine structure (EXAFS) (see, e.g., [5, Ch. 46]), which yield information on the space distribution of constituent atoms. However, the experimental analysis of the amorphous chalcogenide materials is particularly difficult, since they quickly switch to the crystalline state without stabilizing themselves to a solid glass, being this rapid phase change the property that makes these materials so interesting for memory applications [8].

In the last two decades, a strong effort has been devoted to obtain information on the structural properties and the electronic states of amorphous chalcogenides, using computational approaches based on atomistic models (the interested reader is referred to [16] for an extensive review on the subject). The numerical findings about the space distribution and

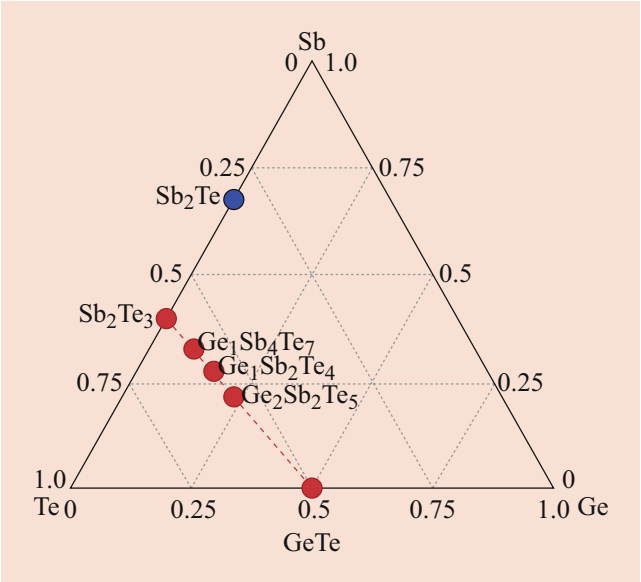

Fig. 40.1 Pseudo-binary alloys of GeTe and Sb_2Te_3. (Reprinted with permission from [23]; copyright ©2010 American Chemical Society)

the bonding features can be validated against experimental observations by means of the statistical quantities mentioned above (for further details, see, e.g., [17, 18]).

Calculations have been performed for several materials, but the most studied chalcogenide compounds are GeTe (the simplest phase-change material), Sb_2Te_3 and ternary materials, such as $Ge_2Sb_2Te_5$ (GST–225) and $Ge_1Sb_2Te_4$ [17, 19–22]. Among them, GST–225 is the material most used for memory applications, since it provides a good compromise between a high speed of the phase transition and a good stability of the amorphous phase. Moreover, many GeSbTe ternary alloys have been studied. They are regarded as pseudo-binary alloys of the compounds GeTe and Sb_2Te_3. In Fig. 40.1 three examples are shown, namely, $Ge_1Sb_2Te_4$, which is considered as $(GeTe)_1(Sb_2Te_3)_1$; then, $GeSb_4Te_7$, which is considered as $(GeTe)_1(Sb_2Te_3)_2$; and finally, $Ge_2Sb_2Te_5$, which is considered as $(GeTe)_2(Sb_2Te_3)_1$. In recent years, ab initio molecular dynamics has been the most advanced numerical method applied to predict or test the atomic distribution in amorphous (and crystalline) chalcogenides. Details on the fundamentals of this simulation technique are found in [8] and in Chap. ▶ 42 by M. Fischetti et al. Focusing on GeTe and GST–225, results show [17] that both compounds in the amorphous phase, obtained by quenching from the liquid phase, display two different types of short-range order: about 30% of the Ge atoms show tetrahedral sp^3 bonds promoted by the presence of Ge-Ge bonds, as in elemental or III-V semiconductors; the remaining Ge atoms, linked to Sb and/or Te chalcogen atoms, tend to form 3-coordinated or 4-coordinated defective octahedral orthogonal p bonds. The three corresponding

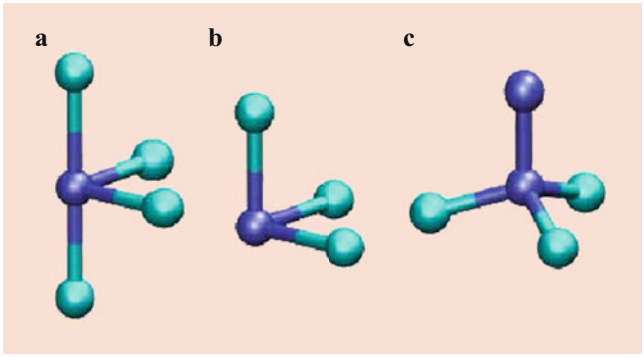

Fig. 40.2 Building blocks of a-GeTe (blue spheres represent Ge, light-blue spheres represent Te): (**a**) defective octahedra, (**b**) pyramids, and (**c**) tetrahedra with Ge-Ge bond. (After [22])

building blocks are shown in Fig. 40.2. The tendency of Ge atoms to form octahedral environments, reminiscent of the cubic crystalline phase, can be understood by noting that the main difference between the complex atomic structures of chalcogenide alloys with respect to that of the most common and well-known semiconductors of group IV or III–V is that, in the latter, a strong sp_3 hybridization of orbitals is present, whereas it is absent in the chalcogenide alloys. In fact, sp_3 hybridization is forbidden due to the large energy difference between the *s* and *p* orbitals produced by the stronger Coulomb attraction of the nuclei of group VI. Therefore, the bond is provided by the *p* orbitals, while *s* orbitals do not participate [24, 25]. This bond configuration favors the octahedral, rather than tetrahedral, structure. The crystalline octahedral structure, however, is not stable in GeTe and ternary alloys: it is followed by a Peierls distortion that generates a more stable trigonal symmetry. The energy gained by the Peierls distortion is larger than the elastic energy necessary to maintain the distortion (Fig. 40.3).

Furthermore, simulations in [20] reported for the amorphous phase a long-range order of Te atoms and an important structural motif consisting of four-membered ABAB squares, where A stands for atoms of Ge and Sb, and B stands for Te. A detailed analysis of possible bonds in Ge-Te-Sb alloys, on the basis of the electronic configurations of the atoms involved, is given in [5, Ch. 46]. This analysis suggests that the fast crystallization and high cyclability between amorphous and crystalline phases are related to small atomic displacements producing ordering (disordering) of pre-existing four-membered rings, with preservation of the covalent backbone. The concentration of vacancies in GST–225 is found to be larger than in GeTe. The reduction of imperfections in an amorphous chalcogenide favors the phase transition to the crystal, since vacancies provide the necessary space for atomic readjustment. This explains why phase-change performance in GST–225 is better. A combination of various experimental results with theoretical

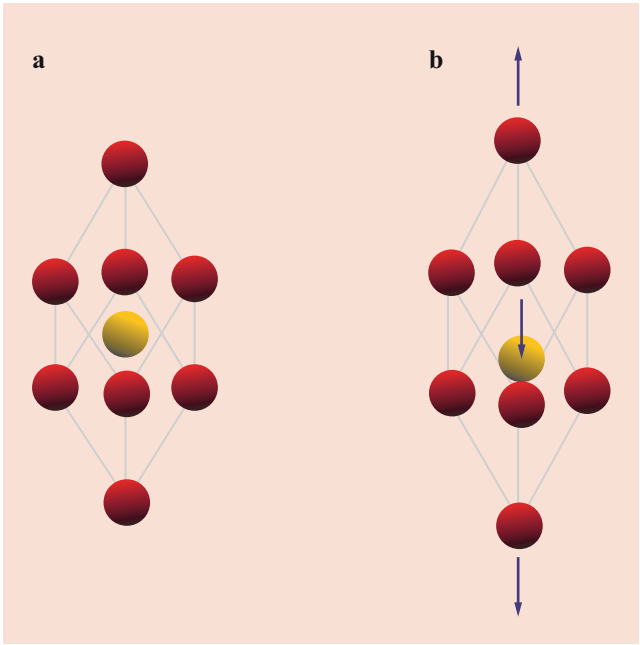

Fig. 40.3 Rock-salt structure (**a**) and trigonal structure (**b**) of GeTe in the primitive unit cell. The trigonal structure is obtained by stretching the rock-salt cell along the ⟨111⟩ direction and shifting the central atom. (Reprinted with permission from [23]; copyright ©2010 American Chemical Society)

interpretations by means of reverse Monte Carlo calculations [18, 26] confirmed that a variety of local motifs are present, without a predominance of tetrahedral $GeTe_4$, as previously suggested by [27]. Furthermore, EXAFS spectra proved that Ge-Te and Sb-Te bonds are shorter for the amorphous phase, even though the density of the latter is about 5% lower than that of the crystalline phase; this suggests that a significant change occurs in the local structure from the amorphous to the crystalline phase [5, Ch. 46].

As it regards the transition from the amorphous to the crystalline phase, recent experimental and theoretical findings [28] evidenced that, contrary to the case of the amorphous phase characterized by ordinary covalent bonding, the bonding mechanism in crystalline phase-change materials cannot be classified according to the conventional bonding theory: a novel bonding structure, named "metavalent bonding" [29, 30], has been suggested.

As far as symmetry properties are concerned, crystalline GeTe exhibits a stable rock-salt crystalline structure (Fig. 40.3a) at temperatures above about 400 °C. One sublattice is occupied by Te atoms and the other by Ge atoms. At lower temperatures, below about 200 °C, a phase transition occurs to a still rock-salt crystalline structure, which is unstable and relaxes to the trigonal structure (referred to above as Peierls distortion, Fig. 40.3b). Furthermore, a shift of the central atom along the [111] direction is present, generating alternating short and long

bonds; finally, in this stable structure, a large number of Ge vacancies are present [31]. Several authors suggested that vacancies stabilize the structure by decreasing the total energy of the system; they are not electronic defects but are an intrinsic feature of the atomic structure. This is the case, for example, of the GST–225 rock-salt structure ([27], [5, Ch. 46] and references therein). EXAFS studies [27] proved that the local structure around the Ge species is very similar to that of the binary Ge-Te, which possesses a rhombohedral structure with subsets of free-shorter and free-longer bonds. Peierls distortions are also present in GST–225. The stable structure of these ternary alloys is a layered trigonal structure. One sublattice is occupied by Te atoms, while the other is occupied by Ge atoms, Sb atoms, and vacancies [8]. A large vacancy concentration has been observed in several pseudo-binary alloys along the GeTe $-$ Sb_2Te_3 line. For the case of $GeSb_2Te_4$, e.g., the stacking order suggested in [32, 33], consists of alternating blocks of GeTe and Sb_2Te_3 (see also [8]).

40.2.2 Electron States in Amorphous and Crystalline Chalcogenides

In crystalline semiconductors, the electron energy structure consists of energy bands and gaps; the corresponding energy wave functions are Bloch states, extending over the whole crystal. Localized electron states in highly ordered systems are usually associated with donor or acceptor dopants, impurities, or structural defects and introduce discrete energy levels within the semiconductor band gap. In disordered semiconductors, like amorphous chalcogenide alloys, extended and localized states still exist, but the electron energy distribution has different features. Usually, electronic states in amorphous semiconductors are described by means of a tight-binding, Hartree-Fock approach, with the introduction of spatial fluctuations of the bond arrangement (e.g., length and angle). In the particular case of chalcogenides, starting from p-type atomic orbitals, which produce hybridized bonding, non-bonding, and anti-bonding states, the valence band is generated by the non-bonding state, while the conduction band arises from the anti-bonding state (Fig. 40.4). The energy gaps of amorphous materials are usually larger than those of crystals. The spatial fluctuation of the bond energy leads to a broadening of the edges of the conduction and valence bands and introduces energy levels associated to localized states; the latter reduce, or completely fill, the energy gap (Fig. 40.5). In general, the energy density of states (DOS) of electrons and holes decreases moving toward the mid-gap, generating energy tails commonly referred to as "Urbach tails." The energy that separates the extended from the localized states is called "mobility edge." Electron (hole) states above (below) the mobility edge are extended states, while electron (hole) states below (above) the mobility edge are spatially localized. The mobility gap of amorphous materials is defined as the minimum energy separation between the extended states of the valence and conduction bands ($\varepsilon_c - \varepsilon_v$ in Fig. 40.5).

Furthermore, in amorphous semiconductors the coordination number of constituent atoms deviates from that of the ideal random network. In chalcogenide glasses this number is 2. Onefold- and threefold-coordinated chalcogen atoms are called *valence-alternation pairs* (VAP, Fig. 40.6); they constitute structural defects with associated electron energy levels within the band-gap region. Moreover, donor- and acceptor-like trap states may be present in the amorphous materials as well.

The knowledge of the energy spectrum of amorphous chalcogenides is, of course, of extreme relevance for any charge-transport analysis. A large number of experimental techniques based on optical and electrical measurements have been applied [6] and confirmed the general features discussed above for a large number of amorphous chalcogenides. As an example, measurements of steady-state photocurrent (SSPC), modulated photocurrent (MPC), and Seebeck effect for the case of a-GeTe have been performed in [35]; from an elaborate analysis of the experimental results, an electron DOS for the samples under investigation, shown in Fig. 40.7, was calculated and found consistent with the obtained experimental data. However, in many cases the experimental information about the energy spectrum and the (extended or localized) nature of the electron wave functions close to the mobility edges and within the mobility gap is not accurate enough to provide reliable grounds for a transport theory.

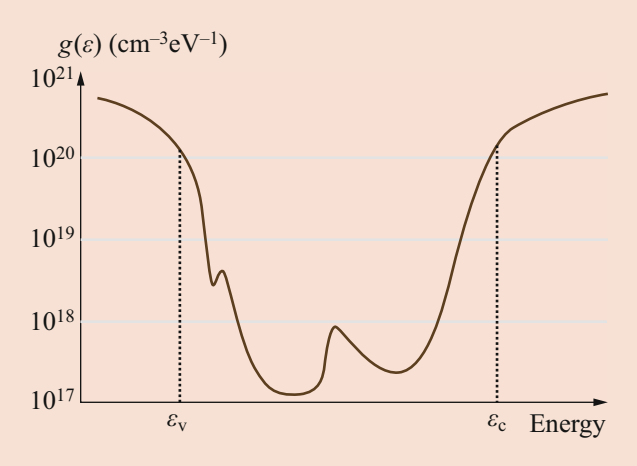

Fig. 40.5 Sketch of a typical energy density of states for a disordered semiconductor; here, ε_c and ε_v indicate the conduction and valence mobility edges, respectively (see text). (After [34])

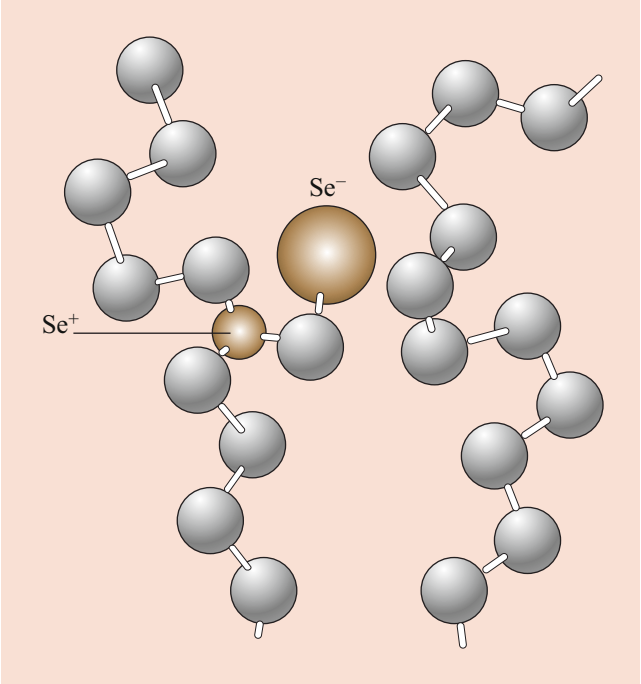

Fig. 40.6 Sketch of onefold-coordinated (negatively charged) chalcogen atom and threefold-coordinated (positively charged) chalcogen atom. The case of Se has been considered. (After [6])

Atomistic calculations are also very challenging, since the high accuracy in the determination of the DOS, necessary for investigating transport phenomena, requires large cells and a huge number of atoms, resulting in very heavy computational loads. Simulations of GeTe in [36] showed that localized states inside the gap in phase-change materials mostly come from band tails and are due to Te atoms; they also confirmed that the Fermi energy for these materials is located at mid-gap, in agreement with experimental findings.

Among chalcogenides, a-GeTe has extensively been studied by many groups; DFT and classical MD simulations in [37, 38] suggest that most of the localized states in the band gap of this chalcogenide alloy are introduced by defective groups of Ge atoms, in which at least one Ge atom is over- or under-coordinated. During the structural relaxation following a fast quenching, a slow time evolution of the bond spatial arrangement has been observed toward lower-energy structures, having a nearest-neighbor distribution similar to that of the crystalline phase, with a reduction of the localized states. For the same chalcogenide, a distribution of defect states in the gap, whose localization decreases as the energy of the states gets closer to the band edges, has been obtained [22]. Such states are connected with chains of Ge-Ge homopolar bonds.

40.2.3 Resistance Drift

An outstanding example of how atomistic, physics-based approaches can successfully be applied to analyze, and possibly overcome, technological limitations in semiconductor device design is provided by the resistance-drift effect.

The technology of PCM devices exploits the resistance difference between the crystalline and amorphous phase of chalcogenide materials; while the former is characterized by a stable resistance, the amorphous phase is characterized by a time instability of the resistance, due to two different phenomena: crystallization at high applied fields and the so-called *resistance drift* (RD) [39–41] at low fields. The latter effect is an irreversible phenomenon, present in amorphous chalcogenide materials, by which the electric resistance R of an amorphous sample slowly increases with time; RD is of course very relevant from the technological point of view: it is in fact a detrimental phenomenon for the memory applications of chalcogenides, particularly for multilevel-storage devices [42].

The phenomenological formula that accounts for the resistance change with time is

$$R(t) = R_0 \left(\frac{t}{t_0}\right)^{\nu}, \tag{40.3}$$

where $R_0 = R(t_0)$ and ν are material parameters. Even though the physical origin and dynamics of RD are not fully understood yet, there is a consensus that the effect must depend on changes in the atomic and electronic structures of the amorphous phase that take place in time. As a consequence, different atomistic approaches have been applied to the purpose of explaining the RD effect, and the study of RD has often merged with the study of atomic structures, being the RD experimental data a validation check of the adopted atomistic model.

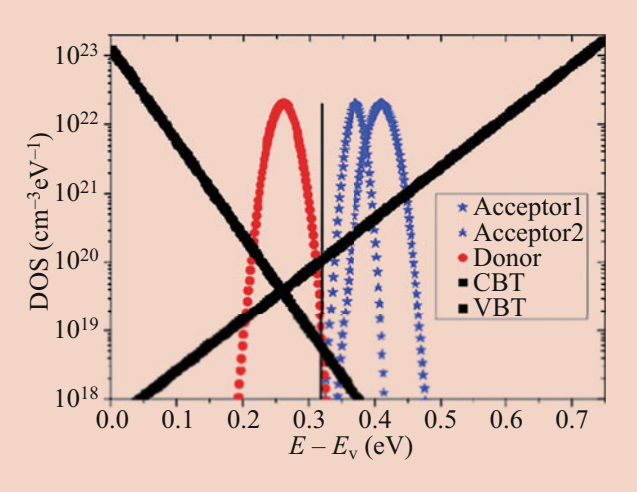

Fig. 40.7 Density of states as a function of energy for a-GeTe films obtained from numerical calculations reproducing experimental results. (After [35])

The first atomistic studies linked the origin of RD to a time-dependent, structural relaxation effect related to the stress in PCM systems after the reset operation, also depending on the sample history [43, 44] (the reset operation is defined in Sect. 40.1). However, stress has not been confirmed to be present in all chalcogenides, and RD has been found also in systems where stress is not present [45]. Furthermore, RD cannot be ascribed to partial crystallization taking place while devices are operated, since crystallization would bring a decrease, not an increase, of resistance.

Recently, a number of independent analyses based either on ab initio or classical potential molecular dynamics agreed in identifying the physical origin of RD as structural aging, i.e., a structural relaxation with time of the nonequilibrium, metastable amorphous materials, independent of the presence of stress [39, 46–49]. In particular, according to the theoretical model in [47], the structural relaxation process to a lower-energy, still amorphous phase, is associated with the decay of metastable defects during structural relaxation, with a consequent enhancement of the electron activation energy for conduction; this effect produces an increase of the resistance with time. The hypothesis, evidenced by atomistic structural calculations, was validated by comparing the theoretically predicted power exponent ν of RD in (40.3) with experimental data. An additional confirmation of this idea came from time-dependent ellipsometric measurements in a-GST [49], which have shown that RD is correlated to a band-gap widening, supporting its origin as due to a structural relaxation with atomic rearrangements of the amorphous material. In particular, such a relaxation determines an increase of the energy gap and a reduction of the number of localized states within the gap. Both these occurrences contribute to an increase of the resistance.

For the sake of completeness, it must be mentioned that a different explanation of this effect has been given assuming that RD is related to material changes induced by an external electric bias, rather than an intrinsic structural effect ([42] and refs. therein). In a first study based on amorphous GST, the increase of resistance with time was ascribed to a parallel increase of the density of a class of charged, coupled, and localized defects of the chalcogen atom (Te)—the *valence alternation pairs*, or VAP, mentioned above—induced by the drift phenomenon [39]. However, atomistic simulations based on molecular dynamics proved that atomic configurations associated with gap defects in amorphous chalcogenides are not simple VAP point-like defects, being instead spatially extended and with different energy shifts when occupied by electrons.

In a recent study, RD of amorphized GST line cells has been studied as a function of the sample temperature, from room temperature down to 125 K, where structural relaxation effects are expected to be much smaller than at room temperature; RD was detected in the full range of temperatures [50]. In the same study, the time evolution of RD of illuminated and non-illuminated samples was compared. The photoexcitation effect taking place under light exposure gives rise to a clearly observable change in resistance and to lower drift coefficients, suggesting that photoexcited carriers give a significant contribution to conductance at low temperatures. Experiments with periodic exposure to light evidence the existence of two different responses, one fast and one slow. The timescale of the slow response (about 10 min at 150 K) suggests that slow trap-to-trap charge exchanges have a significant impact on electrical conductivity and that the resistance can be stabilized under light exposure within each cycle; this seems to confirm that RD, at least in amorphous GST, is predominantly an electronic process.

In Ref. [42] the intrinsic electronic mechanism for RD is identified with the long-time, deep-trap release and subsequent recombination of charge carriers following electron-hole injection during the reset pulse; the phenomenon is also believed to be responsible for the long-time photocurrent decay in amorphous semiconductors, such as hydrogenated amorphous silicon. The effect is controlled by the energy width of the (localized) valence and conduction band tails in the vicinity of the band gap.

40.3 Physical Models and Numerical Approaches to Charge Transport

The first general microscopic theory of charge transport in amorphous materials was developed by Mott in the late 1960s (see, e.g., [1,51]). It represents a milestone in the field and has been widely and successfully applied, since then, to a variety of amorphous materials.

On the other hand, the Mott theory, being based on the hypothesis of hopping conduction, does not fully explain the peculiar features of transport in some chalcogenide glasses: specifically, a reversible electrical switching behavior, i.e., a sudden change in resistivity by several orders of magnitude when a threshold field is reached, with no transition to the crystalline phase. This effect was first evidenced by Goryunova and Kolomiets in 1955 [52], but only in 1968 Stanford Ovshinsky brought it to the attention of the international scientific community [53]. For this reason the phenomenon is commonly referred to as "Ovonic threshold switching" (OTS). In the last 30 years, the switching behavior of the amorphous state of chalcogenide materials proved to be of great interest for the technology of phase-change memories (PCM) [54], so that the study of electron transport in the amorphous state and the associated computational implementations raised renewed interest.

The theoretical approaches can be grouped on the basis of the prevailing mechanism used to describe the Ovonic swiching [55]. Several mechanisms have been proposed, and some of them can possibly be present at the same time with different relative importance in different materials and experimental conditions.

The first systematic study was presented by Adler in the late 1970 [56, 57]. Both electrons and holes are considered as mobile carriers, and charged trapping centers are included. When the threshold field is approached, extra pairs of carriers are generated via impact ionization, which are captured by the majority of traps and make them neutral. Since carriers are generated throughout the whole sample, some enter the external circuit instead of filling a trap and produce a significant current. The latter, in turn, can produce filamentation prior to the switching transition. Highly conductive micrometer-size filaments are thus created, which constitute privileged pathways for the electric conduction that dramatically decrease the electric resistance of the material.

The nucleation model proposed in [58, 59] is based on the assumption that a high electric field lowers the energy barrier to the point that the formation of a crystal nucleus becomes possible. A number of crystalline grains are then created within the amorphous matrix because of local energy dissipation; they do not alter the conductivity properties as long as they are far away from each other. A strong electric field and/or an external heat source enhance the formation of these grains so that, under suitable conditions, a conductive filament connecting the contacts is formed. This low-resistivity path produces the Ovonic switching observed in the $I(V)$ characteristic of the amorphous material. This hypothesis is supported, on one hand, by the fact that the conductivity of such materials, being thermally activated, increases exponentially with temperature; on the other hand, this mechanism is too slow to account for the experimental observations of the typical switching speed. Furthermore, the complexity of the reaction kinetics and the dimensions of the filaments are not compatible with the performances of the present-day Ovonic devices. Thus, new models were considered.

In the model proposed in [60], states with negative correlation energy are supposed to play a key role in determining the electric switching (the correlation energy is the sum of the electron positive-repulsion Coulomb energy and the negative energy interaction with the lattice). These states are usually referred to as *U-centers* and are modeled as defects in glassy semiconductors. Electric switching results from multiphonon tunneling ionization of U-centers, due to the electric field and Joule heating [55]; a high concentration of such centers is in fact present in chalcogenide glasses.

In [61], a thermally assisted, threshold-switching behavior is described by means of a modeling approach consisting of a feedback between electric transport and thermal models based on phenomenological equations. Using a field- and temperature-dependent subthreshold-conductivity model coupled with thermal feedback, a thermally assisted, threshold-switching dynamics is demonstrated in nanometer-scale devices. In fact, the high thermal efficiency and fast thermal dynamics of chalcogenide devices at the nanometer scale support the idea that a self-heating mechanism can trigger the electric response.

Other approaches assume purely electric phenomena. Pirovano et al. [62] departed from the common framework for charge transport in semiconductors and tried to describe the Ovonic switching by assuming the existence of trap states in the energy gap of the amorphous chalcogenides. These states favor transitions between the valence and conduction bands (band-to-band impact ionization is, instead, a very improbable process due to the width of the gap). The generation process increases at increasing biases, while the recombination rate is only weakly dependent on the applied field. As a consequence, when generation prevails over recombination, a net increase of the high-mobility carriers produces a drastic change in the electric behavior. Even with the assistance of intermediate trap states, however, the energy required by the carriers in order to impact ionize is still very high and incompatible with the estimated carrier mean free path in chalcogenide glasses, even though the inclusion of a cooperative electron-electron interaction can mitigate the problem (Sect. 40.4.3 and [63]). Furthermore, the impact ionization mechanism cannot correctly account for the experimentally demonstrated existence of an activation energy.

In [64, 65], electrical transport in chalcogenide glasses is analyzed by means of numerical estimates. In the presence of a large concentration of localized states in the energy gap, three electron transport processes involving localized states can take place (Fig. 40.8). Tunneling through the energy barrier between two localized states, without entering the

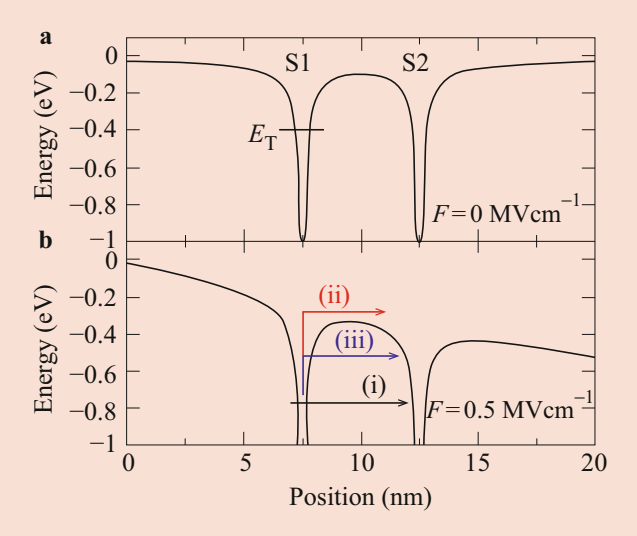

Fig. 40.8 (**a**) Profile of the electron potential energy along the minimum path between two localized states S1 and S2 in absence (*upper part of the figure*) and (**b**) presence (*lower part*) of an electric field. In the lower part, three different transport processes are sketched, namely, (**i**) direct and (**iii**) thermally assisted tunneling through the energy barrier between the two localized states, (**ii**) trap-limited transport. (After [65])

conduction band (process (i) in the figure), happens under the assumptions that (a) traps are spatially very close to each other, and (b) the energy barrier between two localized states is much smaller than the energy difference between the trap level and the bottom of the conduction band. Furthermore, field-assisted emission over the energy barrier with activation of band transport (process (ii) in the figure) and thermally assisted tunneling through the energy barrier (process (iii)) can take place as well.

Numerical estimates of the three mechanisms described above proved that tunneling is practically negligible as compared to thermally assisted tunneling and field-assisted emission over the barrier. Moreover, it has been shown by Monte Carlo simulations that transitions between two localized centers generate successive back and forth jumps between the two centers, which contribute to the high-frequency noise, but do not contribute significantly to transport: the two centers behave de facto as a single trap [66]. The contributions of the last two processes are, instead, comparable for typical trap levels and energy gaps in amorphous chalcogenides. The two mechanisms are treated with a unified theoretical approach, and they have been referred to as "thermally assisted hopping" [65] or "trap-limited conduction" [64,67,68] when carriers transfer to band states between successive capture events. In any case, carriers transfer from one trap to another in a time which is much shorter than the time they spend within the trap. At equilibrium, detrapping events in any direction are equally probable; when an electric field is applied, the energy profile around each trap is modified, and the transition probability for some transitions is exponentially enhanced or decreased. At high electric fields, an almost one-directional carrier flux is eventually observed with the formation of a heated carrier distribution, since the energy gained from the external field is not fully dissipated to the lattice. The mobility increase associated to the heating effect produces the observed Ovonic switching from a low- to a high-conductance state. The above-described assumptions have been included in a continuum-medium 1D analytical model which successfully predicts the Ovonic switching effect. The original model of [64] applies to a steady-state transport condition.

Based on the model of [64], Piccinini et al. [67] investigated the same problem by numerically solving a set of equations provided by a hydrodynamic model coupled with the Poisson equation, suitable to describe local nonuniformities which can be relevant to determine the Ovonic effect. Diffusion effects are thus taken into account, and the carrier energy distribution is self-consistently evaluated with the local concentration and average energy of the carriers, along with the charge and energy fluxes. The two abovementioned features make it possible to implement numerical simulations for real devices in steady-state conditions.

An interesting alternative approach to the continuum-medium models for trap-limited transport discussed above has been introduced by Cappelli et al. [69, 70], who simulated the microscopic time evolution preceding the onset of the Ovonic effect, and possible crystallization, through a disordered network of localized states. They considered that, due to the structure of the chalcogenide material in the amorphous phase, it is reasonable to suppose a trap-limited conduction mechanism, where electrons travel in extended states above the mobility edge between two successive capture events. The localized states are assumed to be nodes of a 3D network. The application of a strong electric field reduces the barrier to be overcome by the trapped electrons to reach the extended states (Poole [71] or Poole-Frenkel [72] effects), thus increasing the chalcogenide conductivity. The model couples the self-consistent solution of the charge-transport and energy-transport equations with that of the Poisson and Fourier heat-transport equations, thus including both electrical and thermal effects into the final results. The validation of the model against experimental data evidences that both Ovonic switching and crystallization take place after the formation of hot-carrier conduction paths inside the disordered network. This numerical approach is suitable for the study of few-carrier phenomena in small devices, or the analysis of the statistical dependence of the electrical properties on the degree of disorder of the amorphous matrix.

Based on the trap-limited transport hypothesis encoded in a set of space- and time-dependent balance equations for the

carrier charge, current, and energy, self-consistently solved with the Poisson equation for the local electric potential, Buscemi et al. proposed analytical and numerical models of increasing complexity [14, 73, 74], all including both trapped and (dispersionless) band states. Eventually, in [75] the approach has been generalized to include a band with parabolic dispersion; the last approach can be integrated into standard tools for device simulation.

As stated in Betti Beneventi et al. [76], both the Pool and Poole-Frenkel approaches include thermal emission and thermal-assisted tunneling into the transport description. In the Poole approach, traps are supposed to be strongly interacting, while in the Poole-Frenkel approach, traps are assumed not to interact. The choice of any of the two approaches is, of course, justified by the knowledge of the localized-state spatial concentration and energy distribution which, unfortunately, is not known for most of the chalcogenide materials. Furthermore, both models assume an exponential dependence of the electric current upon the barrier lowering at high fields (even if the dependence on the electric potential is different in the two cases), which seems to be a key feature of the $I(V)$ curve when the threshold field is approached. The Poole model correctly accounts for the Ohm law at low fields, while the Poole-Frenkel model seems to work better at high fields; to exploit both benefits, a combination of the two approaches is proposed in [76]. In [75], the most used Poole approach has been used in absence of reliable information about the spatial trap distribution.

Besides the microscopic models listed so far, a number of macroscopic approaches, aimed at formulating compact models suitable for inclusion into device simulation frameworks, have also been developed. These approaches complement the microscopic description, trying to "lump" the complex physics into few simple equations featuring a small number of parameters.

All the abovementioned theoretical and computational approaches can be tested on an increasingly higher quantity of experimental data for a variety of chalcogenide alloys, both in transient and steady-state conditions, for devices with different configurations, where the active layer of Ovonic material ranges from the micrometer to the nanometer scale. Since each transport theory includes several fitting parameters, only the interpretation of a large number of measurements of the electric properties in different conditions can validate a given model. In the following, we provide a more detailed description of some of the microscopic and macroscopic computational approaches just introduced, being forced by space reasons to focus on a selection of recent references in the field. To explore a wider scenery, the interested reader may avail herself of the references listed at the end of the chapter.

40.4 Microscopic Models

We describe here how the models of [64, 65] have evolved to include self-consistency between the local carrier concentration and electric potential. This continuum description of the transport process in amorphous chalcogenides follows a procedure commonly used in standard semiconductor theory when the Boltzmann equation holds, encoded in a hydrodynamic-like approach [77].

40.4.1 A Hydrodynamic Approach to Trap-Limited Transport

The model unknowns are the local carrier concentration and the charge and energy fluxes, which are calculated by a suitable integration over the energy region filled with trap states within the energy gap of the amorphous chalcogenide [67]; to this purpose, a nonequilibrium Fermi-like distribution function $f_F(E_F, T_e)$ is used, including a nonequilibrium Fermi energy E_F and a carrier temperature T_e. Due to the complexity of the mathematical problem at hand, a very accurate approximation of the Fermi distribution, which still makes analytical integrations possible, has been used [67]. The quantities of interest are assumed to depend on the coordinate parallel to the current flow (here the z coordinate).

As for the trap-energy distribution, an energy range ΔE_T around the equilibrium Fermi energy at mid-gap is considered, which can eventually span the entire band gap $\Delta E_G = E_C - E_V$ (E_C and E_V being the energies of the conduction and valence band edges, respectively). The energy range ΔE_T is an input parameter of the model and must be fixed, for the material at hand, from experimental data and/or first-principle calculations on the amorphous structure, able to describe the defectiveness of the matrix [20, 78, 79]. A flat density of states $\gamma = n_T/\Delta E_T$ is assumed within ΔE_T, where n_T is the trap concentration; in [67], ΔE_T is equal to the band gap. Following [64], the average escape time of a carrier belonging to a trap located at z with energy E is given by

$$\tau_{\rightleftharpoons}(E, z) = \tau_0 \exp\left[\frac{E_C - E \pm q\,F(z)\,\Delta z/2}{k\,T}\right]. \qquad (40.4)$$

In (40.4), τ_0 is a characteristic time constant, q, k, and T are the absolute value of the carrier charge, the Boltzmann constant and the temperature of the amorphous matrix, respectively. In turn, F is the electric field and Δz is the average distance between two traps. The escape times in the two directions of motion, indicated by the arrows at the l.h.s. of (40.4), are different because of the presence of the field.

In a transport phenomenon dominated by hopping, the escape process is (by orders of magnitude) the slowest process in the conduction chain; thus, the carrier velocity during a

transition can be approximated by the ratio between Δz and the escape time $\tau_{\rightleftharpoons}(E, z)$ of (40.4):

$$v_{\rightleftharpoons}(E, z) = \frac{\Delta z}{\tau_{\rightleftharpoons}(E, z)} = \frac{\Delta z}{\tau_0} \exp\left[-\frac{E_C - E \pm q F(z)\,\Delta z/2}{k T}\right]. \tag{40.5}$$

The moments of the distribution function that are included in the model are:

(i) Carrier concentration (zero-order moment)

$$n(z) = \int_{\Delta E_T} \gamma f_F(E, z)\, \mathrm{d}E\,, \tag{40.6}$$

(ii) Average carrier velocity (first-order moment)

$$\langle v_{\rightleftharpoons}(z)\rangle = \frac{1}{n(z)} \int_{\Delta E_T} \gamma f_F(E, z)\, v_{\rightleftharpoons}(E, z)\, \mathrm{d}E\,, \tag{40.7}$$

(iii) Average carrier energy (second-order moment)

$$\langle E(z)\rangle = \frac{1}{n(z)} \int_{\Delta E_T} \gamma f_F(E, z)\, (E - E_V)\, \mathrm{d}E\,, \tag{40.8}$$

(iv) Average energy flux (third-order moment)

$$\langle P_{\rightleftharpoons}(z)\rangle = \frac{1}{n(z)} \int_{\Delta E_T} \gamma f_F(E, z)\, (E - E_V)\, v_{\rightleftharpoons}(E, z)\, \mathrm{d}E\,. \tag{40.9}$$

The two even-order moments depend on two unknowns, the nonequilibrium Fermi energy $E_F(z)$ and the carrier temperature $T_e(z)$. The odd-order moments contain also a third unknown, the electric field $F(z)$, through the carrier velocity, and can be combined together to yield the transport equations. In this way, a set of three differential equations can be written, to be solved for the triplet $F(z)$, $n(z)$, and $\langle E(z)\rangle$; the differential equations read [67]:

1. *Poisson equation*

$$\frac{\mathrm{d}F(z)}{\mathrm{d}z} = -\frac{q}{\varepsilon}\,[n(z) - n_{eq}]\,, \tag{40.10}$$

where ε is the permittivity of the material and n_{eq} the equilibrium carrier concentration. Under equilibrium conditions, the system is neutral for all z.

2. *Carrier flux equation*

$$\frac{J}{q} = -n(z)\,[\langle v_{\rightarrow}(z)\rangle - \langle v_{\leftarrow}(z)\rangle] + \frac{\Delta z}{2}\frac{\mathrm{d}}{\mathrm{d}z}\left\{n(z)\,[\langle v_{\rightarrow}(z)\rangle + \langle v_{\leftarrow}(z)\rangle]\right\} \tag{40.11}$$

In a current-driven situation, appropriate for studying the typical S-shaped $I(V)$ characteristics of Ovonic materials, the l.h.s. of (40.11) is known a priori; in turn, the r.h.s. consists of two terms: the former stems from drift conduction, and the latter represents the diffusive contribution to the current, being related to the nonuniformity of the carrier concentration and velocity.

3. *Energy balance equation*

$$\frac{\mathrm{d}}{\mathrm{d}z}\left\{n(z)\,[\langle P_{\rightarrow}(z)\rangle - \langle P_{\leftarrow}(z)\rangle]\right\} - \frac{\Delta z}{2}\frac{\mathrm{d}^2}{\mathrm{d}z^2}\left\{n(z)\,[\langle P_{\rightarrow}(z)\rangle + \langle P_{\leftarrow}(z)\rangle]\right\} = J F(z) - \frac{n(z)\,[\langle E(z)\rangle - \langle E_{\circ}(z)\rangle]}{\tau_R}\,. \tag{40.12}$$

This equation is derived in the first-order approximation of the energy relaxation through a relaxation time constant τ_R and a "target energy" $\langle E_{\circ}(z)\rangle$, namely, the energy that the population $n(z)$ would have if it was at thermal equilibrium with the lattice at temperature T.

The analytical derivation of these equations is reported in [67] assuming that the trap-energy states fill the band gap. Some relevant results obtained from the theory outlined above, using the parameters of GST–225, are shown in Figs. 40.9 (black curve), 40.10, and 40.11 (dotted line). Figure 40.9 displays the $I(V)$ characteristics obtained by a numerical solution of (40.10, 40.11, 40.12). All standard features of the conduction in Ovonic materials, i.e., an Ohmic region at the lowest current, followed by an exponential regime, are reproduced. When the electric field reaches a threshold value, a voltage snapback occurs. In the subthreshold region, the profiles of the electric field and carrier temperature are essentially uniform, consistent with the fact that very small heating effects are detected (see Fig. 40.10). As a consequence, the carrier concentration is constant; any increase in the input current leads simply to a spatially uniform growth of the electric field.

When the threshold condition is approached, the spatial uniformity of the three profiles is lost in a region close to the injecting contact (here referred to as "off" region), where the quantities of interest vary appreciably. What happens in this region determines the switching effect: the intense electric field transfers to the carriers a large amount of energy, which is only partially relaxed to the lattice by the energy-dissipative mechanisms. As a consequence, carriers are heated up while they move from the injecting to the collecting contact. As their average energy (thus temperature) increases, carriers move faster, and, to keep the current equal to the prescribed value, the carrier concentration $n(z)$ decreases. Furthermore, hotter carriers can overcome energy

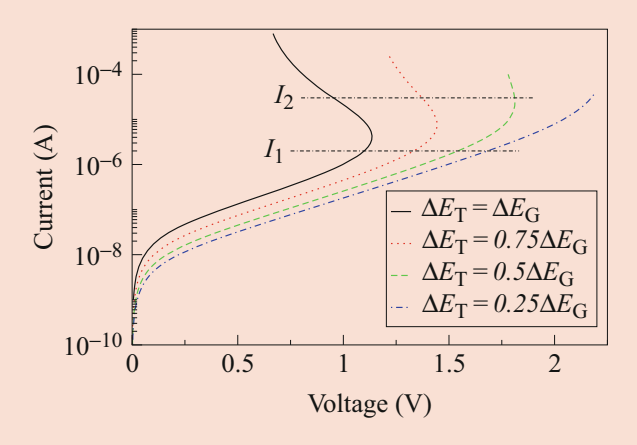

Fig. 40.9 $I(V)$ characteristics of a 40-nm-long device with a 1000 nm^2 cross-sectional area, for different values of ΔE_T ranging from ΔE_G down to 0.25 ΔE_G, with $\Delta E_G = 0.68$ eV. (After [68]). The parameters used in the numerical calculations are $\Delta z = 7$ nm, $\tau_0 = 1.2 \cdot 10^{-14}$ s, $\tau_R = 7.8 \cdot 10^{-14}$ s, $n_T = 6.8 \cdot 10^{19}$ cm^{-3}, and $T_0 = 300$ K. The *two horizontal lines* indicate the currents $I_1 = 2 \cdot 10^{-6}$ A and $I_2 = 3 \cdot 10^{-5}$ A, for which the profiles of $F(z)$, $T_e(z)$, and $n(z)$ are shown in Fig. 40.11

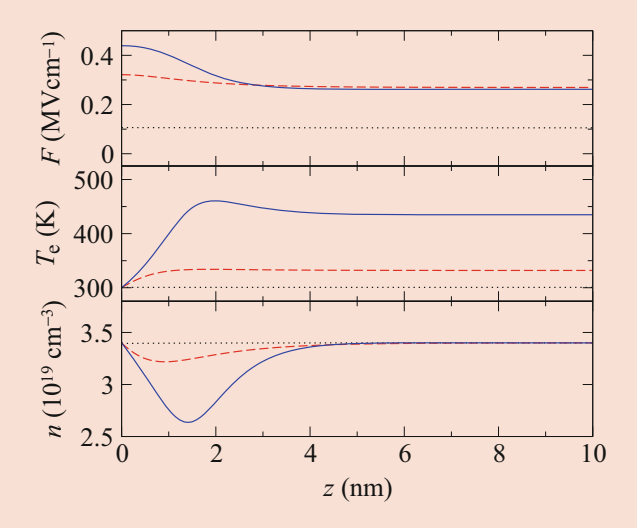

Fig. 40.10 Profiles of $F(z)$ (*top panel*), $T_e(z)$ (*middle panel*), and $n(z)$ (*bottom panel*) in the region of the device from 0 to 10 nm for the black curve of Fig. 40.9 evaluated at three selected currents: $1 \cdot 10^{-7}$ A (*dotted lines*), $2 \cdot 10^{-6}$ A (*dashed lines*), and $1 \cdot 10^{-5}$ A (*solid lines*). (After [68])

barriers more easily, and a lower field is required to sustain the current. In turn, lower fields transfer less energy so that, for a sufficiently high carrier temperature, the energy relaxation balances again the energy gain from the field. When this regime is attained, the spatial uniformity of the field, of carrier temperature and carrier concentration, is restored. This "on" region is much longer than the "off" region, close to the injecting contact, where carriers are heated up. The value of the field in the "on" region is thus assumed as representative of the whole device; this assumption is justified when the total device length is larger than the "off" region. While the field close to the injecting contact always increases with the current, the field in the "on" region increases at a slower rate at bias conditions close to the subthreshold region and eventually decreases, giving origin to the threshold-switching effect. The onset of the steady-state situation described above is crucially dependent on the interplay between energy gain and energy relaxation at a microscopic level.

The above analysis is influenced by the value of the energy range ΔE_T of the trap levels. To test this effect, four $I(V)$ characteristics are shown in Fig. 40.9, obtained by progressively reducing ΔE_T at a fixed spatial concentration n_T of the traps. It clearly appears that, at decreasing ΔE_T, the conductivity in the subthreshold region decreases and the threshold voltage and current increase. While the suppression of the very deep states does not alter significantly the results (as the contribution of these states to transport is substantially negligible), the lower conductivities found for smaller energy ranges can be attributed to the suppression of the shallow states within the band gap. According to (40.4), (40.5), if the trap energies are farther away from the bottom of the conduction band, the escape time is longer and the carrier velocity lower.

To complete the transport picture provided by the theory, in Fig. 40.11 the profiles of the electric field $F(z)$, carrier temperature $T_e(z)$, and carrier concentration $n(z)$ are shown as functions of the position along the device for two currents around the threshold value. A reduction by a factor 2 of the range of the trap-energy levels (solid line vs dashed line in Fig. 40.9) moves the threshold point roughly from $I_1 = 2 \cdot 10^{-6}$ A to $I_2 = 3 \cdot 10^{-5}$ A.

The lower conductivities obtained from reduced energy ranges imply that a given current is sustained only if the energy barriers between traps are further reduced by the action of a higher electric field. Since the field is almost constant along the device, but for a narrow region close to the injecting contact, higher overall potential drops are found, as seen in Figs. 40.9 and 40.11. In the "off" region, the average energy of the carriers is increased by the prevalence of energy gain over relaxation. In the absence of shallow energy levels in the band gap, larger threshold currents and voltages occur: the carrier average energy necessary for the switching event is established only at higher fields and currents, able to strongly increase the temperature of the carriers whose energies are close to the Fermi energy; this is visible in Fig. 40.11. In summary, the physical model and the numerical approach presented in this section are applicable to the study of electron transport in Ovonic materials when the current is dominated by hopping between localized states [64, 67]. Experimental data are well reproduced below and around the switching point.

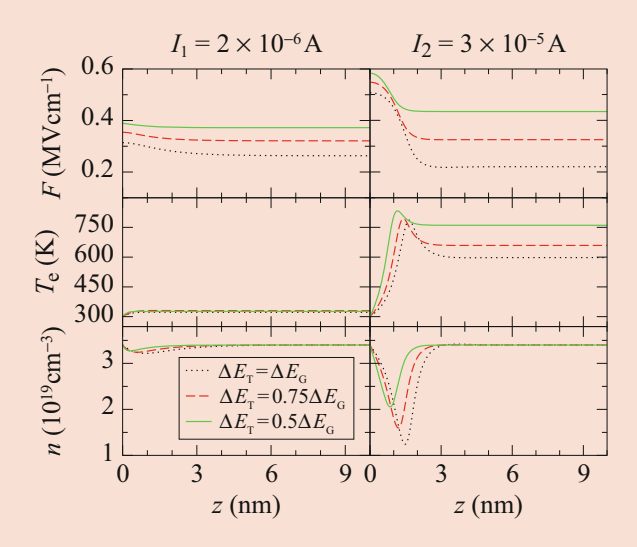

Fig. 40.11 Profiles of $F(z)$ (*top panels*), $T_e(z)$ (*middle panels*), and $n(z)$ (*bottom panels*), in the region of the device from 0 to 10 nm, when $\Delta E_T = \Delta E_G$ (*dotted line*), $\Delta E_T = 0.75 \cdot \Delta E_G$ (*dashed line*), and $\Delta E_T = 0.5 \cdot \Delta E_G$ (*solid line*), as in Fig. 40.9. For longer z's all curves keep their saturation values. (After [68])

40.4.2 Inclusion of Dispersive Band States

In the last years, many experiments have focused on the time-resolved electric response of nanometer scale layers of chalcogenide alloys inserted in high-performance electric setups; the aim was to assess the impact of the material choice on the read, write, and reset times of nonvolatile memories for advanced computation [80, 81]. The reduction of parasitic effects allows one to test the ultimate speed of threshold switching in different materials. On the modeling side, the first proposed time-dependent approach [82] is based on hopping transport and extends the analytical approach of [64] to transient conditions.

Then, a simulative approach merging the circuit equation with a set of differential equations of the hydrodynamic type, describing a trap-limited, time-dependent transport process for an Ovonic chalcogenide, has been applied to test how the transport time of the Ovonic material and the characteristic time of the external circuit interfere to determine the response to a time-variable voltage on different time scales [74, 83]. This approach was eventually extended to include, for the first time, a dispersion of the energy band states [75].

In the following we will describe this last development in detail. In order to focus on the effect of the band-state dispersion on transport, a very simple device structure is considered (as in the experiments used for validation purposes): a homogeneous chalcogenide layer with nanometer dimensions placed between two planar contacts; the latter are included into the physical model as boundary conditions for the model equations. As in previous models [14, 73, 74, 83], all relevant transport quantities depend upon the coordinate along the field direction (here denoted as z), while homogeneity is assumed in the perpendicular (x, y) plane; for simplicity, unipolar electron conduction is assumed.

Two types of electron energy states are considered. A set of localized states (referred to as "traps" in the following), all having the same energy E_T, are located in the middle of the gap (assumed to be the energy reference, $E_T = 0$), with g_T states per unit volume and carrier density $n_T(z, t)$; they have null mobility and do not contribute directly to the transport process. A parabolic band with minimum at energy Δ, effective mass m, and energy density of states per unit volume $g(E)$ describes the mobile extended states. The density of carriers in the band is $n_B(z, t)$; the band-state mobility μ is assumed to be independent of field and energy.

At equilibrium at temperature $T_\circ$, the total density of electrons $n_\circ$ is neutralized by an equal density of opposite fixed charges. Furthermore, the densities of carriers in the trap and mobile states are given by

$$n_{T_\circ} = \frac{g_T}{1 + \exp[(E_T - E_{F_\circ})/(k\,T_\circ)]}\,,$$
$$n_{B_\circ} = \int_\Delta^\infty \frac{g(E)\ \mathrm{d}E}{1 + \exp[(E - E_{F_\circ})/(k\,T_\circ)]}\,, \qquad (40.13)$$

where $E_{F_\circ}$ is the equilibrium Fermi energy and the second integral is evaluated over the band states. Densities $n_{B_\circ}$ and $n_{T_\circ}$ are homogeneous for a homogeneous distribution of traps, as supposed here.

Out of equilibrium, the occupation probability of an energy state is still taken as a Fermi distribution with an electron temperature T_e. Furthermore, the carrier energy necessary to reach the bottom of the conduction band is reduced by the amount gained from the electric field according to the Poole formula: $\Delta' = \Delta - \gamma\,|F|$. For a given electron temperature and Fermi energy E_F, the stationary position-dependent densities of carriers in the trap and mobile states are given by

$$\tilde{n}_T = \frac{g_T}{1 + \exp[(E_T - E_F)/(k\,T_e)]}\,,$$
$$\tilde{n}_B = \int_{\Delta'}^\infty \frac{g(E)\ \mathrm{d}E}{1 + \exp[(E - E_F)/(k\,T_e)]}\,. \qquad (40.14)$$

According to experimental evidence [84], we assume that the nonequilibrium Fermi energy E_F is well below the band edge, so that $E - E_F \gg k\,T_e$ and $\tilde{n}_B$ in (40.14) can be written as

$$\tilde{n}_B = \exp[E_F/(k\,T_e)] \int_{\Delta'}^\infty g(E)\ \exp[-E/(k\,T_e)]\ \mathrm{d}E\,. \qquad (40.15)$$

Assuming for $g(E)$ the standard form of a parabolic band [85], after straightforward calculations, one gets

$$\tilde{n}_\mathrm{B} = g_\mathrm{B}(T_\mathrm{e})\, \exp[-(\Delta' - E_\mathrm{F})/(k\,T_\mathrm{e})]\,,$$
$$g_\mathrm{B}(T_\mathrm{e}) = \frac{M}{\sqrt{2}} \left(\frac{m\,k\,T_\mathrm{e}}{\pi\,\hbar^2}\right)^{3/2}. \tag{40.16}$$

Coefficient M accounts for the possible concurrence of many bands to the determination of the energy density of states. The Fermi energy is analytically obtained as a function of the electron temperature T_e by imposing the normalization constraint to the density of carriers n:

$$\tilde{n}_\mathrm{T} + \tilde{n}_\mathrm{B} = n\,. \tag{40.17}$$

Replacing (40.14) and (40.16) in (40.17), an algebraic equation is obtained to be solved for the unknown $E_\mathrm{F}(T_\mathrm{e})$, which is position-dependent in nonequilibrium conditions.

Following the approach of [74, 75], particle- and energy-continuity equations along with the Poisson equation are solved with given boundary/initial conditions. The particle-continuity equation reads

$$\frac{\partial n}{\partial t} = \frac{1}{q}\,\frac{\partial J}{\partial z}\,, \tag{40.18}$$

where $n = n_\mathrm{B} + n_\mathrm{T}$ and the electron-current density J includes the drift and diffusion contributions:

$$J = q\,n_\mathrm{B}\,\mu\,F + \mu\,\frac{\partial}{\partial z}\,(n_\mathrm{B}\,k\,T_\mathrm{e})\,. \tag{40.19}$$

In the above equation, a generalized Einstein relation $D = \mu\,k\,T_\mathrm{e}/q$ is assumed in terms of the carrier temperature T_e. Owing to the asymmetry of the contacts present in real structures, the boundary conditions considered in the calculations are asymmetric as well. At the boundary with the source contact ($z = 0$), n is maintained constant and equal to the equilibrium value at any time, i.e., the contact is assumed to constantly inject the electrons that are necessary to maintain electrical neutrality right inside the device:

$$n(0,t) = n_\circ\,, \qquad \frac{\partial n(0,t)}{\partial t} = 0\,, \qquad T_\mathrm{e}(0,t) = T_\circ\,. \tag{40.20}$$

Elsewhere in the device, the transport dynamics determines a position-dependent value $n(z,t)$ of the carrier concentration, and the Poisson equation is used to evaluate the electric field $F(z,t)$.

At the exit contact ($z = L$), the condition $\partial n(z,t)/\partial z|_{z=L} = 0$ at any time is assumed; the value of n, in turn, is provided by the solution of the transport-Poisson equations. While moving across the device, the carriers redistribute themselves between band and trap states so that, at each z, the following equation holds

$$\frac{\partial n_\mathrm{B}}{\partial t} = \frac{\partial n}{\partial t} - \frac{n_\mathrm{B} - \tilde{n}_\mathrm{B}}{\tau_\mathrm{n}}\,, \tag{40.21}$$

where τ_n is the band-concentration relaxation time. In a time-dependent situation, $\tilde{n}_\mathrm{B}$ is the "tendential" stationary value of the mobile carrier concentration after a time variation of the electric field, i.e., $\tilde{n}_\mathrm{B}$ is the steady-state electron band population, given by (40.16), corresponding to the instantaneous values of F and T_e.

The rate of change of the total energy density w is obtained from the energy provided by the field, the spatial variation of the energy flux, including the energy lost in recombination processes, and the carrier energy loss to the phonon bath, assuming a relaxation time approximation:

$$\frac{\partial w}{\partial t} = -J\,F - \frac{\partial}{\partial z}(w\,v_\mathrm{B}) - \frac{w - w_\circ}{\tau_\mathrm{w}}\,. \tag{40.22}$$

where v_B is the average velocity of the band electrons at z. Combining the above equations yields the energy-continuity equation [75]:

$$\frac{\partial}{\partial t}\,(k\,T_\mathrm{e}) = \frac{2}{3\,n_\mathrm{B}}\left[-J\,F + \frac{3}{2}\,\frac{J}{q}\,\frac{\partial}{\partial z}\,(k\,T_\mathrm{e}) - \frac{k\,T_\mathrm{e} - k\,T_\circ}{\tau_\mathrm{wB}\,[k\,T_\circ/(k\,T_\mathrm{e})]}\,n_\mathrm{B} - \frac{k\,T_\mathrm{e} - k\,T_\circ}{\tau_\mathrm{wT}}\,n_\mathrm{T} + \frac{n_\mathrm{B} - \tilde{n}_\mathrm{B}}{\tau_n}\left(\Delta' + \frac{3}{2}\,k\,T_\mathrm{e}\right)\right], \tag{40.23}$$

with w_B the energy of the bottom of the band. The energy relaxation to the lattice, consistently with the assumption of Fermi-like distributions of carriers in trap and band states, is described through the carrier temperature relaxation, with contributions from both trapped (relaxation time τ_wT) and mobile (relaxation time τ_wB) states. In (40.23), the temperature relaxation time for band electrons is multiplied by the factor $k\,T_\circ/(k\,T_\mathrm{e})$ to phenomenologically account for faster relaxation of more energetic electrons. The particle- and energy-continuity equations are coupled to the Poisson equation (40.10). Since $n(0,t) = n_\circ$, then $\partial F(0,t)/\partial z = 0$ at any time. Furthermore, an integral condition on the field is imposed in terms of the applied bias $V(t)$:

$$V(t) = -\int_0^L F(z,t)\,\mathrm{d}z\,. \tag{40.24}$$

In summary, Eqs. (40.21), (40.23), and (40.10), along with the particle-continuity equation and the initial/boundary conditions, describe the transport process. They are numerically solved for the unknowns n, n_B, F, and T_e; other quantities like, e.g., j, $\tilde{n}_\mathrm{B}$, and $\tilde{n}_\mathrm{T}$ are calculated from them.

The model has been solved here through the Euler method; in fact, the inclusion of the Poole effect contribution to

the band population and of the steady-state projection $\tilde{n}_B$ makes it much more complex to implement methods like exponential fitting for space integration or Gear-like methods for time integration.

Numerical results obtained with the above-described model are shown here for different chalcogenide materials, which have been experimentally studied in view of their relevance for technological applications, namely, GST–225 [65], AIST [81], and $Zn_{0.35}Te_{0.65}$ [86]. Above threshold, phase change can possibly take place in the considered experiments. Since the model does not include the phase-change effect, the simulated characteristics are interrupted at threshold. Figures 40.12, 40.13, and 40.14 show the current flowing across chalcogenide layers of different thicknesses as a function of the applied voltage. Different layer thicknesses have been considered for each material, namely, 10, 20, and 40 nm; in addition, a thickness of 80 nm has also been considered for AIST. The reported experimental results are from [65] for a 40 nm GST–225 layer, from [81] for an 80 nm AIST layer, and from [86] for a 10 nm $Zn_{0.35}Te_{0.65}$ layer. In all cases the computed $I(V)$ curves show very good agreement with the experiments; a common feature of the three chalcogenides considered here is the overlap of the current curves when data are reported as functions of the mean applied field V/L.

Thus, in the considered range of device thicknesses, the computational approach confirms (see Fig. 40.15) that the threshold voltage scales linearly with the device thickness (i.e., the average electric field at threshold is independent of the device thickness); this is consistent with the findings of [65,87,88]. The result is also consistent with the microscopic

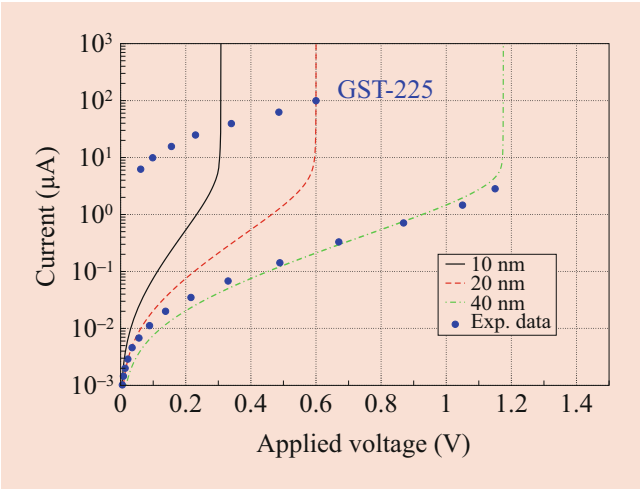

Fig. 40.12 Current flowing across GST–225 layers of different thicknesses as a function of the applied voltage. (After [75]). Experimental data from [65] refer to a 40 nm layer. The above-threshold measurements, which are outside the predictivity range of the present model, have been reported for the sake of completeness

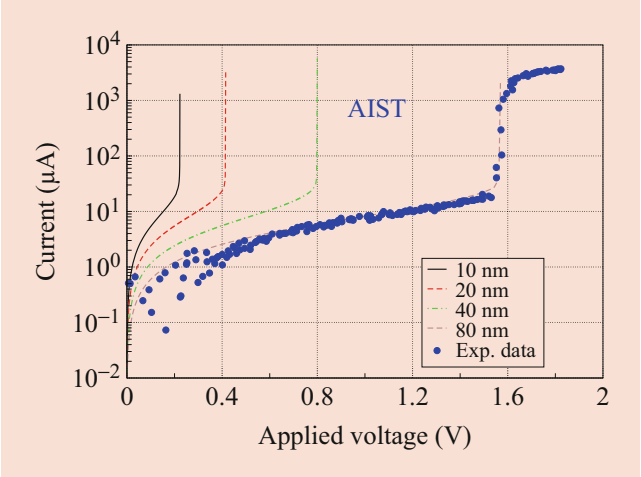

Fig. 40.13 Current flowing across AIST layers of different thicknesses as a function of the applied voltage. (After [75]). Experimental data from [81] refer to an 80 nm layer. The above-threshold measurements, which are outside the predictivity range of the present model, have been reported for the sake of completeness

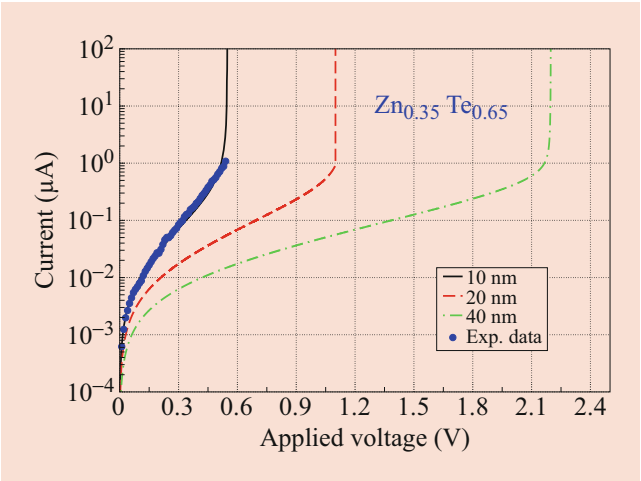

Fig. 40.14 Current flowing across $Zn_{0.35}Te_{0.65}$ layers of different thicknesses as a function of the applied voltage. (After [75]). Experimental data from [86] for a 10 nm layer are shown here up to the threshold voltage, due to the very high on/off current ratio

picture of the transport process at the origin of the switching effect provided by the present approach, already proposed in the literature from other theoretical models [65, 67, 74] and confirmed experimentally for chalcogenide layers larger than 10 nm [89]: in such cases, in fact, the device is large enough to allow carriers to gain the energy required to transfer from localized to extended states. Due to the Poole effect, this energy is actually lower than the bottom of the conduction band.

Experiments performed with chalcogenide layers below 10 nm [89] evidenced a constant voltage scaling with a minimum voltage value close to Δ/q; this has been justified

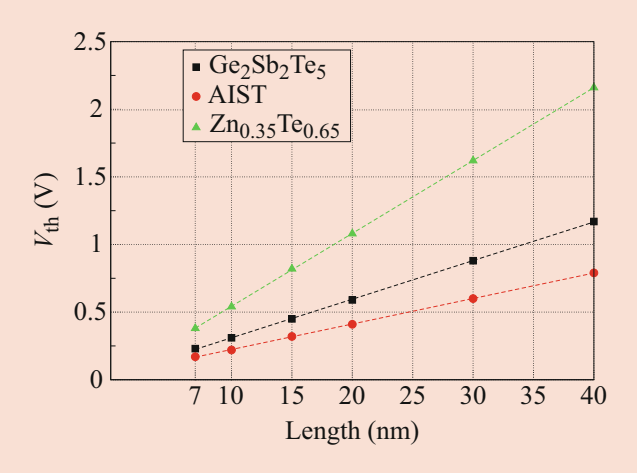

Fig. 40.15 Threshold voltage as a function of the chalcogenide layer thickness for the three materials considered in Sect. 40.4.2. (After [75])

as a consequence of the fact that in short samples electrons cannot relax energy to the phonon bath. Thus, when the energy gain from the external field is eventually enough to promote electrons to the mobile states, the switch takes place. This experimental evidence indicates that the present model is not applicable to devices whose thickness is smaller than a few nanometers.

40.4.3 Detrapping Due to Electron-Electron Interaction

As discussed above, carrier transport in chalcogenide materials typically includes two contributions, namely, that of band electrons (carrier motion in extended states) and hopping via traps (localized states). The sharpness of the trap-to-band transition mechanism is considered as the origin of the snapback event typical of these materials [90]. There may be different causes for the transition; among them is impact ionization which, however, is not frequent near threshold for the typical operating conditions of the devices; another cause is field emission which, by itself, is not able to provide the feedback mechanism necessary to produce the negative differential resistance; a third mechanism is the cooperative influence of the band electrons onto the trapped electrons, which is similar to impact ionization but involves also the lower-energy electrons of the band. The process has been investigated from first principles in [91] and has been included in a macroscopic model in [63], using a generation rate induced by the Coulomb interaction of trap electrons with band electrons. The first-principle analysis of the trap-to-trap transitions is shown here, based on the numerical solver for the time-dependent Schrödinger equation presented in [92].

The starting point is a flow of independent band electrons, having the same energy. The Coulomb interaction of such electrons with a trapped electron is described as the succession of electron-electron scattering events, each amenable to a two-particle analysis; given the number of band electrons at a given energy, the detrapping probability is found in terms of the band electron flow. It is assumed that the trapped electron is initially in the ground state E_0 of a potential well; in turn, the free-propagating band electrons belong initially to the energy state E_k (Fig. 40.16). A rectangular well is considered for simplicity; it is assumed that each band electron interacts with the trap electron only after the previous scattering event is over, so that one scattering event at the time is examined. It follows that the Hamiltonian is of the two-particle type:

$$\mathscr{H}(x_1, x_2) = \mathscr{H}_0(x_1) + \mathscr{H}_0(x_2) + \frac{q^2}{4\,\pi\,\varepsilon\,s}\,,$$
$$\mathscr{H}_0(x) = -\frac{\hbar^2}{2m^*}\,\frac{\partial^2}{\partial x^2} + V_T(x)\,, \qquad (40.25)$$

with V_T the potential energy of the well, m^* the effective mass of the material, and $s = |x_1 - x_2|$.

The trapped electron is initially in the ground state $\chi_0(x_2)$ of the single-particle Hamiltonian $\mathscr{H}_0$ with energy $-E_0$; the incoming electron is described by a Gaussian wave packet $w(x_1)$ with energy $E_k = \hbar^2 k^2/(2\,m^*)$: the center of the Gaussian is initially placed at a large distance from the well to make the interaction negligible at $t = 0$. The two-particle wave function of the system at $t = 0$ reads $\psi(x_1, x_2, 0) = w(x_1)\,\chi_0(x_2)$. The Schrödinger equation for ψ

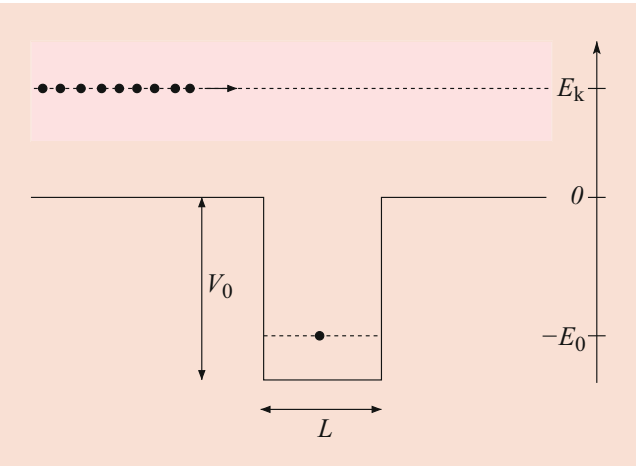

Fig. 40.16 Free-propagating band electrons at an initial energy E_k interact with an electron initially in the ground state E_0 of a rectangular well. (After [91]). The parameters used here are $V_0 = 350$ meV, $E_0 = 189$ meV, and $L = 1$ nm. The band electrons are described by a wave packet having a 5-nm standard deviation

$$i\hbar\frac{\partial}{\partial t}\psi(x_1, x_2, t) = \mathscr{H}(x_1, x_2)\,\psi(x_1, x_2, t)\,, \qquad (40.26)$$

yields a spatial wave function for each time step. To better understand the dynamics of the scattering event, the solution of (40.26) is used here to evaluate the single-particle probability density $\int |\psi(x_1, x_2, t)|^2\,\mathrm{d}x_1$ of the trapped electron before, during, and after the scattering (Fig. 40.17); one finds that, due to the electron-electron interaction, the band electron shares part of its energy with the trapped one, which initially belongs to the ground state χ_0 of the single-particle Hamiltonian (40.25).

It may happen that the trapped electron increases in energy and transits to non-bound states; as a consequence its spatial-density probability, which at $t = 0$ was peaked within the well, broadens up, and becomes non negligible also in regions far away from the well: the detrapping process is thus marked by the broadening of the trap-electron wave packet. Assume that at $t = t_\mathrm{f}$ the interaction is again negligible; then, the analysis of the wave functions provides information about the probability of detrapping: the latter occurs when both electrons are found in an extended state.

The duration of the electron-electron scattering is a few hundred fs; for this reason, one may neglect the relaxation to the ground level of the trapped electron; thus, when a scattering event takes place, the trapped electron is described by superposition of states of the form

$$\psi(x_1, x_2, t_\mathrm{f}) = \sum_{n=0}^{N} \alpha_n\,\varphi_n(x_1)\,\chi_n(x_2)\,, \qquad (40.27)$$

with $\chi_n(x_2)$ the n-th eigenstate of the single-particle Hamiltonian $\mathscr{H}_0$ and $\varphi_n(x_1)$ a freely propagating state associated to the incoming electron after scattering.

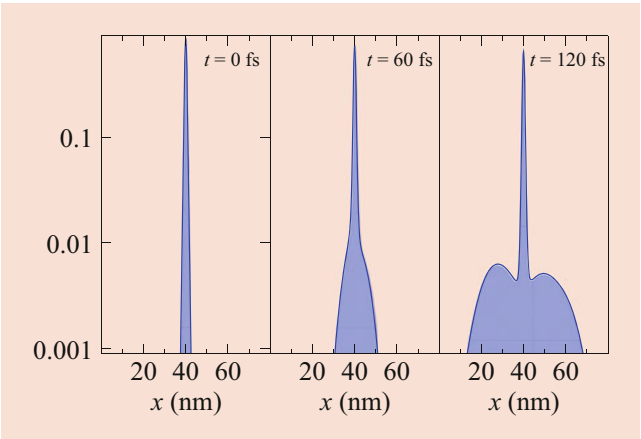

Fig. 40.17 Single-particle probability density of the trapped electron at different time steps. (After [91]). The probability density at $t = 0$ is $|\chi_0(x_2)|^2$, and its peak coincides with center of the potential well ($x_0 = 40\,\mathrm{nm}$). In this simulation, the initial kinetic energy of the incoming carrier is $E_\mathrm{k} = 50\,\mathrm{meV}$

Equation (40.26) has been solved here by the Crank-Nicholson scheme also used in [92, 93] to describe electron systems in semiconductor nanostructures. A one-dimensional, 80-nm-long region has been considered, discretized with a 640-point grid having a $\Delta x = 0.125\,\mathrm{nm}$ resolution [91]. The probability due to a single scattering event is evaluated at $t = t_\mathrm{f}$ from (40.27); for the problem in hand, and with reference to (40.25), χ_0 is the only eigenfunction of the single-particle Hamiltonian $\mathscr{H}_0$ corresponding to a bound state that describes a trapped electron. As a consequence, the square modulus of coefficient α_0 in (40.27) is the probability that, after a single scattering event with a band electron injected at energy E_k, the trapped electron is found in the ground state.

The detrapping probability due to successive interactions is also found from α_0; specifically, after the first two-particle collision is over, the electron described by a superposition of bound and extended states undergoes another Coulomb interaction with an incoming electron, again described by a Gaussian wave packet w. The scattering between w and the extended states of the other particle does not make the latter to relax; in turn, the interaction of w with state χ_0 has an $|\alpha_0|^2$ probability of leaving the latter state unchanged. Assuming independent scattering events, the probability that after n collision the trapped electron is still in the ground state is $|\alpha_0|^{2n}$; it follows that the probability that multiple electron-electron scatterings bring the initially trapped electron into an extended state is

$$P_\mathrm{D} = 1 - |\alpha_0|^{2n}\,. \qquad (40.28)$$

The dependence of P_D on the number n of injected electrons is shown in Fig. 40.18 for different values of the injection energy E_k; as expected, $|\alpha_0|$ decreases when E_k increases. When, instead, E_k is fixed, P_D increases with n and approaches unity within a few tens of interactions; this happens also when E_k is of the order of the thermal energy: such energies of the band electrons are realistic in amorphous GST–225 switching devices, near threshold or in the snapback regime, because the voltage drop across the device is relatively small. It follows from the considerations above that the increase of the device current that takes place in the snapback regime could be ascribed to the larger number of band electrons rather than to an increased velocity of the latter [90]. As the drift velocity of the band electrons is prescribed by their energy E_k, the current density is proportional to n; thus, the form of P_D in (40.28) indicates that the process of electron extraction from the traps has a sharp dependence on the current density. The exponential dependence of probability P_D on n and, therefore, on the current density, originates the function

$$r(I_\mathrm{n}) = 1 - \exp(-I_\mathrm{n}/I_\mathrm{A}) \qquad (40.29)$$

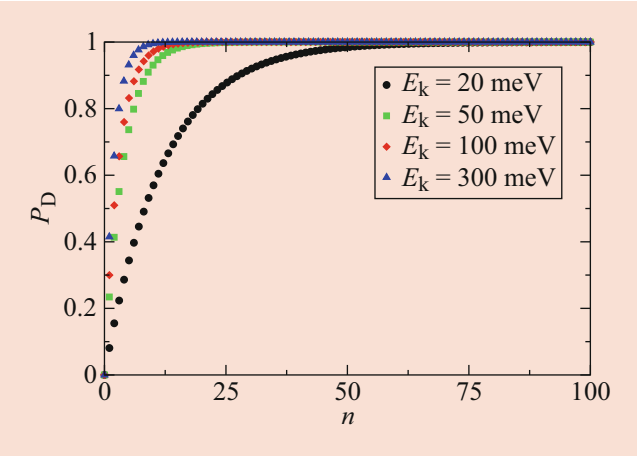

Fig. 40.18 Probability P_D of a detrapping event in terms of the number n of injected electrons; the curves correspond to the different injection energies shown in the inset. (After [91])

used in [63] as a macroscopic model describing the generation rate of the band electrons as a function of the band electron-current I_n, with I_A a constant. The sharpness of the dependence of r on I_n is essential for producing the negative differential resistance in the $I(V)$ curve of amorphous chalcogenides. It is therefore reasonable to conclude that, for the snap back to occur, the mechanism promoting an initially trapped electron to the conduction band must depend strongly on the current density: when this happens, the voltage increase across the device induced by the increasing current is overcome by a competitive effect, that is, the voltage decrease induced by the sudden increase in conductivity. The competitive effect produces the negative differential resistance observed in the amorphous GST–225 devices.

40.4.4 3D Simulation on a Random Network

An attempt to go beyond continuous-medium analytical models for the simulation of transport properties, in both OTS and PCM devices, has been carried out by Cappelli et al. [69, 70], by means of a random network approach that disposes of the one-dimensional limitation and allows one to couple the Fourier heat equation with the constitutive carrier-transport equations; in this way, both electric and thermal effects are accounted for self-consistently. Furthermore, this approach is suitable for describing local nonuniformities and few-carrier phenomena, both relevant in ultrascaled nanodevices.

In [69, 70] an amorphous chalcogenide layer, sandwiched between two conductive surfaces, is modeled as a three-dimensional network of N randomly placed nodes. At two opposite edges, two planar equipotential nodes (0 and $N+1$) play the role of contacts. The electrostatic potential φ_i and the carrier concentration n_i are associated to the i-th node; the average energy E_i is attributed to all members of the population sitting at node i. Following the concept of trap-limited conduction and considering for simplicity only the case of electrons, carrier motion comprises three stages: emission of a carrier from the i-th node to a traveling state with energy just above the conduction band mobility edge E_C, propagation toward the j-th node, and, finally, recapture by the j-th node. To represent the overall process the transition rate is assumed as

$$S_{ij} = \frac{f(r_{ij})}{\tau_0} \exp\left(-\frac{E_C - E_i}{k\,T}\right) \exp\left[-\frac{q\,(\varphi_i - \varphi_j)\,\eta}{r_{ij}\,k\,T}\right], \tag{40.30}$$

where τ_0 is the characteristic time of the transition process, T the lattice temperature, and r_{ij} the distance between nodes i and j. Term $f(r_{ij})$ in (40.30) is a function of the internode distance r_{ij}, describing propagation and recapture. For simplicity it is assumed $f(r_{ij}) = 0$ when r_{ij} is larger than a cutoff distance r_{cut}, and $f(r_{ij}) = 1$ otherwise. Furthermore, the two exponentials in (40.30) account for the thermally activated nature of the excitation process [64, 94]. The first one accounts for the energy barrier in the absence of field; the second one is a correction given by the average electric field $F = -(\varphi_j - \varphi_i)/r_{ij}$ between nodes i and j at a characteristic distance $\eta \le r_{cut}$; following [76], when $r_{ij} < 2\,\eta$ the correction is evaluated at $\eta = r_{ij}/2$.

The connections among nodes define a network of transition rates; given any pair of nodes (i, j), the current between them is $I_{ij} = -q\,(n_i\,S_{ij} - n_j\,S_{ji})$. To find the steady-state value of the node variables (φ_i, E_i, n_i), charge- and energy-flux balances are imposed at each node. As for the latter, three contributions are taken into account: the energy lost at the node site due to outgoing carriers, the energy gained from the incoming carriers (corrected by the effect of the field experienced during the transition), and the energy transferred to the lattice via phonon scattering with a relaxation time τ_R. Neglecting higher order terms, for a given current I the two balance conditions [69] yield

$$-\frac{I}{q}\,\delta_{0,i} + \sum_j n_i\,S_{ij} = \sum_j n_j\,S_{ji} - \frac{I}{q}\,\delta_{N+1,i}\,, \tag{40.31}$$

$$\sum_j n_j\,S_{ji}\,[E_j - q\,(\varphi_j - \varphi_i)] - \frac{I}{q}\,E_i\,\delta_{0,i} = E_i\left[\sum_j n_i\,S_{ij} - \frac{I}{q}\,\delta_{N+1,i}\right] + n_i\,\frac{E_i - E_i^{eq}}{\tau_R}, \tag{40.32}$$

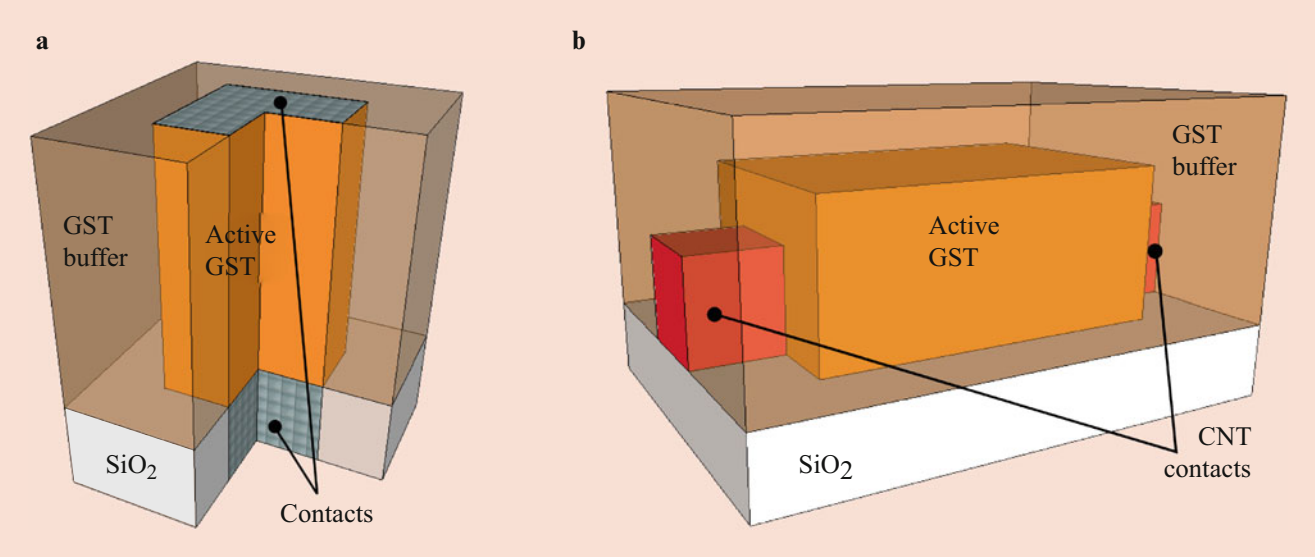

Fig. 40.19 (**a**) Schematics of the simulated devices. (After [70]): a traditional "mushroom-like" cell and (**b**) the novel device of [95] using carbon nanotubes as contacting leads

with $i = 0, 1, \ldots, N+1$. Since the device is current driven, the two equations for nodes 0 and $N + 1$ embed the fluxes from and to the external circuit through Kronecker's $\delta_{0,i}$ and $\delta_{N+1,i}$. The two sets of nonlinear equations (40.31) and (40.32) are solved along with the Poisson and the Fourier heat equations:

$$-\,\mathrm{div}(\varepsilon\,\mathrm{grad}\varphi) = Q_j\,, \qquad -\mathrm{div}(\kappa\,\mathrm{grad}T) = W_{ij}\,, \quad (40.33)$$

where $Q_j = -q\,(n_j - n_i^{\mathrm{eq}})$ at the scattering centers ($Q_j = 0$ otherwise) and $W_{ij} = q\,(n_i\,S_{ij} - n_j\,S_{ji})\,[E_i - E_j - q\,(\varphi_i - \varphi_j)]$ uniformly distributed along the line connecting the i and j centers ($W_{ij} = 0$ otherwise). In (40.33), κ is the thermal conductivity of the material.

The unknowns φ_i, E_i, n_i, and T_i are self-consistently evaluated at all nodes of the network, using a Newton-Raphson scheme coupled with a finite-element procedure. Given the network configuration, the algorithm leads to an $I(V)$ curve, with $V = \varphi_{N+1} - \varphi_0$.

Figure 40.19 provides a schematic view of the simulated devices: a traditional "mushroom-like" cell (left) [54] and a nanostructure with carbon nanotubes as contacting leads (right) [95]; the case of GST–225 has been considered. The SiO_2 bottom layer is kept at 300 K in both cases, and adiabatic boundary conditions are assumed at the sides [70]. The interplay among energy relaxation time of the carriers, local electric field, and local lattice temperature determines three different conditions, depending on the energy relaxation time constant τ_R and thermal conductivity κ (Fig. 40.20). When the energy gained from the electric field is efficiently dissipated to the lattice via phonon scattering, Joule heating and phase change prevail over other nonlinear effects. When, instead, the energy transfer to the lattice is low, the energy

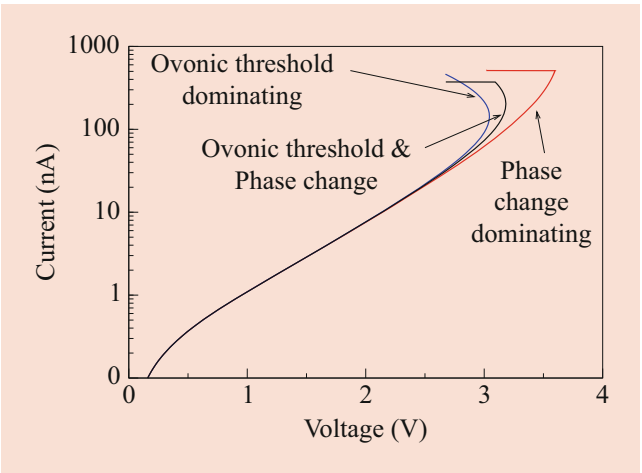

Fig. 40.20 Different threshold events evidenced in the $I(V)$ curve, depending on the values of thermal conductivity κ and energy relaxation time constant τ_R. (After [70])

gained from the electric field produces a hot-carrier distribution; under these conditions, the OTS event takes place. In intermediate cases, hot-carrier effects are limited, and the phase-change event may or may not be preceded by the OTS, depending on the transition temperature T_c.

The experimental device of [95] is analyzed in Fig. 40.21, showing the outcome of a microscopic simulation where preferential pathways for conduction are progressively created as the current is increased. In the figure, three frames of a ball-and-stick animation [70] from a single network configuration are shown, representing the mean energies E_i at the nodes and the normalized currents I_{ij}/I for the three points (a), (b) and, (c) of the $I(V)$ curve of Fig. 40.22. In the Ohmic

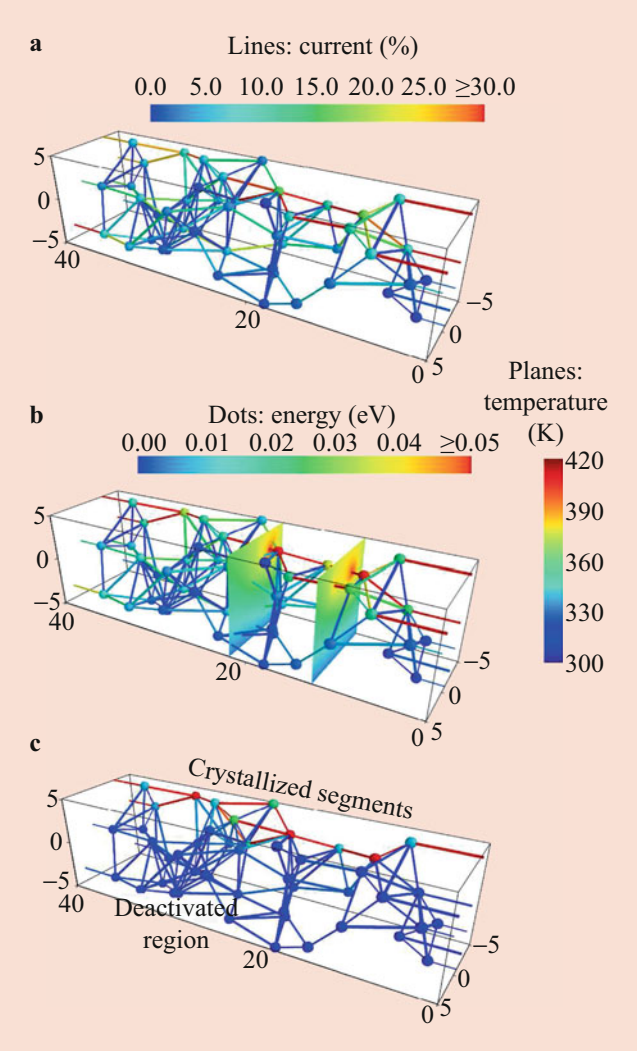

Fig. 40.21 Snapshots of the preferential path creation for conduction and first crystallization events when both (**a**) OTS) and (**b**) MTS are present. (After [70]). Panel (**c**) refers to a post-MTS condition. Note the high temperature along the preferential path

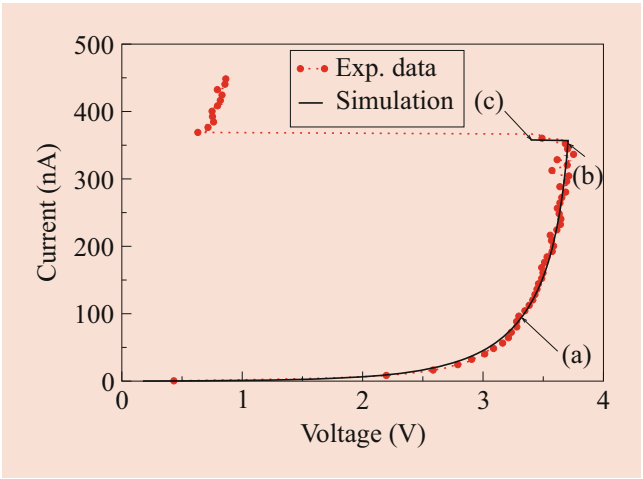

Fig. 40.22 $I(V)$ characteristic of a CNT test device ($10 \times 10 \times 40\,\text{nm}^3$) compared to experimental data. (After [70])

and exponential conduction regimes, the current is initially almost evenly distributed over several paths; heat transfer to the lattice is negligible or moderate. When the exponential conduction turns into the super-exponential regime, the small differences in the resistances among paths, due to local disorder, start to play a role: the current is progressively gathered along a single path, populated by slightly heated carriers. Due to current concentration, a significant Joule heating occurs. When OTS is present, as in Fig. 40.21, carrier heating near the OTS point enhances the creation of a preferential path. The outcome of the process is the positive feedback needed to trigger the switching event: more current implies more heating and faster transition rates and so on. Such a loop determines a steady-state condition where one or a few highly conductive paths connect the contacts (Fig. 40.22c) carrying most of the prescribed current; in turn, the lower resistance of the paths makes the voltage across the device to decrease. This generates a few negative differential-resistance regions featuring hot carriers with high mobility, while all other paths in the device become inactive; as a consequence, a large current can be sustained by a moderate electric field, until the crystallization of the preferential paths eventually takes place.

The concept of filamentation was introduced by Adler and coworkers [57] for large samples (see also p. 28). However, the size of the filaments predicted in this case does not appear compatible with nanoscale devices [96]: although the effect on the $I(V)$ characteristic is similar, the preferential paths identified by the model described here have a different origin than the filaments of Adler's model: in the present case, they are associated with nonequilibrium energy transport, not with a change in the quality or charge of the traps. The paths just indicate preferred sequences of connected nodes without any reference to the filament size.

The configuration-dependent nature of the model allows one to study the impact of intrinsic disorder on the threshold conditions. Figure 40.23 shows a set of one hundred $I(V)$ curves, differing only in the node positions; the statistical analysis of the corresponding threshold voltages V_{th} and currents I_{th} shows variations of up to ∼15% for V_{th} and ∼ 40% for I_{th}, with respect to the corresponding average values $\langle V_{\text{th}} \rangle$ and $\langle I_{\text{th}} \rangle$. Despite quantitative differences, the three known conduction regimes identified by the analytical models [65, 67]—Ohmic, exponential and super-exponential—are recovered in all curves, together with the onset of the voltage snapback. To validate the model against experimental data, a "theoretical" $I(V)$ curve has been constructed, for a given set of parameters, by averaging the potential drops of 30 simulations with random configurations. The standard

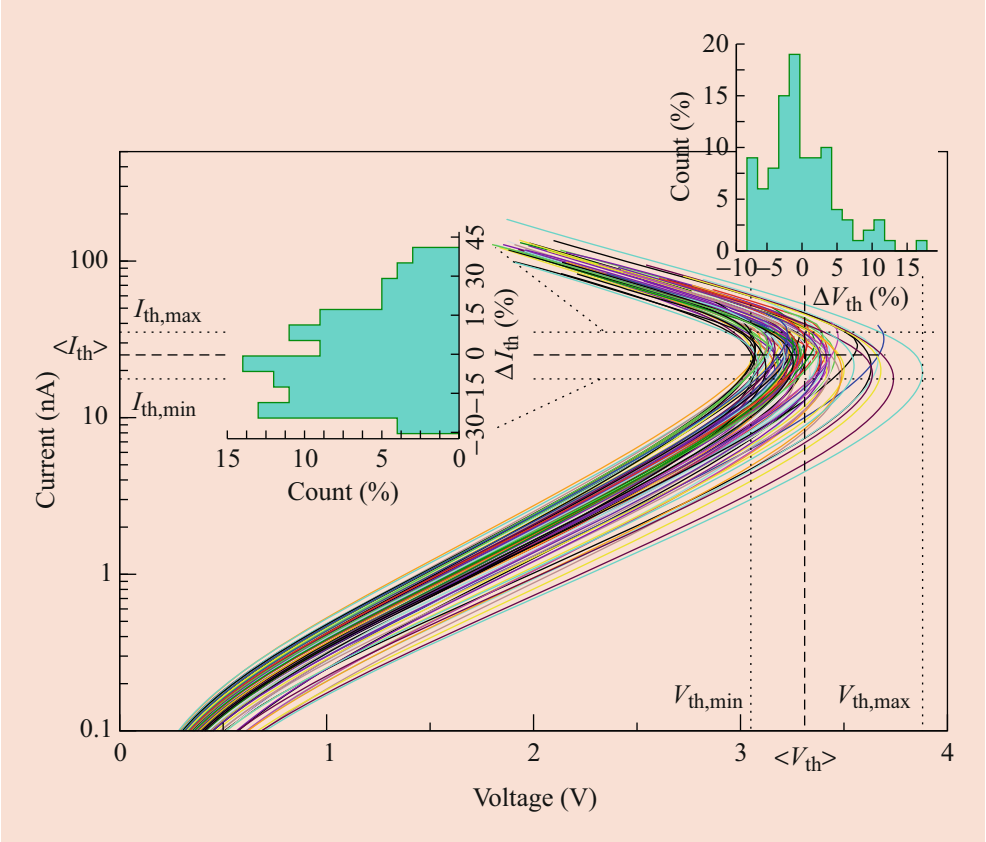

Fig. 40.23 Statistical fluctuations in the $I(V)$ curves for different spatial configurations of the network. (After [69]). The *dashed* and the *dotted lines* show the average and the minimum and maximum values for V_{th} and I_{th}, respectively. The two insets report the frequency analysis for the occurrence of the deviations from the average values $\langle V_{th}\rangle$ and $\langle I_{th}\rangle$. The analysis has been performed on a test device of $10 \times 10 \times 40\,\text{nm}^3$, using $\tau_0 = 10^2$ fs, $\tau_R = 10^3$ fs, $r_{cut} = 6$ nm, $\eta = 2$ nm, and a node concentration $1.2 \times 10^{19}\,\text{cm}^{-3}$

deviation of the potential drops provides an estimate of the expected variability. In Fig. 40.24, the calculated average curves and standard deviations best fitting three experimental $I(V)$ curves of memory devices are shown. In the subthreshold region, the agreement is good; the experimental points lie within the dispersion range, this confirming that the fitting parameters are reasonable. The onset of the threshold switching in the theoretical curve, i.e., the point where $\mathrm{d}V/\mathrm{d}I \approx 0$, corresponds quite accurately to the experimental threshold point. The abrupt voltage drop of the experimental curves above threshold eventually involves the crystallization of the system, which is not addressed by the model [97]. The sensitivity of the threshold condition to the particular location of the nodes is significantly reduced for longer cutoff distances, becoming of the order of ∼1% for V_{th} and of ∼13% for I_{th} in the limit of large r_{cut} (the latter is of the order of 12 nm).

40.4.5 Inter-Trap Transitions

Expression (40.30) of the inter-trap transition rate, or other expressions like (40.36) below, to be used in the balance equations (40.31 and 40.32), embed euristic parameters. An alternative expression, based on a first-principle derivation, is proposed in [98] and reads

$$S_{ij}^{0+} = \int_{E_m}^{\infty} F_{ij}\, n_i^{\text{ph}}\, (n_j^{\text{ph}} + 1)\, \mathrm{d}E\,,$$
$$S_{ji}^{0+} = \int_{E_m}^{\infty} F_{ji}\, n_j^{\text{ph}}\, (n_i^{\text{ph}} + 1)\, \mathrm{d}E\,. \qquad (40.34)$$

In (40.34), S_{ij}^{0+} is the probability per unit time that an electron transits from a filled trap belonging to site i to an empty trap belonging to site j (labels "0" and "+" indicate the charge state of the trap); in turn, n_i^{ph} is the phonon average occupation number at site i, $F_{ij} = F_{ji}$ a coefficient embedding the inter-trap transmission coefficient T_{ij} and E_m the bottom of the conduction band of the contact leads [98]. An analytical approximation of (40.34) is possible, that reads

$$S_{ij}^{0+} = \nu_{ij}^{0+} \left[T_{ij}\, n_i^{\text{ph}}\, (n_j^{\text{ph}} + 1) \right]_{E_{\text{av}}},$$
$$S_{ji}^{0+} = \nu_{ji}^{0+} \left[T_{ji}\, n_j^{\text{ph}}\, (n_i^{\text{ph}} + 1) \right]_{E_{\text{av}}}, \qquad (40.35)$$

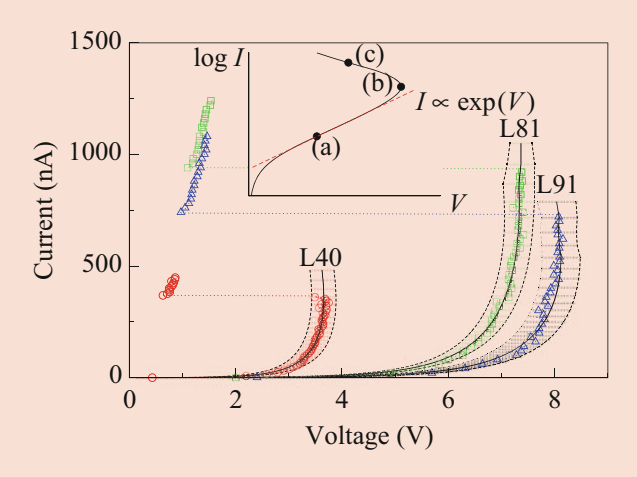

Fig. 40.24 Experimental $I(V)$ characteristics of three different CNT-GST–225 devices. (After [96]), whose estimated lengths are [69] 40 nm (*red circles*), 81 nm (*green squares*), and 91 nm (*blue triangles*). The *black solid lines* and the *dashed sides* show, up to the threshold region, the simulated average characteristics and the standard deviations obtained running a set of 30 simulations in each case. The *inset* shows a typical $I(V)$ characteristic in a semilog scale; the *dashed line* identifies the exponential regime. Points (**a**), (**b**), and (**c**) used in the microscopic analysis of Fig. 40.21 are also highlighted [70]

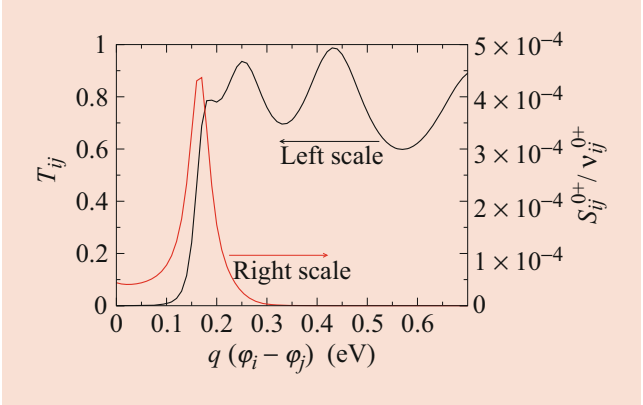

Fig. 40.25 Transmission coefficient T_{ij} (*left scale*) and normalized probability per unit time $S_{ij}^{0+}/\nu_{ij}^{0+}$ (*right scale*), at $T_L = 300$ K, in terms of the difference $q\,(\varphi_i - \varphi_j)$ of the potential energy between two traps. (After [98]). The calculation has been carried out by considering a 4-nm-thick rectangular barrier, with $\varphi_j = 0$. The simulation parameters are such that, depending on the value of $q\,\varphi_i$, both the oscillatory and real-exponential behavior of T_{ij} occur

with $E_{av} = (E_{ni} + E_{nj})/2$. Symbols E_{ni}, E_{nj} indicate the nonequilibrium Fermi energies at sites i, j; these values are available in a TCAD simulation because they are extracted at each iteration of the solution scheme from the electric potential and carrier concentration of the site. In turn, $\nu_{ij}^{0+} = \nu_{ji}^{0+}$ is the attempt-to-escape frequency, which is expressible in terms of the material properties [98]. Using (40.35) one calculates the normalized probability per unit time $S_{ij}^{0+}/\nu_{ij}^{0+}$; the latter is shown in Fig. 40.25 (right scale) in terms of the energy difference $q\,(\varphi_i - \varphi_j)$ between two neighboring traps, for a 4-nm-thick barrier with $\varphi_j = 0$. The same figure also reports the transmission coefficient T_{ij} (left scale); the calibration of parameters was such as to obtain both the real-exponential and the oscillatory behavior of T_{ij}.

The ratio $S_{ij}^{0+}/\nu_{ij}^{0+}$ has a peak at the transition between the real-exponential and oscillatory behavior of T_{ij}; on the right of the peak, $S_{ij}^{0+}/\nu_{ij}^{0+}$ drops quickly due to the vanishing of $n_i^{ph} = 1/\{\exp[(E_N + q\,\varphi_i)/(k\,T)] - 1\}$ that prevails over the oscillatory behavior of T_{ij} (E_N is a constant energy that depends on the form of the trap). In turn, the form of $S_{ij}^{0+}/\nu_{ij}^{0+}$ on the left of the peak is due to the competition between the decreasing exponential within n_i^{ph} and the increasing exponential that characterizes T_{ij} when $q\,\varphi_i$ becomes small. To summarize, Eq. (40.34), supplemented with the expression of F_{ij}, provides a first-principle derivation of the coefficients; the latter is rendered in terms of the local potential φ and the properties of the traps. A closed-form simplification of (40.34) is given by (40.35).

It is interesting to compare the behavior of S_{ij}^{0+} given by this model with that of [99], that reads

$$S_{ij}^{0+} = \nu_0 \exp[-r_{ij}/r_0 - q\,(\varphi_i - \varphi_j + |\varphi_i - \varphi_j|)/(2\,k\,T)]\,, \tag{40.36}$$

with r_{ij} the distance between sites i and j and r_0 a normalization factor that depends on the energy barrier between the two sites; due to the form of the exponent, the electric potential in (40.36) plays a role only when $\varphi_i > \varphi_j$. The normalized probability per unit time calculated with (40.35) and (40.36) is shown in Fig. 40.26 for different thicknesses of the barrier and different values of the ratio r_{ij}/r_0; the curves differ substantially: in fact, in (40.36) the effect of the local potential disappears when $\varphi_j > \varphi_i$ (this is equivalent to setting the probability of a phonon emission that brings the electron into the destination site, equal to unity). Another difference is in the real-exponential dependence on r_{ij} used in (40.36); such a dependence is, in fact, applicable only in a specific range of the final energy of the absorption event. In contrast, (40.35) does not suffer from such limitations: it considers both the absorption and emission probabilities, and the transmission coefficient T_{ij} accounts for the propagation at constant energy in both the oscillatory and real-exponential cases.

40.4.6 Ab Initio Quantum Transport Models for Ultrascaled Chalcogenide Devices

The transport approaches discussed so far are based on balance equations that assume diffusive transport and include a number of tunable parameters not directly connected to

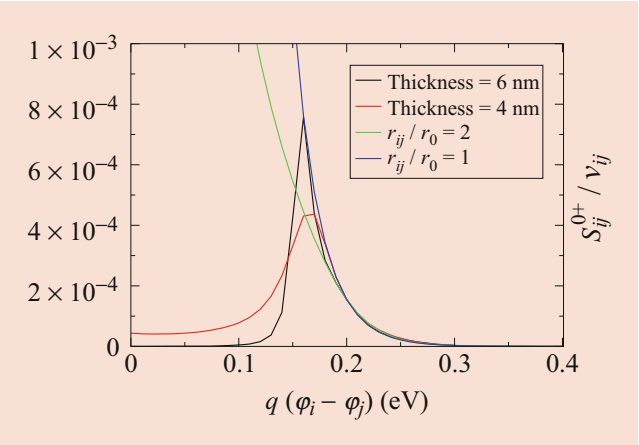

Fig. 40.26 Normalized probability per unit time, Eq. (40.35), calculated for two different thicknesses of a rectangular barrier (*black and red lines*). (After [98]). The same probability calculated following the theory of [99], reported here in Eq. (40.36), is shown by the *green and blue lines* for different values of the ratio r_{ij}/r_0

measurable quantities. Furthermore, as PCM devices scale down to the nanometer dimensions, new technological opportunities and modeling challenges open up [100]. In particular, for chalcogenide layers well below 10 nm, a small number of localized states are present in the atomic structure, which introduce an intrinsic granularity in the description of transport, and quantum effects become relevant when the de Broglie wavelength of the charge carrier becomes comparable with the layer length.

An attempt to deal with such effects relies on a first-principle quantum approach to the microscopic charge-transport process based, e.g., on the density functional theory (DFT), the nonequilibrium Green function (NEGF) method, or quantum hydrodynamics (QHD) [101–104]; for the basic concepts of the theoretical approach, the interested reader may refer, in this book, to Chaps. "▶ 42" by M. Fischetti et al., "▶ 43" by Ph. Dollfus and J. M. Sellier, "▶ 44" by S. Datta et al., and "▶ 45" by G. Klimeck and T. Boykin, and to [104] and references therein for more technical details about the application of the methods to the case of chalcogenides, the simulation packages used, and the input parameters of the calculations. Even though the atomistic approach cannot be applied to the simulation of complex devices due to the heavy computational load, it certainly provides the best tool for obtaining a unified understanding of the peculiar electrical properties of chalcogenides at the atomic scale, and clarifying what is the ultimate size PCM films can be scaled to, still retaining the crystalline-to-amorphous conductance ratio required by the technological applications.

The ab initio approaches, applicable to both amorphous and crystalline structures, in principle require, as input parameters, the lattice structure for the crystalline phase and the mass density for the amorphous one. As for the amorphous phase, the atomic structure is obtained from ab initio molecular dynamics (AIMD) starting from the liquid phase; then, the liquid is suitably quenched and, finally, relaxed to generate the amorphous structure. By means of a simulated annealing, an implementation of the AIMD procedure starting from the amorphous phase, at a temperature lower than the melting temperature and higher than the crystallization temperature, provides the recrystallised phase. Due to the small size of the samples, the procedure must be repeated to make different amorphous configurations available. The comparison between the computed and measured pair distribution functions provides a check about the reliability of the final result. Figure 40.27 shows some results of such a calculation for the case of GeTe [104]. In order to carry out the simulation of a transport process, the nanometer scale chalcogenide structure must be completed with the inclusion of two metal layers working as electrodes, to form a very simple device. In order to achieve a realistic structure at the metal-chalcogenide interfaces, all atoms are allowed to relax within a fixed region at the two interfaces. Open-source simulation packages are commonly used to implement the DFT-based, conjugate-gradient method and the AIMD; the results shown in [104] have been obtained with package SIESTA [105].

GeTe has been analyzed as case study [101] since binary PCM is found to maintain phase-change properties down to the smallest nanometer scale, probably due to the simple stoichiometry and small crystalline unit cell. Furthermore, TiN has been used to simulate metal contacts due to its wide experimental use, justified by the optimal thermal and mechanical properties at the interface with chalcogenide materials. The first calculations were performed for equilibrium electron transport [101]; the approach has then been extended to the nonzero bias case in the subthreshold regime under the assumption of ballistic transport [102]. The role of inelastic electron-phonon scattering in electron quantum transport has been assessed by using the Born approximation [103]. The results indicate that less than 4% of the energy carried by the electrons injected by the source contact is transferred to the lattice before carriers are collected at the drain contact. The main effect is a broadening of the calculated current density peaks (not shown in the figures), which has little influence on the quantitative shape of the $I(V)$ characteristic of the device.

In view of these results, the general quantum methodology to calculate electron transport quantities is outlined below for the ballistic case. The typical structure used for transport simulation at the atomic level is shown in Fig. 40.28. A combination of DFT, NEGF, and QHD approaches is applied starting from the lattice structure previously generated, which constitutes an input information (see the original literature [104] and the chapters of this book referred to at p. 1474 for a detailed description of the methodologies). The appli-

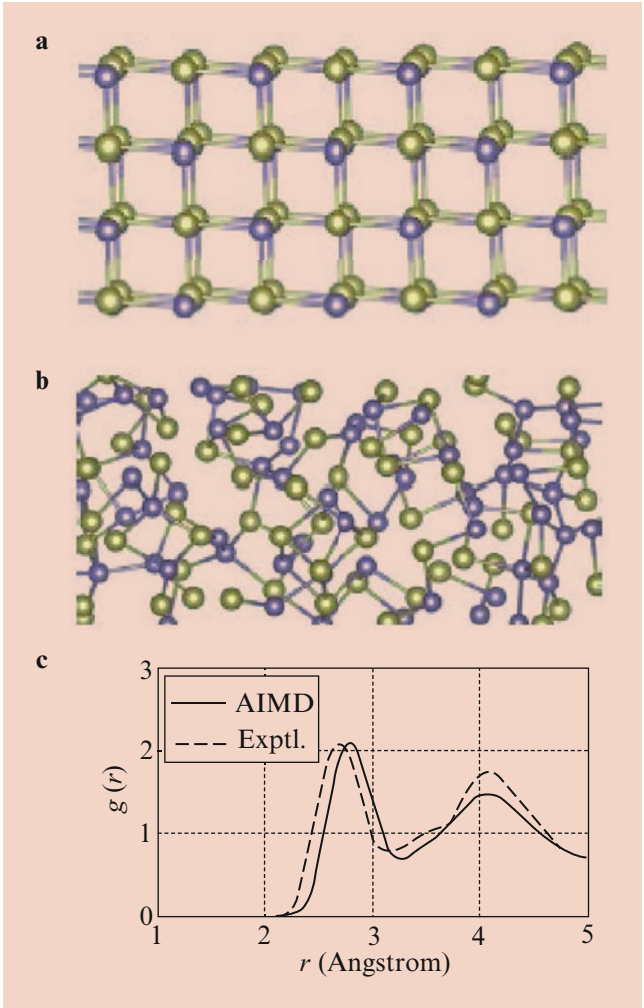

Fig. 40.27 Atomic structure of (**a**) crystalline and (**b**) amorphous GeTe; in (**c**) a comparison between computed and measured pair distribution function of amorphous GeTe is shown. (After [104])

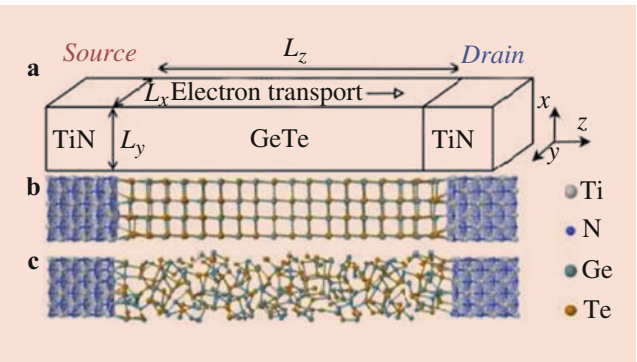

Fig. 40.28 Structure of the device used for simulations of transport at the atomic scale (*upper part*); crystalline (*middle part*) and amorphous (*lower part*) layers of GeTe chalcogenide within two layers of TiN acting as electrodes. (After [102]). Typical dimensions are $L_z = 6\,\text{nm}$, $L_x = L_y \approx 1.2\,\text{nm}$

cation of DFT to the device structure at zero bias provides the Hamiltonian matrix **H** and the overlap matrix **S**, which contain the ab initio equilibrium electronic structure. Then, an external bias V is applied, and the electron density is calculated in the pseudoatomic orbital (PAO) representation using an iterative self-consistent field solution:

$$n(\mathbf{r}) = \sum_{\mu\,\sigma} \mathbf{D}_{\mu\,\sigma}\,\phi_\mu(\mathbf{r})\,\phi^*_\sigma(\mathbf{r})\,, \tag{40.37}$$

where ϕ is the PAO basis function and **D** the density matrix:

$$\mathbf{D} = \frac{1}{2\,\pi\,\mathrm{i}} \int \mathbf{G}^<(E)\,\mathrm{d}E\,. \tag{40.38}$$

The lesser Green function $\mathbf{G}^<$ of (40.38) is computed as

$$\mathbf{G}^< = \mathbf{G}^+\,\mathbf{\Sigma}^<\,\left(\mathbf{G}^+\right)^\dagger\,, \tag{40.39}$$

where the retarded Green function $\mathbf{G}^+$ and the lesser self energy $\mathbf{\Sigma}^<$ are given by

$$\mathbf{G}^+ = \left(E\,\mathbf{S} - \mathbf{H} - \mathbf{H}_\mathrm{V} - \mathbf{\Sigma}^+_\mathrm{L} - \mathbf{\Sigma}^+_\mathrm{R}\right)^{-1}\,, \tag{40.40}$$

$$\mathbf{\Sigma}^< = -2\,\mathrm{i}\,\left(\mathrm{Im}\{\mathbf{\Sigma}^+_\mathrm{L}\}f_\mathrm{L} + \mathrm{Im}\{\mathbf{\Sigma}^+_\mathrm{R}\}f_\mathrm{R}\right)\,. \tag{40.41}$$

As mentioned above, **H** and **S** are the equilibrium Hamiltonian matrix and the overlap matrix; in turn, $\mathbf{H}_\mathrm{V}$ is the Hamiltonian term due to the external bias, E is the electron energy, $\mathbf{\Sigma}^+_{\mathrm{L,R}}$ is the retarded self-energy of the left/right electrodes (computed by means of the iterative surface Green-function algorithm [104]), and $f_{\mathrm{L/R}}$ the Fermi function of the left/right electrode:

$$f_{\mathrm{L/R}} = \left\{1 + \exp\left[(E - E_\mathrm{F} \pm q\,V/2)/(k\,T_\circ)\right]\right\}^{-1}\,. \tag{40.42}$$

In (40.42), E_F is the Fermi energy and $T_\circ$ the lattice temperature.

The self-consistent electric field solution inside the device for each external bias V is obtained by the iterative solution of (40.37) for the electron density and Poisson equation. Then, after the calculation of (a) the L/R electrode self-energy matrices $\mathbf{\Sigma}^+_{\mathrm{L,R}}$ [106], (b) the retarded Green function $\mathbf{G}^+$, and (c) the lesser Green function $\mathbf{G}^<$ [107, 108], the electron transport properties can be obtained; in particular, the analysis of the energy-resolved transmission coefficients $T(E)$ and current density $\mathbf{J}(\mathbf{r})$ evidences the microscopic origin of the peculiar electron transport properties below threshold for amorphous chalcogenides.

The energy-resolved transmission coefficient $T(E)$ provides a quantitative information about the probability that an electron with energy E propagates from the injecting contact to the drain contact: a low value of T means a high electron

backscattering in the device. In turn, the current density is evaluated as the sum of two terms: a local, conventional part $\mathbf{j}_c(\mathbf{r}, E)$ and a nonlocal term $\mathbf{j}_{nl}(\mathbf{r}, E)$, which guarantees the current-continuity condition in presence of a nonlocal potential in the DFT Hamiltonian [109]:

$$\mathbf{J}(\mathbf{r}) = \int \mathbf{j}(\mathbf{r}, E)\, \mathrm{d}E = \int \left[\, \mathbf{j}_c(\mathbf{r}, E) + \mathbf{j}_{nl}(\mathbf{r}, E) \,\right] \mathrm{d}E\,. \tag{40.43}$$

The average current density is defined from (40.43) as

$$J_{av} = \frac{1}{S_0} \int \mathbf{J}(\mathbf{r}) \cdot \mathrm{d}\mathbf{S}_0\,, \tag{40.44}$$

where $\mathbf{S}_0$ is the cross section perpendicular to the electron transport direction and S_0 is its area [104]. The theoretical predition for the case of GeTe, shown in Fig. 40.29, well compares with the experimental results. At voltages around $V = 0.2\,\mathrm{V}$ or lower, the ratio between the crystalline vs amorphous current densities is about 10^2–10^3 (see the C_1 and A_1 points in Fig. 40.29). This marked difference is well understood by considering the bias-dependent transmission coefficients, shown in Fig. 40.30. The amorphous case exhibits an empty band gap, while the crystalline case has metal-induced gap states near the Fermi energy, which bring about a large transmission through the device. A detailed microscopic analysis of the above quantities [104] evidences that a full explanation of the linear, exponential, and S-shaped $I(V)$ characteristic in the amorphous phase comes from a microscopic balance between (i) bias-dependent quantum dynamics of current swirls that set in at the Å scale due to the presence of defect-induced electron backscattering and localization and (ii) electron delocalization along the device produced by the external bias. Due to the large density of defects of the amorphous phase, the transmission effect is considerably reduced at low bias. As the applied voltage is increased, the field-induced progressive electron delocalization enhances the carrier drift along the electric force direction, and swirl localization is progressively destroyed. Figure 40.31 evidences the evolution of the current swirl localization pattern in the linear (A) and exponential (B) regions of the current-voltage characteristic of the a-GeTe layer through local 2D slices of the normalised, space-resolved scaled current density; the latter is defined as

$$\mathbf{D}(\mathbf{r}) = \frac{1}{J_{av}} \int \mathbf{j}(\mathbf{r}, E)\, \mathrm{d}E\,. \tag{40.45}$$

with J_{av} given by (40.44). The swirl patterns, well confined in the Å scale and separated from each other, are progressively destroyed when the external bias approaches the Ovonic switching field.

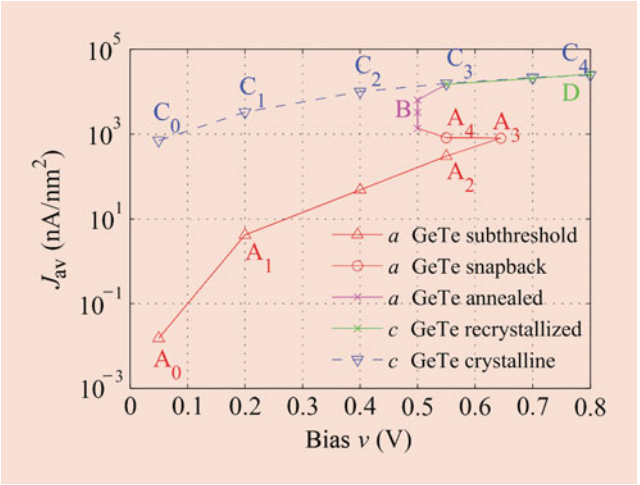

Fig. 40.29 $J_{av}(V)$ characteristic computed by means of an ab initio approach for a GeTe chalcogenide layer about 5.5-nm-long, with lateral dimensions about $1.2 \times 1.2\,\mathrm{nm}^2$, supplemented with TiN metallic contacts. (After [104])

40.5 Macroscopic Models

The preceding sections of this chapter dealt with simulation approaches based on microscopic models, which are usually applied to understand specific transport features of the large amorphous chalcogenide family. The effectiveness of the physical models is usually tested on simple structures. In order to move to the simulation of the more complex devices engineered for specific electronic applications, the theoretical framework must be simplified in order to reduce the computational burden to a reasonable extent and ease the interfacing with commercial device simulation platforms. An attempt to bridge microscopic and macroscopic approaches into a device simulation tool is described in [110], where a finite-element modeling of nucleation, growth, and amorphization processes in phase-change memory devices is carried out using a simplified 3D cylindrical geometry. A rate equation describing the evolution of the crystal density at each mesh point is coupled with the current-continuity and Fourier-heat equations; using the parameters of GST–225, the model performs electrothermal simulations describing consecutive set and reset cycles of a "mushroom" cell of the type presented in [54]. The model also allows for the simulation of cycle-to-cycle variations due to the stochastic nature of the nucleation process and of the interplay of crystallization, formation of percolation paths, and thermal runaway [111].

In a recent paper, where the same cylindrical geometry as in [110] is used (Fig. 40.32), the electric conductivity of GST-225 is written as the sum of two independent contributions $\sigma_{\mathbf{E}}$ and σ_T; it is assumed that the band mobile carriers are generated by two independent processes (a thermal and

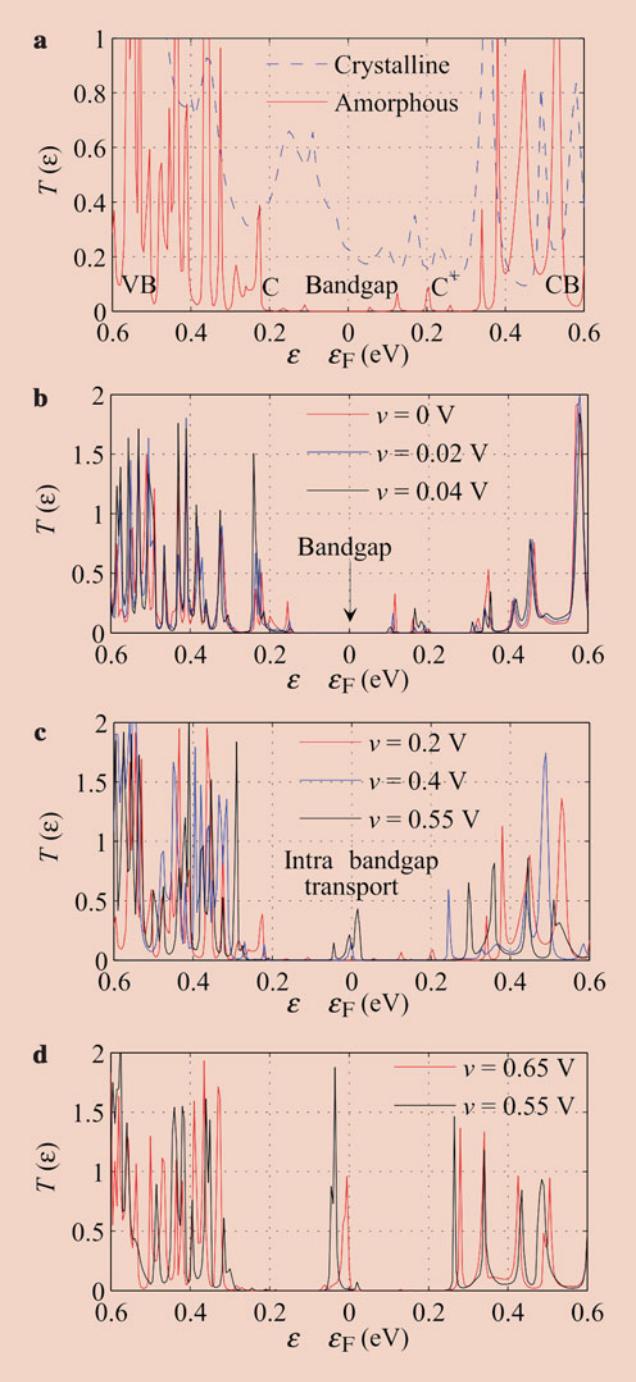

Fig. 40.30 Transmission coefficients as functions of the electron energy for the GeTe structure of Fig. 40.29. (After [104]). (**a**) a-GeTe and c-GeTe cases for $v = 0.2$ V (points A_1 and C_1 in Fig. 40.29); (**b**) and (**c**) a-GeTe case for small and moderate bias region (points A_0, A_1, A_2, A_3 in Fig. 40.29); (**d**) a-GeTe in the S-shaped part of the $J_{av}(V)$ curve (points A_3 and A_4 in Fig. 40.29)

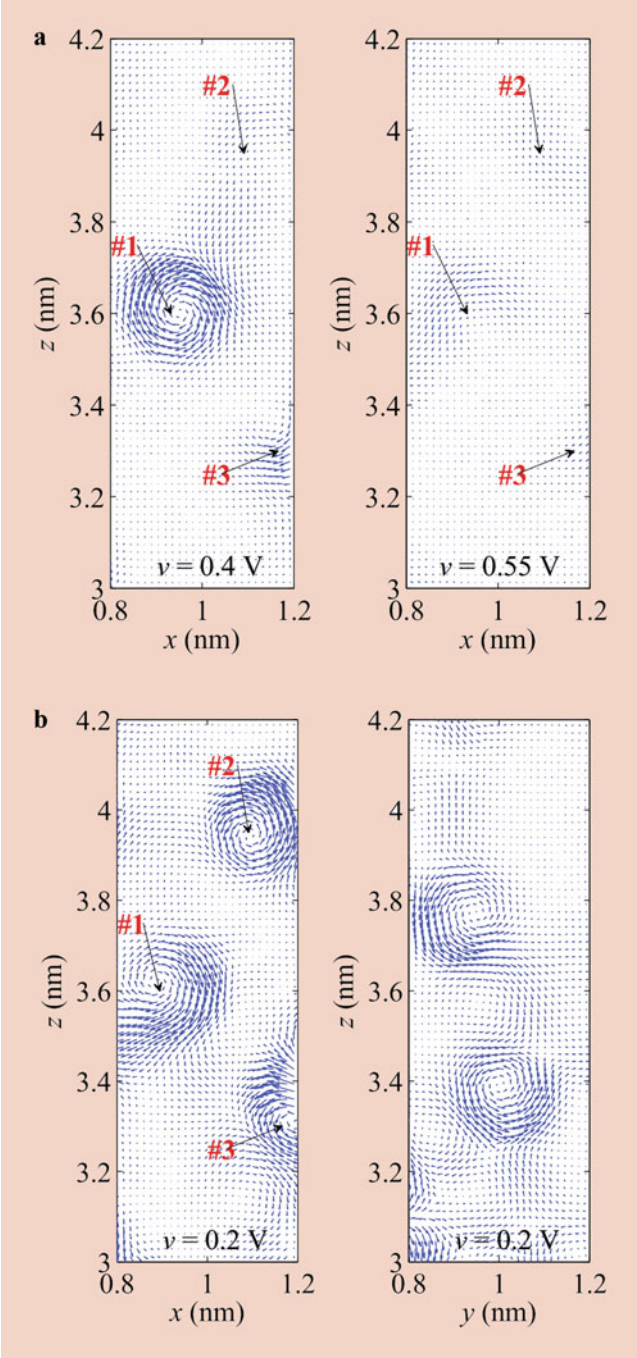

Fig. 40.31 2D plots of the normalised space-resolved scaled current density $\mathbf{D}(\mathbf{r})$ in the subthreshold linear (**a**) and exponential (**b**) regions of the $I(V)$ characteristic of the a-GeTe layer (see text). (After [104]). *Numbers* and *black arrows* in the figure identify the different detected swirls in the 2D mapping, in order to easily visualize their evolution at increasingly higher biases

an electric one), thus empirically decoupling the effect of the electric field $\mathbf{E}$ on the transport properties from that of temperature T. This ansatz avoids the more accurate, but computationally expensive, evaluation of the band-carrier concentration n in terms of integrals involving a nonequilibrium distribution at each iteration step and allows for an easier implementation of the numerical scheme simulating the transients. The relations yielding $\sigma_{\mathbf{E}} = q\,\mu\,n_{\mathbf{E}}$ and $\sigma_{\mathrm{T}} = q\,\mu\,n_{\mathrm{T}}$, with μ the carrier mobility and $n = n_{\mathbf{E}} + n_{\mathrm{T}}$ the

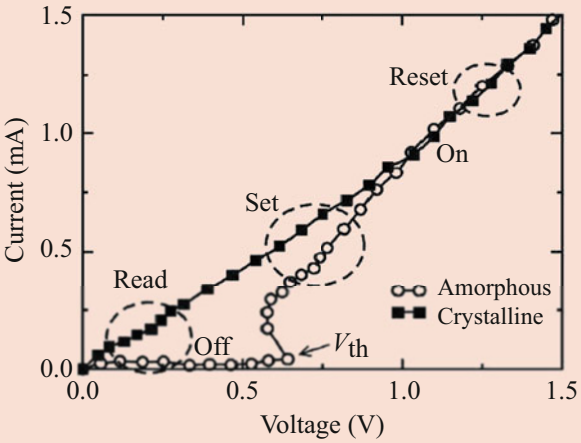

Fig. 40.33 Characteristic of a PCM in an $I(V)$ reference. (After [113]). The *linear curve* belongs to the crystalline phase, whereas the *S-shaped* one belongs to the amorphous phase. The device is current-driven; therefore, the actual characteristic is N-shaped and, consequently, single-valued (the N-shaped curve is sketched in Fig. 40.36). The threshold voltage is indicated with V_{th}

band-carrier concentrations produced by the two processes, are fitted on experiments [112].

Coming now closer to the industrial applications of amorphous semiconductors, in particular in the field of solid-state memories, this section provides a brief outline of how macroscopic simulation models are actually useful to design the device characteristics of the industrial prototypes. As mentioned in Sect. 40.1, the electric property of chalcogenides exploited to write, read, or erase a PCM device is that the $V(I)$ characteristic of the amorphous phase is N-shaped; an example is given in Fig. 40.33. In the following, the issue of modeling PCM oscillations under heating or quenching conditions, also in presence of crystallization, will be addressed after a preliminary discussion of the experimental problems one encounters when measuring the PCM characteristics in the amorphous phase; GST–225 will be considered as case study. Then, a stability analysis of the PCM oscillations will be carried out, and, finally, a study of the crystallization process will be discussed by means of a time-dependent analysis of the PCM temperature.

40.5.1 Macroscopic Modeling of PCM Oscillations

In the following analysis, we refer to the memory device illustrated in Fig. 40.34 (for further details about the design of PCM devices, see, e.g., [13,54] and, in this book, Chap. ▶ 30 by E. Piccinini and C. Jacoboni. Furthermore, we consider the "intrinsic" device, namely, the device obtained by ideally removing the series resistance due to the heater and contacts, along with the parasitic devices inevitably associated with the wiring and the measuring apparatus. A schematic cross section of the whole device is shown in the left part of Fig. 40.34; the rectangular region, limited above by the top electrode and below by the insulator or heater, visualizes the intrinsic device, which is initially amorphous; the white half sphere right above the heater is the volume that crystallizes first; finally, the red spherical shell is the maximum volume that crystallizes in the normal functioning regime of the PCM. The voltage-current characteristic of the intrinsic device will be indicated here and in the following with $V_S(I)$.

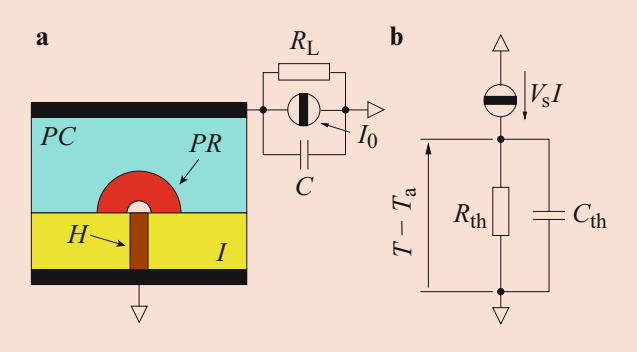

Fig. 40.34 (**a**) Schematic cross section of the device. (Adapted from [97]), connected to a lumped circuit representing the current drive and the parasitic devices; PC phase-change material, PR programmable region, I insulator, H heater. In the analysis carried out in Sect. 40.5, the material of the PC region is amorphous; initially, also the material of the red and white regions (PR) is such. The white region indicates the volume that crystallizes during the first, larger oscillation peak shown in Fig. 40.35. (**b**) thermal circuit for the PCM. (After [113]). A slightly different version of the figure is also in [114]

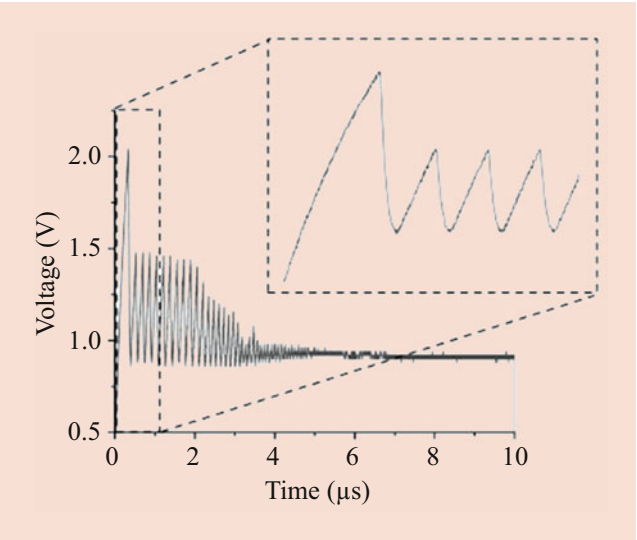

Fig. 40.35 Time evolution of the voltage V_S across a PCM in the amorphous phase during a dynamic measurement. (From Fig. 3 of [117], also in [114]). The oscillations are due to the instability produced by the NDR branch of the $V_S(I)$ characteristic. The *zoom* shows the amplitude of the first peaks, whose behavior is explained in the text

40.5.2 Measuring PCM Characteristics in the Amorphous Phase

Setting up a static measurement setup for $V_S(I)$ or other electric parameters of the amorphous PCM is notoriously complicated, because of the intrinsic instability due to the negative differential-resistance (NDR) branch. In fact, the amount of data available in the literature about the NDR branch of the characteristic is rather limited. A different approach tackles the problem using a dynamic setup, namely, it exploits the instability associated with the NDR branch of the PCM characteristic; this is done, e.g., in [115–117]. The arrangement is such that the voltage-current curve of the external load intersects that of the PCM in the NDR branch, with a suitably chosen slope that forces the circuit to oscillate. The analysis of the oscillatory regime shown in the following is based on the theory of [114].

One of the problems brought about by a dynamic measurement is the partial crystallization of the material produced by the heat injected into the device. When part of the volume crystallizes, the increase in the device conductance modifies, and possibly extinguishes, the oscillations. A typical pattern of the oscillatory condition is shown in Fig. 40.35 [117]: the first oscillation exhibits a large peak, followed by oscillations whose amplitude is smaller than that of the first peak and relatively stable; after a while the oscillation amplitude starts decaying. The decrease in amplitude from the first peak to the next ones is explained by observing that the concentration of the current lines flowing from the heater produces a sudden crystallization of a finite portion of material (the white half sphere right above the heater in Fig. 40.34a). The heater is in fact narrower than the amorphous region, and the temperature is the highest because the whole device is still amorphous. The sudden crystallization of the region in contact with the heater, which takes place during the first oscillation, leaves a smaller resistance for the next cycles. This event is followed by oscillations with a stable amplitude; in fact, although the temperature of the amorphous phase increases due to the injected heat, it is still $T < T_g$, with T_g the *glass temperature* (i.e., the temperature above which the amorphous-to-crystalline phase change occurs; it is $T_g < T_m$, with T_m the melting temperature). When the material temperature exceeds T_g, so that $T_g < T < T_m$, the oscillation amplitude starts to decay due to the decrease in the amorphous phase volume [82, 117] (for GST–225 it is $T_g = 550$ K and $T_m = 810$ K [113]). We conclude that the description of the oscillations must combine time-dependent circuit and thermal analyses with the modeling of crystallization; both of them can be carried out by means of the macroscopic model described in the next section.

Macroscopic Time-Dependent Modeling of PCM Dynamic Response

The description of the events that take place in the dynamic measurement described above must address a number of aspects, namely, *(a)* the analysis of a nonlinear circuit having an NDR branch whose properties depend on time, *(b)* a thermal analysis describing the dependence of the PCM temperature on time, *(c)* the time evolution of the crystallization of a part of the volume, and *(d)* the change in resistivity of the PCM due to crystallization and its effect on the shape of the voltage-current characteristic.

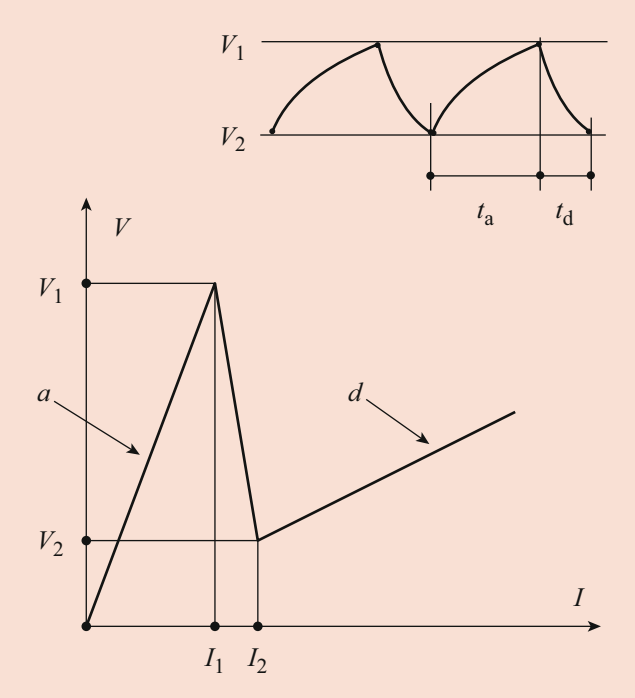

Fig. 40.36 The $V(I)$ characteristic approximated by a piecewise-linear curve (compare with Fig. 40.33). The *inset* shows the corresponding saw-like form of $V(t)$ that occurs when crystallization is absent. In the ascending part of the oscillation, corresponding to period t_a of the inset, I and V vary along the branch marked with a; in the descending part of the oscillation, they vary along the branch marked with d

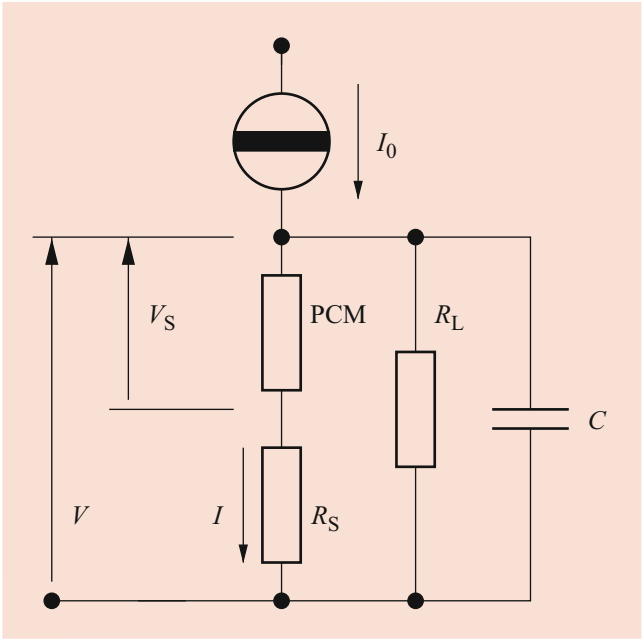

Fig. 40.37 Scheme of the circuit used for measuring the PCM parameters. Compare with Fig. 40.34a

As mentioned in Sect. 40.4.3, the origin of the N-type characteristic is traced back to a sharp increase in the trap-to-band transition rate, driven by the injected current I and starting at I_1 (Fig. 40.36). When the current reaches I_2, many of the initially trapped electrons have undergone the transition. The phenomenon, whose detailed analysis is given in [63], is equivalent to a filamentation that occurs in the energy domain instead of the space domain. Due to the larger mobility of the band electrons, it follows that, of the two positive-slope branches, the one crossing the origin has a larger slope than the other one. Also, for a given current density (equivalent to a given cross-sectional area in the case considered here), the collective electron-electron interaction that promotes the electrons from the traps to the band is such that the currents I_1 and I_2 enclosing the NDR branch do not depend on the volume of the amorphous phase [63].

The device of Fig. 40.34 is schematically described in Fig. 40.37 as the series of an intrinsic part, labeled PCM, embedding the N-shaped characteristic, and a constant series resistance R_S due to the heater and contacts. Prescribed parameters are the constant current I_0 and the load resistance R_L. They are chosen in such a way as to force an oscillatory regime in the circuit, which is sustained by the parasitic capacitance C due to the measurement setup. The quantity that is measured is the voltage $V(t)$ across the series made of the PCM and R_S. The circuit is described by the two coupled equations:

$$V = R_S\, I + V_S(I)\,, \qquad I = I_0 - \frac{V}{R_L} - C\,\frac{\mathrm{d}V}{\mathrm{d}t}\,. \tag{40.46}$$

The limit cycle in the I,V plane is determined essentially by the two points (I_1,V_1), (I_2,V_2), visible in Fig. 40.36, that enclose the NDR branch. Following [115,116], one estimates I_1 and I_2 by approximating the $V_S(I)$ curve with a piecewise-linear function; $V(I)$ becomes piecewise-linear as well, as better shown in Fig. 40.36.

As long as crystallization is absent, which happens when the amplitude of the oscillations is still stable as described earlier, the piecewise-linear approximation of $V_S(I)$ makes (40.46) easily integrable, to yield a saw-like oscillation as the one shown in the inset of Fig. 40.36; in fact, all parameters describing the coefficients of (40.46) are constant with respect to time, so that their extraction from the experiments is a relatively simple matter: in fact, defining $R_a = R_L \parallel (R_S + R_1)$ and $R_d = R_L \parallel (R_S + R_2)$ and using the symbols of Fig. 40.36, a straightforward calculation yields

$$t_a = R_a\, C\, \log\frac{V_2 - R_a\, I_0}{V_1 - R_a\, I_0}\,, \qquad t_d = R_d\, C\, \log\frac{V_1 - R_d\, I_0}{V_2 - R_d\, I_0} \tag{40.47}$$

(in general, the values of the circuit elements thus extracted are faulty due to noise or measurement errors; the calculation

must be improved by using the extracted elements as the initial guess of a fitting procedure).

In a realistic situation, instead, only some parameters are constant, specifically, R_S, C, I_1, and I_2, while V_1 and V_2 change with time because of the progressive crystallization of the material. Hence, they must be evaluated by consistently coupling their equations with other equations, produced by the thermal analysis, that are described in Sect. 40.5.3.

40.5.3 Thermal Analysis of the PCM

To find the time dependence of the PCM temperature, one solves the equivalent thermal circuit, shown in Fig. 40.34 (right) [113]. The latter is driven by the power $V_S\, I$ dissipated within the PCM, and is described by

$$\frac{\mathrm{d}T}{\mathrm{d}t} + \frac{T - T_a}{\tau_{th}} = \frac{V_S\, I}{C_{th}}\,, \tag{40.48}$$

where T_a is the ambient temperature and $\tau_{th} = R_{th}\, C_{th}$, with R_{th} and C_{th} the thermal resistance and capacitance, respectively. Typical values of the parameters of (40.48) are given below. It is worth remarking that, when a cell supplemented with an external heater is considered, the boundary conditions of (40.48) must account for the temperature of the boundary region where the heater contacts the cell; such a proviso is not necessary in a self-heating cell.

Crystallization often starts with the formation of small unstable clusters of the new phase (*nucleation process*, where "nucleus" indicates the minimum-size volume that crystallizes). Eventually some clusters reach a critical radius beyond which they are stable, so that they can grow rather than dissolve (*growth process*). As mentioned above, the dynamic model describing crystallization is that of [118]; letting g indicate the number of nuclei of the cluster, one must consider a balance equation for each index $g = 1, 2, \ldots, M$; such equations embed the corresponding condensation rates C_g and evaporation rates E_g, along with the generation rate r of the nuclei and a small number of fitting parameters. They form a set of nonlinear, coupled differential equations of the first order with respect to time, whose unknowns are the concentrations N_g of the g-clusters (i.e., clusters made of g nuclei). Once the maximum index $M = g_{max}$ has been fixed, the balance equations are supplemented with the closure condition $\sum_{g=1}^{M} P_g = 1$, with $P_g = N_g / \sum_{g=1}^{M} N_g$ the probability that a g-cluster exists; the initial condition is $T = T_a, P_g(0) = \delta_{1g}$, with T_a the room temperature. Note that M is unknown at the beginning: the unknown functions N_g or P_g enter the problem one by one; their number is fixed when the contribution to the crystal volume of the last function entering the problem is found to be negligibly small.

The cluster formation becomes effective when T is in the interval $[T_g, T_m]$. When, during the oscillations, the temperature increases beyond T_g, a portion of the volume crystallizes and the dissipated power lowers due to the decrease in resistance; for the same reason, the amplitude of the oscillations decays. On the other hand, the input power is still sufficient to continue the crystallization process; when the whole material is amorphous, the positive slopes are either R_1 or R_2. If, due to the heating and quenching process, the whole material crystallized, the two slopes would merge, namely, $R_1, R_2 \to R_c$, with R_c the resistance of a crystalline volume equal to that of the original material; when, instead, only a portion of the volume crystallizes, the $V(I)$ relations of the two positive-slope branches read

$$V = (R_S + r_{1(2)})\, I\,, \qquad r_{1(2)}(t) = (1 - \lambda)\; R_{1(2)} + R_c\, \lambda\,, \tag{40.49}$$

where $\lambda(t) = w \sum_{g=1}^{M} g\, N_g$ is the fraction of the crystallized volume (w is the volume of a nucleus). One may relate it to the geometrical parameters of the device by writing $0 \le \lambda = (H - H_{am})/H \le 1$, with $H_{am}(t)$ the length of the material that has not crystallized yet and H the initial length introduced above. Clearly (40.49) holds exactly for a one-dimensional device only; here it is used as an approximation. In turn, the thermal resistance at t is obtained from

$$R_{th} = (1 - \lambda)\, R_{th}^{am} + R_{th}^{cr}\, \lambda\,, \quad A\, R_{th}^{am(cr)} = H\, \rho_{th}^{am(cr)}\,, \tag{40.50}$$

where A is the area of the PCM cross section and ρ_{th} the thermal resistivity; suffix "am" ("cr") refers to the amorphous (crystalline) phase. The values used in the analysis carried out here are taken from [119] and read $H = 100\,\mathrm{nm}$, $A = 180 \times 180\,\mathrm{nm}^2$, $\rho_{th}^{am} = 500\,\mathrm{K\,cm\,W^{-1}}$, and $\rho_{th}^{cr} = 200\,\mathrm{K\,cm\,W^{-1}}$; the value of the thermal capacitance is $C_{th} = c_p\, H\, A$, $c_p = 1.25\,\mathrm{J\,cm^{-3}\,K^{-1}}$ (this parameter does not depend on the phase). The form of the N-shaped curve changes with time due to the time dependence of V_1 and V_2; the oscillation regime continues as long as the current-voltage of the external load intersects the NDR branch of the PCM characteristic.

In conclusion, the model is made of the M equations for $P_1, \ldots, P_M$ combined with (40.46)–(40.50). They constitute a set of nonlinear, coupled equations (differential or algebraic) in the unknowns $P_1, \ldots, P_M$, λ, V, I, T, r_1, r_2, R_{th}. The differential equations of the set are of the first order, which entails an open integration that may become rather cumbersome, also considering that in general M is large; the equations are dealt with, e.g., the integral equation method of [120].

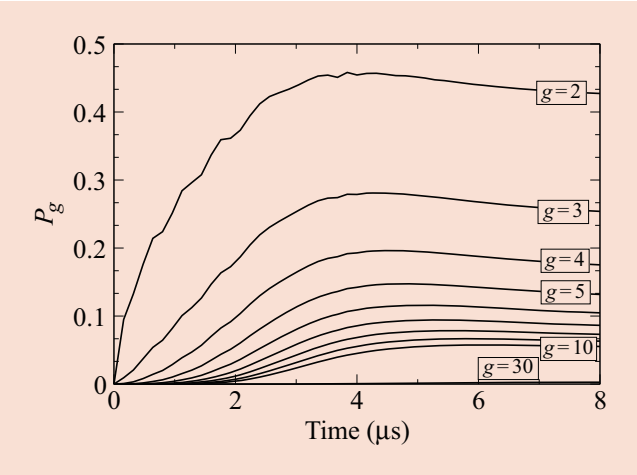

Fig. 40.38 Time dependence of $P_1, \ldots, P_{30}$. (After [114]). The figure shows that in the case in hand the probability of clusters with $g = 30$, or larger, is negligible. Each probability tends to saturate with time

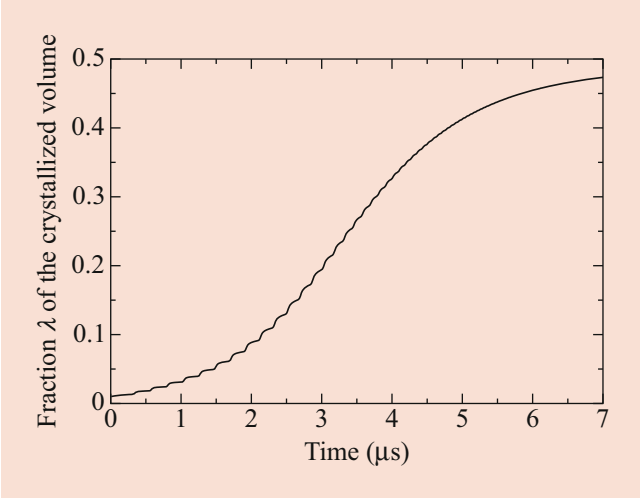

Fig. 40.39 Time dependence of the fraction λ of the crystallized volume. (After [114])

40.5.4 Comparison with Experiments

The model outlined above is compared here with the experiments of [117]. For the case in hand, it was found that the probability of clusters with a size larger than 30 is negligible; this made it possible to fix the value of M. The time dependence of $P_1, \ldots, P_{30}$ is shown in Fig. 40.38: indeed, the probability P_{30} is negligible. As anticipated above, the first peak visible in Fig. 40.35 is due to three-dimensional effects not included in the model; therefore, the comparison with the experiments starts from the second peak.

The integration of the differential equations of the model was carried out using a 5th-order method of the type [120] with a 1-ps discretization time. The circuit parameters were found to be $C = 2$ pF, $I_1 = 1.12$ μA, $I_2 = 33$ μA; in turn, the constant resistances in (40.49), through which the time dependences of voltages $V_1(t)$ and $V_2(t)$ are determined, were found to be $R_S + R_1 \simeq R_1 = 1.6$ MΩ, $R_S + R_2 \simeq R_2 = 24$ kΩ (the approximations are due to the fact that a separate estimate indicates that here R_S is of the order of 100 Ω).

The fraction λ of the crystallized volume, whose change in time is relatively slower than the period of the oscillations, is shown in Fig. 40.39; the decay of the peaks amplitude, visible in Figs. 40.35 and 40.40, is due to the increase in λ as illustrated above.

Finally, Fig. 40.40 compares the model with the experiments: both the decay of peaks due to the progressive crystallization and the oscillation period, are well captured by the model. Due to the peak decay, the crystallization conditions weaken and the fraction of crystallized material saturates (Fig. 40.39). In the case considered here, when saturation occurred the characteristic of the external load and that of the PCM still intersected in the NDR branch: in fact, after some decay, the oscillation amplitude stabilized (Fig. 40.40). In other experiments (not shown), the deformation of the PCM characteristic was such that the bias point shifted out of the NDR branch of the PCM, this eventually bringing the oscillations to an end.

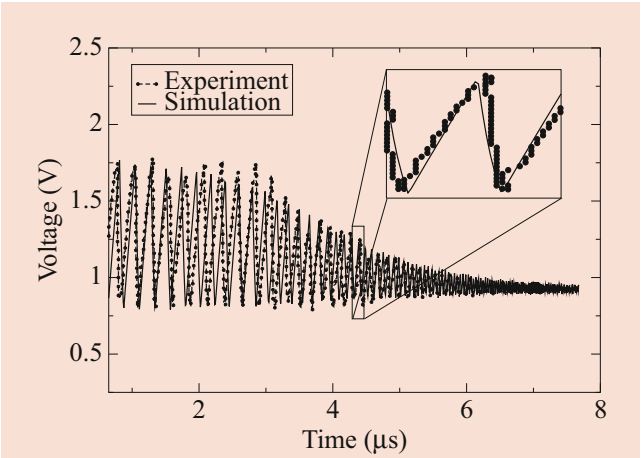

Fig. 40.40 Comparison between model (*continuous line*) and experiment of Fig. 40.35 (*dotted line*). (After [114]). To make the parameter fitting possible, the experimental curve was converted into a discrete set

40.5.5 Stability Analysis of PCM Oscillations

It is of interest to carry out a stability analysis of the electric response of the PCM, in order to ascertain the conditions under which the device electric performances are stable; this task is carried out in this section basing on the model proposed in [14] for the steady-state case and later extended in [73] to the dynamic case. The model can be viewed

as a simplified version of the hydrodynamic approach of Sect. 40.4.2: the electron energy is expressed in terms of the electron temperature T_e, spatial uniformity is assumed, a single energy is considered for the traps, and another single energy is considered for the conduction band. The model reproduces the electrical bistability and is able to identify the conditions that stabilize the measurement [121]; it reads

$$J = q\,\mu\,n_B\,F\,, \qquad \frac{n}{n_B} = 1 + c\,\exp\left(\frac{\Delta E}{k\,T_e}\right), \tag{40.51}$$

$$J\,F = n\,k\,\frac{T_e - T_0}{\tau_R} + \Delta E\,\frac{d}{dt}[n_B(T_e) - n_B(T_0)]\,, \tag{40.52}$$

where μ is the mobility of the band electrons, while J and F are the current density and electric field. As a one-dimensional and uniform device is considered, the equations do not depend on position; for this reason, carrier transport is described by the drift-only equation appearing in (40.51). Symbols T_0 and T_e denote, respectively, the room temperature and the band electron temperature, while τ_R and ΔE are the electron-temperature relaxation time and the difference between the band energy and the trap energy. Finally, c is the ratio between the density of states of the traps and that of the band [14].

The $J\,F$ product in (40.52) is the power per unit volume provided by the field: part of this power is absorbed by the phonons, while the remaining part produces the time change of the electron population of the band; the two parts are described by the first and second term at the right hand side of (40.52), respectively. Globally, (40.52) expresses the power balance of the band electrons. In turn, the second equation in (40.51) links the electron temperature with the fraction n_B/n of the electrons belonging to the band.

The model equations (40.51) and (40.52) in the four unknowns J, F, n_B, and T_e reduce, in the steady-state condition, to an algebraic relation involving only F and J. As the relation between F and J is clumsy, using auxiliary variables is preferable because the resulting expressions are managed analytically with more ease; this advantage manifests itself also in the time-dependent analysis. To proceed one defines the auxiliary variables $r = T_e/T_0$ and $f = F^2/F_0^2$, along with the normalization constants $a = \Delta E/(k\,T_0) = 14$ and $F_0^2 = k\,T_0/(q\,\mu\,\tau_R) = 10^{10}\ \mathrm{V^2\,cm^{-2}}$. Using the auxiliary variables reduces the steady-state form of (40.52) to

$$f = (r-1)\,[1 + c\,\exp(a/r)]\,, \tag{40.53}$$

whose graph is shown in the left part of Fig. 40.41 along with the line $f = f_u = 2.6$, corresponding to $F \simeq 1.6 \times 10^5$ V/cm. The latter value has been chosen purposedly, because the $f = 2.6$ line intersects the $f(r)$ curve in three points of which, in particular, the $r_u = 1.4$ one belongs to the branch of $f(r)$ having a negative slope. As in this representation the independent variable is r, the devices must be considered as "temperature driven" and constant field loaded.

Stability Analysis

To analyze stability one must use the dynamic model (40.51) and (40.52) and focus on the $r = r_u$ equilibrium point (in fact, the two intersections with the positive-slope branches are stable). Letting

$$N(r,f) = (r-1)\,\frac{n}{n_B} - f\,, \quad D(r) = \frac{a^2}{r^2}\left(\frac{n_B}{n} - 1\right). \tag{40.54}$$

turn (40.52) into

$$\frac{dr}{d\theta} = A(r,f) = \frac{N(r,f)}{D(r)}\,, \qquad \theta = \frac{t}{\tau_R}\,, \tag{40.55}$$

to be coupled with $df/d\theta = 0$ which is the differential equation for f. As in dynamic conditions (40.53) is not fulfilled, the right hand side of (40.55) does not vanish, apart from the equilibrium point where $N_u = N(r_u, f_u) = 0$. The analysis is carried out in the standard way [122], namely, by examining the system behavior near equilibrium; linearizing (40.55) about (r_u, f_u) after letting $r = r_u + \delta r$, $f = f_u$ yields $d(\delta r)/d\theta = s_{ru}\,\delta r$ and $s_{ru} = (\partial A/\partial r)_u$, whence $\delta r = \delta r_{t=0}\,\exp(s_{ru}\,\theta)$. Thus, the equilibrium point is stable (unstable) if $s_{ru} < 0$ ($s_{ru} > 0$). From (40.55) one finds $s_{ru} = (D_u\,N_u' - N_u\,D_u')/D_u^2$ with $N_u = 0$ and $D_u = (a/r)^2\,(n_B/n - 1) < 0$ for all r. It follows $s_{ru} = -N_u'/|D_u|$, so that stability is prescribed by the sign of N_u'. On the other hand,

$$N_u' = \left(\frac{\partial N}{\partial r}\right)_u = \frac{n}{n_B} - a\,\frac{r-1}{r^2}\left(\frac{n}{n_B} - 1\right), \tag{40.56}$$

which may have either sign; thus, the limit between stability and instability corresponds to $N_u' = 0$, namely, from (40.51),

$$r_u^2 - a\,(r_u - 1) = -\frac{r_u^2}{c}\,\exp(-a/r_u). \tag{40.57}$$

whose graphic solution is visible in the right part of Fig. 40.41. Two solutions r_{u1}, r_{u2} exist, indicated with the vertical lines: in the interval $r_{u1} < r_u < r_{u2}$, it is $N_u' < 0$ and $s_{ru} = N_u'/D_u > 0$; therefore, the solution at $r_u = 1.4$ is unstable. As from (40.53), (40.54) it also follows that $\partial N/\partial r = 0$ is equivalent to $df/dr = 0$, points r_{u1} and r_{u2} are the boundaries of the negative-slope branch; in other terms, for a load like $f = \text{const}$, all points of this branch are unstable, as expected.

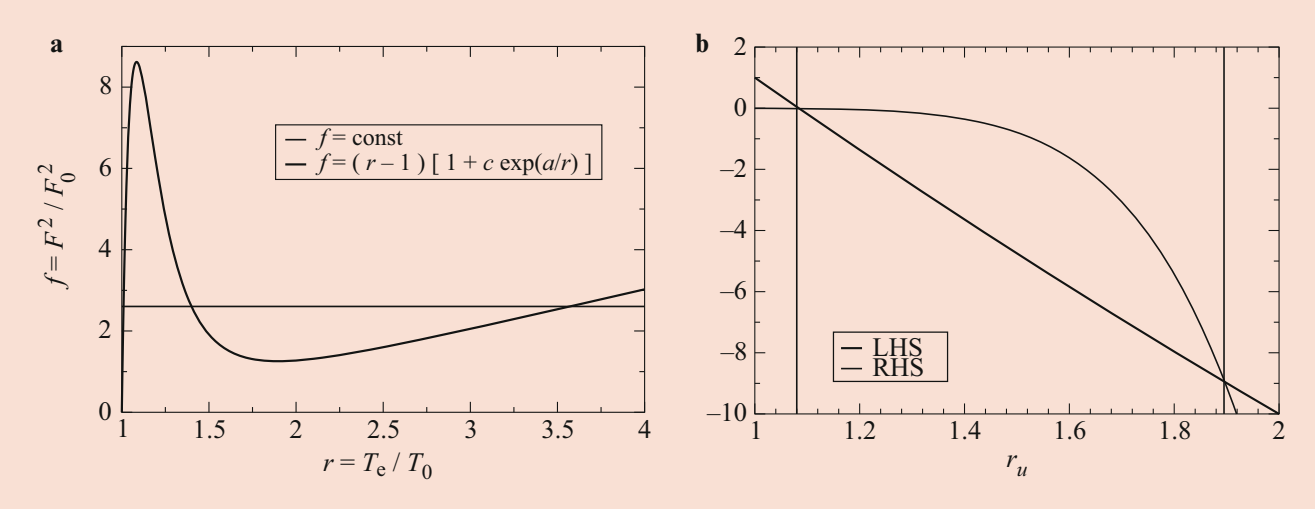

Fig. 40.41 (**a**) Graph of (40.53) (*thick line*) intersecting $f = f_u = 2.6$ in three equilibrium points; the one corresponding to $r_u = 1.4$ intersects (40.53) in the negative-slope branch. (**b**) Graphic solution of (40.57); the left (right) hand side is represented by the *thick (thin) line*, while the *vertical lines* indicate the two solutions r_{u1}, r_{u2}. (Both figures after [121])

Variable-Field Case

To carry out the stability analysis when the electric field to which the Ovonic device is subjected is allowed to change, one connects a series resistance R to the device and applies a voltage V_C as shown in Fig. 40.42, so that $V_C = V + RI$ with $V = LF$ the voltage across the device. The length and cross-sectional area of the latter are L, A, with $I = AJ$ the current through it. As in the previous analysis, the sample is considered one-dimensional and uniform; hence the equations do not depend on position. Letting L_R and A_R be the length and cross-sectional area of the resistor and $\rho = RA_R/L_R$ the resistivity of its material, one finds $V_C/L_R = \lambda F + \alpha\rho J$ with $\lambda = L/L_R$ and $\alpha = A/A_R$. Replacing J from (40.51) provides

$$\frac{F}{F_C} = \frac{1 + c\,\exp(a/r)}{\omega + 1 + c\,\exp(a/r)}\,, \qquad F_C = \frac{V_C}{L}\,, \tag{40.58}$$

with $m = \rho q \mu n$, $\omega = m\alpha/\lambda$ dimensionless parameters. Taking the $\omega \to 0$ limit in the above yields the original setup $R = 0$; the $R \neq 0$ setup is actually able to increase the number of degrees of freedom of the system and to provide the necessary information about the measurement stability. The load curve is obtained by taking the square of the first of (40.58) and letting $f_C = F_C^2/F_0^2$,

$$\frac{f}{f_C} = \left[\frac{1 + c\,\exp(a/r)}{\omega + 1 + c\,\exp(a/r)}\right]^2 . \tag{40.59}$$

shown in Fig. 40.43. Due to the choice of the variables, the load curve is not a straight line although a linear resistor R is used in the bias circuit. This does not affect the stability analysis, which is carried out by linearizing (40.55) along with

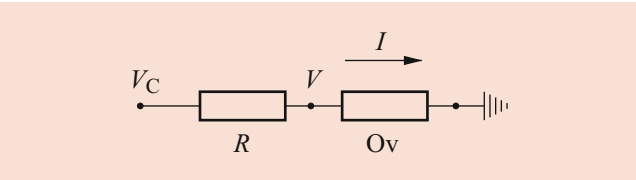

Fig. 40.42 When a resistance R is connected to the Ovonic device (Ov), the load characteristic is controlled by the value of R and of the applied voltage V_C, or other two parameters related to them (e.g., f_C and ω introduced in the text). (After [121])

$$B(r,f) = \frac{f}{f_C} - \left[\frac{1 + c\,\exp(a/r)}{\omega + 1 + c\,\exp(a/r)}\right]^2 = 0 \tag{40.60}$$

around r_u, f_u; letting

$$s_{ru} = \frac{N'_u}{D_u}\,, \quad w_{ru} = -\frac{\mathrm{d}}{\mathrm{d}r}\left[\frac{1 + c\,\exp(a/r)}{\omega + 1 + c\,\exp(a/r)}\right]_u^2, \tag{40.61}$$

one finds $\mathrm{d}(\delta r)/\mathrm{d}\theta = s_{ru}\,\delta r - \delta f/D_u$ and $w_{ru}\,\delta r = -\delta f/f_C$ whence, eliminating δf from the latter yields $\mathrm{d}(\delta r)/\mathrm{d}\theta = (N'_u + f_C\,w_{ru})\,\delta r/D_u$. Remembering that $D_u < 0$, one finds that the equilibrium point is stable when $N'_u + f_C\,w_{ru} > 0$, unstable when $N'_u + f_C\,w_{ru} < 0$. It is $N'_u < 0$ along the negative-slope branch, whereas

$$w_{ru} = \frac{2\,\omega\,a/r_u^2}{(\omega + n/n_B)^3}\left(\frac{n}{n_B} - 1\right)\frac{n}{n_B} > 0\,. \tag{40.62}$$

It follows that the sign of $N'_u + f_C\,w_{ru}$ depends on the value of f_C and ω. Replacing N'_u with $\mathrm{d}f/\mathrm{d}r$ and observing that

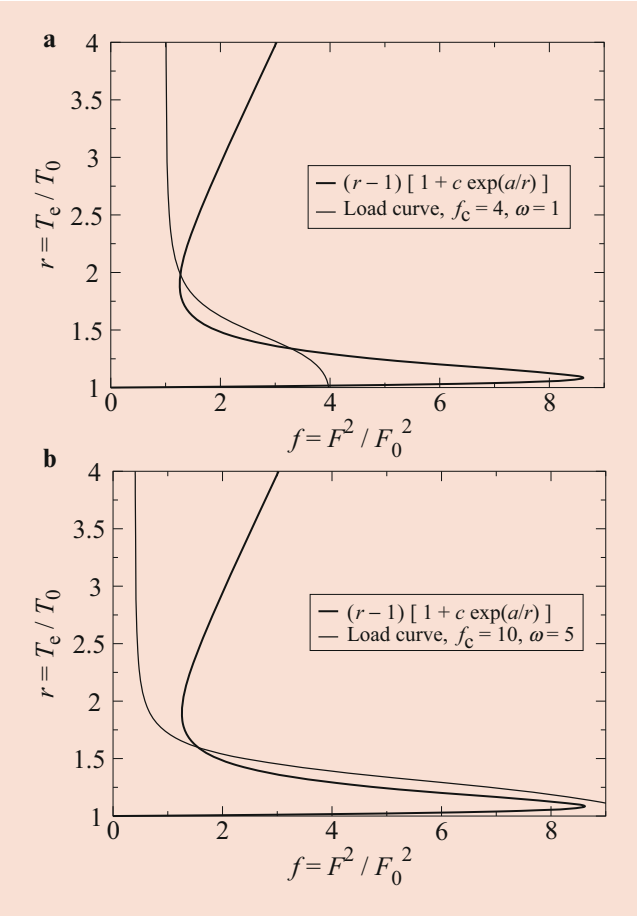

Fig. 40.43 (**a**) Inverse function of (40.53) (*thick line*) and of (40.59) with $f_C = 4$, $\omega = 1$ (*thin line*). The three intersections correspond to equilibrium points, of which the unstable one belongs to the negative-slope branch ($f_u \simeq 3.3$). (**b**) The thick line is the same as in the upper part of the figure; the thin line shows the inverse function of (40.59), with $f_C = 10$, $\omega = 5$. The two lines cross each other in only one point belonging to the negative-slope branch; this equilibrium point is stable. (Both figures after [121])

$-f_C\, w_{ru}$ is the derivative of (40.59) with respect to r, one renders the stability condition in compact form as $|\mathrm{d}f/\mathrm{d}r|_{\text{load}} > |\mathrm{d}f/\mathrm{d}r|_{\text{Ov}}$. Note that, in order to check the above inequality in Fig. 40.43, one must view the slopes from the r axis. For instance, point $f_u \simeq 3.3$ in the upper part of Fig. 40.43 is unstable, whereas the intersection between the Ovonic and load curves in the lower part of Fig. 40.43 is stable.

The analysis outlined above shows that a suitable tuning of the load curve provides a stable intersection point with the negative-slope branch. Thus, by choosing successive values of V_C and/or R, one sweeps the negative-slope branch completely, this making the measurement of the whole $I(V)$ curve possible.

This theory assumes that the time variation of the unknowns derives from the last term of (40.52) only, namely, is due to the internal behavior of the device; parasitic effects induced by the measuring equipment are not included. In fact these effects exist, and their description is achieved by adding a capacitance C in parallel to the Ovonic device. The new time constant $\tau = R\,C$ thus introduced is to be compared with the intrinsic one produced by the interplay of τ_R and ΔE of (40.52). Although the quantitative results are influenced by the new time constant, the analysis of stability is unaffected.

40.6 Open Challenges in Modeling: A Brief Outline

In the last 60 years, amorphous chalcogenide materials have provided many challenges to the scientific community working in the field of modeling and simulation. Despite an intense effort, both in academia and industry, which has already led to the release of products into the market, open questions still remain as for the physical models and numerical approaches. On the one side, it is clear that both charge and heat transport must be taken into account to model chalcogenide devices and that, close to threshold, an interplay between carrier and crystal heating determines whether the OTS or PCM effect, or both take place; on the other side, uncertainty still exists about the parameters to be included for simulating the material at hand. MD simulations, which proved very effective to characterize atomic structures and atomic states, are still not accurate enough as for the information about the trap and band density of states to be included into a transport simulation. The role of the interface between the electrodes and the amorphous chalcogenide and the effect of the electrode material on the switching voltage, typically accounted for as boundary conditions of the transport model, need to be modeled more accurately [123].

As PCM devices were integrated with advanced CMOS technology nodes, the necessity became apparent of scaling their dimensions to the nanometer range; the reduced dimensions require, in turn, a simulation approach to transport that goes beyond the hydrodynamic scheme. In fact, it is still questionable whether the ability to switch between two states, whose electrical conductivities differ by at least two orders of magnitude, is preserved in layers where the size of the amorphous region becomes comparable to the distance between two trap centers [81]. Also, the granularity of the atomic composition of the layer suggests that noise plays a key role in determining the electric response of these nanometer scale devices; at present, noise is one of the least studied topics of chalcogenide device physics. Furthermore, under extreme miniaturization the device dimensions become comparable to the wavelength of the carriers; numerical approaches based on quantum transport schemes are then necessary [101, 102, 124]. The energy exchange between carriers and lattice, commonly dealt with by assuming a

relaxation time approximation, is also likely to require a more accurate modeling in chalcogenides.

New materials are being envisaged to open new perspectives. Modeling tools are required to engineer the best alloy composition in order to fulfill assigned technology requirements [86]. The use of monatomic phase-change materials may remove compositional optimization issues and make nanosize elements for information storage more easily achievable [125]. Single-atom-scale Te nanowires encapsulated in carbon nanotubes constitute the smallest periodic materials with atom-wide motifs repeated in one dimension; single-walled carbon nanotubes provide ideal environments for the creation of such materials [126]. The ability to control functional properties of these systems opens the way to the implementation of future device applications. Furthermore, chalcogenide superlattice structures demonstrated superior switching performance in terms of time and energy [127]; the well-established expertise in the field of simulation of low-dimensional semiconductors can fruitfully be exploited to support the experimental activity in this area.

In another direction, the need of modeling PCM and OTS, starting from the device level and up to the description of circuits made of these devices, is strongly felt. The implementation of large arrays where the memory elements are PCM with OTS-based selectors is, in fact, one of the most studied candidates for next-generation, nonvolatile memories (NVM). On the one side, it is compatible with the standard process of integrated circuits; on the other side, using two- instead of three-terminal devices is quite attractive for manufacturers, as this approach simplifies the memory layout and allows achieving a very dense storage capability in the back end of line (BEOL).

Last, but not least, multilevel storage and non-von Neumann neuromorphic computer architectures using PCM foresee the possibility of incrementally crystallize the amorphous chalcogenide layer of the device by applying low-power pulses. A physics-based simulation of the process must couple the heat and transport equations with the numerical simulation of the nucleation process. A deeper insight into the aging effects is mandatory [38] to envisage applications of chalcogenides to neuromorphic computing [42].

Acknowledgments The authors wish to thank Prof. Carlo Jacoboni and Dr. Enrico Piccinini for reading the manuscript and providing suggestions and material. Courtesy of Dr. Jake Scoggin for providing Fig. 40.32 is also gratefully acknowledged.

Abstract

As electronic devices approach the sub 10-nm size and new device topologies emerge specifically exploiting quantum mechanical effects, new device simulation tools are needed addressing such issues. Among full quantum approaches, the $\boldsymbol{k} \cdot \boldsymbol{p}$ model is known to provide a reasonably simple way to describe with good accuracy the complex system of valence and conduction bands of many semiconductors, including also their deformations induced by strain, which play a fundamental role in determining the electronic properties of the material. When used within the Non-Equilibrium Green's Functions framework for the charge transport problem and coupled with Poisson's equation, the $\boldsymbol{k} \cdot \boldsymbol{p}$ model becomes a powerful tool for the simulation of full nanoelectronic devices featuring lateral confinement and quantum transport.

In this chapter, a review of the $\boldsymbol{k} \cdot \boldsymbol{p}$ model is presented, with special emphasis on its applications to the simulation of nanoelectronic devices. The mathematical model of the so called eight-band version is duly recalled first, including the correction terms accounting for strain. Examples of energy band calculations are provided for III–V semiconductors, which are of great potential for the future development of the nanoelectronic industry, relative to both bulk and confined structures.

Significant examples of application of the $\boldsymbol{k} \cdot \boldsymbol{p}$ model to full device simulation are then given, all of them relative to tunnel FETs. Specific topics include the investigation of strain in homojunction and heterojunction nanowire tunnel FETs, the optimization of complementary tunnel FETs and the evaluation of the performance of inverters built with the latter FETs, the investigation of the effect of interface traps on the same nanowire tunnel FETs.

The main idea that this chapter would like to convey is that in the next future there will most likely be an increasing type and number of nanoelectronic devices for which the $\boldsymbol{k} \cdot \boldsymbol{p}$ model represents a well targeted simulation basis.

41.1 Introduction

Technology computer-aided design (TCAD) tools have actually replaced the former trial-and-error methodology for device design in the nanoscale, and its impact in terms of shortening the technology cycle is now widely recognized. The progressive device miniaturization down to minimum feature sizes of a few tens of nanometers anyway requires a continuous development of the modeling approaches. More specifically, the next-generation devices based on nanowire technologies will experience shrinkage in the transversal direction by structural confinement, leading to an increasing importance of quantization effects and the formation of energy subbands. In addition, as the gate length becomes comparable with the carrier mean-free path, carrier transport becomes quasi-ballistic. Thus, most carriers travel with a kinetic energy well above the band edge, where the subband energy dispersion relationships $E_n(k)$ are no longer parabolic and the effective-mass approximation (EMA) breaks down. Moreover, band-to-band and direct source-to-drain tunneling become increasingly important in scaled devices, while strain engineering continues to keep an important role as technology booster. On the other hand, novel device concepts are being developed, featuring band-to-band tunneling as the key working principle, leading to abrupt transition between the off- and on-states and allowing for a substantial reduction of the supply voltage. The performance of such new tunnel FET (TFET) devices will be largely improved by the use of III–V compound semiconductors, which are direct gap materials with small effective masses. A detailed description of the latter technologies is reported in Chaps. ▶ 6 and ▶ 9. The device architecture and operation principles are addressed in Chap. ▶ 24.

For the modeling tools to keep the pace with the technological developments and preserve their predictive capabilities, new specific modeling tools and schemes are therefore necessary accounting for the above quantum effects as well as for the relevant electronic properties of the new III–V channel materials, also in the presence of strain.

Concerning quantum approaches, a first classification can be made according to the adopted Hamiltonian model, which is built upon well-established theories for the calculation of the electronic and optical properties of solids. Tight-binding (TB) is an atomistic model, which has been proven very powerful also for device simulation, as described in Chap. ▶ 45. Provided a sufficient number of orbital functions per atom are included in the calculation, the full band structure of most semiconductors, including also the effect of mechanical strain, can be accurately captured by the TB model. Besides, defects at atomic level can be naturally accounted for. Of course, there is a limitation on the maximum number of atoms, and therefore the maximum device size, that can be handled in practical computations.

The $\boldsymbol{k} \cdot \boldsymbol{p}$ theory is another important semiempirical approach that has been very successful for understanding all the main properties of most semiconductors. Fundamental for its development have been the works of Luttinger and Kohn [1] and Kane [2]. Its basic principles are now illustrated in many solid-state physics textbooks [3–5], and detailed derivations of its many forms can be found in specialized literature [6]. In essence, the theory is based on a perturbation method around a high symmetry point of the crystal momentum space and leads to a $\boldsymbol{k}$-dependent Hamiltonian matrix, which in a space-dependent problem (i.e., in device simulation) becomes a differential operator acting on the multiple components of the wave-function envelope. Eventually, the resulting system of partial differential equations is discretized, typically by means of a finite-difference scheme. Therefore, as opposed to TB, the $\boldsymbol{k} \cdot \boldsymbol{p}$ method gives the user the flexibility of selecting a suitable discretization grid, resulting in a considerable saving of computational resources.

Even if it is possible to extend the $\boldsymbol{k} \cdot \boldsymbol{p}$ theory to the full Brillouin zone using an adequate number of basis functions [7], one of the major attractiveness of the theory, as far as device simulation is concerned, is its capability of providing a complete description of the complex system of valence bands around the Γ-point using only a limited number of basis functions, namely, six. Moreover, in the so-called eight-band version (i.e., with eight basis functions) [6], the description is extended to the first conduction band of direct bandgap semiconductors. For this reason, the method has been applied to full device simulation involving hole transport in silicon nanowires [8] and band-to-band tunneling in InAs nanowires [9] and has found since then a rather wide application in the simulation of novel devices employing several types of direct bandgap materials, such as III–V alloys, namely, when tunneling effects are to be investigated in detail [10–12]. To this purpose, the $\boldsymbol{k} \cdot \boldsymbol{p}$ algorithm is coupled with the nonequilibrium Green's function (NEGF) formalism as described in Chap. ▶ 44.

This chapter deals in particular with the eight-band $\boldsymbol{k} \cdot \boldsymbol{p}$ model and its applications to the simulation of III–V TFETs. The mathematical model is described in Sect. 41.2, where the Hamiltonian matrix, including also strain, is reported in full. The section includes a survey of the main band structure features and results for some bulk III–V materials and, for similar confined structures, underlying the effect of strain in particular. Section 41.3 is devoted to the applications of the model to the investigation of III–V TFETs under different stress conditions. An optimization study of TFET-based inverters for a complementary technology platform carried out in the framework of the $\boldsymbol{k} \cdot \boldsymbol{p}$ approach is addressed in Sect. 41.4. Finally, a simulation study where transport is treated with the $\boldsymbol{k} \cdot \boldsymbol{p}$ model and interface traps are also

consistently accounted for in the device electrostatics is described with details and examples in Sect. 41.5.

41.2 The Eight-Band k·p Model

In this section, the mathematical model of the Hamiltonian matrix for 3D bulk semiconductors is introduced first with an exhaustive description of the equations for the eight-band $\boldsymbol{k} \cdot \boldsymbol{p}$ model. The additional assumptions and equations required to accurately account for mechanical deformation are discussed along with some examples of calculated bulk band structures in unstrained and strained conditions. The generalization to confined structures is finally treated with special focus on 1D nanowire devices as the most promising potential candidates for future applications.

41.2.1 Bulk Unstrained Semiconductors

With the set of basis functions

$$[S\uparrow,\ X\uparrow,\ Y\uparrow,\ Z\uparrow,\ S\downarrow,\ X\downarrow,\ Y\downarrow,\ Z\downarrow]^{\mathrm{T}}\,, \tag{41.1}$$

where the arrows indicate the spin orientation, S the s-like spatial function for the conduction band and X, Y, and Z the p-like spatial functions for the valence band, the eight-band $\boldsymbol{k} \cdot \boldsymbol{p}$ Hamiltonian for values of $\boldsymbol{k}$ near the Γ point of zinc-blende crystals can be written as

$$H_8 = \begin{bmatrix} H_4 & 0 \\ 0 & H_4 \end{bmatrix} + H_{\mathrm{SO}}\,, \tag{41.2}$$

where H_4 is a 4×4 matrix given by

$$H_4 = \begin{bmatrix} H_{\mathrm{CC}} & H_{\mathrm{CV}} \\ H_{\mathrm{VC}} & H_{\mathrm{VV}} \end{bmatrix}\,, \tag{41.3}$$

with H_{CC}, H_{VV}, and H_{CV} reported below, and H_{SO} is the spin-orbit coupling matrix

$$H_{\mathrm{SO}} = \frac{\Delta}{3}\begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & -i & 0 & 0 & 0 & 0 & 1 \\ 0 & i & -1 & 0 & 0 & 0 & 0 & -i \\ 0 & 0 & 0 & -1 & 0 & -1 & i & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & -1 & i & 0 \\ 0 & 0 & 0 & -i & 0 & -i & -1 & 0 \\ 0 & 1 & i & 0 & 0 & 0 & 0 & -1 \end{bmatrix}\,, \tag{41.4}$$

i being the imaginary unit and Δ the spin-orbit splitting parameter. In (41.3), H_{CC} is a scalar

$$H_{\mathrm{CC}} = E_{\mathrm{C}} + A_{\mathrm{C}}k^2\,, \tag{41.5}$$

where E_{C} is the conduction band edge, $k = \|\boldsymbol{k}\|$ and

$$A_{\mathrm{C}} = \frac{\hbar^2}{2m_{\mathrm{o}}}(1+2F)\,, \tag{41.6}$$

with m_{o} the free-electron mass and F the Kane parameter, which is formally related with the momentum matrix elements between the s-like conduction band and the remote bands. $H_{\mathrm{CV}} = H_{\mathrm{VC}}^{\dagger}$ is written as

$$H_{\mathrm{CV}} = [iPk_x \quad iPk_y \quad iPk_z]\,, \tag{41.7}$$

where the parameter P introduced by Kane

$$P = -\frac{i\hbar}{m_{\mathrm{o}}}\langle S|p_x|X\rangle \tag{41.8}$$

is proportional to the momentum matrix element between the s-like conduction band and the p-like valence band. H_{VV} is a 3×3 matrix given by

$$H_{\mathrm{VV}} = \begin{bmatrix} E_{\mathrm{V}} + Lk_x^2 + M(k_y^2+k_z^2) & Nk_xk_y & Nk_xk_z \\ Nk_yk_x & E_{\mathrm{V}} + Lk_y^2 + M(k_z^2+k_x^2) & Nk_yk_z \\ Nk_zk_x & Nk_zk_y & E_{\mathrm{V}} + Lk_z^2 + M(k_x^2+k_y^2) \end{bmatrix}\,, \tag{41.9}$$

where E_{V} is the valence band edge. The parameters L, M, and N are expressed in terms of the modified Luttinger parameters by

$$\begin{aligned} L &= -\frac{\hbar^2}{2m_{\mathrm{o}}}(\gamma_1 + 4\gamma_2)\,, \\ M &= -\frac{\hbar^2}{2m_{\mathrm{o}}}(\gamma_1 - 2\gamma_2)\,, \\ N &= -\frac{\hbar^2}{2m_{\mathrm{o}}}(6\gamma_3)\,, \end{aligned} \tag{41.10}$$

the modified parameters being in turn related with the original Luttinger parameters, which formally depend on the momentum matrix elements between the p-like valence bands and the remote bands, by

$$\begin{aligned} \gamma_1 &= \gamma_{1\mathrm{L}} - \frac{E_{\mathrm{P}}}{3E_{\mathrm{G}}}\,, \\ \gamma_2 &= \gamma_{2\mathrm{L}} - \frac{E_{\mathrm{P}}}{6E_{\mathrm{G}}}\,, \\ \gamma_3 &= \gamma_{3\mathrm{L}} - \frac{E_{\mathrm{P}}}{6E_{\mathrm{G}}}\,, \end{aligned} \tag{41.11}$$

where $E_P = (2m_o/\hbar^2)P^2$ and $E_G = E_C - E_V$ is the energy gap.

From the above equations, it is seen that the 8×8 $\boldsymbol{k} \cdot \boldsymbol{p}$ Hamiltonian is completely defined by the following set of seven parameters: the three Luttinger parameters γ_{1L}, γ_{2L} and γ_{3L}, the energy gap E_G, the band-coupling parameter P, the conduction band parameter F, and the spin-orbit splitting Δ. Though in principle such parameters can be calculated from their formal definitions in terms of matrix elements with first-principle methods, in practice they are extracted through a calibration on experimentally observable quantities. To this end, the following useful expressions of the electron effective mass m_e and of the light-hole (m_{lh}), heavy-hole (m_{hh}), and split-off (m_{so}) effective masses along high symmetry directions are obtained from the calculation of the eight-band energy dispersion relation

$$\frac{m_o}{m_e} = 1 + 2F + \frac{E_P(E_G + 2\Delta/3)}{E_G(E_G + \Delta)}, \tag{41.12}$$

$$\left(\frac{m_o}{m_{hh}}\right)_{[100]} = \gamma_{1L} - 2\gamma_{2L},$$
$$\left(\frac{m_o}{m_{hh}}\right)_{[111]} = \gamma_{1L} - 2\gamma_{3L}, \tag{41.13}$$

$$\left(\frac{m_o}{m_{lh}}\right)_{[100]} = \gamma_{1L} + 2\gamma_{2L},$$
$$\left(\frac{m_o}{m_{lh}}\right)_{[111]} = \gamma_{1L} + 2\gamma_{3L}, \tag{41.14}$$

$$\frac{m_o}{m_{so}} = \gamma_{1L} - \frac{E_P\Delta}{3E_G(E_G + \Delta)}. \tag{41.15}$$

An exhaustive compilation of the required parameters for the main III–V binary materials as well as ternary and quaternary alloys is found in [13], together with the valence band offsets for III–V heterostructures. In the case of alloys, linear or quadratic interpolating expressions are used as a function of the alloy composition.

Examples of bulk band structures are shown in Figs. 41.1 and 41.2. They refer to bulk GaAs and InAs crystals and are calculated along the [100] and [110] directions. Every band is spin degenerate. It is seen that the spin-orbit parameter Δ is mainly responsible for the breaking of the sixfold degeneracy of the valence band at the Γ-point into two groups, the first one fourfold degenerate, including light and heavy holes, and the second one double degenerate (split-off band). One can also notice the significant band non-parabolicity, especially for the conduction and *lh* bands in low bandgap materials. This makes the simple effective mass model inaccurate and is one of the reasons for going to the $\boldsymbol{k} \cdot \boldsymbol{p}$ approach.

The complex branches of the energy dispersion relation play an important role in devices where band-to-band tunneling is involved, such as tunnel FETs. Figures 41.3 and 41.4 show the bulk GaAs and InAs complex band structures along the [100] direction. They have been calculated by solving the inverse eigenvalue problem, i.e., by finding for any energy E the corresponding values of $\boldsymbol{k}_{100} \in \mathbb{C}$. In the figures, $|k|$ is reported on the x-axis if k is real and $-|k|$ if k is imaginary. Band-to-band tunneling is controlled by the shape of the imaginary branch connecting the valence and the conduction band edges. Since the *so*-band is not directly involved in the tunneling process, one is tempted to ignore spin-orbit coupling by setting $\Delta = 0$ and adjusting F in (41.12) in order

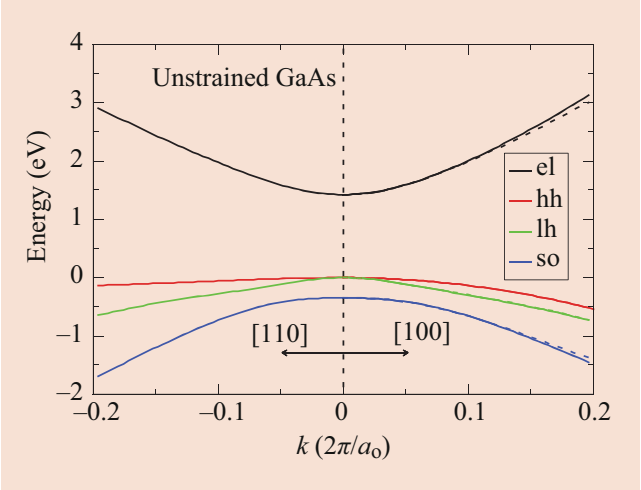

Fig. 41.1 Energy dispersion for the unstrained bulk GaAs along the [100] and [110] crystal directions. Continuous lines: bands calculated using the $\boldsymbol{k} \cdot \boldsymbol{p}$ approach with spurious solutions. Fig. 41.4 Complex band structure for the unstrained bulk InAs along the [100] crystal direction

to obtain the correct electron effective mass. This procedure effectively reduces the Hamiltonian to a 4×4 matrix, with a significant numerical speedup in device simulations and is referred to as 4×4 $\boldsymbol{k} \cdot \boldsymbol{p}$ method. However, it must be noticed that so doing the total valence-band density-of-states is slightly modified, since without spin-orbit coupling the *so*-band collapses on top of the *hh*-band. The impact of this change on the simulated device behavior ultimately depends on the position of the Fermi level, and the opportunity of such simplification must be considered on a case by case basis.

In Figs. 41.3 and 41.4, the leftmost imaginary branch, which is not connected to any real branch, can be considered a spurious unphysical solution and is related with the high-order terms in k in the characteristic equation. Such spurious solutions can endanger the validity of the results of $\boldsymbol{k} \cdot \boldsymbol{p}$ calculations, in particular for confined heterostructures (quantum wells and wires), depending also on the model parameters as well as on the discretization grid [14, 15], where they can give rise to unphysical non-evanescent states within the gap. One possible recipe to solve this problem consists in a careful modification of the parameter E_P. For example, in [15] A_C in (41.5) is set equal to zero, thus reducing the order of the characteristic equation, at the same time modifying E_P through (41.12) and (41.6) so as to obtain the correct value of the electron effective mass. The required change in E_P is rather small for most important III–V Semiconductors, and, since the values of the effective masses are preserved, only the non-parabolic parts of the band structures are slightly modified. Figures 41.1 and 41.2 show (dotted lines, [100] direction) that this is indeed the case for bulk GaAs and InAs.

41.2.2 Strained Semiconductors

The mechanical deformation of the crystal leads to a displacement of the atomic sites and to a change in the energy-band structure. The $\boldsymbol{k} \cdot \boldsymbol{p}$ theory in the presence of strain has been developed in [16] and [17, 18]. The main result is that in order to account for strain, it is necessary to add to the matrix H_4 in (41.3) a strain-dependent matrix D function of the components ε_{ij} of the strain tensor [17, 18] given by

$$D = \begin{bmatrix} D_{CC} & D_{CV} \\ D_{VC} & D_{VV} \end{bmatrix}, \tag{41.16}$$

where

$$D_{CC} = a_c(\varepsilon_{xx} + \varepsilon_{yy} + \varepsilon_{zz}), \tag{41.17}$$

$$D_{CV} = \begin{bmatrix} b'\epsilon_{yz} - iP\sum_j \varepsilon_{xj}k_j & b'\epsilon_{zx} - iP\sum_j \varepsilon_{yj}k_j \\ & b'\epsilon_{xy} - iP\sum_j \varepsilon_{zj}k_j \end{bmatrix}, \tag{41.18}$$

$$D_{VV} = \begin{bmatrix} l\varepsilon_{xx} + m(\varepsilon_{yy} + \varepsilon_{zz}) & n\varepsilon_{xy} & n\varepsilon_{xz} \\ n\varepsilon_{yx} & l\varepsilon_{yy} + m(\varepsilon_{xx} + \varepsilon_{zz}) & n\varepsilon_{yz} \\ n\varepsilon_{zx} & n\varepsilon_{zy} & l\varepsilon_{zz} + m(\varepsilon_{xx} + \varepsilon_{yy}) \end{bmatrix}, \tag{41.19}$$

and $D_{VC} = D_{CV}^{\dagger}$.

In (41.17) and (41.18), the deformation-potential constants a_c and b' describe the conduction-band strain interactions due to hydrostatic and shear deformations, respectively. The effect of b' is small and is often neglected. It is exactly zero in a diamond structure. The coefficients l, m, and n in (41.19) are related to the Pikus–Bir deformation-potential constants a_v, b, and d through

$$
\begin{aligned}
l &= 2b + a_\mathrm{v} \\
m &= a_\mathrm{v} - b \\
n &= \sqrt{3}d\,,
\end{aligned}
\tag{41.20}
$$

which are tabulated in [19] and [13] for the main III–V semiconductors. The parameter a_c can be easily related to the change in the conduction-band edge energy due to a hydrostatic deformation. It is negative in general, meaning that a compressive hydrostatic strain ($\varepsilon_{xx} = \varepsilon_{yy} = \varepsilon_{zz} < 0$) shifts the conduction band upward. Similarly, a positive a_v shifts the valence-band edge downward for a compressive hydrostatic deformation. The effect of both for compressive hydrostatic strain is therefore an increase in energy gap, which is the quantity that is directly measured. Finally, parameters b and d are responsible for *lh*- and *hh*-band splitting under non-hydrostatic strain configurations.

Additional strain interaction terms related to the spin-orbit coupling are reported in [17, 18]. They should be added to the H_SO matrix (41.4). They are typically small and are not considered here. The interested reader is referred to the original paper [17, 18] for details.

An example of band structure of a III–V semiconductor crystal subject to strain is shown in Fig. 41.5. The material is GaAs, and both the real and imaginary branches are reported as a function of the normalized k in the [001] direction. A biaxial stress condition in the [110] plane is applied, i.e., the only non-null stress tensor components T_{ij} are $T_{xx} = T_{yy} \equiv T \neq 0$, being the coordinate reference system aligned with the main crystal axes. The strain tensor components are calculated using the elastic constant matrix. In crystals with cubic symmetry, there are only three independent elastic constants c_{11}, c_{12}, and c_{44}, which give

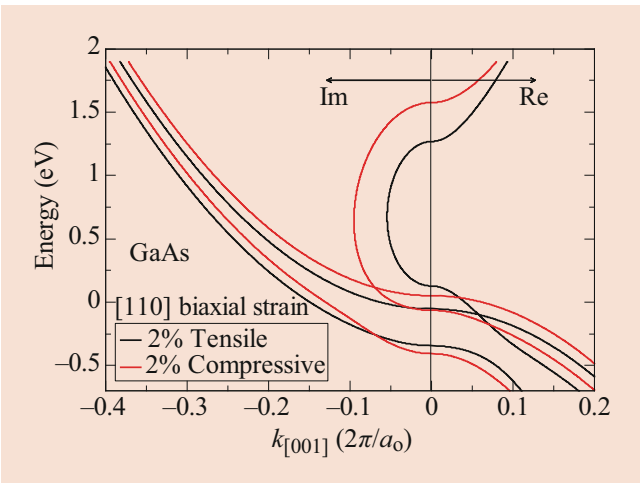

Fig. 41.5 Complex band structures for bulk GaAs along the [001] crystal direction under different [110] biaxial strain conditions. Black curves: tensile strain $\varepsilon = +2\%$. Red curves: compressive strain $\varepsilon = -2\%$

$$
\begin{bmatrix} T_{xx} \\ T_{yy} \\ T_{zz} \\ T_{xy} \\ T_{xz} \\ T_{yz} \end{bmatrix}
=
\begin{bmatrix}
c_{11} & c_{12} & c_{12} & 0 & 0 & 0 \\
c_{12} & c_{11} & c_{12} & 0 & 0 & 0 \\
c_{12} & c_{12} & c_{11} & 0 & 0 & 0 \\
0 & 0 & 0 & c_{44} & 0 & 0 \\
0 & 0 & 0 & 0 & c_{44} & 0 \\
0 & 0 & 0 & 0 & 0 & c_{44}
\end{bmatrix}
\begin{bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{zz} \\ \varepsilon_{xy} \\ \varepsilon_{xz} \\ \varepsilon_{yz} \end{bmatrix}
\,. \tag{41.21}
$$

Such elastic constants are tabulated in material databases. The result is that the only nonzero components of the strain tensor are $\varepsilon_{xx} = \varepsilon_{yy} \equiv \varepsilon = T\,c_{11}/(c_{11}^2 + c_{12}c_{11} - 2c_{12}^2)$ and $\varepsilon_{zz} = -2\,c_{12}/c_{11}\,\varepsilon$. Figure 41.5 reports the results for $\varepsilon = +2\%$ (tensile strain) and $\varepsilon = -2\%$ (compressive strain).

It is seen that strain has important implications on the gap energy and on the effective masses. Besides, the imaginary branches are particularly important for the modeling of band-to-band tunneling. To this end, it should be noticed that, due to *lh*- and *hh*-band splitting, the imaginary branch connecting the valence and the conduction bands is not always the one (compressive case) that is responsible for gap energy.

41.2.3 Confined Structures

The energy dispersion relationships in confined structures can be easily obtained with the $\boldsymbol{k} \cdot \boldsymbol{p}$ approach by solving Schrödinger equation with $\boldsymbol{k}$ in the Hamiltonian described in the previous sections being replaced with the differential operator $-i\,\nabla$ and then using a finite difference discretization scheme.

The effect of quantization is manifold. First of all it increases the effective energy gap and changes the density-of-states according to the dimensionality of the carrier gas. In addition, quantization changes the imaginary branches of the dispersion relationship inside the gap. The effect of quantization on the energy dispersion in the gap of III–V materials was analyzed using the $\boldsymbol{k} \cdot \boldsymbol{p}$ method by [20]. Investigations on the band structures of quantum wells (2D gas) and nanowires (1D gas) with and without the effect of strain were reported in [21, 22] and [23].

In the following, the results of $\boldsymbol{k} \cdot \boldsymbol{p}$ calculations of an InAs nanowire with and without strain are reported with the aim of giving a description of the main features of the band structure. To this purpose, a square InAs nanowire with [100] transport orientation and 5 nm sides along the [010] and [001] directions is considered. The most interesting strain conditions are biaxial stress within the nanowire cross section, which can be obtained during the growing process, and uniaxial stress along the transport direction, which can be controlled via SiN offset spacers. Figure 41.6 reports the calculated energy dispersion relationships for the aforementioned strain conditions for both the tensile and compressive cases [23].

For each case, the nonzero components of the stress tensor are explicitly indicated in the figure caption, (y, z) being the

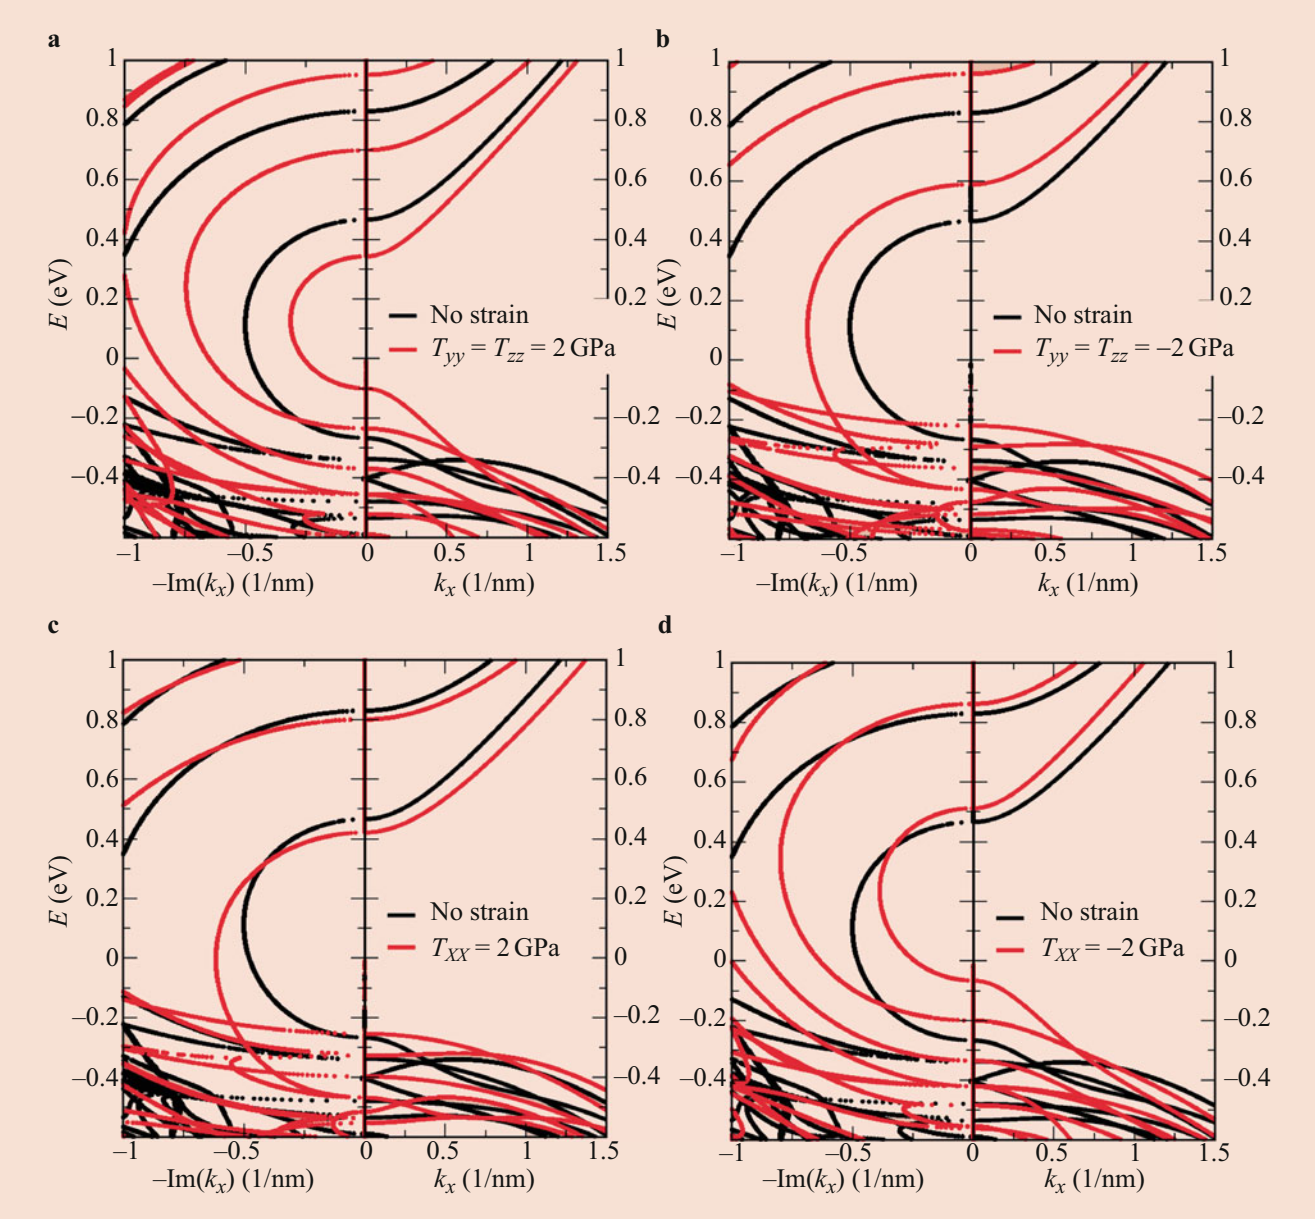

Fig. 41.6 Energy dispersion for a $5 \times 5\,\text{nm}^2$ InAs nanowire: (**a**) biaxial tensile $T_{yy} = T_{zz} = 2\,\text{GPa}$; (**b**) biaxial compressive $T_{yy} = T_{zz} = -2\,\text{GPa}$; (**c**) uniaxial tensile $T_{xx} = 2\,\text{GPa}$; (**d**) uniaxial compressive $T_{xx} = -2\,\text{GPa}$

cross-section plane and x the longitudinal direction of the nanowire. The strain tensor is then calculated with (41.21). By comparing the band structures in Fig. 41.6, we can observe the effects of the different strain conditions on bandgap and density-of-states. Starting from the tensile biaxial stress, significant changes are observed for the valence and conduction subbands, giving rise to a large reduction of the bandgap and of the imaginary wave vector in the gap. On the contrary, by applying a compressive biaxial stress, the opposite shifts of the valence and conduction bands are found, leading also to the fact that the lowest conduction subband is not connected to the highest valence subband by an imaginary branch. This leads to an effective bandgap, which is relevant for the band-to-band tunneling process, that is, ≈0.2 eV larger than the density-of-states (DOS) bandgap. The effect is very similar to the one shown in Fig. 41.5 for bulk GaAs and biaxial compressive stress. The values of both the effective and DOS bandgaps are reported in Table 41.1.

Such kind of condition plays a key role in nanoscale devices based on band-to-band tunneling, as it causes a reduction of the tunneling probability, which is determined by the imaginary branch of the $E(k)$ and not by the DOS bandgap.

Table 41.1 InAs NW bandgap, "effective" bandgap, and electron/hole effective mass of the first conduction/valence subband for the unstrained, biaxial, and uniaxial stress conditions as in Fig. 41.6. The effective masses are evaluated from the real branches of the $E(k)$ shown in Fig. 41.6

	E_G (eV)	"effective" E_G (eV)	m_e (m_0)	m_h (m_0)
Unstrained	0.735	–	0.057	0.057
Biax. tens.	0.45 (−39%)	–	0.036 (−37%)	0.033 (−42%)
Biax. comp.	0.81 (+10%)	1.0 (+25.5%)	0.077 (+35%)	0.33 (+226%)
Uniax. tens.	0.67 (−8%)	0.88 (+31%)	0.072 (+26%)	0.33 (+226%)
Uniax. comp.	0.58 (−21%)	–	0.043 (−24.5%)	0.039 (−31%)

Table 41.2 GaSb NW bandgap and electron/hole effective mass of the first conduction/valence subband for the unstrained, biaxial, and uniaxial stress conditions. The effective masses are evaluated from the real branches of the dispersion relations $E(k)$

	E_G (eV)	m_e [m_0]	m_h [m_0]
$5\times5\,nm^2$ GaSb NW − stress = 2 GPa			
Unstrained	1.18	0.068	0.13
Biax. tens.	0.86 (−28%)	0.05 (−26%)	0.07 (−46%)
Biax. comp.	1.29 (+9%)	0.084 (+23.5%)	0.25 (+97%)
Uniax. tens.	1.08 (−8%)	0.079 (+16%)	0.25 (+97%)
Uniax. comp.	1.06 (−11%)	0.058 (−15%)	0.08 (−38%)

Similar considerations apply for the uniaxial tensile and compressive strain conditions. In the tensile case, the same branch crossing already seen for biaxial compressive strain occurs. This is clearly confirmed by the bandgap values reported in Table 41.1.

The electron and hole effective masses of the InAs nanowire evaluated from the curvatures of the real branches defining the DOS bandgaps are also reported in Table 41.1. As expected, the density-of-states is significantly affected by the applied strain, leading to relative changes larger than 24% in all configurations. Moreover, due to the crossing of the valence subbands induced by biaxial compressive and uniaxial tensile strain, an increase as high as +226% of the hole effective masses is experienced.

It is worth noting that a similar effect takes place also for other materials (e.g., GaSb) and also for thin body structures (quantum wells) and is independent of the device cross section [24]. The results of similar calculations carried out for GaSb nanowires for the same stress conditions are reported in Table 41.2 and show very similar trends to those reported in Table 41.1 for InAs.

41.3 The k · p Method Applied to Tunnel Field-Effect Transistors

Tunnel FETs (TFETs) are among the potential disruptive solutions to overcome the conventional CMOS limitations in power consumption control, as they provide a very steep subthreshold slope (SS) and a reduced random dopant-induced variability, thanks to the use of intrinsic channels. Moreover, they provide an ample design flexibility, allowing for both horizontal and vertical implementations with double-gate (DG) and gate-all-around (GAA) configurations to suppress short channel effects (SCEs) and enhance device scalability [25,26]. Unlike conventional MOSFETs, which work by raising or lowering an energy barrier to control the current flow, TFETs keep this energy barrier high. The device switches on and off by altering the likelihood for electrons on one side of that barrier to tunnel to the other side, the barrier being the energy bandgap. The basic operation of such devices is reported in Chap. ▶ 24, while different device architectures based on new technologies, more specifically on III–V GAA nanowire structures, are detailed in Chaps. ▶ 6 and ▶ 9.

Current challenges to mainstream introduction of the TFET technology include the difficulty to achieve sufficiently high ON-currents (I_{ON}), to suppress the ambipolar effects affecting the off-state performance, and to deal with the superlinear onset and the unconventional saturation voltage of the output characteristics [27,28].

In this section, two different types of TFET devices are considered: (i) homojunction nanowires and (ii) heterojunction nanowires. Homojunction n-channel TFETs are investigated first, based on InAs, by assuming p-type/n-type doping in the source/drain regions, respectively, and an intrinsic channel. Next, heterostructure n-channel TFETs are considered as they have the potential to achieve larger I_{ON} levels, as reported in promising experimental studies on III–V compounds [29].

As far as charge transport is concerned, a quantum ballistic model is adopted in all cases, using the four-band or the eight-band $\boldsymbol{k}\cdot\boldsymbol{p}$ Hamiltonian, as indicated in Sect. 41.2, combined with the NEGF formalism [30] to cope with full 3D quantum transport. Details on the NEGF model can be found in Chap. ▶ 44. The NEGF module is self-consistently coupled with a 3D Poisson solver. The adopted software was validated against atomistic TB calculations [31], and a nice agreement between the two simulation approaches was reported in [32], boosting confidence in the predictive capabilities of the $\boldsymbol{k}\cdot\boldsymbol{p}$ framework.

41.3.1 Device Structures

Homojunction and heterojunction devices have a similar structure. The schematic view of the heterojunction device is

reported in Fig. 41.7 [33]. The homojunction device geometry is identical, with InAs being the only semiconducting material. A careful optimization of the device geometry, doping levels, and gate stack is required to optimize the overall TFET performance in both the homojunction and heterojunction cases.

A squared cross section of thickness $T_{side} = 5\,nm$ is assumed for both devices. The length of the source region is $L_S = 20\,nm$, the gate length is $L_G = 17\,nm$, and the drain-region length is $L_D = 40\,nm$ [33]. The source doping is assumed uniform and fixed to $N_A = 5 \times 10^{19}\ cm^{-3}$, the channel is intrinsic, and the drain doping is uniform and fixed to $N_D = 10^{19}\ cm^{-3}$. An abrupt doping variation is considered at the source/channel junction, consistently with a vertical fabrication process [34, 35]. It is worth pointing out that a gradual doping profile would have a strong impact on the tunneling probability and thus on the TFET performance. The drain doping is lower than the source doping to limit ambipolar effects. Therefore, a longer drain region is required to ensure charge neutrality at the drain contact. As far as the gate stack is concerned, the thickness of the gate oxide is fixed to $T_{ox} = 1\,nm$ of SiO_2 [33]. It is worth noting here that TFETs are less sensitive to fringing-field effects of the gate capacitance as compared with conventional field-effect transistors.

In the following analysis, the nanowire transport direction is [100], consistent with the assumptions made in the previous section for the band structure calculations under different stress conditions. However, recent studies of the energy dispersion curves carried out with the $\boldsymbol{k} \cdot \boldsymbol{p}$ method have shown that the real and imaginary branches have a similar behavior also when [110] and [111] transport orientations are assumed [36].

41.3.2 Impact of Strain on the Tunneling Current of Homojunction TFETs

In Fig. 41.8, the I–V curves for the $5 \times 5\,nm^2$ homojunction InAs nanowire TFET are reported for different stress conditions [23]. As indicated in the figure caption, the current is normalized to the nanowire side and all simulations are carried out at $V_{DS} = 0.3\,V$. By comparing the turn-on characteristics, the significant impact of stress can be appreciated, leading to changes in the leakage current in a range of almost 12 orders of magnitude, a shift of the threshold voltage V_T of about 0.5 V along with a substantial change in the subthreshold slope SS, and a variation of the ON-current in the 1–1000 μA/μm range.

A clear correlation can be inferred between leakage current and bandgap narrowing induced by stress (Table 41.1): the lower the bandgap, the larger the leakage current. From a physical standpoint, the leakage current is due to the ambipolarity of the device, i.e., to band-to-band tunneling occurring at the drain junction at low V_{GS}. The V_T as well as the SS variations follow the bandgap changes. The significant reduction of SS observed for the biaxial tensile and uniaxial compressive cases is mostly ascribed to the higher degeneracy caused by the effective-mass decrease, as reported in Table 41.1.

The role of the "effective" bandgap needs to be accounted for in order to fully explain the current reduction experienced in the uniaxial tensile case. To this purpose, Fig. 41.9 reports the current spectra (i.e., the current densities vs. energy) and the subband profiles for the uniaxial compressive (a) and uniaxial tensile (b) cases [23]. Different V_{GS} have been applied in the two cases to have almost the same conduction

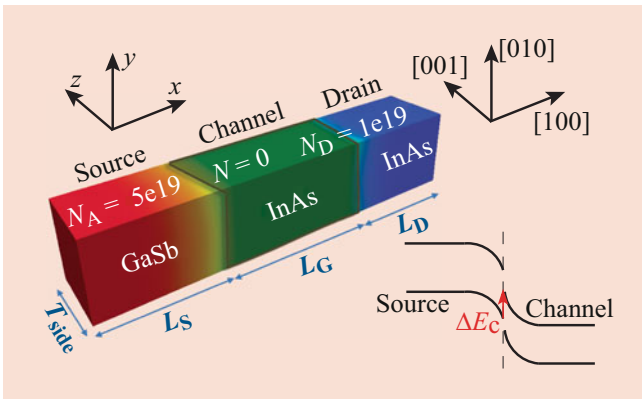

Fig. 41.7 Schematic view of the TFET device realized with a GaSb/InAs heterostructure. ΔE_C is defined as the energy difference between the channel conduction band edge and the source valence band edge at the heterojunction

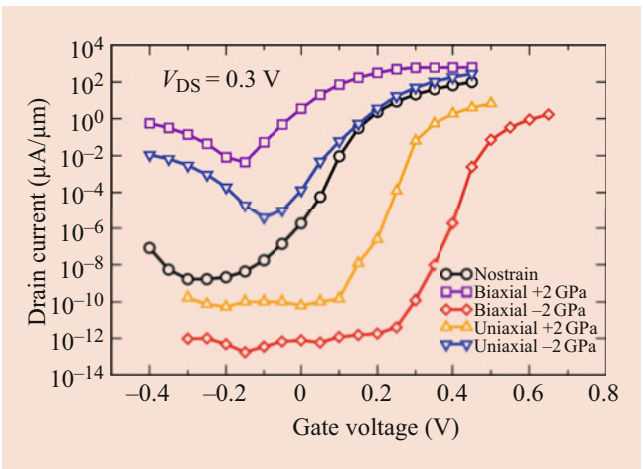

Fig. 41.8 I_{DS} versus V_{GS} curves at $V_{DS} = 0.3\,V$ for the InAs homojunction device with different strain types. The current is normalized with respect to the nanowire side. There are two unfavorable strain configurations which give a small I_{ON} and an unusual behavior: uniaxial tensile and biaxial compressive strain

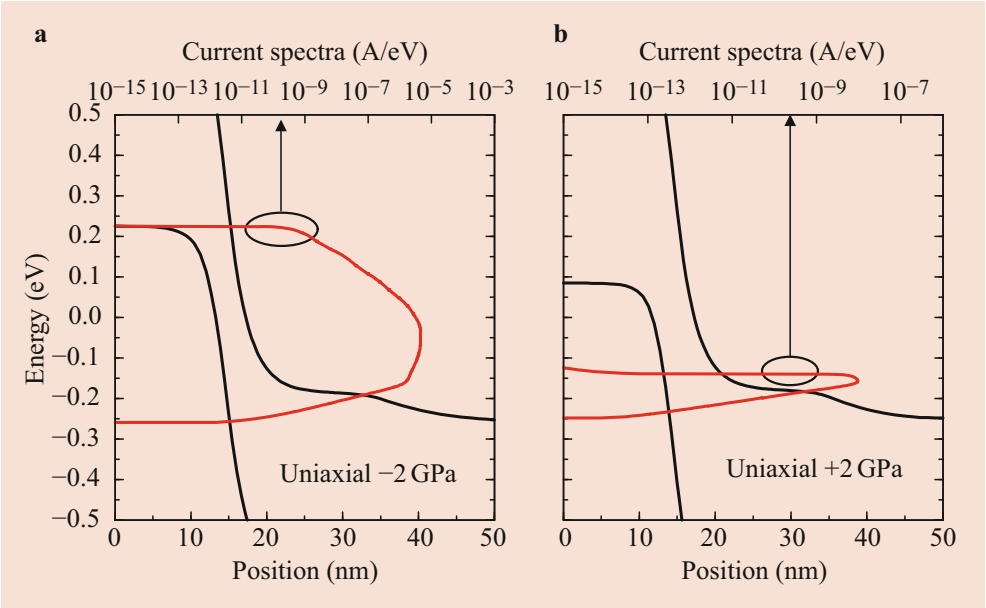

Fig. 41.9 Subband profile vs. position and current spectrum vs. energy for the InAs homojunction, for uniaxial compressive (**a**) and uniaxial tensile strain (**b**). Two different V_{GS} values have been chosen to have the conduction band edges almost aligned within the channel. For the uniaxial compressive case, the current flows at all energies for which there are available states both in the source and in the channel. In the uniaxial tensile case, the current is negligible up to 0.2 eV below the first valence subband in the source

band-edge level within the channel. The plot illustrates the change in the degeneracy level within the source. Moreover, in the compressive case, tunneling occurs in an energy window ranging from the top of the valence band in the source to the bottom of the conduction band in the channel, while in the tensile case, tunneling occurs in a limited energy window, ranging from about 0.2 eV below the valence band in the source to the bottom of the conduction band in the channel. This corresponds to the effective bandgap shown in Fig. 41.6c. The transport results confirm that the effective bandgap gives rise to an unexpected significant reduction of the ON-current.

In order to compare the subthreshold trend of the different curves, the metal gate work function has been adjusted for each stress case to fix the OFF-current $I_{OFF} = 1\,\text{nA}/\mu\text{m}$ at $V_{GS} = 0\,\text{V}$, following the specification of the ITRS Low Operation Power (LOP) application [37]. The resulting curves are compared in Fig. 41.10, showing a substantial SS degradation at low V_{GS} for the stress cases with higher ON-current, which provide the best overall trade-off.

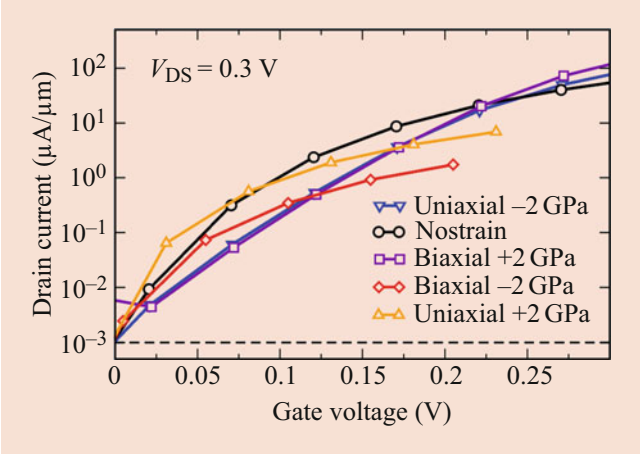

Fig. 41.10 I_{DS} vs. V_{GS} curves at $V_{DS} = 0.3$ V for the InAs homojunction device with different strain types. The current is normalized with respect to the nanowire side. The metal gate work function has been adjusted for each case to have $I_{OFF} = 1\,\text{nA}/\mu\text{m}$ at $V_{GS} = 0\,\text{V}$

41.3.3 Impact of Strain on the Tunneling Current of Heterojunction TFETs

In Fig. 41.7, a GaSb/InAs heterostructure at the source/channel interface is assumed. The corresponding band-edge profiles are plotted in the inset, showing how the heterojunction alignment between the channel conduction-band and the source valence-band edges ΔE_C can affect the tunneling probability. Compared to the homojunction devices reported in the previous subsection, this additional parameter can be used for band engineering as it is strictly related to the band-to-band tunneling at the source/channel junction. In analogy with the homojunction structures, the TFET performance is strongly influenced by structure confinement and applied

strain due to the band structure modifications explained in Sects. 41.2.2 and 41.2.3. More specifically, a GaSb/InAs nanowire with $T_{side} = 5$ nm shows a ΔE_C of 0.24 eV in the unstrained case, which decreases to −0.005 eV and 0.163 eV for the biaxial tensile and uniaxial compressive cases, respectively. A negative ΔE_C means a broken-gap heterojunction rather than a staggered one.

Even if heterojunctions feature an improved ON-current due to the band-structure engineering at the source/channel interface, further improvements are expected with strain similarly to the homojunction-based nanowires. Figure 41.11 compares the I–V curves of a 5×5 nm^2 GaSb/InAs heterojunction NW TFET for different stress conditions [33]. The reported current curves are normalized to the nanowire side and shifted with respect to V_{GS} in order to have $I_{OFF} = 5$ nA/μm at $V_{GS} = V_{GSoff} \equiv 0$ V and $V_{DS} = V_{DD} = 0.3$ V, as indicated by the specification of the ITRS Low Operation Power (LOP) application [37]. Accordingly, I_{ON} is defined as the current corresponding to $V_{GS} = V_{GSoff} + 0.3$ V and $V_{DS} = V_{DD} = 0.3$ V. The experienced V_T shift is in the range from −0.3 V to +0.4 V as shown in the inset. The main effects of strain on the heterojunction-NW TFETs are in line with those reported for the homojunction TFETs. We can observe a significant V_T reduction for the biaxial tensile case as well as an increase in I_{ON} but also a subthreshold slope degradation. The biaxial tensile and uniaxial compressive cases again provide the best trade-off between I_{ON} and SS, but with an advantageous increase of I_{ON} given by the heterostructure. The extracted values of I_{ON} for the latter stress cases are reported in Table 41.3 along with the average SS, calculated over three current decades, and the peak SS.

Table 41.3 I_{ON}, average subthreshold slope (SS_{avg}) computed over three current decades, and peak slope (SS_{peak}) extracted from the GaSb/InAs NW TFET currents reported in Fig. 41.11 for two stress conditions

5×5 nm^2 GaSb/InAs NW TFET			
	I_{ON}	SS_{avg}	SS_{peak}
	(μA/μm)	(mV/dec)	(mV/dec)
No strain	150.1	30	26
Biax. tens. +2 GPa	245.7	51	45
uniax. comp. −2 GPa	177.1	41	35

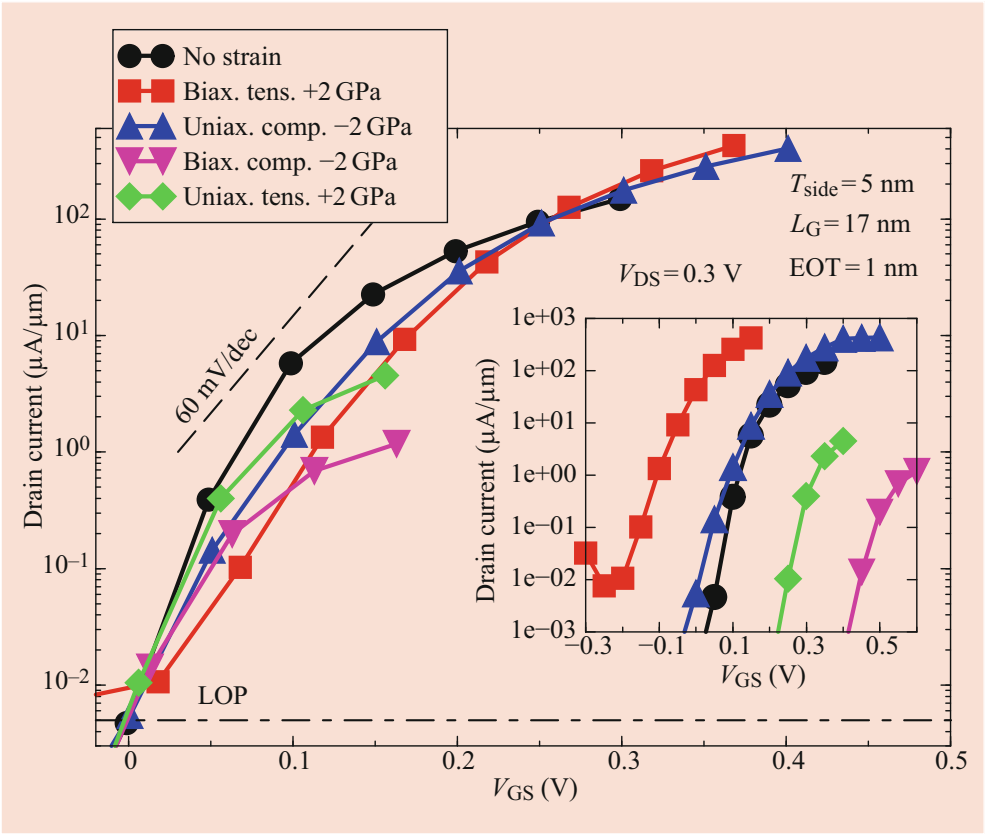

Fig. 41.11 Turn-on characteristics of a 5×5 nm^2 GaSb/InAs NW TFET for different stress conditions. The current is normalized by the device side and is shifted to match the I_{OFF} target of the LOP application (5 nA/μm). $V_{DS} = 0.3$ V. Inset: I–V curves with no gate voltage shift. The biaxial tensile stress increases the on-state current, while the uniaxial compressive stress has a smaller impact on the I–V curve. The uniaxial tensile and biaxial compressive strains produce unfavorable I_{ON} and a large threshold voltage shift

41.3.4 GaSb-/InAs-Based TFET Optimization Exploiting Strain and Device Geometry

A deep investigation on stress effects and on the choice of geometrical parameters in homojunction TFETs has been recently carried out in the literature by extensive use of the $\boldsymbol{k} \cdot \boldsymbol{p}$ method [36, 38, 39]. In [33], a similar systematic study was carried out on GaSb/InAs nanowire TFETs. To this purpose, the subthreshold swing, the ON-current, and the ON-/OFF-current ratio at low supply voltage have been calculated by means of a full 3D NEGF framework based on the eight-band $\boldsymbol{k} \cdot \boldsymbol{p}$ model.

The main outcomes of the latter investigations are briefly reported in the following with the aim of highlighting the potential and scope of the $\boldsymbol{k} \cdot \boldsymbol{p}$ method for the exploitation of novel nanoscale solutions. More specifically, the effects of changing the gate length and cross-section area are analyzed under different stress conditions, clearly showing the major role played by band structure engineering in such kind of devices.

I–V curves of GaSb/InAs TFETs with two different gate lengths are compared in Fig. 41.12 [33]. As in conventional MOSFETs, the increase of L_G in a TFET reduces source-to-drain tunneling, which is the main contribution to the leakage current in subthreshold regime. As a result, a significant improvement in the subthreshold slope is found along with a slight increase in the ON-current. The effect of strain in the TFET with a longer channel is comparable to the one in the short device so that, for the +2-GPa biaxial tensile stress, a 36% increase in I_{ON} and a 47% decrease in the average SS are achieved. The extracted data are reported in Table 41.4. However, it must be pointed out that even if a longer L_G is favorable to the device static performance, the corresponding augmented total gate capacitance and overall occupation area must also be considered in applications.

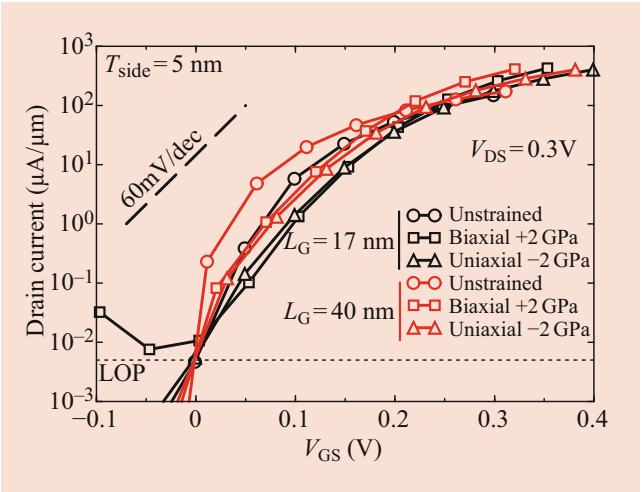

Fig. 41.12 Turn-on characteristics of a 5 × 5 nm^2 GaSb/InAs NW TFET for L_G = 17 and 40 nm for the unstrained, biaxial strain and uniaxial strain conditions. The current is normalized to the cross-section side, and the curves are shifted to match the target I_{OFF} of the LOP application (5 nA/μm). V_{DS} = 0.3 V. The L_G increase from 17 nm to 40 nm provides a decrease in leakage current and a slope improvement. For the biaxial tensile stress condition, a 36% increase in I_{ON} can be achieved

The *I–V* curves of GaSb/InAs TFETs with different cross-section sizes in unstrained conditions are reported in Fig. 41.13 [33]. The large differences between the curves can be explained by considering that the bandgap and the electron and hole effective masses are significantly influenced by the cross-section area, as illustrated for the 10 × 10 nm^2 InAs and GaSb nanowires by the data in Table 41.5, which must be compared with the corresponding data for 5 × 5 nm^2 nanowires in Tables 41.1 and 41.2. Besides, also ΔE_C at the source-channel interface depends on the cross-section size, due to the different quantization properties of the two materials (see, e.g., the different bandgaps reported for the two materials in Table 41.5). For a cross section of 10 × 10 nm^2, ΔE_C becomes 0.048 eV in the unstrained case, which is −80% of the 5 × 5 nm^2 nanowire.

Table 41.5 reports also the data for the same strain conditions discussed in the previous subsections, namely, biaxial tensile and uniaxial compressive, but with two different stress intensities, i.e., 1-GPa and 2-GPa. The 2-GPa results can be directly compared with the 5 × 5 nm^2 case and clearly show a huge reduction in the bandgap. As a significant ambipolarity is expected for such low bandgaps, the strain intensity of 1 GPa can be preferable to mitigate the effect. Besides, the drain region can be optimized [33] by using a nonuniform drain doping with a 20-nm-long region abutting the channel with $N_D = 10^{18}$ cm^{-3} and a 20 nm region with graded doping up to $N_D = 10^{19}$ cm^{-3} next to the drain contact.

The *I–V* curves of GaSb/InAs TFETs with different cross-section sizes under strain conditions are reported in Fig. 41.14 [33]. As expected, a significant increase in the current is observed when a 1-GPa biaxial tensile stress is applied in the larger nanowires. This is mostly due to a further decrease of ΔE_C at the source-channel interface,

Table 41.4 I_{ON}, average subthreshold slope (SS_{avg}) computed over three current decades, and peak slope (SS_{peak}) extracted from the GaSb/InAs NW TFET currents with L_G = 40 nm reported in Fig. 41.12 for various stress conditions

which for the $10 \times 10\,\text{nm}^2$ NW becomes $-0.093\,\text{eV}$ for 1-GPa biaxial tensile stress. The intermediate $7 \times 7\,\text{nm}^2$ TFET with 1-GPa biaxial tensile stress is able to fulfill the I_{OFF} requirement with $I_{ON} = 0.4\,\text{mA}/\mu\text{m}$. Table 41.6 collects the most significant extracted parameters.

41.4 TFET Inverters for a Complementary Technology Platform

The need of a complementary logic requires to investigate the complementary p-channel TFET in addition to the n-channel TFET already discussed. The investigations on n-channel TFETs clearly showed that heterostructures featuring broken or staggered band lineups are the most promising candidates [31]. Experimental and numerical investigations, like, e.g., those discussed in [29, 33, 40] and in the previous section, suggest that the GaSb/InAs heterojunction is most attractive for n-type devices. On the contrary, a different couple of III–V materials gained some interest for the realization of p-TFETs, namely, the InAs/AlGaSb one, which was proposed in [41] by exploring the possibility to achieve either staggered or broken gap alignments by varying the Al mole fraction in the channel.

In this section, simulation results of complementary heterojunction nanowire TFETs are reported based on the same InAs/AlGaSb heterostructure platform. The simulation framework is based on the four-band $\boldsymbol{k} \cdot \boldsymbol{p}$ model [42]. The schematic representation of the two devices is shown in Fig. 41.15 for the specifically chosen InAs/$Al_{0.05}Ga_{0.95}Sb$ couple [42]. A gate-all-around architecture is assumed. The gate, not shown in the figure, is self-aligned to the intrin-

sic channel. The square cross section of the nanowires is 7 × 7 nm^2 and the source, channel, and drain lengths are fixed to 20 nm. The source of the n-type TFET is made of AlGaSb doped with 5 × 10^{19} cm^{-3} acceptors, the InAs channel is assumed intrinsic, and the InAs drain is doped with a graded doping from 10^{18} to 10^{19} cm^{-3} donors to reduce the ambipolarity effect [42]. The p-channel device is realized with abrupt doping profiles in the source, channel, and drain regions as illustrated in Fig. 41.15.

In contrast with the majority of literature, where typically TCAD tools are used for the simulation of full inverters, the results reported hereafter are based on full quantum NEGF simulations with the four-band $\boldsymbol{k} \cdot \boldsymbol{p}$ model for both n- and p-channel devices.

The turn-on characteristics of the optimum n- and p-type TFETs are reported in Fig. 41.16a [32], showing full compliance with the ITRS requirements of the low operating power (LOP) nodes, with I_{OFF} = 5 nA/μm [37] when V_{DS} = V_{DD} = 0.4 V. The ITRS requirement on the off-state current for the low-standby-power (LSTP) nodes is also indicated in the figure (I_{OFF} = 10 pA/μm). The main features obtained for the n-type (Tn) and p-type (Tp) devices can be extracted from the *I*–*V* curves and are compared in diagrams (b), (c), (d), and (e) of Fig. 41.16. The turn-on characteristics are compared by assuming the same off-state at $V_{GS} - V_{OFF} = 0$. Starting from the subthreshold behavior, both devices exhibit a minimum SS lower than 40 mV/dec, with an average SS lower than 60 mV/dec, having defined the average over a number of current decades of about 3 for both Tn and Tp. The SS values experienced by the InAs/$Al_{0.05}Ga_{0.95}Sb$ nanowires do not compete with the results obtained by the GaSb/InAs TFETs reported in the previous section. Due to this lower performance, a larger V_{DD} has been applied here in order to reach larger on-state currents. The I_{ON} levels are relatively high, especially for the Tn device, which nicely compares with similar n-ch GaSb/InAs TFETs featuring strain effect. The Tp I_{ON} is four times smaller than the Tn one. Such a difference might require a compensation approach when dealing with practical circuits.

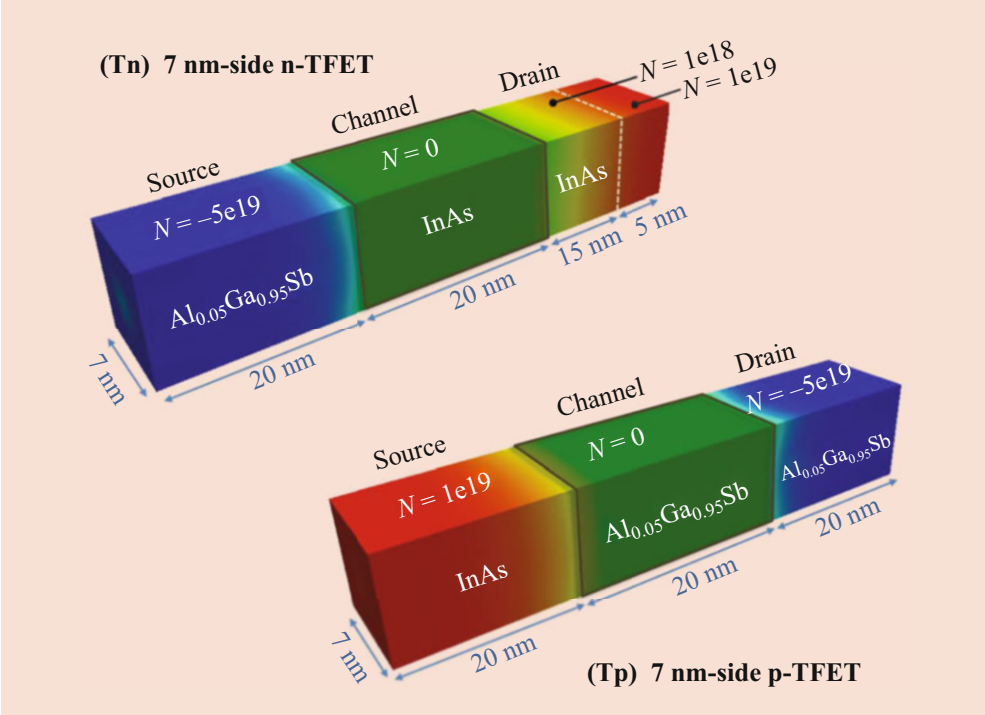

Fig. 41.15 Considered n-type (Tn) and p-type (Tp) heterojunction TFETs based on the same InAs/$Al_{0.05}Ga_{0.95}Sb$ material pair. Doping concentrations are indicated in cm^{-3} and abrupt profiles are assumed. A nonuniform drain doping is used to reduce ambipolarity in Tn. The gate dielectric is Al_2O_3 with an equivalent oxide thickness EOT = 1 nm

The design of a complementary TFET inverter, which can be assumed as the simplest circuit for a fair comparison with the conventional CMOS logic as far as power consumption and time response are concerned, was addressed in [32] by proposing two different solutions. The first one is indicated as *I*1 in Fig. 41.17: it is based on one p-channel and one n-channel transistor without any compensation of the asymmetry discussed above. The second one, called *I*2 in Fig. 41.17, compensates the lower I_{ON} of the p-channel device by using four devices in parallel. In order to normalize the off-state dissipation of both circuits to the same value, the turn-on characteristics of the four p-channel devices in *I*2 have been shifted in order to obtain the same OFF-current as in *I*1. Finally, a two-stage inverter chain is used to estimate the transient performance under self-loading. The main differences observed when comparing the *I*1 and *I*2 configurations are illustrated in the following figures taken from [32]. First of all, the n-TFET and p-TFET output characteristics calculated with the $\boldsymbol{k \cdot p}$ framework for I1 and I2 are shown in Figs. 41.18a and b, respectively, as a function of the inverter output voltage V_o, which corresponds to V_{DS} for the n-channel devices and to $V_{DD} + V_{DS}$ for the p-channel ones, for a number of inverter input voltages V_i, corresponding to V_{GS} for the n-channel devices and to $V_{DD} + V_{GS}$ for the p-channel ones. The voltage transfer characteristics (VTCs) of the two different circuits require to determine the V_o-V_i relationship from the analyzed *I*–*V* curves. To this purpose, the intersections between the *I*–*V* curves illustrated by the black dots in Fig. 41.18 for each input voltage V_i have been extracted and reported in Fig. 41.19a (a nonlinear interpolation is assumed between the *I*–*V* curves when needed). The improvement related to the symmetry of the *I*2 configuration is clearly visible in the corresponding VTC. Similar voltage gain is obtained for both configurations, while a larger current consumption is found for *I*2 due to the larger number of transistors used in the pull-up network (Fig. 41.19b and c, respectively).

The transient responses of the two inverters to an input voltage step have been calculated by considering a load capacitance C_L either equal to a fixed value or assuming a self-loading condition, i.e., a chain of two identical inverters [32]. To this end, the total gate capacitances of Tn and Tp have been calculated as

$$C_g = \frac{Q_{ON} - Q_{OFF}}{V_{DD}} \tag{41.22}$$

where $Q_{ON} - Q_{OFF}$ is the net charge variation inside the device between the on- and the off-states. Such quantities have been obtained by integrating the net charge density derived from the 3D simulations on the full nanowire domain. As shown in Fig. 41.20a, the n- and p-channel devices exhibit similar C_g values. The total input capacitances of the inverters (Fig. 41.20b) clearly show that a significantly larger C_{in} is

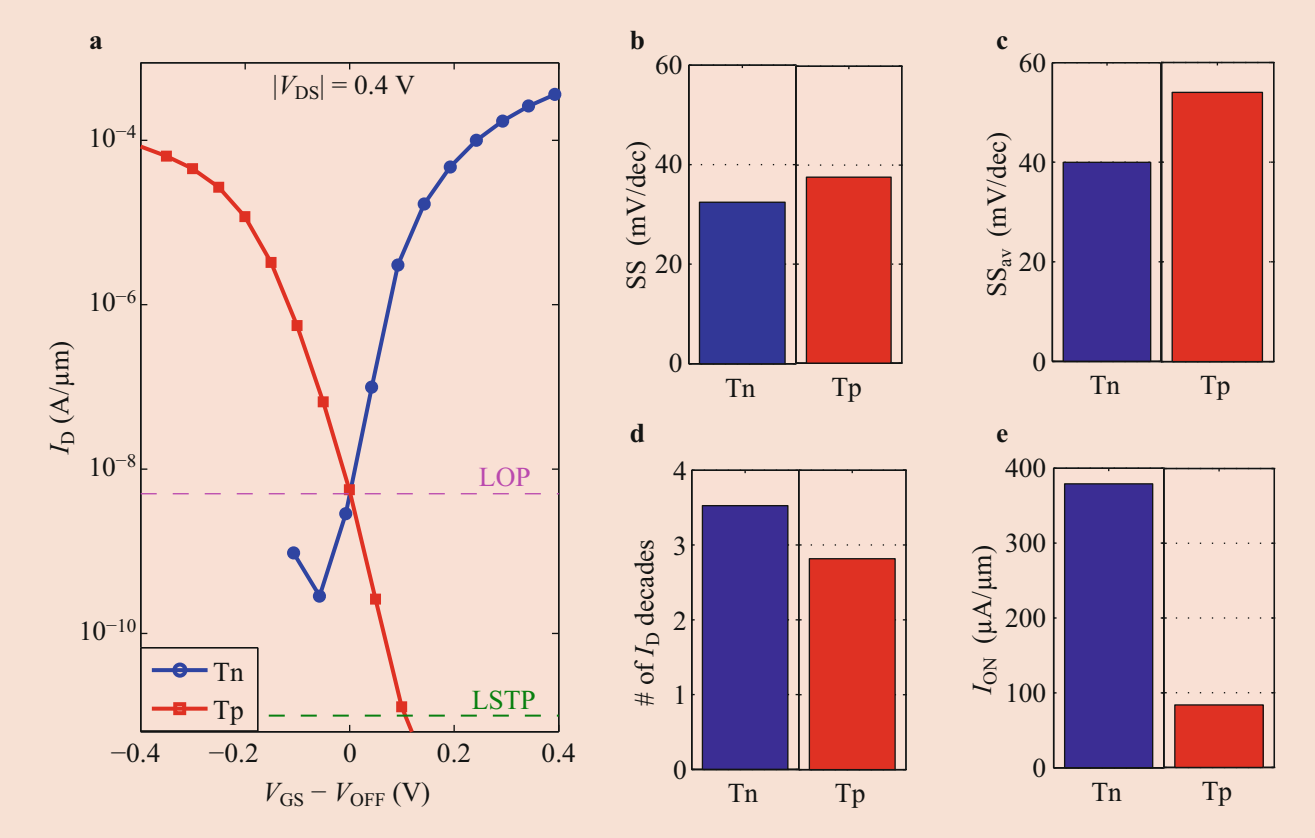

Fig. 41.16 (**a**) Simulated I_D-V_{GS} curves at $|V_{DS}| = 0.4$ V for the TFETs in Fig. 41.15 (normalized by device side for consistency with quantization-induced charge distribution). LSTP (10 pA/μm) and LOP (5 nA/μm) specs on I_{OFF} are indicated. Curves are shifted by the respective V_{OFF}, i.e., the V_{GS} at which $I_D = 5$ nA/μm ($=I_{OFF,LOP}$). Corresponding device performance is evaluated in terms of (**b**) minimum SS, (**c**) average subthreshold slope, SS_{av}, (**d**) number of current decades over which SS_{av} is computed, and (**e**) I_{ON} at $V_{DD} = 0.4$ V

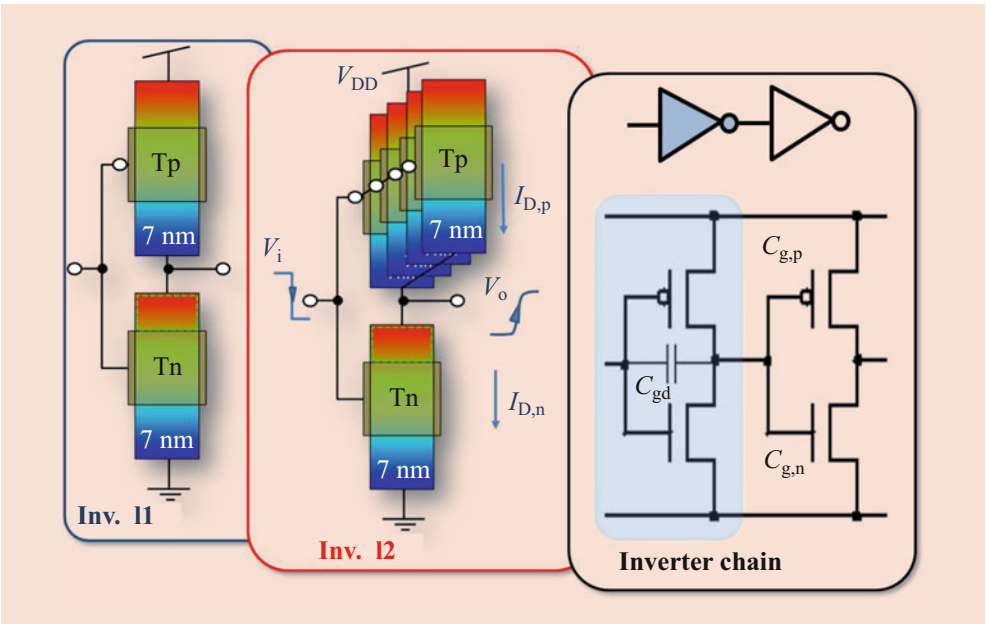

Fig. 41.17 Inverter designs I1 (Tn + Tp) and I2 (Tn + four Tp instances with modified WF), with indication of the switching behavior. A two-stage inverter chain is shown on the right, which is used for transient performance estimation under self-loading. The schematic illustrates device input capacitances $C_{g,n}$ and $C_{g,p}$ as well as the gate-drain capacitance C_{gd}, which is responsible for Miller effects

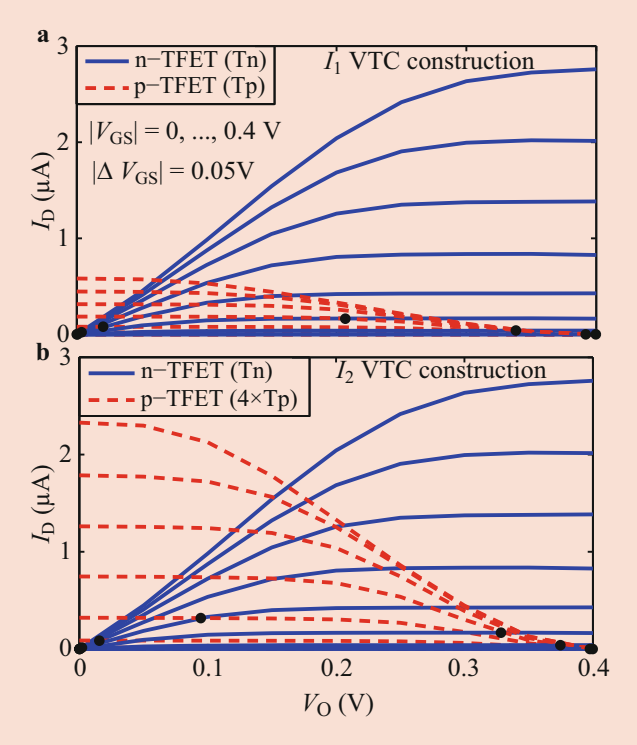

Fig. 41.18 Simulated I_D-V_{DS} families in 0.05 V V_{GS} steps for Tn and Tp. Additional curves at intermediate V_{GS} values are obtained through nonlinear interpolation between these characteristics. Curves are combined exploiting $V_o = V_{DS,n} = V_{DD} + V_{DS,p}$ (see Fig. 41.17) to compute VTCs in Fig. 41.19a for inverters I1 (**a**) and I2 (**b**)

given by the *I*2 inverter, which is clearly due to the presence of four Tp transistors in the pull-up block. In the self-loading case, the Miller effect has been approximately accounted for by adding to C_L a capacitance equal to $2 \times C_{gd}$, the gate-to-drain capacitance C_{gd} being calculated by using the estimation given by [43], with $C_{gd} \approx 0.8 \times C_g$. The rise and fall times $t_{r,f}$ of each inverter in response to an input voltage step are then computed by integrating the output currents obtained from Fig. 41.18 in the interval between 10% and 90% of V_{DD}:

$$t_{r,f} = C_L \int_{0.1V_{DD}}^{0.9V_{DD}} \frac{dV_o}{|I_{D,p}(V_o) - I_{D,n}(V_o)|} \tag{41.23}$$

The rise and fall times relative to the self-loading condition are reported in Fig. 41.21a for inverters *I*1 and *I*2, showing a fairly balanced response for *I*2, which is faster than *I*1. On the contrary, if a fixed C_L is assumed, the same fall time is determined for both inverters, while a factor of about 4 in the rise time is evinced between the two inverters, due to the different pull-up networks (Fig. 41.21b).

As a final outcome of the proposed investigation, in [42] the performance of the considered inverters has been compared with best-case predictions for aggressively scaled CMOS logic based on multi-gate architectures. The comparison was conducted for equal static power consumption, exploiting predictive technology models (PTM-MG) for CMOS simulation [44], and allows identifying favorable V_{DD} windows where TFET has the potential to outperform the traditional technology.

41.5 Modelling of Interface Traps in the k · p Scenario

Trap states located at the semiconductor/insulator interfaces may have a significant impact on the current of III–V TFETs, degrading I_{ON} and SS [45, 46]. In this respect, the achievement of low interface and border trap densities is one of the major technological challenges to be addressed [45, 47].

The combined effects of traps and strain on nanowire TFET characteristics have been investigated in the framework of the $\boldsymbol{k} \cdot \boldsymbol{p}$ approach in [40, 48]. Both acceptor and donor traps can be considered at the semiconductor/oxide interfaces. The trap occupation probability is calculated through a generalization of the Shockley-Read-Hall (SRH) theory consistent with the quantum ballistic NEGF approach and fully accounting for carrier degeneracy. The mathematical framework was first presented in [48] and then extended in [40]. In essence, the occupation probability of traps at energy E_t in steady state is determined from the balance of electrons and holes emission and capture processes. Only the electrostatic effect of traps is considered via Poisson's equation, while transport is still considered ballistic. The end result is that the densities per unit energy and area of electrons and holes trapped inside interface centers at energy E_t and position x are given by

$$n_t(E_t, x) = P_t(E_t, x) D_{it}^{(A)}(E_t, x) \tag{41.24a}$$

$$p_t(E_t, x) = [1 - P_t(E_t, x)] D_{it}^{(D)}(E_t, x) \tag{41.24b}$$

where $D_{it}^{(A)}$ and $D_{it}^{(D)}$ are the acceptor and donor trap densities per unit energy and area at energy E_t and position x and the trap occupation probability $P_t(E_t, x)$ can be approximated in the case of one type of dominant carriers as

$$P_t(E_t, x) \simeq \frac{n(x)}{n(x) + n_1(x)} \quad \text{(electronsmajoritycarriers)}$$

$$P_t(E_t, x) \simeq \frac{p_1(x)}{p(x) + p_1(x)} \quad \text{(holesmajoritycarriers)} \tag{41.25}$$

In (41.25) $n(x)$ and $p(x)$ are the total free electron, and hole densities at x and $n_1(x)$, $p_1(x)$ are given by

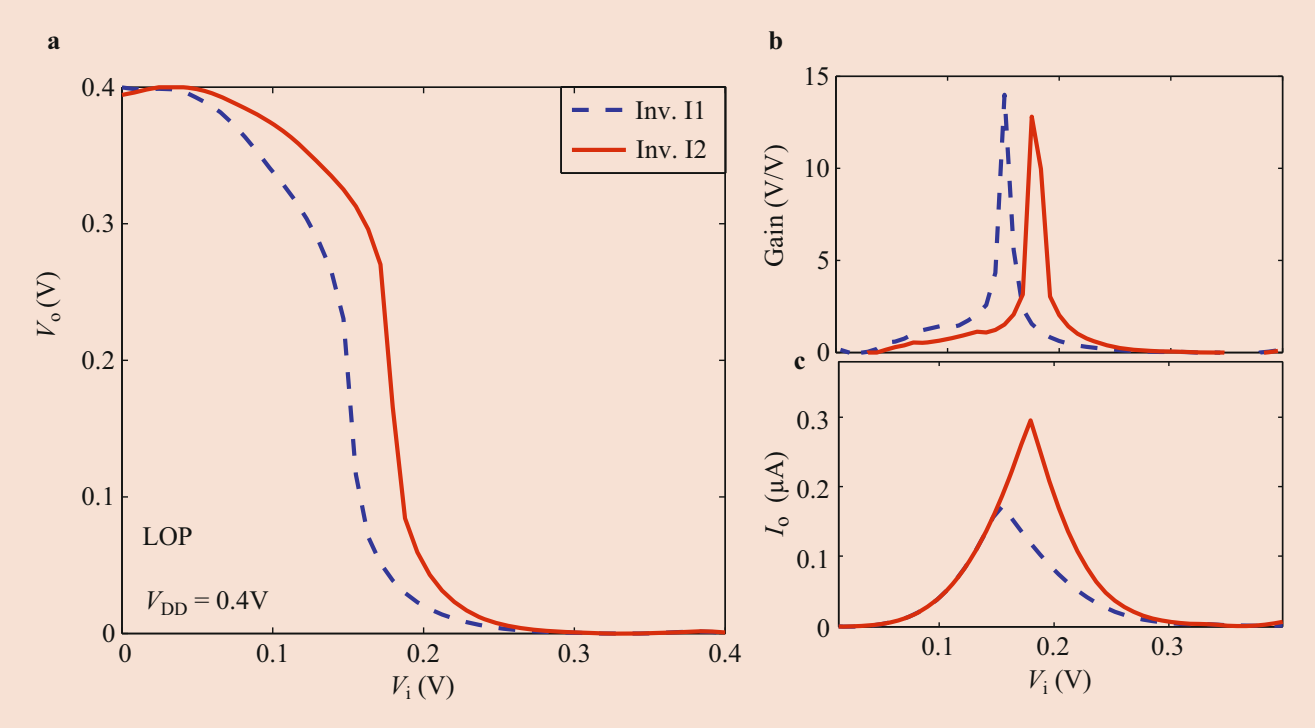

Fig. 41.19 (**a**) VTCs of inverters *I*1 and *I*2 in Fig. 41.17, computed exploiting nonlinear interpolation between simulated I_D-V_{DS} families, as described in Fig. 41.18. (**b**) Voltage gain and (**c**) current consumption during switching of the two inverters

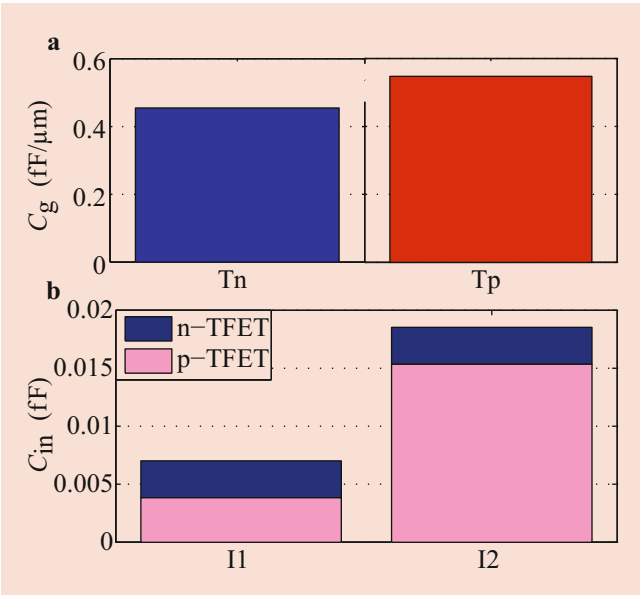

Fig. 41.20 (**a**) Gate capacitance computed through Eq. (41.22) for TFETs Tn and Tp and normalized by device side. (**b**) Total input capacitance of the two inverters, used to compute t_r and t_f in a self-loading configuration

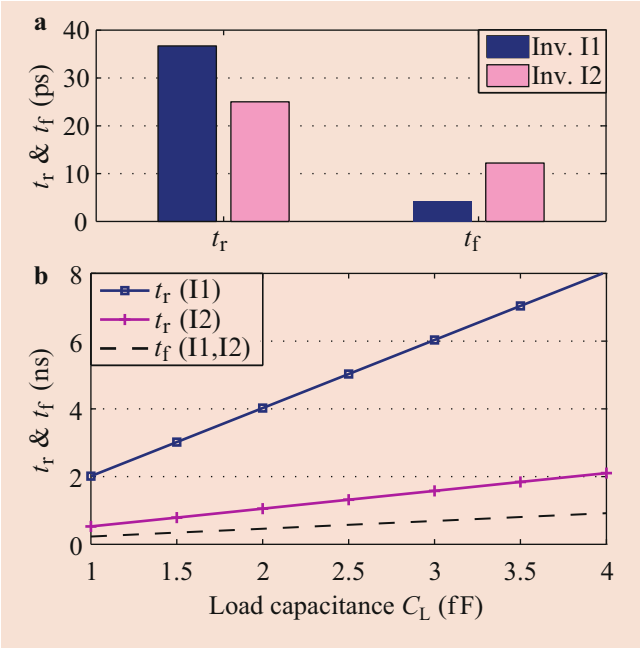

Fig. 41.21 Rise and fall times computed for inverters *I*1 and *I*2 in (**a**) self-loading (with Miller effects included) and (**b**) constant-loading. *I*2 provides more balanced and overall faster performance than *I*1

$$n_1(x) = n_S(x)\ \exp\left(\frac{E_t - E_{FS}}{k_B T}\right) + n_D(x)\ \exp\left(\frac{E_t - E_{FD}}{k_B T}\right) \quad (41.26a)$$

$$p_1(x) = p_S(x)\ \exp\left(\frac{E_{FS} - E_t}{k_B T}\right) + p_D(x)\ \exp\left(\frac{E_{FD} - E_t}{k_B T}\right) \quad (41.26b)$$

$n_{S/D}(x)$ and $p_{S/D}(x)$ being the electron and hole densities, respectively, at location x injected from the source/drain contact reservoir with Fermi level $E_{FS/D}$.

The following results refer to the same optimized Tn and Tp devices investigated in Sect. 41.4, in which traps at the semiconductor/oxide interfaces have been added. In order to use in the simulations a realistic trap density, the trap distribution measured in [49] on bulk MOS InAs structures was assumed for the InAs/oxide interfaces of the Tn and Tp heterostructures. Such D_{it}, assumed to be of acceptor type, is shown in Fig. 41.22, where E_C refers to the conduction band edge of the bulk material. For simplicity, the same D_{it} is also assumed for the AlGaSb/oxide interfaces, relative to the bulk conduction band edge of AlGaSb [40]. It should be noticed that in the investigated TFETs the oxide completely surrounds the nanowire for its full length, thus covering also the source and drain regions. Besides, D_{it} is assumed spatially uniform over the interface areas.

The turn-on characteristics of the optimum Tn and Tp TFETs with and without interface traps and in a stressed/unstressed condition are reported in Fig. 41.23 where no V_{GS}-shift has been applied [40]. $V_{DD} = 0.4\,V$ as in Sect. 41.4 and the currents are normalized to the nanowire side. A 0.5 GPa biaxial tensile stress is applied to improve I_{ON}: as shown in Sect. 41.3.3, this leads to a significant reduction in the bandgaps and effective masses, which causes an increase in the off-state current and a degradation of the subthreshold slope but also a relevant increase in I_{ON}. Indeed, the figure shows that when applying stress to both n- and p-channel devices with traps, the I_{ON} level of the ideal case is totally recovered (Fig. 41.24).

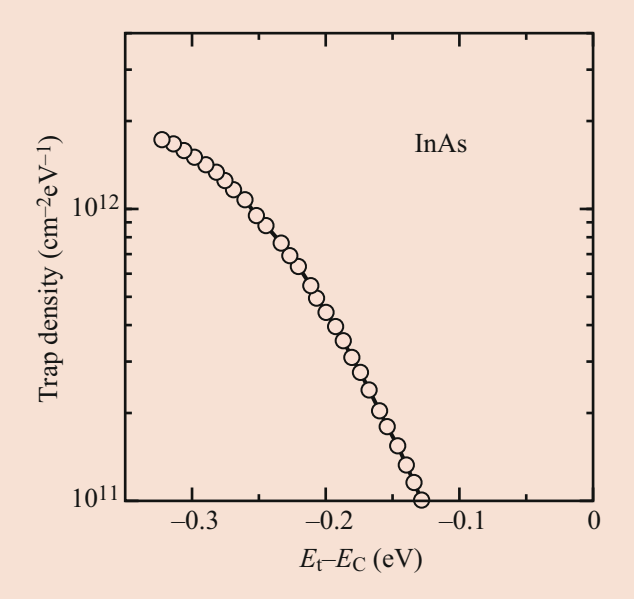

Fig. 41.22 Trap distribution taken from [49]

It is worth noting that traps play a different role in p- and n-channel devices, as traps are located at different energy windows within the two semiconductor bandgaps. A clear picture of the trap distribution in the AlGaSb and InAs nanowires is given in Fig. 41.25, where the trap energy windows are shown along with the band-edge profiles calculated with and without traps. The top panel of Fig. 41.25 refers to the n-channel TFET biased in subthreshold. Traps in the AlGaSb source region are almost empty, while the trapped electrons in the channel lift up the band edges and increase the source-to-drain tunneling distance. Thus, a threshold voltage shift comes out to be the most relevant effect induced by traps in Tn devices. In the bottom panel of Fig. 41.25, the subband profiles of the p-channel TFET are similarly reported in subthreshold regime. In this case, traps are empty in the channel region, while trapped electrons lift up the band edges in the InAs source region, thus reducing the amount of free electrons. The latter effect occurs at any gate bias. Thus, in the Tp devices, traps mainly induce a lower carrier injection.

As a final consideration, it is interesting to compare the different I–V curves after applying a V_{GS}-shift to match the same I_{OFF}, as shown in Fig. 41.24. The performance in terms of I_{ON}, average SS (SS_{avg}), and minimum SS (SS_{peak}) extracted from the curves in Fig. 41.24 is reported in Table 41.7 for both n- and p-channel devices. The detrimental effect of interface traps is quite evident, but strain shows a performance boost even with respect to the ideal cases.

41.6 Conclusions

In this chapter, a review of the $\boldsymbol{k} \cdot \boldsymbol{p}$ model has been presented, focusing in particular on its applications to the field of the simulation of nanoelectronic devices. The mathematical model of the eight-band version has been reported in full, including the additional terms required to cope with strain. The main goal was to convey the idea that the $\boldsymbol{k} \cdot \boldsymbol{p}$ model provides a reasonably simple way to describe with good accuracy the complex system of valence and conduction bands around the Γ point of many semiconductors and their deformations induced by strain, which play a fundamental

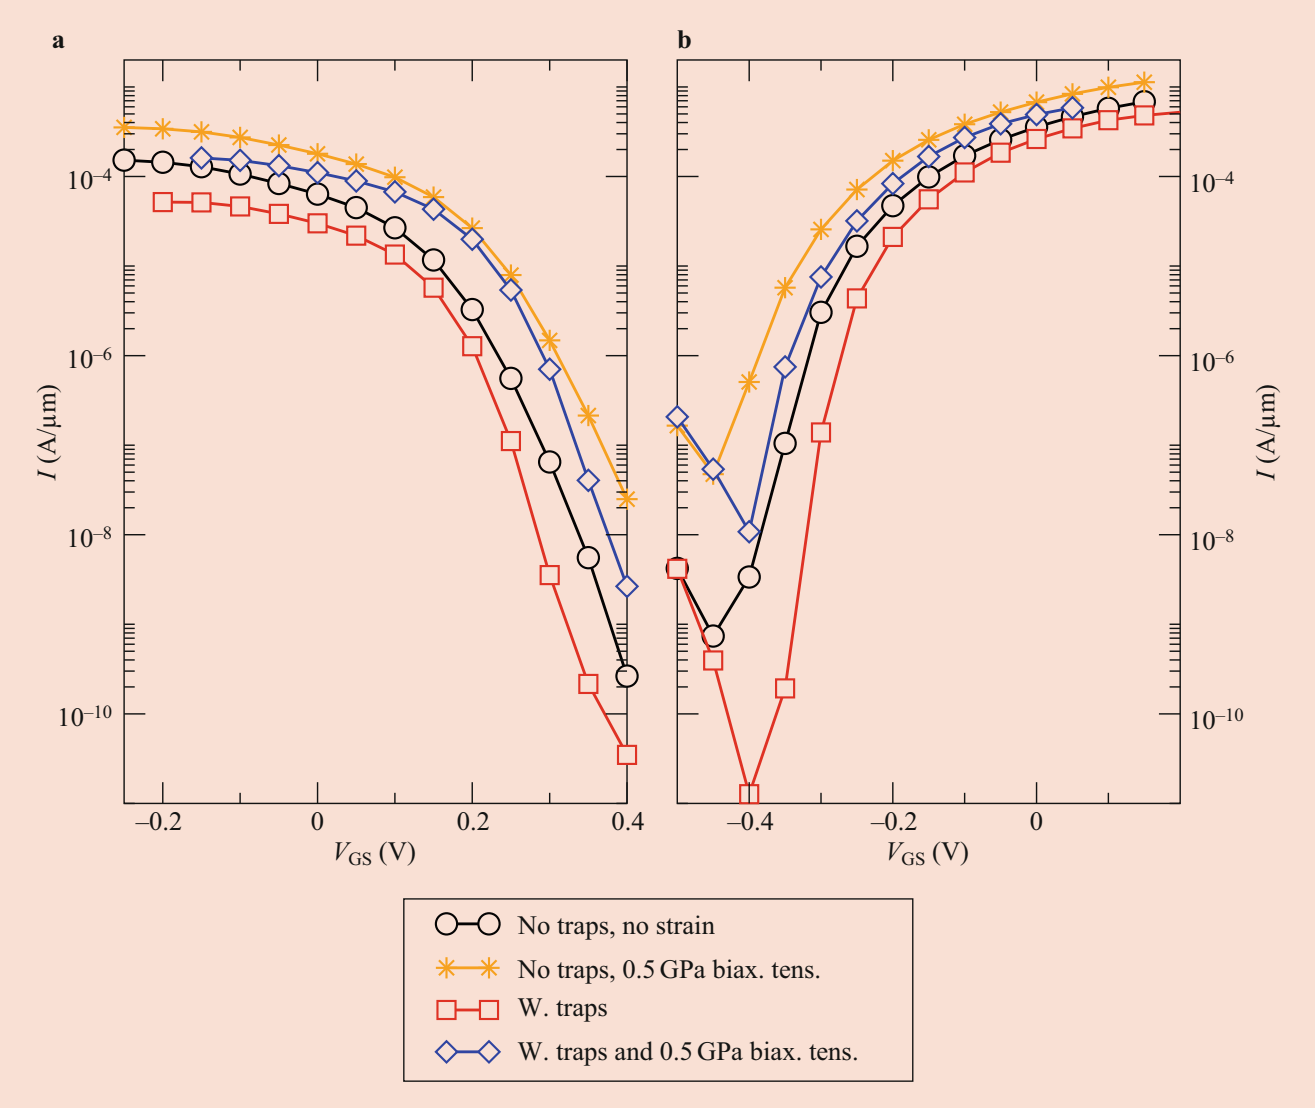

Fig. 41.23 I_{DS} versus V_{GS} at $|V_{DS}| = 0.4$ V with and without interface traps and with and without uniform biaxial tensile strain of 0.5 GPa on the cross section of the nanowire. (**a**): Tp. (**b**): Tn. Currents are normalized to the nanowire side

role in determining the electrical properties of the material. Several examples of energy-band calculations have been provided for III–V semiconductors of great potential for the nanoelectronic industry, relative to both bulk and confined structures.

When coupled with Poisson's equation and used within the nonequilibrium Green's functions framework, the $\boldsymbol{k} \cdot \boldsymbol{p}$ model becomes a powerful tool for the simulation of full devices. This is the case in particular for those devices where purely quantum mechanical effects, such as direct source-to-drain tunneling and band-to-band tunneling, play an essential role requiring also an accurate modeling of the details of the valence band, namely, Si and Ge p-channel FETs and direct-gap III–V tunnel FETs. This is because simpler approaches based on the effective mass are not adequate and, on the other hand, the physical picture does not justify to move to full-band atomistic methods, such as tight-binding, which become appropriate when high energy carriers far from the Γ point play an important role in the device.

Significant examples of application of the $\boldsymbol{k} \cdot \boldsymbol{p}$ model to device simulation have been given in this chapter, all of them relative to the field of tunnel FETs. Specific topics where the $\boldsymbol{k} \cdot \boldsymbol{p}$ model has been extensively applied are the investigation of the effects of strain in homojunction and heterojunction nanowire TFETs, the optimization of complementary TFETs and related inverters, and the investigation of the effect of interface traps on the same nanowire TFETs.

It is believed that the type and number of applications of the $\boldsymbol{k} \cdot \boldsymbol{p}$ model will increase as the device sizes will be pushed to the ultimate scaling limits and new emerging nanoelectronic devices will become available.

Antonio Gnudi graduated in Electrical Engineering in 1983 at the University of Bologna and received the PhD degree in Electrical Engineering and Computer Science in 1989 from the same university. Since 1998 he is Associate Professor of Electronics at the University of Bologna. His research interests are in the area of numerical device simulation and analog circuit design.

Susanna Reggiani received the PhD degree in Electrical Engineering in 2001 and became Associate Professor in 2011 at the University of Bologna. She is with the Department of Electronics and with Advanced Research Center for Electronic Systems. Her scientific activity has been devoted to the modeling and characterization of electron devices, with special emphasis on transport models in semiconductors.

Elena Gnani received the MS degree in Electrical Engineering "summa cum laude" in 1999 and the PhD degree in Electrical Engineering and Computer Science in 2003. Since year 2014 she is Associate Professor in the same university. Her research interests are physical transport models in semiconductor devices and numerical-analysis techniques, with special emphasis on the study of quantum-confined devices.

Giorgio Baccarani graduated in Electrical Engineering in 1967 and in Physics in 1969 at the University of Bologna. In 1981, he was a visiting scientist at the IBM T.J. Watson Research Center, Yorktown Heights, NY. Full Professor of Electronics since 1980, he is presently Professor Emeritus at the University of Bologna. His research interests are in the area of device physics.

Ab initio Methods for Electronic Transport in Semiconductors and Nanostructures

Abstract

The past decade has seen the growing use of *ab initio* methods to study theoretically not only the atomic and electronic structure of semiconductors but also their charge-transport properties. This chapter focuses on "intrinsic" charge transport (limited by scattering with phonons) and starts with a brief historical overview of early work, mostly based at first on the deformation potential theorem and, later, on empirical pseudopotentials and on the rigid-ion approximation, to calculate electron-phonon matrix elements in semiconductors. This historical overview is followed by an outline of the theoretical framework employed when using density functional theory. Having described the full-band Monte Carlo method to solve the Boltzmann transport equation, the chapter presents examples of the use of *ab initio* methods to study the low-field mobility, high-field transport, and device performance in silicon, group-III nitrides, and two-dimensional materials. Throughout the discussion attention is paid to the limitations of *ab initio* methods. Finally, the chapter discusses how *ab initio* methods are used to study the dielectric response of solids and charge transport in the quantum limit.

42.1 Introduction

Until recently, the theoretical study of charge transport in semiconductors and semiconductor devices has been based on some level of "empiricism." The library of software tools that constitute the technology computer-aided design (TCAD) in this area may indeed range from simple – but computationally efficient – models based on a drift-and-diffusion approximation of the semiclassical Boltzmann equation (BTE) [1], to models based on a hydrodynamic approximation [2, 3] or even to full-band Monte Carlo methods [4]. Yet, all of these models require some degree of empirical information, such as models for the carrier mobility as a function of doping and temperature, for the energy and momentum relaxation times, or deformation potentials to describe the strength of the interaction between charge carriers and phonons.

This degree of empiricism has been possible – and highly successful – thanks to the wealth of experimental information that has become available, since the late 1940s, about charge transport in silicon, germanium, and III–V compound semiconductors, materials used in the bulk of the micro- and nanotechnology products in logic, memory, and optoelectronics offered by the very-large-scale integration industry (VLSI). However, in the past decade or so, research has shifted to novel materials that may possibly replace or augment these "conventional" semiconductors, such as wide band gap semiconductors for power electronics (diamond, silicon carbide, group-III nitrides, or gallia – Ga_2O_3), or the growing number of two-dimensional (2D) materials that have attracted attention since the advent of graphene [5–8]. In many cases, little information is available about these materials, often not even their stability, and even less information is available about their charge-transport properties (*e.g.*, band gap, effective mass, and carrier mobility).

The rise of these new materials has moved the old dream of predicting the performance of an electronic device exclusively from "first-principles" (or *ab initio*) from the realm of a cultural and academic exercise to a necessity. Therefore, it is perhaps a fortunate coincidence that at the same time theoretical progress and improvement of the computational hardware have rendered *ab initio* methods reliable and predictable *almost* to the point at which experimental information is required not to build new empirical models but to simply confirm the theoretical predictions. (The reasons why we wrote *almost* will be evident below in Sect. 42.7.)

In the past, the use of first-principles methods has been restricted to small systems, mainly focused on their structures, total and formation energies, and bonding configurations but had little or no connection to electronic transport. However, the recent progress we have mentioned above has broadened their range of applications, improved their accuracy, and extended their scope to electronic transport [9, 10]. Density functional theory (DFT) is now routinely used to predict the atomic and electronic structure of new materials, thanks to the wide availability of computer packages, such as the Vienna *Ab initio* Software Package (VASP) [11–14] or Quantum ESPRESSO (QE) [15, 16]. Even the strength of the electron-phonon interaction can now be calculated using DFT using either the finite ion displacements [17] or density function perturbation theory (DFPT) [18, 19]. This constitutes a dramatic improvement since the early "pioneering" days in which the rigid-ion approximation [20] and empirical pseudopotentials were painstakingly used to estimate deformation potentials in Si, intervalley deformation potentials in III-V compound semiconductors [21–24], and used in Monte Carlo transport studies [25–28]. Even transport in open systems has been studied using DFT [29], and such an *ab initio* formalism has also been used to study dissipative transport in the two-dimensional materials of current interest [30].

In this chapter we present a birds-eye view of the historical evolution of "first-principles" methods toward the present state of art. Keeping in mind the scope of this chapter, we shall limit our attention to the use of first-principles methods in the study of electronic transport. Therefore, in this historical overview, we shall pay attention to the deformation potential theorem and the rigid-(pseudo)ion approximation, approximations that are now replaced by genuine *ab initio* methods, but that still play a huge role in research, thanks to their computational efficiency and their sound physical basis. Restricting our attention to density functional theory, in Sect. 42.3 we shall briefly present a general formulation of DFT and its application to the study of the electron-phonon interaction. As important examples of application of the theory, in Sect. 42.4 we shall consider silicon (obviously), considering the electron-phonon scattering rates, both intra-band and inter-band; the transport properties of group-III nitrides and selected 2D materials (to follow the present trend), employing DFT to compute the electron-phonon scattering rates and their transport properties (low-field mobility, velocity-field characteristics); and also device characteristics (in some cases) obtained from full-band Monte Carlo simulations based on the band structure and scattering rates obtained from these *ab initio* calculations. We shall then present, in Sect. 42.5, a different application of *ab initio* methods, namely, the calculation of the dielectric response of nanostructures, an important factor that controls the electrostatics of devices as well as dielectric screening of several perturbations. We shall present in Sect. 42.6 a brief overview of the use of pseudopotentials to deal with quantum transport in ultra-scaled devices, considering graphene nanoribbons as examples. In our final section, Sect. 42.7, having assessed the predictive power of *ab initio* methods, we shall consider also their limitations and speculate on what the future may promise.

Throughout this discussion, we consider only the electron-phonon interaction, since it is the subject that has received more attention as it is an intrinsic element in determining the charge-transport properties of electron devices. However, additional scattering processes, such as Coulomb scattering with ionized impurities and roughness at the semiconductor-insulator interface, have also been addressed using *ab initio* methods, as illustrated in Refs. [31, 32], for example. We also refrain from discussing molecular devices, although also in this case first-principles methods have been employed successfully (see Refs. [33, 34], for example).

42.2 Historical Overview

It is hard to define precisely the term "first principles" or *ab initio*. If we take a broad view and define a first-principles' approach as a way of expressing a transport-related quantity (such as the electron mobility, for example) in terms of "higher-level" physical quantities that are not directly related to transport (*e.g.*, a change of the band structure in the presence of vibrations of the crystal, phonons), probably the first example of such an *ab initio* approach is given by Bardeen's and Shockley's "deformation potential" theorem [35].

As we shall see below, the interaction between electrons and phonons can be expressed as the perturbation of the electronic motion caused by the displacements of the ions away from their equilibrium positions, displacements that are associated with the thermal vibrations of the lattice. Therefore, the Hamiltonian that describes this perturbation can be written as:

$$\widehat{H}_{\rm ep} = \int_{\Omega} {\rm d}\mathbf{r}\, \delta\widehat{U}_{\rm tot}(\mathbf{r})\widehat{\rho}(\mathbf{r})\,, \tag{42.1}$$

having indicated operators with a "hat." The quantity $\delta\widehat{U}_{\rm tot}(\mathbf{r})$ is the change of the total crystal potential at position $\mathbf{r}$ due to the presence of phonons and $\widehat{\rho}(\mathbf{r})$ is the electron density (that is, $\widehat{\psi}^{\dagger}(\mathbf{r})\widehat{\psi}(\mathbf{r})$ in terms of the (second-quantized) electron field $\widehat{\psi}$). The term $\delta\widehat{U}_{\rm tot}(\mathbf{r})$ can be written explicitly in terms of the displacement, $\delta\widehat{\mathbf{R}}^{(\eta)}_{l,\alpha,\mathbf{q}}$ of each ion α in the unit cell l caused by a phonon of wave vector $\mathbf{q}$ of branch η (longitudinal or transverse, acoustic or optical):

$$\delta\widehat{U}_{\rm tot}(\mathbf{r}) = \sum_{l,\alpha,\eta,\mathbf{q}} \frac{\delta E_{\rm tot}(\mathbf{r})}{\delta\mathbf{R}_{l,\alpha}} \cdot \delta\widehat{\mathbf{R}}^{(\eta)}_{l,\alpha,\mathbf{q}}\, {\rm e}^{{\rm i}\mathbf{q}\cdot\mathbf{r}}\,. \tag{42.2}$$

The quantity $\delta E_{\rm tot}(\mathbf{r})/\delta\mathbf{R}_{l,\alpha}$ represents the change of the total energy of the crystal at position $\mathbf{r}$ when the ion α in cell l is displaced from its equilibrium position by a shift $\delta\mathbf{R}_{l,\alpha}$. (In the following we shall express $\mathbf{R}_{l,\alpha}$ as $\mathbf{R}_l + \boldsymbol{\tau}_\alpha$, where $\boldsymbol{\tau}_\alpha$ is the position of ion α in the unit cell.) In second quantization, the ionic displacement can be expressed in terms of the phonon creation and annihilation operators $\widehat{b}^{(\eta)\dagger}_{\mathbf{q}}$ and $\widehat{b}^{(\eta)}_{\mathbf{q}}$, respectively:

$$\delta\widehat{\mathbf{R}}^{(\eta)}_{l,\alpha,\mathbf{q}} = \left(\frac{\hbar}{2\rho_{\rm x}\omega_{\mathbf{q}}}\right)^{1/2} \mathbf{e}^{(\eta)}_{\mathbf{q}}\, (\widehat{b}^{(\eta)\dagger}_{\mathbf{q}} + \widehat{b}^{(\eta)}_{-\mathbf{q}})\,, \tag{42.3}$$

where $\hbar$ is the reduced Planck's constant and $\mathbf{e}^{(\eta)}_{\mathbf{q}}$ is the phonon polarization vector. The use of first-order perturbation theory is standard practice in our context. Therefore, the matrix element for this process is given by (see Eq. (42.29) below):

$$\left\langle n', \mathbf{k}+\mathbf{q} \left| \delta\widehat{U}_{\rm tot}(\mathbf{r}) \right| n, \mathbf{k} \right\rangle\,, \tag{42.4}$$

where for simplicity we have denoted by $|n, \mathbf{k}\rangle$ a state in Fock space that contains a (Bloch) electron in band n and with wave vector $\mathbf{k}$. We have also omitted to write explicitly the phonons states, as we shall do in the following, since we shall assume them to be at thermal equilibrium.

42.2.1 The Deformation Potential Theorem

In the early days of research of semiconductor physics (around the late 1940s or 1950s), it was impossible to calculate the matrix element given by Eq. (42.4). However, Bardeen and Shockley viewed the *nonpolar* scattering of electrons with acoustic phonons (the process that limits the carrier mobility in Si and Ge), for example as caused by the local change of the energy of the conduction band minimum (or valence band maximum for the hole-phonon process) due to the local strain wave associated with the propagation of a phonon [35]. For example, under an isotropic (hydrostatic) dilatation/compression of the lattice, the lattice constant changes locally from a to $a+u$. This shifts the energy of the conduction band minimum. Therefore, as a dilatation/compression wave propagates in the crystal (*i.e.*, an acoustic phonon), an electron sees a "scattering potential":

$$\Delta E_{\rm c} = \frac{{\rm d}E_{\rm c}}{{\rm d}a} u\,. \tag{42.5}$$

More generally, since a displacement $\mathbf{u}$ of the medium corresponds to a local change $\Delta\Omega \approx \Omega\nabla\cdot\mathbf{u}$, of the volume Ω, we have (omitting the operator "hats" for simplicity):

$$\begin{aligned}\delta U_{\rm tot}(\mathbf{r}) &\sim \Delta E_{\rm c}(\mathbf{r}) \\ &= \Omega\frac{{\rm d}E_{\rm c}}{{\rm d}\Omega}\nabla\cdot\mathbf{u}(\mathbf{r}) \sim \Delta_{\rm ac}\, \mathbf{q}\cdot\mathbf{u}_{\mathbf{q}}\, {\rm e}^{{\rm i}\mathbf{q}\cdot\mathbf{r}}\,,\end{aligned} \tag{42.6}$$

where the last expression considers a single Fourier component $\mathbf{u}_{\mathbf{q}}{\rm e}^{{\rm i}\mathbf{q}\cdot\mathbf{r}}$ of the displacement $\mathbf{u}(\mathbf{r})$. The quantity $\Delta_{\rm ac} = \Omega{\rm d}E_{\rm c}/{\rm d}\Omega$ is called the "deformation potential". From Eq. (42.3) we see that the presence of an acoustic phonon

of wavelength $\lambda = 2\pi/q$ and frequency $\omega_{\mathbf{q}}$ (where $\mathbf{q}$ is the phonon wave vector) implies a shift of the atomic positions of magnitude:

$$u_{\mathbf{q}} \approx \left(\frac{\hbar}{2\rho_{\mathrm{x}}\omega_{\mathbf{q}}}\right)^{1/2}, \tag{42.7}$$

(where ρ_{x} is the crystal mass density). Thus, the scattering potential becomes:

$$\Delta E_{\mathrm{c}}\, q u_{\mathbf{q}}\, \mathrm{e}^{\mathrm{i}\mathbf{q}\cdot\mathbf{r}} \approx \Delta E_{\mathrm{c}} q \left(\frac{\hbar}{2\rho_{\mathrm{x}}\omega_{\mathbf{q}}}\right)^{1/2} \mathrm{e}^{\mathrm{i}\mathbf{q}\cdot\mathbf{r}}, \tag{42.8}$$

so that, for longitudinal phonons, the squared electron-phonon matrix element can be approximated as:

$$|\langle \mathbf{k}+\mathbf{q}|\widehat{H}_{\mathrm{ac}}|\mathbf{k}\rangle|^2 \approx \frac{\hbar\Delta_{\mathrm{ac}}^2 q^2}{2\rho_{\mathrm{x}}\omega_{\mathbf{q}}}\left(N_{\mathbf{q}} + \frac{1}{2} \pm \frac{1}{2}\right), \tag{42.9}$$

where the plus (minus) sign applies to emission (absorption) processes and $N_{\mathbf{q}}$ is the Bose-Einstein population of phonons of momentum $\hbar\mathbf{q}$ at thermal equilibrium. Therefore, considering that for small energies electrons emit or absorb only small-q acoustic phonons, we can assume a linear phonon dispersion with a slope given by the sound velocity υ_{s}, that is, $\omega_{\mathbf{q}} = \upsilon_{\mathrm{s}} q$. We can also assume that the phonon energy is much smaller than the thermal energy $k_{\mathrm{B}}T$ (where k_{B} is the Boltzmann constant), so that $N_{\mathbf{q}} \approx k_{\mathrm{B}}T/(\hbar\upsilon_{\mathrm{s}}q) \gg 1$ and scattering can be treated as an elastic process. Thus, finally, the momentum relaxation rate becomes simply:

$$\frac{1}{\tau_{\mathrm{ac}}(E)} = \frac{2^{1/2}\Delta_{\mathrm{ac}}^2 m^{*3/2} k_{\mathrm{B}}T}{\pi\hbar^4\rho_{\mathrm{x}}\upsilon_{\mathrm{s}}^2} E^{1/2}, \tag{42.10}$$

and the electron mobility can now be calculated with the only unknown parameter Δ_{ac} that can be obtained experimentally from measurements of the band gap of the crystal as a function of hydrostatic compression. Therefore, a transport quantity, the electron mobility, is now linked to a more fundamental quantity, the deformation potential, which is not directly related to charge transport.

In this oversimplified picture, electrons can couple only to longitudinal acoustic (LA) phonons, since the anisotropy of the band structure of silicon and germanium near the band extrema has been ignored. A few years later, Herring and Vogt [36] accounted for this effect and provided an approximated form for the deformation potentials for the interaction of electrons with LA and transverse acoustic (TA) phonons in terms of the dilatation deformation potential, Ξ_{d}, of the uniaxial shear deformation potential, Ξ_{u}, and of the angle $\theta_{\mathbf{q}}$ between the wave vector $\mathbf{q}$ of the phonon and the longitudinal axis of the ellipsoidal equi-energy surfaces:

$$\begin{aligned} \Delta_{\mathrm{LA}} &\approx \Xi_{\mathrm{d}} + \Xi_{\mathrm{u}}\cos^2\theta_q \\ \Delta_{\mathrm{TA}} &\approx \Xi_{\mathrm{u}}\sin\theta_q\,\cos\theta_q\,. \end{aligned} \tag{42.11}$$

42.2.2 The Rigid (Pseudo)ion

When Bardeen and Shockley presented their deformation potential theorem, there was only scant and often incorrect experimental information about both the band structure and the transport properties of silicon and germanium. However, in the mid-to-late 1960s, as more reliable experimental information became available and computer technology continued to progress, it became possible to perform full-band structure calculations, empirical pseudopotentials being at the time the preferred choice.

Developed for bulk semiconductors of the diamond and zinc blende structure at first [37,38], the pseudopotential only needs "form factors" for a small set of wave vectors coinciding with reciprocal lattice $\mathbf{G}$ vectors. For nanostructures, full functional forms $V_{\alpha q}$ were developed to study strained materials and nanostructures that require larger "supercells," since in both cases knowledge of $V_{\alpha q}$ is required for arbitrary values of q. Details about these functional forms for various semiconductors, as well as details about their applications to study electronic transport in nanostructures, can be found in Refs. [39,40].

These empirical pseudopotentials were used to calculate the phonon-induced narrowing of the band gap at high temperatures [41–44], finally giving a solid (if not *ab initio*) justification of the empirical models that were in use (see, *e.g.*, Ref. [45]). This problem has been revisited recently using methods that can be labeled genuine *ab initio* calculations [46]. However, this interesting problem falls outside the scope of this chapter.

Moreover, and more to the point of our discussion, these empirical pseudopotentials were used to improve upon the deformation potential approximation: once the empirical pseudopotential $V_\alpha(\mathbf{r})$ of an ion α is known, Eq. (42.2) can be re-expressed in terms of the Fourier components of the ionic pseudopotential, $V_{\alpha,\mathbf{p}}$, assuming that the ionic potential shifts rigidly:

$$\begin{aligned} &\delta\widehat{U}_{\mathrm{tot}}(\mathbf{r}) \\ &\quad\approx \sum_{l,\alpha,\eta,\mathbf{q},\mathbf{p}} \mathrm{i}\, V_{\alpha,\mathbf{p}}\, \mathrm{e}^{\mathrm{i}\mathbf{p}\cdot(\mathbf{r}+\mathbf{R}_{l,\alpha})}\mathbf{p}\cdot\delta\widehat{\mathbf{R}}_{l,\alpha,\mathbf{q}}^{(\eta)}\, \mathrm{e}^{\mathrm{i}\mathbf{q}\cdot\mathbf{r}}. \end{aligned} \tag{42.12}$$

Using some semiempirical models to obtain the phonon dispersion and polarization vectors, such as the valence shell model [47,48]), Zollner and Cardona were able to calculate the scattering rates for intervalley scattering in several III–V compound semiconductors [21–24], thus confirming the ex-

perimental results obtained by sub-picosecond pump-probe measurements [49].

At the same time, empirical pseudopotentials were beginning to be used not only to calculate the electron-phonon interaction (so, the electron dynamics) but also to extend the validity of transport models to a range of high energy in which the universally used effective mass approximation clearly failed. This was of tremendous practical interest because of the reliability issues caused by hot electrons in the ever-shrinking devices of the VLSI technology. The major breakthrough occurred in 1981, when Shichijo and Hess [50] developed a Monte Carlo approach to account for the electron kinematics (energy and group velocity) using the band structure of GaAs calculated using local empirical pseudopotentials. The electron-phonon scattering rates were treated empirically starting from the *Ansatz* that their energy dependence must reflect the density of (final) states, an *Ansatz* whose validity has been confirmed recently (see Ref. [51] and references therein). This "full-band" approach was later extended by Tang and Hess to silicon [52, 53], by Brennan and Hess to several other III–V compound semiconductors [54] and by Fischetti and Laux to simulate not only homogeneous transport but also inhomogeneous and realistic semiconductor devices [4].

Obviously, silicon has been the subject of studies performed by several groups also employing empirical pseudopotentials and empirical "deformation potentials" fitted to available experimental data on high-energy transport, such as velocity-field characteristics at high fields [55, 56], impact ionization [52, 55, 57–59], and injection into the SiO_2 gate insulator. Theoretical support for these semiempirical full-band models has been obtained by using empirical pseudopotentials (and Harris potentials) to calculate the electron-phonon scattering rates in Si and other semiconductors within the rigid-ion approximation [25–28], as discussed recently in Ref. [51]. In Fig. 42.1 we show the total electron-phonon scattering rates averaged over equi-energy surfaces and bands plotted as a function of electron kinetic energy as calculated using empirical deformation potentials [4, 55, 56] compared to quasi-*ab initio* calculations using Harris potentials [26–28, 56] and empirical pseudopotential [25].

More recently, the rigid-(pseudo)ion method has been extended to 2D materials, specifically to calculate the electron-phonon scattering rates in free-standing graphene [60]. Figure 42.2 shows the electron-phonon scattering rates calculated at 300 K for a free-standing sheet. The mobility and velocity-field characteristics obtained using these results (as reported in Ref. [60]) are in good agreement with available experimental data and show that even relatively poorly known materials (at least, less known than Si) can be studied successfully using these models.

The discussion presented so far can be viewed as a snapshot of the state of the art before DFT began to replace these

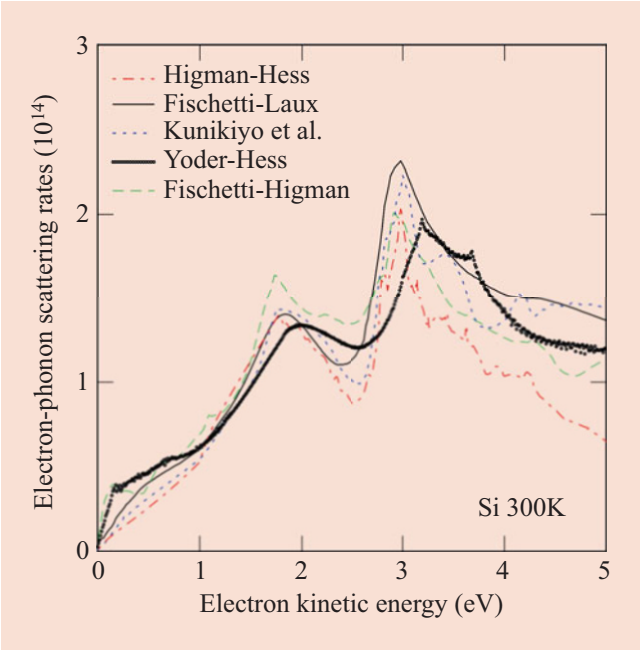

Fig. 42.1 Electron-phonon scattering rates calculated using the rigid-(pseudo)ion model and empirical pseudopotentials [25, 55] (labeled "Fischetti-Higman" and "Kunikiyo et al."), Harris potentials [27, 56] (labeled "Higman-Hess" and "Yoder-Hess") compared to rates calculated using empirically determined deformation potential calibrated to reproduce known experimental data [4] (labeled "Fischetti-Laux")

quasi-empirical methods. Most of the research has focused on electron transport in silicon, and undeniably the empirical nature of these models (via the calibrated pseudopotentials and simple models for the phonon spectra and polarization) limits their predictive power. Therefore, exploring novel materials requires the more fundamental approach inherent to genuine *ab initio* methods that we discuss next. Nevertheless, the very empirical nature of these pseudopotentials guarantees "by definition" an accurate description of the excited spectrum of semiconductors (viz., band gap and effective masses), as required when attempting to assess the performance of devices based on "known" materials. Considering also their relative numerical simplicity, these quasi-first-principles method are still used in useful applications.

42.3 Theoretical Framework

In this chapter we restrict our discussion to plane-wave DFT together with (self-consistent) pseudopotentials. However, we should at least mention the fact that ballistic electronic transport has been studied also using all-electron methods [62, 63] by Polizzi's group [64, 65], among others, thus avoiding the need to "pseudize" the system. Moreover, at least when studying relatively small molecules, all-electron methods have also been used without resorting to approxi-

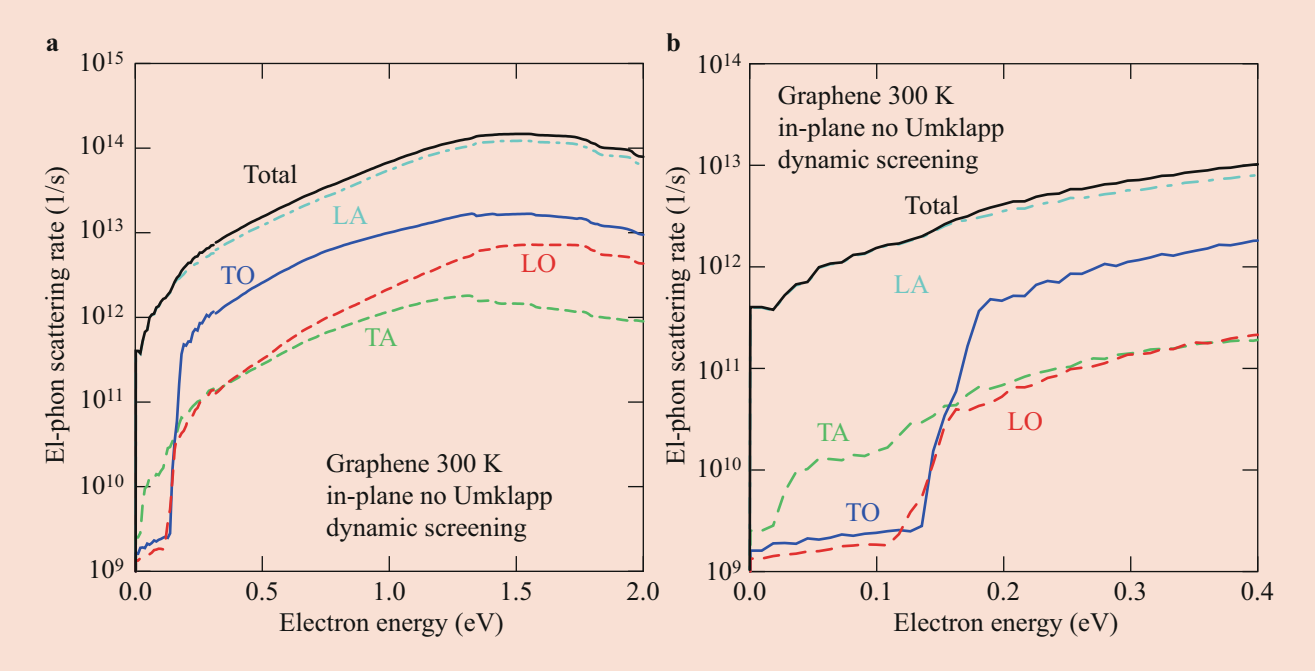

Fig. 42.2 (**a**) calculated total electron-phonon scattering rates in graphene at 300 K using the dynamic screening model by Wunsch et al. [61]. (**b**) as in the left frame but expanding the low-energy region. (After M. V. Fischetti et al. [60], with permission from the Institute of Physics ©2013 Institute of Physics)

mated exchange and correlation functionals but employing, instead, the GW method (see Ref. [66], for example).

The maturity of DFT can be judged by the number of software packages that are presently available. Most of them are based on plane waves or projector-augmented plane waves (VASP [11–14], Quantum ESPRESSO [15, 16], GPAW [67, 68], CASTEP [69], ABINIT [70]), others on localized orbitals (such as SIESTA [71, 72], or ATK [73, 74]). As we had noted in the Introduction, DFT has been born with the goal of studying the atomic and electronic structure of solids. Only recently some of these computer packages have been extended to handle electronic transport (such as TranSIESTA [75] or Quantum Wise-ATK [73, 74] or EPW [76, 77]). Here we shall focus only in DFT based on a plane-wave basis and look exclusively at electronic transport.

Modern DFT implementations start from the self-consistent solution of the Kohn-Sham equation [14, 15, 78, 79]:

$$H_e\psi_i = \left[-\frac{\hbar^2}{2m}\nabla^2 + V_{\text{eff}}(\mathbf{r})\right]\psi_i = E_i\psi_i(\mathbf{r})\,, \qquad (42.13)$$

where H_e is the electron Hamiltonian whose first term represents the kinetic energy and V_{eff} represents the effective Kohn-Sham potential:

$$V_{\text{eff}} = [V_{\text{ion}}(\mathbf{r}) + V_h(\mathbf{r}) + V_{xc}(\mathbf{r})]\ . \qquad (42.14)$$

Here $V_{\text{ion}}(\mathbf{r})$ is the sum of the ionic potentials $(-Z_j e^2/(4\pi\epsilon_0|\mathbf{r} - \mathbf{R}_j|))$ originating from all atoms, with valence Z_j and located at $\mathbf{R}_j$, in the system. The second term is the Hartree potential, capturing the effect of the interaction of all electrons with each other:

$$V_h = \int \frac{e^2}{4\pi\epsilon_0|\mathbf{r} - \mathbf{r}'|}\rho(\mathbf{r}')\mathrm{d}\mathbf{r}'\,, \qquad (42.15)$$

using SI units (e is the magnitude of the electron charge and ϵ_0 is the vacuum permittivity). The Hartree potential does not fully capture the interaction of electrons with each other. This is where DFT comes with the final term on the left-hand side, the exchange-correlation potential:

$$V_{xc}(\mathbf{r}) = \frac{\partial E_{xc}[\rho]}{\partial\rho(\mathbf{r})}\,, \qquad (42.16)$$

where $E_{xc}[\rho(\mathbf{r})]$ is the exchange-correlation functional. The final element required to generate a closed set of equations, is the charge density $e\rho(\mathbf{r})$ which is simply calculated by summing over all occupied Kohn-Sham wavefunctions:

$$\rho(\mathbf{r}) = 2\sum_i^{N/2}|\psi_i(\mathbf{r})|^2\,. \qquad (42.17)$$

The prefactor 2 accounts for spin degeneracy, and the sum runs over $N/2$ wavefunctions where N is the total number of electrons in the system.

Equations (42.13–42.17) provide a set of equations which can be solved for any atomic configuration, provided an exchange-correlation functional is selected. Some minor and major numerical issues appear in a practical implementation. Several approximations are generally in order. We discuss two important approximations that we use to study the electron-phonon interaction in crystals.

First, we consider ideal crystals; this means that an infinite number of atoms, arranged in a periodic configuration, is present in the system under consideration. The periodic system is described by a set of three basis vectors, spanning the unit cell, and an additional set of vectors specifying the location of all composing atomic species inside the unit cell, $\boldsymbol{\tau}_\alpha$. In Eq. (42.17), we introduced i as a generic quantum number. In a crystal, the ionic potential is periodic, and the quantum number i actually consists of a wave vector $\mathbf{k}$ and a band index n. The charge density is then determined by summing over an appropriate k-space discretization, possibly exploiting crystal symmetry, and a number of bands defined by the number of electrons in the system. We also introduced a second generic index j for the position of each atom; however, from now on we will use $\mathbf{R}_{l,\alpha}$ to denote the position of ion α in unit cell l.

Second, a numerical all-electron solution, solving Eq. (42.14) directly, is possible but requires a very fine discretization of the wavefunctions. To deal with systems of sufficiently large size, an approximation needs to be introduced that significantly reduces the computational burden. The need for a very fine discretization stems from the $-Z_j e^2/|\mathbf{r} - \mathbf{R}_{l,\alpha}|$ contributions to the ionic potential, which are singular at $\mathbf{R}_{l,\alpha}$. There are also a large number of core electronic states, which remain identical regardless of the crystal under consideration. A first simplification to reduce the computational burden is to compute only the charge density of the valence electrons, *i.e.*, the electrons which are not core electrons, and to incorporate the impact of core electrons through a modification of the (bare) ionic potential $V_{\text{ion}}(\mathbf{r})$. However, even when calculating only the valence states, rapid wavefunction oscillations remain near the center location of the ion $\mathbf{R}_{l,\alpha}$. To avoid these rapid oscillations, a pseudopotential approximation is introduced.

We omit the details of the implementation of modern pseudopotential-like approximations, such as the projector-augmented wavefunction approach [80, 81], but the general picture of these approaches is captured by a wavefunction composed of plane waves:

$$\psi_{\text{pw}}(\mathbf{r}) = \sum_{\mathbf{G}} c_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}} , \tag{42.18}$$

where $\mathbf{G}$ are reciprocal lattice vectors. The number of reciprocal lattice vectors $\mathbf{G}$ determines the size of the Hamiltonian in its numerical implementation. To realize maximal computational efficiency, approaches try to minimize the number of reciprocal lattice vectors while still faithfully capturing the electronic behavior of the system. The plane-wave wavefunctions are not actual wavefunctions and need to be augmented to accurately capture the rapidly oscillating nature of the actual wavefunction near the core. Overall, the pseudopotential approach gives excellent results and limits the number of plane waves required for an accurate solution quite efficiently.

Once the Kohn-Sham wavefunctions are found, the ground-state energy of the crystal is determined as:

$$\begin{aligned} E = &\sum_i \langle\psi_i| - \frac{\hbar^2\nabla^2}{2m} |\psi_i\rangle \\ &+ \frac{e^2}{2} \int\int \mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}' \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{4\pi\epsilon_0|\mathbf{r}-\mathbf{r}'|} \\ &+ \int \mathrm{d}\mathbf{r}\, V_{\text{ion}}(\mathbf{r})\rho(\mathbf{r}) + E_{\text{xc}}[\rho] + E_{\text{ions}} \end{aligned} \tag{42.19}$$

where the sum over i runs over all valence band states. This ground-state energy is a function of the atomic positions and is a measure of the stability of the structure under study, *i.e.*, a lower energy means a more favorable atomic configuration. The favorable/unfavorable nature of the configuration can be quantified through the calculation of the force acting on each atom:

$$\mathbf{F}_{l,\alpha} = -\frac{\partial E}{\partial \mathbf{R}_{l,\alpha}} . \tag{42.20}$$

This force can be evaluated from the Kohn-Sham wavefunctions using the Hellmann-Feynman theorem [82] and comes at minimal computational cost once the Kohn-Sham equation is solved.

This means that once an initial atomic configuration is provided, the energy of the atomic configuration can be computed as well as the force acting on each atom. Based on these forces, a new atomic configuration can be constructed and again the energy and the forces can be computed. Repeating this process and using an optimization algorithm like the Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm [83], the atomic configuration with minimal energy can be determined. This process is referred to as "structural relaxation," and at the end of relaxation, the crystal is in its minimal energy configuration and the force acting on each atom vanishes.

Next, we are interested in the possible lattice vibrations in the system: the phonons. To determine the phonon spectrum, the second-order force-constant tensor is required:

$$\Phi_{l\alpha l'\alpha'} = \frac{\partial \mathbf{F}_{l,\alpha}}{\partial \mathbf{R}_{l'\alpha'}} \tag{42.21}$$

to construct the dynamical matrix. Unfortunately, the calculation of the second-order force constants is much more expensive compared to the calculation of the forces, *i.e.*, the first-

order force constants acting on each atom. The reason why the evaluation of the first-order constants is computationally cheap is because the ground-state energy minimizes the energy with respect to the charge density: $\partial E[\rho(\mathbf{r})]/\partial\rho(\mathbf{r}) = 0$. This enables the evaluation of the first-order force constants without computing $\Delta\rho(\mathbf{r}) = \partial\rho(\mathbf{r})/\partial\mathbf{R}_{l,\alpha}$. For the second-order force constants on the other hand, $\Delta\rho(\mathbf{r})$ has to be computed.

Similarly, the final quantity of interest for the electron-phonon interaction is the change in potential due to the displacement of an atom:

$$\frac{\partial(V_{\text{ion}} + V_{\text{h}} + V_{\text{xc}})}{\partial\mathbf{R}_{l,\alpha}}. \tag{42.22}$$

Just like for the second-order force constants, more information than is available from the solutions of the Kohn-Sham equation is required and $\Delta\rho(\mathbf{r})$ must be calculated.

Two methods are available to compute the second-order force constants and the change in potential due to atomic displacements: the density functional perturbation theory (DFPT) method and the finite-displacement method. Both methods are equivalent if implemented with sufficient accuracy; we give a brief overview of both methods next sections.

42.3.1 Density Functional Perturbation Theory

The density functional perturbation theory [16,84] approach introduces a new set of equations that have to be solved simultaneously to determine the change in the Kohn-Sham wavefunctions $\Delta\psi_n$ and the change in the energies ΔE_n under the application of a perturbation of the ionic potential $\Delta V_{\text{ion}}(\mathbf{r})$:

$$(H_{\text{e}} - E_n)\,|\Delta\psi_n\rangle = -(\Delta V_{\text{eff}} - \Delta E_n)\,|\psi_n\rangle\,, \tag{42.23}$$

$$\Delta V_{\text{eff}}(\mathbf{r}) = \Delta V_{\text{ion}}(\mathbf{r}) + e^2\int\frac{\Delta\rho(\mathbf{r}')}{4\pi\epsilon_0|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' + \left.\frac{\mathrm{d}v_{\text{xc}}(\rho)}{\mathrm{d}\rho}\right|_{\rho=\rho(\mathbf{r})}\Delta\rho(\mathbf{r})\,, \tag{42.24}$$

where:

$$\Delta\rho(\mathbf{r}) = \sum_i \psi_i^*(\mathbf{r})\Delta\psi_i(\mathbf{r}). \tag{42.25}$$

These three equations have to solved simultaneously for every displacement of every relevant perturbation of the ionic potential under consideration. Assuming the computational burden to solve the DFPT equations (42.23–42.25) is similar to that of solving the Kohn-Sham equation (42.13–42.17); computing the phonon spectrum and the electron-phonon interaction strength is nominally $3N_{\text{ion}}N_q$ more expensive where N_{ion} counts the number of ions in each unit cell and N_q counts the number of phonon wave vectors of interest. Computing the phonon dispersion (or spectrum) is relatively straightforward for crystals with smaller unit cells, especially when symmetry further reduces the computational expense [85,86]. On the other hand, determining the phonon spectrum of crystals with large unit cells quickly becomes very expensive.

Having determined $\Delta\rho(\mathbf{r})$ and $\Delta V_{\text{eff}}(\mathbf{r})$, the second-order force constants as well as the change of the potential can be determined, and we can proceed with the calculation of the phonon spectrum or the electron-phonon matrix elements. To save computational resources, interpolation methods [76] can be used to interpolate calculated phonon energies and electron-phonon matrix elements onto a finer grid of phonon wave vectors.

42.3.2 Finite-Displacement Method

In the finite-displacement method [17,87], atoms are slightly displaced away from their equilibrium position $\mathbf{R}^{(0)}_{l,\alpha}$ to a new position $\mathbf{R}^{(0)}_{l,\alpha}+\delta\mathbf{R}$. The whole procedure of solving the Kohn-Sham equation (42.13–42.17) is repeated for a whole set of displacements, and for every displacement the forces are computed. The second-order force constants and the potential change due to atom displacement can then be found using the finite difference method.

For example, to determine the derivative of the total energy required to evaluate the electron-phonon matrix elements, the Kohn-Sham equation is solved when the atom $l\alpha$ is slightly displaced from its equilibrium position $\mathbf{R}^{(0)}_{l'\alpha'}$ along the positive and negative j direction, $\mathbf{R}_{l'\alpha'} = \mathbf{R}^{(0)}_{l'\alpha'} \pm \epsilon\mathbf{e}_j$, where $\mathbf{e}_j$ is a unit vector along the direction j and ϵ is a small number. This gives us the total crystal energies, E^{j+}_{tot} and E^{j-}_{tot}, after the positive and negative displacement along the j Cartesian direction. Repeating the procedure for the other two Cartesian directions and using the central difference scheme, the j component of the quantity $\delta E_{\text{tot}}/\delta\mathbf{R}_{l,\alpha}$ appearing in Eq. (42.2) (or ΔV_{eff} in Eq. (42.27) below) can be approximated by the expression:

$$\left.\frac{\delta E_{\text{tot}}}{\delta\mathbf{R}_{l,\alpha}}\right|_j \approx \frac{E^{j+}_{\text{tot}} - E^{j-}_{\text{tot}}}{2\epsilon}\,. \tag{42.26}$$

Moreover, the (j,j') element of the second-order force constant (*i.e.*, the (j,j') element of the dynamical matrix) can be obtained in a similar way, although somewhat more laboriously, by solving the Kohn-Sham equation when both the atom $l\alpha$ and the atom $l'\alpha'$ are slightly displaced from their equilibrium position along the positive and negative Cartesian axes, thus obtaining the second-order change, $\Delta^{(2)}E_{\text{tot}ll'\alpha\alpha'}$, which is central difference approximation to the dynamical matrix $\Phi_{jl\alpha,j'l'\alpha'}$, Eq. (42.21). In practice, such

a cumbersome and time-consuming procedure is streamlined by using the Hellmann-Feynman theorem, as mentioned above.

One important consideration for the finite-displacement method is the interaction between periodic images. When displacing an atom in one unit cell in the simulation, the equivalent atom in every unit cell is displaced in exactly the same way in all other unit cells. This generates spurious interactions between neighboring cells. To minimize these spurious interactions, it is important to perform the calculations on a larger unit cell. For example, in the extreme case of a crystal which has only one atom in its primitive unit cell, no change in the energy will be observed when moving the atom in the primitive unit cell. Instead, the primitive unit cell has to be duplicated forming a supercell that is larger in size by an integer factor γ in each direction. The supercell now contains γ^3 atoms instead of 1. A larger γ will result in reduced spurious interaction but will unfortunately also rapidly increase computational memory requirements.

Both the finite-displacement method and the density functional perturbation approach will give the same quantities, provided calculations are performed with sufficient accuracy. The choice of one method over the other may be motivated by convenience or by a more efficient execution on the available computational resources. The finite-displacement method has the advantage that it only needs the solution of the Kohn-Sham equation and only relies on the most mature part of DFT codes. Parallelization is straightforward in the finite-displacement method, and the calculation over all displacements can be performed as parallel DFT calculations. Interpolation onto a finer grid may also be more straightforward using the finite difference method compared to the DFPT method. The DFPT approach may however be more resource efficient and require fewer iterations than a new solution of the Kohn-Sham equation for every displacement.

42.3.3 Electron-Phonon Interaction

The final object of interest is the electron-phonon interaction Hamiltonian which is computed from ΔV_{eff} (which we can identify with $\delta\widehat{U}_{\text{tot}}$; see Eqs. (42.1), (42.2), and (42.4)):

$$\widehat{H}_{\text{e-ph}} = \int \mathrm{d}\mathbf{r}\, \widehat{\rho}(\mathbf{r})\Delta V_{\text{eff}}(\mathbf{r}) \approx \times \int \mathrm{d}\mathbf{r}\, \widehat{\rho}(\mathbf{r}) \sum_{l,\alpha,\eta,\mathbf{q}} \frac{\delta E_{\text{tot}}(\mathbf{r})}{\delta \mathbf{R}_{l,\alpha}} \cdot \delta\widehat{\mathbf{R}}^{(\eta)}_{l,\alpha,\mathbf{q}}\, \mathrm{e}^{\mathrm{i}\mathbf{q}\cdot\mathbf{r}}\,, \tag{42.27}$$

where $\delta\widehat{\mathbf{R}}^{(\eta)}_{l,\alpha,\mathbf{q}}$ is the ion displacement operator expressed in Eq. (42.3) in terms of the annihilation and creation operators, $\widehat{b}^{(\eta)}_{\mathbf{q}}$ and $\widehat{b}^{(\eta)\dagger}_{\mathbf{q}}$, for a phonon in branch η with wave vector $\mathbf{q}$ and frequency $\omega^{(\eta)}_{\mathbf{q}}$. Using a finite-volume normalization, here we define the amplitude of the displacement $d^{(\eta)}_{\mathbf{q}\alpha}$ as:

$$d^{(\eta)}_{\mathbf{q}\alpha} = \sqrt{\frac{\hbar}{2NM_\alpha\omega^{(\eta)}_{\mathbf{q}}}} \tag{42.28}$$

where M_α is the mass of ion α and N is the number of unit cells in the lattice.

Consider an electron in band n with wave vector $\mathbf{k}$ that makes a transition to band m with wave vector $\mathbf{k+q}$ while emitting a phonon. For this electron, the matrix element between states allowed by Pauli's principle reads:

$$\langle m\mathbf{k}+\mathbf{q} \mid \widehat{H}_{\text{e-ph}}\, \widehat{b}^{(\eta)\dagger}_{\mathbf{q}} \mid n\mathbf{k}\rangle = \sum_{l,\alpha} d^{(\eta)}_{\mathbf{q}\alpha}\mathrm{e}^{\mathrm{i}\mathbf{q}\cdot\mathbf{R}_{l,\alpha}}\mathbf{e}^{(\eta)}_{\mathbf{q}\alpha} \cdot \left(\int_\Omega \mathrm{d}\mathbf{r}\, \psi^*_{m\mathbf{k}+\mathbf{q}}(\mathbf{r})\frac{\delta E_{\text{tot}}}{\delta \mathbf{R}_{l,\alpha}}\, \psi_{n\mathbf{k}}(\mathbf{r})\right)\,. \tag{42.29}$$

Invoking the Bloch theorem, $\psi_{n\mathbf{k}}(\mathbf{r}) = u_{n\mathbf{k}}(\mathbf{r})\mathrm{e}^{\mathrm{i}\mathbf{k}\cdot\mathbf{r}}$, and for Eq. (42.29) to hold, the periodic part $u_{n\mathbf{k}}(\mathbf{r})$ must be normalized on the unit cell.

Equation (42.29) is proportional to the square root of the inverse of the phonon frequency $(\omega^{\eta}_{\mathbf{q}})^{-1/2}$ through the magnitude of the displacement. A smoother quantity measuring electron-phonon interaction strength is the deformation potential which can be implicitly defined using:

$$\langle m\mathbf{k}+\mathbf{q} \mid \widehat{H}_{\text{e-ph}}\, \widehat{b}^{(\eta)\dagger}_{\mathbf{q}} \mid n\mathbf{k}\rangle = \frac{1}{\sqrt{\Omega}}\sum_{\eta} DK^{(\eta)}_{nm\mathbf{k}\mathbf{q}}\sqrt{\frac{\hbar}{2\rho\omega^{(\eta)}_{\mathbf{q}}}}\,, \tag{42.30}$$

where we introduced the mass density $\rho_{\text{x}} = M_{\text{cell}}/\Omega_{\text{cell}}$ and the volume of the unit cell Ω_{cell}. The volume of the crystal Ω is then $N\Omega_{\text{cell}}$. Combining Eqs. (42.29) and (42.30), the deformation potential is:

$$DK^{(\eta)}_{\mathbf{k}\mathbf{q}mn} = \sum_{\alpha} \mathbf{M}_{mn\mathbf{k}\mathbf{q}\alpha}\cdot\mathbf{e}^{(\eta)}_{\mathbf{q}\alpha}\sqrt{\frac{M_{\text{cell}}}{M_\alpha}}\,, \tag{42.31}$$

where

$$\mathbf{M}_{mn\mathbf{k}\mathbf{q}\alpha} = \int_\Omega \mathrm{d}\mathbf{r}\, u^*_{m\mathbf{k}+\mathbf{q}}(\mathbf{r})\Delta V_{\text{eff}} u^*_{n\mathbf{k}}(\mathbf{r})\mathrm{e}^{\mathrm{i}\mathbf{q}\cdot(\boldsymbol{\tau}_\alpha-\mathbf{r})}\,, \tag{42.32}$$

where we should recall that $\boldsymbol{\tau}_\alpha$ is the position of ion α in the unit cell.

One subtlety in the calculation and interpretation of deformation potentials arises when initial or final electronic states are degenerate or when the phonon branches are degenerate. In case of degeneracy, the band or branch index is

not sufficient to uniquely determine the state and denoting the deformation potential as "$D^{(\eta)}_{nm\mathbf{kq}}$" is ambiguous. For example, this is the case for the threefold degenerate valence band at Γ in many popular materials, *e.g.* silicon.

Similarly, many materials have twofold degenerate TA and TO phonons. In the case of degeneracy, depending on which linear combination of the valence band wavefunctions is taken and the direction of the phonon displacement vectors, different values for "$D^{(\eta)}_{nm\mathbf{kq}}$" are obtained. One simple way to remove the ambiguity is to take the square root of the sum of all squared deformation potentials for degenerate initial or final electronic states, or degenerate phonons. An alternative choice is the largest deformation potential upon rotation of any wavefunctions or phonon displacement vectors within the subspace of the degeneracy.

42.3.4 *Ab initio* Simulation of Electronic Transport: The Monte Carlo Method

The Monte Carlo method is the most accurate method to study electron transport at the semiclassical level. It is a well-established method, originally proposed by Kurosawa in the context of semiconductors [88] that has been described in detail in Refs. [89–91]. Its use in conjunction with a description of the band structure of semiconductors obtained from empirical pseudopotentials has been pioneered by Hess' group [50, 52, 53] and by the IBM group [4].

In the context of *ab initio* studies of charge transport, the same numerical methods used in these latter references can be used, the major difference consisting in the use of DFT to obtain the band structure, of the electron-phonon scattering rates obtained using the finite-displacement method or DFPT. Moreover, the "exact" matrix elements given by Eqs. (42.4) and (42.27) are used together with the full phonon dispersion to select the final state after each collision.

Whereas a fully detailed presentation of the full-band Monte Carlo method goes beyond the scope of this chapter, here we present a brief outline.

We have employed the synchronous ensemble Monte Carlo method since it is suitable to study time-dependent transport in inhomogeneous systems, such as electron devices. In this method, the motion of an ensemble of particles (≈300 up to 50,000 particles, depending on whether one considers homogeneous transport or transport in a realistically large device), is simulated subjecting them to the externally applied electric field (possibly obtained self-consistently with Poisson equation) and to the given scattering mechanisms. An initial state $\mathbf{k}$, band n, and position $\mathbf{r}$ are assigned to each particle stochastically. The motion of each particle is then evolved for a constant duration of time Δt (free flight) conforming to the equations of motion: $\hbar \mathrm{d}\mathbf{k}/\mathrm{d}t = \mp e\mathbf{F}(\mathbf{r})$ (the sign depending on the type of carriers under study, electrons of holes) and $\mathrm{d}\mathbf{r}/\mathrm{d}t = \upsilon_n(\mathbf{k})$, where $\mathbf{F}(\mathbf{r})$ is the electric field at position $\mathbf{r}$ and $\upsilon_n(\mathbf{k})$ is the carrier group velocity in band n, $\nabla E_n(\mathbf{k})/\hbar$, $E_n(\mathbf{k})$ being the kinetic energy of the carrier. In synchronous simulations, the duration of the free flight, Δt, is chosen based on the maximum scattering rate in the energy interval under consideration. At the end of their free flight, a random scattering mechanism is chosen stochastically. Based on the selected scattering mechanism, a new $\mathbf{k}$ state is also chosen stochastically for the particles according to the probability distribution given by the density of final states (calculated using the Gilat-Raubenheimer algorithm [92, 93], obviously modified to deal with transport in 2D materials [39]) multiplied by the squared matrix element of the scattering process. This is then treated as the initial state for the next free flight.

Quantities of interest, such as average velocity, energy, carrier density, and currents at the contacts, are recorded at the end of each Monte Carlo iteration. This process is repeated until steady state is reached or until the end of a transient (such as the turn-on of a transistor). In full-band simulations, the energy and group velocity are calculated (in our case, using DFT) on a discretized Brillouin zone, and stored in look up tables, to solve the equations of motion in free flight. The scattering rates are calculated and tabulated on the same mesh.

Calculations performed assuming a homogeneous electric field are usually performed to obtain information about the "intrinsic" transport properties of a material, namely, the low-field mobility and velocity-field characteristics. In order to minimize the stochastic noise at low field (the drift velocity being of the same order of magnitude of – or even much smaller than – the thermal velocity), the low-field mobility, μ_θ, is calculated from the diffusion constant, D_θ, along the chosen direction θ, using the Einstein relation. We should note that in the case of 2D materials with a Dirac-like electron dispersion, μ_θ, has to be extracted from D_θ using a generalization of the Einstein relation [60]:

$$\mu_\theta = \frac{eD_\theta}{k_\mathrm{B}T}\int_0^\infty \mathrm{d}\eta\, \frac{\eta\, \mathrm{e}^{\eta-\eta_\mathrm{F}}}{[1+\mathrm{e}^{\eta-\eta_\mathrm{F}}]^2} \times \left(\int_0^\infty \mathrm{d}\eta \frac{\eta}{[1+\mathrm{e}^{\eta-\eta_\mathrm{F}}]}\right)^{-1}, \tag{42.33}$$

where now $\eta_\mathrm{F} = E_\mathrm{F}/(k_\mathrm{B}T)$ denotes the Fermi energy in thermal units. The diffusion constant is evaluated from the Monte Carlo simulator:

$$D_\theta = \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\left\langle (x_\theta - \langle x_\theta\rangle)^2\right\rangle, \tag{42.34}$$

where $\langle x_\theta \rangle$ is the time-dependent ensemble-average position along the direction θ of electrons initially at the origin, $\mathbf{r} = 0$, diffusing in the absence of an electric field.

The simulation of electronic transport in inhomogeneous conditions, such as in a transistor, is performed in a similar way. In this case the electric field $\mathbf{F}(\mathbf{r})$ is obtained from a numerical solution of the Poisson equation. In "atomistic" simulations, like those considered below in Sect. 42.6, the problem arises of how to define dielectric interfaces (such as the channel/gate insulator interface). In Sect. 42.5 we shall provide an *ab initio* solution of this problem.

42.4 Silicon, Group-III Nitrides, and 2D Materials

42.4.1 Silicon

It is of the utmost interest to show how electron-phonon scattering rates calculated with the DFT method just discussed compare with the semiempirical rates shown in Fig. 42.1 and discussed in Sect. 42.2. Since these results have been verified against a wealth of experimental data (see Ref. [51]), this constitutes a stringent test for *ab initio* methods.

In Fig. 42.3 we show the results obtained using the Quantum ESPRESSO DFT computer program [15, 16] with a kinetic energy cutoff of 35 Ry using the Perdew-Burke-Ernzerhof (PBE) [94] generalized gradient approximation (GGA) exchange-correlation functionals, norm-conserving pseudopotentials [95], a uniform grid of $12 \times 12 \times 12$ **k**-points for the self-consistent charge density calculation, and of $6 \times 6 \times 6$ **q**-points for the calculation of the phonon spectra. The 300 K electron-phonon scattering rates have been calculated using the Wannier interpolation method implemented by the EPW package [76] on a finer grid of $18 \times 18 \times 18$ **k**-points with a Gaussian smearing of 10 meV.

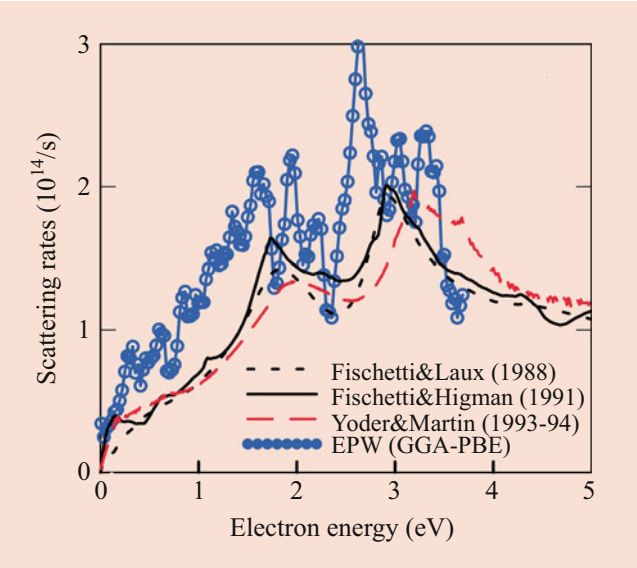

Fig. 42.3 Electron-phonon scattering rates at 300 K calculated following Refs. [76, 77] (EPW) compared to those obtained within the rigid-ion approximation [25–28] and those employed in the Monte Carlo simulations reported in Ref. [4]. The data represent an average over all "initial" wave vectors (distributed on a uniform mesh in the Brillouin zone) and bands at a given energy. The "noise" affecting the EPW data is the result of the coarser mesh used. The lines connecting the symbols are only a guide to the eye. (After M. V. Fischetti et al. [51], with permission from the American Institute of Physics ©2019 American Institute of Physics)

When looking at Fig. 42.3, we should stress that the results of Refs. [4, 25–28] have been averaged over constant-energy shells with weight given by the density of initial states using the algorithm proposed by Gilat and Raubenheimer [92, 93]. On the contrary, the EPW scattering rates shown here have been "smoothed" by averaging the raw data over the **k**-mesh described above over energy bins ∼27 meV wide. This permits a straightforward reproduction of these results.

The overall agreement is quite remarkable. However, as we shall discuss in Sect. 42.7, electron transport is very sensitive to variations of the band structure (such as effective masses and energy of satellite valleys, when present) that are usually considered "small errors" in DFT. For example, an error of the order of $k_B T$ (≈25 meV at room temperature) for the energy of satellite valleys in some 2D TMDs may be considered negligible when looking at optical absorption spectra but may cause very large errors in determining the electron mobility if intervalley scattering dominates transport.

To assess the sensitivity of the computed mobility and velocity-field characteristics to different choices of pseudopotentials and exchange-correlation functionals, we have calculated the mobility *(i)* using the GGA-PBE approximation and the less accurate local density approximation [95], both using the same norm-conserving pseudopotentials [95], and *(ii)* using the norm-conserving and ultrasoft pseudopotentials [96], both within the PBE-GGA approximation.

The results of this exercise are shown in Fig. 42.4. A significant spread of the data is quite evident. We shall discuss below, also in Sect. 42.7, how numerical issues may affect the results. This spread has been also discussed in Ref. [97] in the case of black phosphorus monolayers (phosphorene) and by Poncé et al. [77] in a general case. Accurate scattering rates can be obtained only when employing an extremely fine discretization of the Brillouin zone. This is certainly possible when considering only the "low-energy pockets" that are need to calculate the low-field carrier mobility, as indeed done in Ref. [77]. However, a fine discretization remains numerically challenging when considering the entire Brillouin zone as required when studying high-energy (high-field) transport. The practical need for a coarser discretization results in an additional and significant numerical uncertainty that affects the results. Therefore, at present we cannot yet expect a perfect quantitative or conclusive agreement with experimental data.

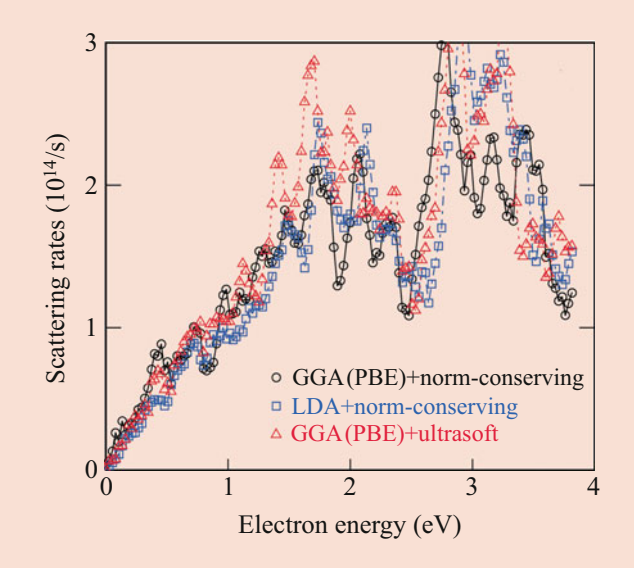

Fig. 42.4 As in the previous figure, but now the scattering rates shown have been calculated using different pseudopotentials and exchange-correlation functionals, as indicated. As in Fig. 42.3, the data represent an average over all "initial" wave vectors (distributed on a uniform mesh in the Brillouin zone) and bands at a given energy. The lines connecting the symbols are only a guide to the eye. (After M. V. Fischetti et al. [51], with permission from the American Institute of Physics ©2019 American Institute of Physics)

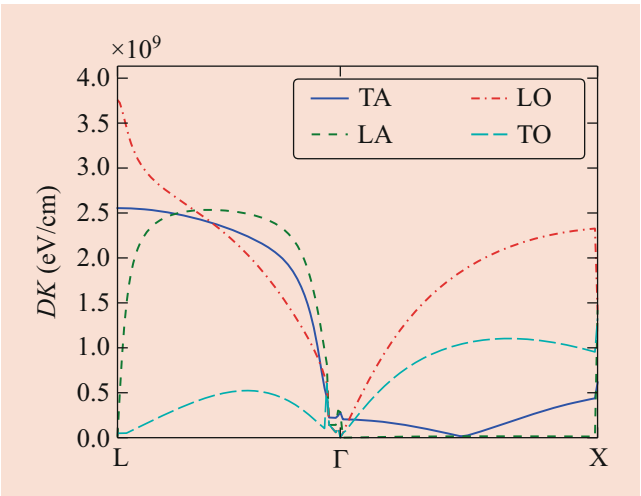

Fig. 42.5 Deformation potentials in bulk silicon for an electron starting at the valence band at Γ, transition to the conduction band along one of the Γ-L or Γ-X symmetry lines. For BTBT, the values at 0.85 in the Γ-X direction are the relevant quantity, and we find $D_{TA} = 3.5\times10^8$eV/cm, $D_{TO} = 1.0\times10^9$eV/cm, and $D_{LO} = 2.3\times10^9$eV/cm. (After W. G. Vandenberghe et al. [17], with permission from the American Institute of Physics ©2015 American Institute of Physics)

As an another important example of deformation potentials obtained from first principles, we consider the deformation potentials that determine the phonon-assisted inter-band tunneling exploited in tunnel field-effect transistors (tFETs). In this case, we have used the Vienna *ab initio* simulation package (VASP) [13] to solve the Kohn-Sham equation. We have used the finite-displacement method to find the phonon frequencies, polarization vectors, and electron-phonon *inter-band* matrix elements. The full details of the calculation can be found in Ref. [17].

In Fig. 42.5 we exhibit the calculated deformation potential for an electron transitioning from the top of the valence band to the first conduction band. We compute the interaction with all phonon branches along the Γ-L and the Γ-X high symmetry lines. Silicon has six phonon branches, but the two transverse branches (TA and TO) are twofold degenerate. Inspecting Fig. 42.5, we see that only the interaction with the TA vanishes. Values of the deformation potentials are quite large and measure up to 4×10^9eV/cm.

The deformation potentials relevant for BTBT are found at 0.85 in the Γ−X direction, and their calculated values are $D_{TA} = 3.5 \times 10^8$ eV/cm, $D_{TO} = 1.0 \times 10^9$ eV/cm, and $D_{LO} = 2.3 \times 10^9$ eV/cm. These values are much larger than previous theoretical estimates [98], but this is in line with the recent experimental estimate $D_{TO} \approx 10$–13×10^8 eV/cm from Ref. [99].

These results are very relevant to many practical applications since inter-band tunneling determines the probability of band-to-band transitions in silicon. In indirect-gap semiconductors, such as Si, band-to-band transitions (BTBT) are assisted by phonons and proceed from the valence band maximum (Γ) to the conduction band minimum, located near the X symmetry point.

42.4.2 Group-III Nitrides

Since wide band gap semiconductors are very important for power electronics, it is important to study their transport properties not just near thermal equilibrium, as it is assumed when calculating the low-field carrier mobility. Studies need to account for the high kinetic energy that electrons can reach at the high electric fields that are present in high-voltage devices. Group-III nitrides in the wurtzite phase constitute a key family of semiconductors that are employed in power devices. They have been investigated extensively theoretically using full-band Monte Carlo simulations based on empirical pseudopotentials and with electron-phonon scattering rates calculated using constant deformation potentials calibrated to experimental data, similarly to what had been done for Si before the "advent" of DFT, as discussed in Sect. 42.2. As in all empirical approaches, these studies – most notably those described in Refs. [100, 101] – must rely on experimental data that are often hard to obtain and interpret.

Most notably, the value of the all-important energy of the satellite valleys at the symmetry point L in GaN plays a crucial role in determining its high-field transport properties. Experimental data [102] and theoretical calculations using calibrated empirical pseudopotentials and DFT (VASP) [103]

have resulted in vastly different values for this quantity (0.8–1 eV experimentally, from Refs. [104, 105], 2.1–2.3 eV theoretically, from Refs. [106, 107]). This has resulted, in turn, in diverging opinions regarding the role of Auger recombination in these devices, a process that plays a major role at high injection levels in power devices. Therefore, it is of utmost interest to investigate this issue theoretically, coupling DFT and Monte Carlo studies to experimental data and establish the correctness of the theory compared to experiments. Here we shall not go into this controversial issue, but we shall see how *ab initio* methods can be used in two group-III nitrides of high interest in this context, GaN (with a band gap of ∼3.4 eV at 300 K [108]) and AlN (with a band gap of ∼6.026 eV at 300 K [109]).

The study has been performed obtaining the electronic band structure and the phonon dispersion using Quantum ESPRESSO [15, 16] with norm-conserving pseudopotentials [110] and the local density approximation (LDA) for the exchange-correlation functional. The dynamical matrix determined using DFPT was used to obtain phonon spectra, and the electron-phonon scattering rates have been calculated using the "electron-phonon coupling using Wannier functions" (EPW) program [76, 111, 112]. The maximally localized Wannier functions are obtained from the Wannier90 software package [113].

GaN

The band structure of wurtzite GaN along selected high symmetry lines is shown in Fig. 42.6a. We also list in Table 42.1 the energies of the satellite valleys compared with previous results [100, 101, 104–107, 114, 115], (one should recall the controversy we have mentioned above regarding the energy of the satellite L-valleys.) Rather than relaxing the structure, we have used the experimentally measured lattice constants $a = 3.215$ Å and $c = 5.241$ Å [116].

Table 42.2 shows the ability of DFT to give reliable values for the effective masses. These are extracted from the curvature of the electron dispersion at the bottom of the first-conduction band valleys. The effective mass at the Γ point of the first conduction band computed from DFT is 0.2 m_0 (where m_0 is the free electron mass). This value is in good agreement with the experimental values reported by Drechsler [117] (0.2 m_0) and Witowski [118] (0.222 m_0). The effective mass at the Γ point in the second conduction band is only slightly larger, 0.28 m_0.

Figure 42.6b shows the phonon dispersion of the wurtzite GaN. The longitudinal and transverse sound velocities are 7930 m/s and 3994 m/s, respectively [125]. Note the rather large energy of the highest-energy optical phonon, about 91.2 meV at Γ. The calculated polar and nonpolar scattering with optical and acoustic phonons are shown in Fig. 42.7a, b, respectively. Note that the polar scattering rate with acoustic phonons (*i.e.*, piezoelectric scattering) has a strength that is very similar to strength of the polar scattering with optical phonons at low energies. This shows that DFT correctly confirms the well-known fact that piezoelectric scattering plays an important role in determining the low-field electron mobility even at room temperature, unlike other III–V compound semiconductors like GaAs or InAs. In these figures we show also the scattering rates calculated with the analytical formulas presented in Ref. [90] to fit the first-principles scattering rates. These "analytic" scattering rates have been calculated using an effective mass of 0.2 m_0, a nonparabolicity factor of 0.58 eV^{-1}, and an intravalley deformation potential in the Γ-valley of ∼4.0 eV. For the nonpolar scattering rates with optical phonons, we have used an optical deformation

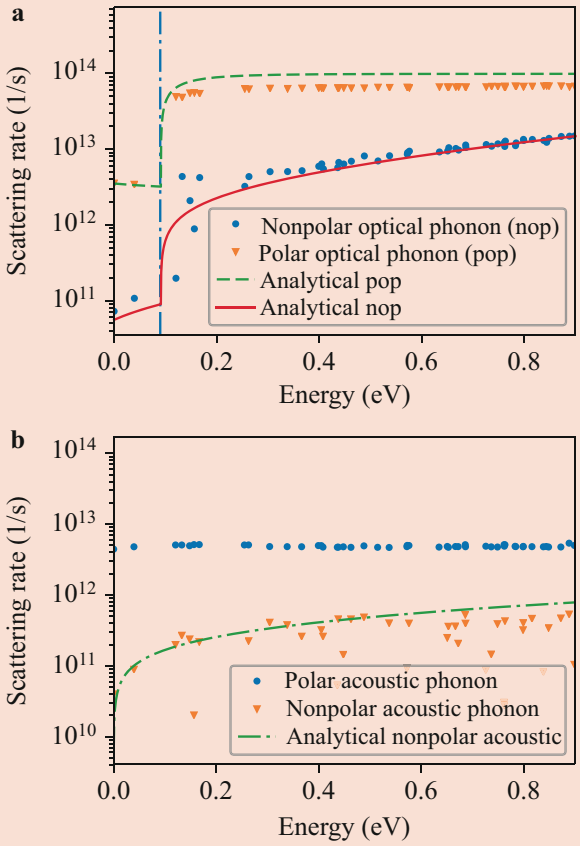

Fig. 42.7 Room-temperature (300 K) polar and nonpolar scattering rates with optical (**a**) and acoustic phonons (**b**) in wurtzite GaN calculated from first principles. A fine q-mesh of 80×80×80 and a Gaussian smearing of 0.1 eV are used in the calculations. The scattering rates calculated using analytical formula are also shown in (**a**) and (**b**). The fitting parameters are given in the text. (After J. Fang et al. [133], with permission from the American Physical Society ©2019 American Physical Society)

potential of 3.8×10^8 eV/cm. Such analytic expressions are a convenient way to simplify transport calculations when one wished to avoid the use of full-band Monte Carlo simulations. A similar analytic formula – that approximates quite well the DFT results – can be found to approximate the polar scattering rate with longitudinal optical (LO) phonons using the conventional Fröhlich expression [126] assuming a static relative dielectric constant of 8.9 and a high-frequency relative dielectric constant of 5.35 [127].

Figure 42.8 shows the low-field and high-field transport characteristics along the Γ-K symmetry line in the basal plane. These have been obtained by solving the Boltzmann transport equation with the full-band Monte Carlo method outlined in Sect. 42.3.4 with first-principles band structure and electron-phonon scattering rates. Our simulation results show a very high peak of the drift velocity of about 2.8×10^7 cm/s. Figure 42.8 also shows the average electron en-

ergies as a function of the homogeneous electric field. For electric fields smaller than 150 kV/cm, the average electron energies are close to the thermal energy. Above 150 kV/cm, the average electron energy increases sharply. It increases slowly again when the field strength exceeds 500 kV/cm. The evolution of the particle valley occupancy is the underlying reason for the trend. The trend shown here is similar to the results from the multi-valley Monte Carlo simulation results [124, 128].

The distribution of MC particles occupying the first and the second conduction bands in the first Brillouin zone is shown in Fig. 42.9 for a given electric field strength of 800 kV/cm. For particles (representing electrons) occupying the first conduction band, most of the particles are located around the Γ-valley with momenta exhibiting a noticeable drift along the reverse direction of the applied electric field, with a few particles located around the 12 satellite U-valleys. For particles occupying the second conduction band, most particles are distributed along the Γ-A symmetry line. Some particles occupy also the L-valleys. The particle occupation of the valleys is consistent with their energy splitting from the conduction band minimum. A two-dimensional plot in the $(k_x - k_y)$ basal plane is given for the convenience.

AlN

As we have done in the case of GaN, we show in Fig. 42.10a the band structure of the wurtzite AlN. Similarly, we list in Table 42.1 the conduction band energies of several satellite valleys. The experimental lattice constants of wurtzite AlN used in the calculations are $a = 3.110$ Å and $c = 4.980$ Å [127]. Table 42.3 lists the electron effective masses in different valleys of the lowest conduction band, compared with previous results [100, 119, 120, 123, 129]. Also in this case, the results obtained from DFT are in satisfactory agreement with the available experimental information. Note that for the first conduction band at the Γ-point, the effective mass is close to an isotropic value of 0.31 m_0, the same value used by Albrecht et al. [129]. From experimental measurements, it has been estimated that the electron effective mass ranges from 0.233 m_0 to 0.336 m_0 [130]. The effective mass for the second conduction band at Γ is 0.36 m_0.

Figure 42.10b illustrates the phonon dispersion. The LO energy at Γ-valley is ∼110 meV. The longitudinal and the transverse acoustic-phonon sound velocities are 10,877 m/s and 5880 m/s, respectively, listed in Table 42.3. Figure 42.11a

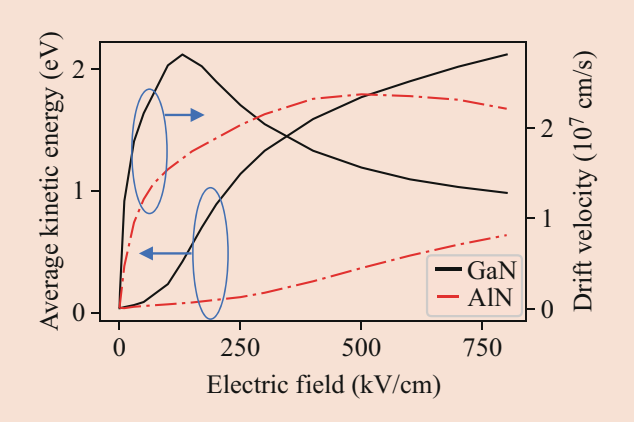

Fig. 42.8 Characteristics of the electric field versus average electron kinetic energy (left axis) and versus drift velocity (right axis) for wurtzite GaN and AlN along the Γ-K high symmetry line in the basal plane. presents the first-principles scattering rates for polar and nonpolar scattering with optical phonons. Figure 42.11a presents both polar and nonpolar scattering with acoustic phonons. We have used a Gaussian smearing of 0.1 eV to deal with the energy-conserving Dirac-delta functions. Interestingly, the rate for polar scattering with acoustic phonons is of the same order of magnitude as the rate for polar scattering with optical phonons for electrons with energies below 110 meV. Above 110 meV, the polar scattering rate with optical phonons is about ten times larger than the piezoelectric scattering rate. The scattering rates calculated from the analytical formula are also plotted in Fig. 42.11a, b. In order to fit these rates to the DFT results, we have used a relative static dielectric constant of 9.14 and a high-frequency relative dielectric constant of 4.84 for polar scattering with optical phonons [131]. Using a nonparabolicity factor of 0.35 eV^{-1}, we have obtained an "effective" nonpolar acoustic deformation potential of 7.0 eV and a nonpolar optical deformation potential of 1.32×10^9 eV/cm.

The velocity-field and average carrier energy-field characteristics are compared in Fig. 42.8 with those of GaN. An electron mobility of ∼450 $cm^2/(V \cdot s)$ at room temperature is extracted from the low electric field region. Taniyasu et al. have measured a room-temperature electron mobility of 426 $cm^2/(V \cdot s)$ for n-type AlN with Si doping concentration of 3×10^{17} cm^{-3} [132]. The peak drift velocity of AlN is smaller than that of GaN, and the corresponding critical field is larger. This is due to the heavier Γ-valley effective mass of AlN and also the smaller U-valley minima. We show in Fig. 42.12 the occupation of electrons at the first and the second conduction bands in reciprocal space at the field strength of 800 kV/cm. Particles populating the Γ-valley exhibit the expected momentum shift along the reverse direction of the electric field. The occupation of the satellite U- and K-valleys is larger in AlN than in GaN, a result of the smaller energy splitting from the conduction band minimum. The L-valleys and the M-valleys in the second conduction band are also occupied at large electric fields.

As "dry" as they may be, the approach and result that we have presented in this section – discussed in more detail in Ref. [133] – hopefully will shed some light on the still open issue of the energy of the satellite L-valleys in GaN, on the role of Auger recombination and its inverse process, impact ionization, in power devices based on group-III/nitrides semiconductors. The uncertainty (and controversy) we have

mentioned at the beginning of this section hints at a more general issue that we shall discuss in Sect. 42.7, namely, the accuracy and reliability of *ab initio* methods in guiding us when dealing with electronic transport.

42.4.3 2D Materials

Since the first isolation of graphene [5], two-dimensional materials have attracted considerable interests not only for the unusual physical properties that some of them exhibit (topological properties, such as quantum spin Hall effect, or superconductivity, for example) but also since extremely thin channels are required in order to continue the never-ending scaling of semiconductor devices. Therefore, in this section we consider some of these 2D materials and see what information *ab initio* methods can give us about their charge-transport properties and assess which of them – if any – could be used as the active channel material in ultra-scaled transistors or which of their unique properties could be exploited. We limit our attention mostly to homogeneous electronic transport (low-field mobility and high-field velocity and energy characteristics) in some of the popular 2D materials such as phosphorene, silicene, and germanene, calculated by full-band synchronous ensemble Monte Carlo method using the *ab initio* methods described above. We shall consider devices only cursorily, looking at a 10 nm gate-length phosphorene-based field-effect transistor (FET), to show the final connection that it is now possible to make between DFT and device characteristics.

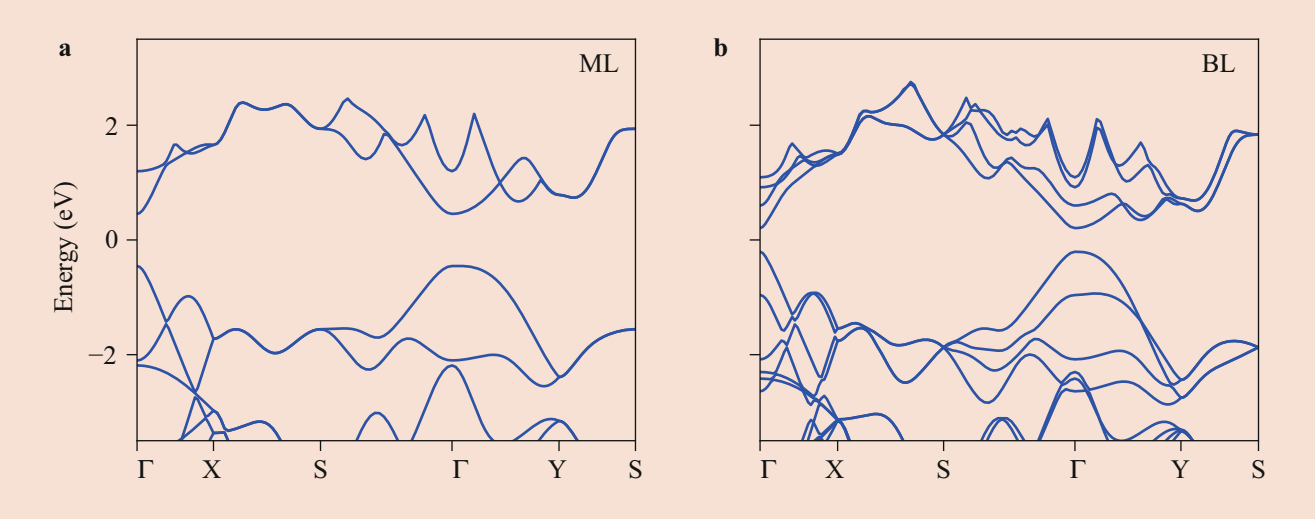

Fig. 42.13 The band structure of (**a**) monolayer phosphorene and (**b**) bilayer phosphorene calculated using VASP

Phosphorene

Phosphorene, mono- or few-layer black phosphorus, has gained wide interest due to high electron mobility observed in its bulk counterpart [134,135]. In this section, we present the results of low- and high-field electron/hole transport studies in monolayer and bilayer phosphorene. Reference [97] provides a more detailed description on transport calculations for phosphorene.

Single layers of black phosphorus, phosphorene, have a puckered honeycomb structure with a rectangular Brillouin zone. We show in Fig. 42.13 the electronic band structures for monolayer and bilayer phosphorene, calculated using the Vienna *ab initio* simulation package (VASP) [11–14], plotted along symmetry lines. VASP uses using projector-augmented wave (PAW) [136] pseudopotentials, and we have employed the Perdew-Burke-Ernzerhof generalized gradient approximations (PBE-GGA) [94] for the exchange-correlation functional. The relaxed lattice constants obtained are 4.62 Å and 3.30 Å for monolayers and 4.51 Å and 3.30 Å for bilayers. A direct band gap of 0.91 eV and 0.51 eV at the Γ symmetry point is obtained for mono- and bilayer. These values are lower than experimental values [137–139]. This is to be expected, since DFT is known to underestimate the band gap. However, this is not going to affect significantly our calculations since here we do consider inter-band transitions between the valence and conduction bands. The band structure of phosphorene exhibits also two additional valleys, the so-called Q and Y satellite valleys, along the Γ – Y symmetry direction. At high fields and large doping densities, electrons tend to populate these valleys. The calculated effective masses for both electrons and holes in monolayers and bilayers at Γ are shown in Table 42.4. Both the valence and the conduction bands are anisotropic with a smaller effective mass along the armchair direction. The electron energy and velocity are calculated on a fine mesh around the Γ symmetry point (145×205 **k** points in the first quadrant) in order to account for the anisotropy and nonparabolicity of the electron dispersion.

We have calculated the phonon dispersion curves for monolayer and bilayer phosphorene calculated using the PHONOPY computer program [140]. In Fig. 42.14 we show the resulting dispersion along symmetry lines. One feature that is clearly evident in that figure – and that is common to all 2D materials – is the parabolic dispersion of the out-of-plane acoustic phonons, the flexural modes usually called ZA phonons. The effect of these phonons on carrier transport is detrimental in some of the 2D materials, such as silicene and germanene, that lack horizontal mirror (σ_h) symmetry [141]. However, in the case of phosphorene, the electron/hole-ZA phonon coupling is forbidden at the first order. Comparing the phonon dispersion of bilayers (Fig. 42.14b) with that of monolayers (Fig. 42.14a), we note the presence of low energy optical modes in bilayers. These are interlayer mode which are caused by weak interlayer coupling of entire unit cells in different layers that oscillate out-of-phase along either the in-plane (LO, TO) or out-of-plane (ZO) direction. Obviously, their low energy is due to the heavy mass of the entire unit cells that oscillate.

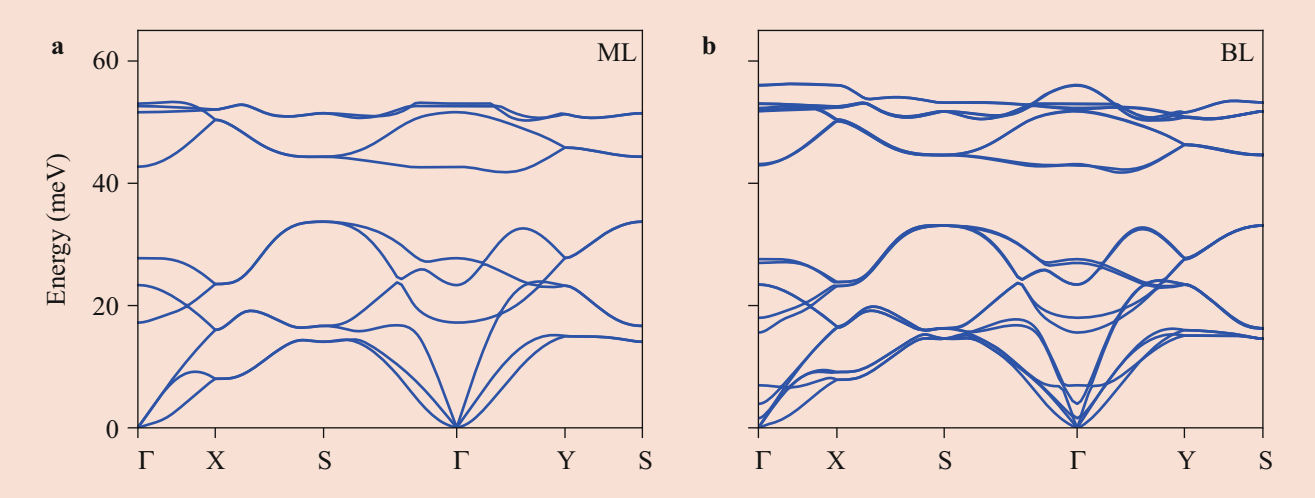

Fig. 42.14 The phonon dispersion for (**a**) monolayer phosphorene and (**b**) bilayer phosphorene calculated using PHONOPY

Figure 42.15 shows the angular average of the electron/hole-phonon scattering rate as a function of carrier kinetic energy for monolayer and bilayer phosphorene. The matrix elements are evaluated following the finite-displacement method described above. These are calculated on a very fine mesh to account for the angular dependence and wavefunction overlap effects. This is a crucial consideration, since failure to do so has shown to give inaccurate scattering rates and to overestimate the carrier mobility. Indeed, this is one of the main causes of the large discrepancy (μ_e = 20–26,000 $cm^2V^{-1}s^{-1}$) among the mobility values present in the literature [97, 137, 142–145]. Such a strong angular dependence is shown in Fig. 42.16. As we have just mentioned, in 2D materials with horizontal mirror symmetry (σ_h-symmetric crystal), scattering of electrons/holes with the ZA phonons is forbidden at first order [141]. Therefore, this process can be ignored in the case of phosphorene, a σ_h-symmetric crystal. In monolayers, in-plane acoustic modes dominate the intravalley scattering processes with a strong backward scattering for electrons (Fig. 42.15a), and optical modes for holes (Fig. 42.15b). For electrons, intervalley scattering between Γ and Q is dominated by the 32 meV optical phonon which has a rather large deformation potential of 1.7×10^9 eV/cm. On the contrary, in bilayers in-plane acoustic modes and low-energy interlayer optical phonons dominate the intravalley scattering processes for both electrons and holes (Fig. 42.15c, d), and the 32 meV optical phonon dominates intervalley scattering for electrons. We should remark that, due to the low energy of these interlayer modes and to the numerous "band crossings" among themselves and with acoustic modes, it is difficult to separate clearly their contribution from the contribution of the acoustic modes.

Table 42.5 lists the calculated low-field carrier mobility for mono- and bilayer phosphorene in the armchair and zigzag direction. When the electron/hole-phonon matrix elements calculations are treated correctly by accounting the angular dependence, including wavefunction overlap effects, including scattering by all phonon modes and intra- and intervalley processes, the mobility obtained is on the lower end of the range of values present in the literature. In both mono- and bilayers, the carrier mobility is larger along the armchair direction compared to zigzag direction due to lower effective mass along the armchair direction. The carrier mobility does not change significantly going from monolayers to bilayers. In fact, the hole mobility decreases slightly.

Figures 42.17 and 42.18 show the velocity-field and energy-field characteristics for electrons and holes in monolayer and bilayer phosphorene. The carrier mobility for electrons and holes obtained from the velocity-field characteristics along the armchair and zigzag directions is in good agreement with the value obtained from the diffusion constant. The saturated velocity for electrons in both mono- and bilayers is relatively low (4×10^6 cm/s in the armchair direction and 1×10^6 cm/s in the zigzag direction) because of strong intervalley transfer of electrons from the Γ to the Q and Y valleys (Fig. 42.19). For holes, the velocity does not saturate in the zigzag direction even at high fields due to extremely low hole mobility along that direction (Figs. 42.17b and 42.17d). The average carrier energy for electrons remains close to the thermal energy (≈25 meV) up to a field of 10^5 V/cm for both monolayers and bilayers (42.18). However, the Ohmic regime extends to higher fields, especially in the case of holes accelerated along the zigzag direction, because of extremely low mobility along that direction (Fig. 42.18b, d).

Finally, we show in Fig. 42.20 the structure and current-voltage characteristics of a double-gate FET with a phosphorene channel, a 10 nm gate length, assuming Al_2O_3 as top and bottom oxide with an equivalent oxide thickness

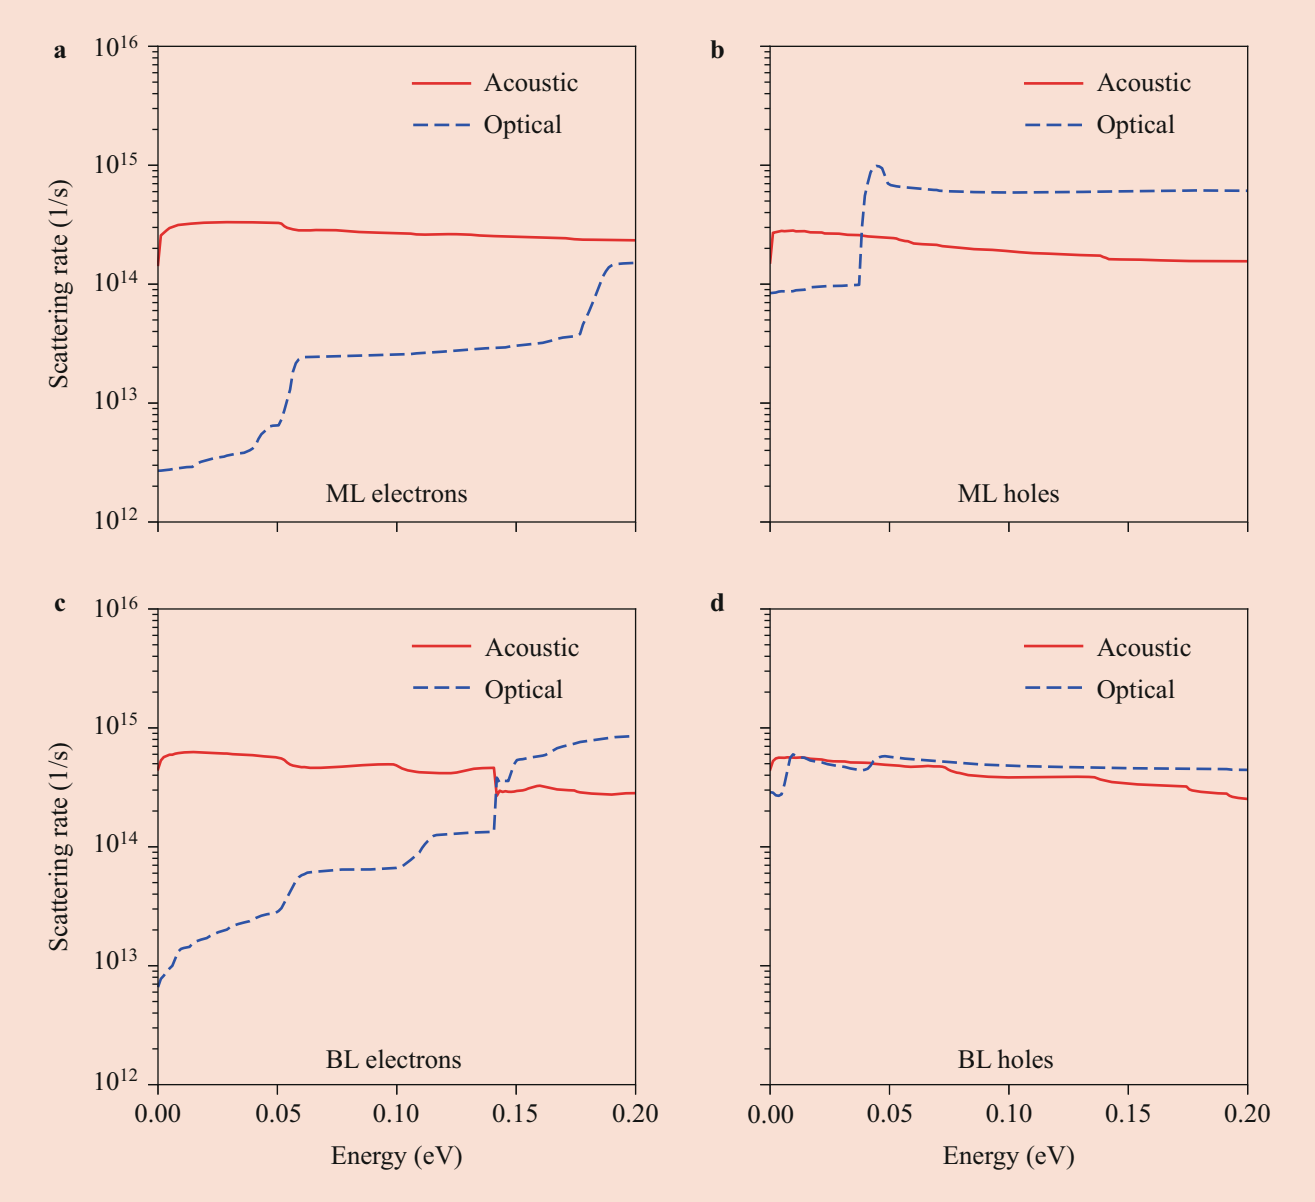

Fig. 42.15 Electron-phonon (left frames, (**a**) and (**c**)) and hole-phonon (right frames, (**b**) and (**d**)) scattering rates for monolayer phosphorene in (**a**) and (**b**), for bilayer phosphorene in (**c**) and (**d**), at 300 K, where the matrix element is obtained from VASP

(EOT) of 0.7 nm. Despite the poor mobility we have calculated for free-standing intrinsic monolayers, the performance of the device is satisfactory: an excellent I_{on}/I_{off} ratio of about 10^4, a transconductance g_m exceeding 1600 μS/μm at $V_{DD} \approx 0.5$ V, a subthreshold slope of 60–70 mV/decade, and a drain-induced barrier lowering (DIBL) of 10 mV/V. Only the on current fails to meet the latest target of the International Technology Roadmap for Semiconductor (ITRS) [146]. Indeed, the mobility is only one of the many factors that control the performance of a device, especially since at the nanoscale transport approaches the ballistic limit. Moreover, the mobility may increase at high carrier density, (thanks to dielectric screening by the free carriers and Pauli blocking), thus minimizing the negative effects of a high resistance in the source and drain regions.

Silicene and Germanene

Monolayer silicon (silicene) and germanium (germanene) have gained wide interest due to the tremendous role played by these semiconductors in their bulk form in the semiconductor industry in the last several decades. In this section we present the results of electron transport in these materials in monolayer form, following the procedure described above. Reference [147] provides for a more detailed description on how transport calculations have been performed to study these materials using first-principles methods.

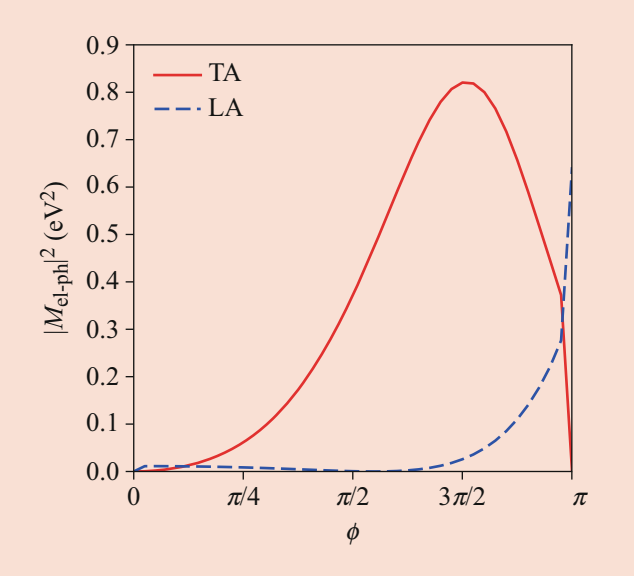

Fig. 42.16 Acoustic electron-phonon matrix element for electrons plotted for an initial and final electron kinetic energies ≈40 meV as functions of the angle ϕ of the final wave vector $\mathbf{k}'$ with respect to the armchair direction. The initial wave vector $\mathbf{k}$ is taken to be along the armchair direction

Figures 42.21 and 42.22 show the electronic band structure and phonon dispersion for ideal free-standing silicene and germanene, calculated by DFT using the VASP and PHONOPY packages. Similar to graphene, both these materials exhibit a Dirac-like electronic dispersion. However, the Fermi velocities we have obtained for silicene (≈5.3×10^7 cm/s) and germanene (≈5.3×10^7 cm/s) are lower than in graphene (≈9.5×10^7 cm/s), and, unlike graphene, their structures are buckled. The lattice and buckling constants we have obtained are 3.86 Å and 0.48 Å for silicene and 4.05 Å and 0.71 Å for germanene, respectively. Furthermore, our calculations were performed by neglecting the contributions of spin-orbit (SO) coupling for computational efficiency. This should not be a source of any major concern, since it has been shown that the SO interaction opens a rather small band gap in these materials (about 1.5 meV for silicene [148–150] and 25 meV for germanene [148, 149]). Given these small values, the effect of the SO interaction on the transport properties should be negligible for silicene and would result only in a slight overestimation of the mobility and drift velocity in germanene. We have chosen a supercell of size 5×5×1 unit-cells when calculating the phonon spectra, in order to avoid nonphysical "negative frequencies" (in reality, imaginary frequencies) of the low-energy acoustic phonons. Often these negative (square)frequencies are interpreted as a sign of the thermodynamic instability of the crystal, but in many cases they are simply the result of numerical artifacts when cells of excessively small dimensions are used to speed up

Table 42.5 Calculated electron and hole mobility, μ_e and μ_h, in monolayer and bilayer phosphorene

the calculations. In Fig. 42.22 the various phonon branches are labeled only for convenience; such an identification of the various branches (acoustic or optical, longitudinal or transverse) should be interpreted with a grain of salt, since these branches are often somewhat mixed, and such a distinction is physically unjustified for wave vectors at the edge of the Brillouin zone.

Figure 42.23 shows the electron-phonon scattering rates for silicene and germanene calculated at 300 K. The lack of horizontal mirror (σ_h) symmetry in these materials results in a very strong coupling, in principle diverging, with the long wavelength flexural (ZA) phonons [141]. This effect is further enhanced by the Dirac-like dispersion which causes strong back scattering, effect that is due to the degeneracy of the valence and conduction band at the K symmetry point. In the absence of a process which suppresses the ZA phonons, the resulting mobility in these materials is extremely low (10^{-3} to 10^{-2} cm^2/V·s). In the calculations presented here, we have assumed a long wavelength cutoff of 1 nm for the ZA phonons to avoid the divergence. The cutoff is chosen such that intravalley scattering is suppressed and intervalley scattering is included. In both silicene and germanene, scattering with ZA and LA phonons dominates the scattering, in particular the K-K′ intervalley process.

Without delving too deeply into the extremely interesting problem of assessing which mechanism may suppress, or at least damp, the first-order interaction (one-phonon processes) with the ZA modes (issue discussed in detail in Ref. [141]), we should mention that, besides obvious effects like the finite grain-size and the rippling or crumpling of the layer, their anharmonic coupling to in-plane acoustic modes [151–154] has been shown to renormalize their dispersion from a square (quadratic) law to a power-law of the form q^r, with r being approximately 3/2. Moreover, in supported and/or gated layers, Amorim and Guinea [155] have shown that at long wavelengths the renormalized dispersion of the ZA phonons, $\tilde{\omega}^{(ZA)}(q)$, approaches a nonzero constant, taking the form $\tilde{\omega}^{(ZA)}(q) \sim \sqrt{\omega^{(ZA)}(q)^2 + \omega_0^2}$, where $\omega^{(ZA)}(q)$ is the dispersion in free-standing layers and $\omega_0 \approx \sqrt{g/\rho_{2D}}$, ρ_{2D} being the mass density of the 2D layer and g is a measure of the strength of the coupling between the layer and the substrate (or gate insulator). Typically, $\hbar\omega_0$ is of the order of a few meV, small but nonzero, which is what matters. These considerations, all derived in the continuum limit, solve the

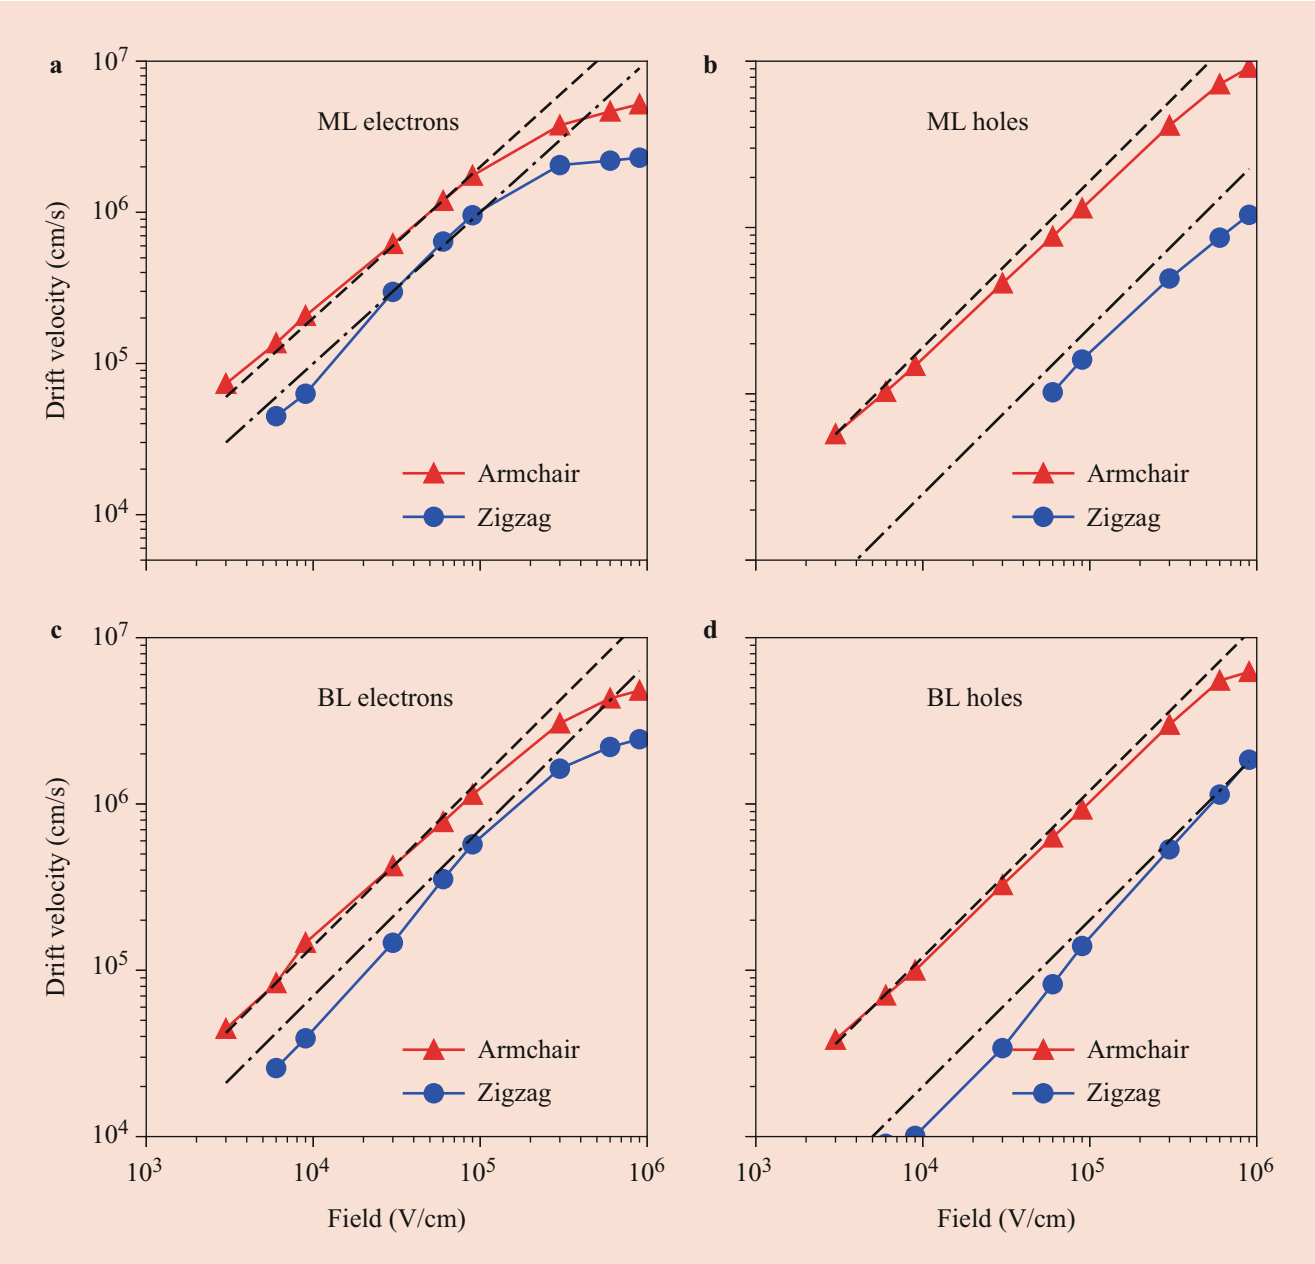

Fig. 42.17 Drift velocity *vs* field at 300 K for electrons (left frames, (**a**) and (**c**)) and holes (right frames, (**b**) and (**d**)), in monolayer phosphorene (**a**) and (**b**), and bilayer phosphorene (**c**) and (**d**)

Mermin-Wagner puzzle [156] but do not necessarily result in a negligible role of the ZA phonons in depressing the carrier mobility. In particular, even accounting for the emergence of a gap in supported and/or gated layers, the coupling with the Rayleigh waves of the substrate and/or gate [155, 157] may still play a huge role. Recently, Rudenko et al. [158] have concluded that even in nonsymmetric materials with a parabolic dispersion, the effect is small, amounting to no more than a 35% reduction of the mobility due to second-order interactions (two-phonon processes), arguing that even in this case the first-order coupling of the carriers to the acoustic flexural modes is forbidden by the rotational symmetry of the crystal. However, these conclusions are reached by approximating the 2D layer as a membrane of zero thickness, thus ignoring the "internal structure" of the membrane, an effect that may result in the breaking of the rotational and inversion symmetry of a non-σ_h-symmetric membrane. The situation is even less clear in the case of non-σ_h-symmetric materials with a Dirac-like electronic dispersion, like silicene and germanene.

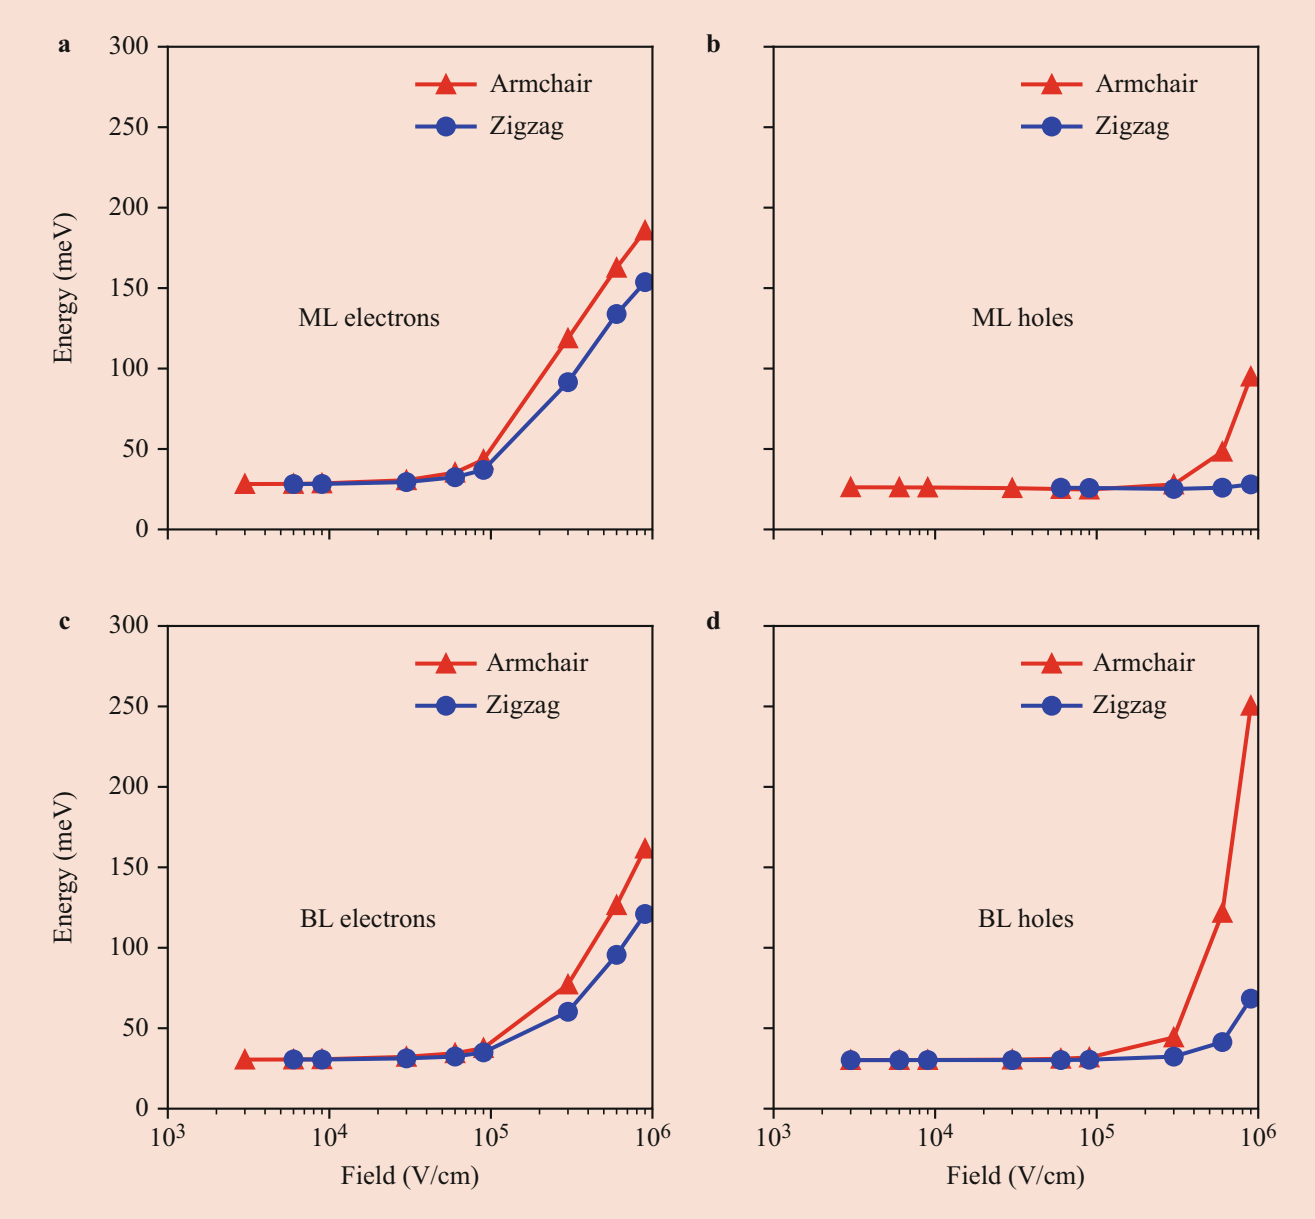

Fig. 42.18 Energy *vs.* field at 300 K for electrons (left frames, (**a**) and (**c**)) and holes (right frames, (**c**) and (**d**)), in monolayer phosphorene (**a**) and (**b**), and bilayer phosphorene (**c**) and (**d**)

Table 42.6 lists the electron mobility calculated along the [01] direction (Γ-K) for various scattering processes from the diffusion constant. With a 1 nm ZA phonon cutoff, the calculated electron mobility is 701 $cm^2/V{\cdot}s$ in silicene and 2327 $cm^2/V{\cdot}s$ in germanene. When we neglect scattering by ZA phonons completely, the mobility rises to 1296 $cm^2/V{\cdot}s$ and 4549 $cm^2/V{\cdot}s$, respectively. When intervalley scattering processes assisted by both LA and ZA phonons are ignored, the mobility increases by an order of magnitude.

Figure 42.24 shows the velocity-field and energy-field characteristics for silicene and germanene for an electric field applied along the [01] direction. The electron mobility extracted from the velocity-field characteristics is in agreement with the value obtained from the evaluation of the diffusion constant. At low fields, electrons remain thermal and exhibit Ohmic behavior in both materials. However, at higher fields, germanene exhibits negative differential mobility due to Γ-K intervalley scattering. Lower scattering rates and a smaller energy difference between the Dirac point K and the bottom of the Γ valley in germanene result in a significant transfer of electrons to the Γ valley, a lower velocity region. However, in silicene, we observe no significant population of the Γ valley due to large energy difference between the two valley minima, and we obtain a saturation velocity of $\approx 8 \times 10^6$ cm/s.

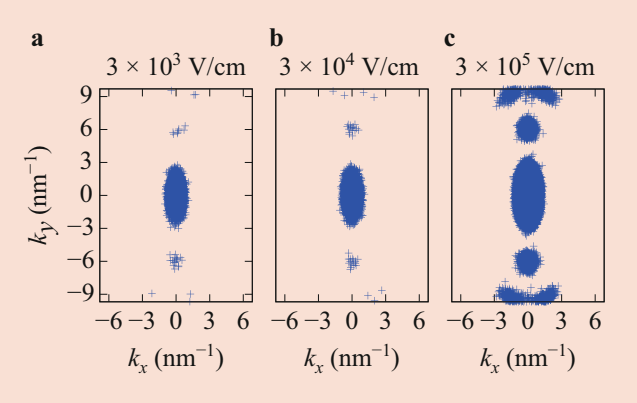

Fig. 42.19 Distribution in reciprocal space for electrons in monolayer phosphorene for a field of 3×10^3 (**a**), 3×10^4 (**b**), and 3×10^5 V/cm (**c**), along the armchair direction. Note the $\Gamma - Q$ intervalley transfer at center, the $\Gamma - Y$, and $Q - Y$ intervalley transfer at the highest field

This difference can be seen in Fig. 42.25, which compares the momentum distribution of electrons in silicene and germanene at high fields.

In summary, at least judging from the DFT results we have just reviewed, and at least in principle, silicene and germanene may exhibit satisfactory properties. However, understanding the role played by the acoustic flexural modes in determining their charge-transport behavior remains an open issue. Moreover, and probably more important, processing these materials (growth/deposition of the layers, their passivation, doping, and gating, formation of Ohmic contact, etc.) could constitute a formidable challenge.

42.5 Dielectric Response of Low-dimensional Materials

In Sect. 42.1, when outlining the content of this chapter, we mentioned the need to use a position-dependent dielectric constant (or function) when simulating nanoscale devices using atomistic models. Indeed, looking at the top frame of Fig. 42.20, a solution of Poisson equation requires the knowledge of the location of the interface between the 2D layers (for phosphorene a thin layer but still of a finite thickness) and the top and bottom insulators. When using conventional continuum models, approximating the location of this interface, the straight line drawn in the diagram will suffice. Not so when using atomistic models. In this case, the smooth transition between the dielectric and the 2D layer has to be resolved accurately. Moreover, a more intriguing question is how to define the dielectric constants (in plane and out of plane) of the 2D layer itself.

The case illustrated in Fig. 42.20 is only one example. Indeed, devices based on the many low-dimensionality nanomaterials of present interest, such as graphene nanoribbons

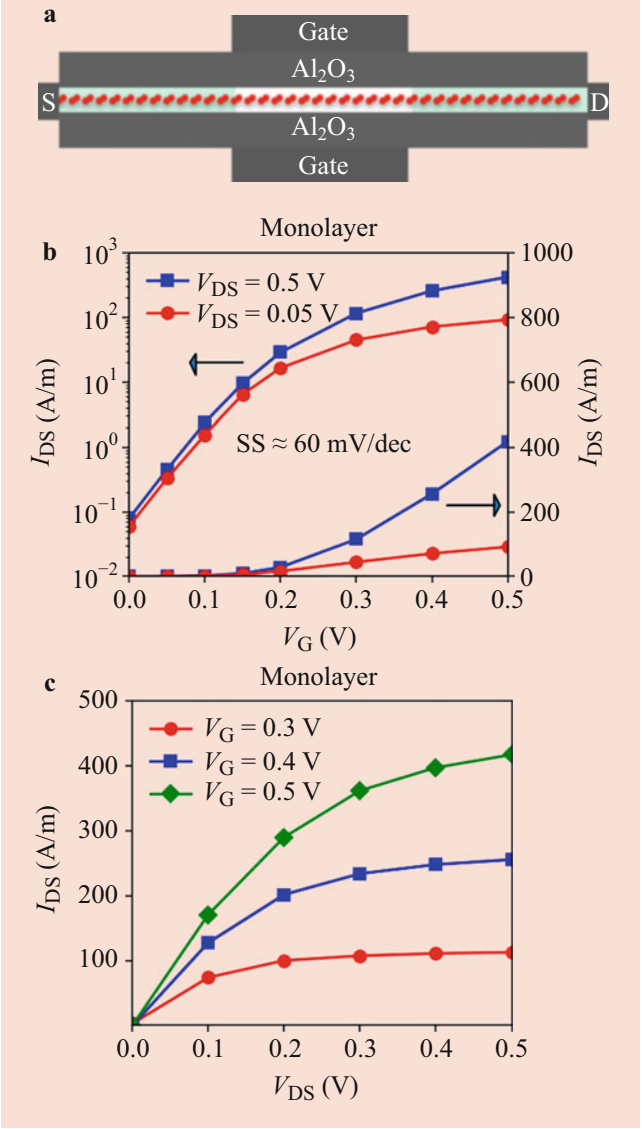

Fig. 42.20 (**a**) Schematic of the 10 nm gate-length phosphorene-based FET we have simulated. (**b**) Transfer characteristics of the device. (**c**) output characteristics of the device

[159], carbon nanotubes [160], silicon nanowires [161], graphene [5], silicene [162], phosphorene [163], and transition metal dichalcogenide (TMD) monolayers [164], all require this knowledge. Indeed, their dielectric properties determine macroscopic quantities, such as the gate capacitance and transconductance, and transport properties, as affected by dielectric screening and by the coupling of collective modes (plasmons) in the layers and insulators. However, the dielectric properties of these nanomaterials are not well studied, either experimentally or theoretically, compared with the bulk form of these materials. Different from the bulk materials which can usually be characterized by a single isotropic macroscopic dielectric constant if it has a

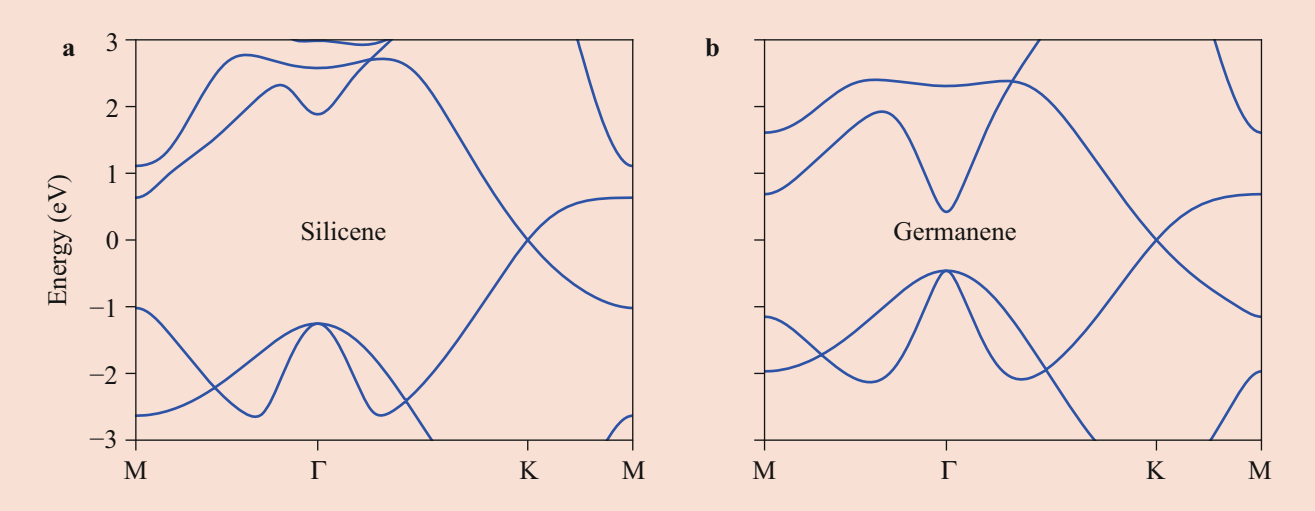

Fig. 42.21 The band structure of (**a**) silicene and (**b**) germanene calculated using VASP

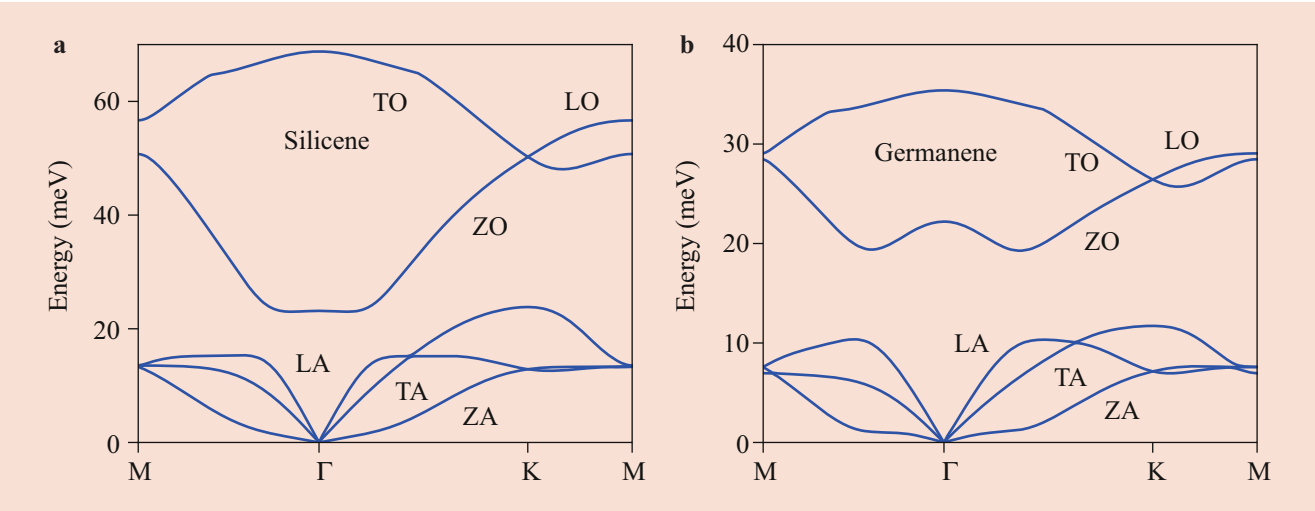

Fig. 42.22 The phonon dispersion of (**a**) silicene and (**b**) germanene calculated using PHONOPY

cubic crystal structure, low-dimensional nanomaterials are anisotropic by definition, and the study of their dielectric properties is more complex. Anisotropic tensorial dielectric properties are expected.

Here we shall outline how *ab initio* methods can provide the missing information. To keep the treatment simple and general, we shall consider only empirical pseudopotentials. Whereas this may be viewed as not a "first-principles" approach, the formalism can be extended to self-consistent pseudopotentials (DFT) in a straightforward way.

Several theoretical methods have been developed to study either the macroscopic or the microscopic dielectric response of nanosystems [165–176]. However, not much attention has been paid to the microscopic dielectric tensor of low-dimensionality nanomaterials. Therefore, here we present the derivation of a microscopic Poisson equation based on the density-density response function [177, 178] and its application to the study of these systems. We consider the particular case of the static dielectric properties of armchair-edge graphene nanoribbons (aGNRs) and graphene, but the method can be extended to other nanomaterials, such as Si nanowires (NWs, as illustrated in Fig. 42.30) and TMD monolayers (as recently reported by Laturia et al. using DFT [179]).

42.5.1 Density-Density Response Function

In the static linear response theory [177, 178, 180], the density-density response function, $\chi(\mathbf{r}, \mathbf{r}')$, describes the

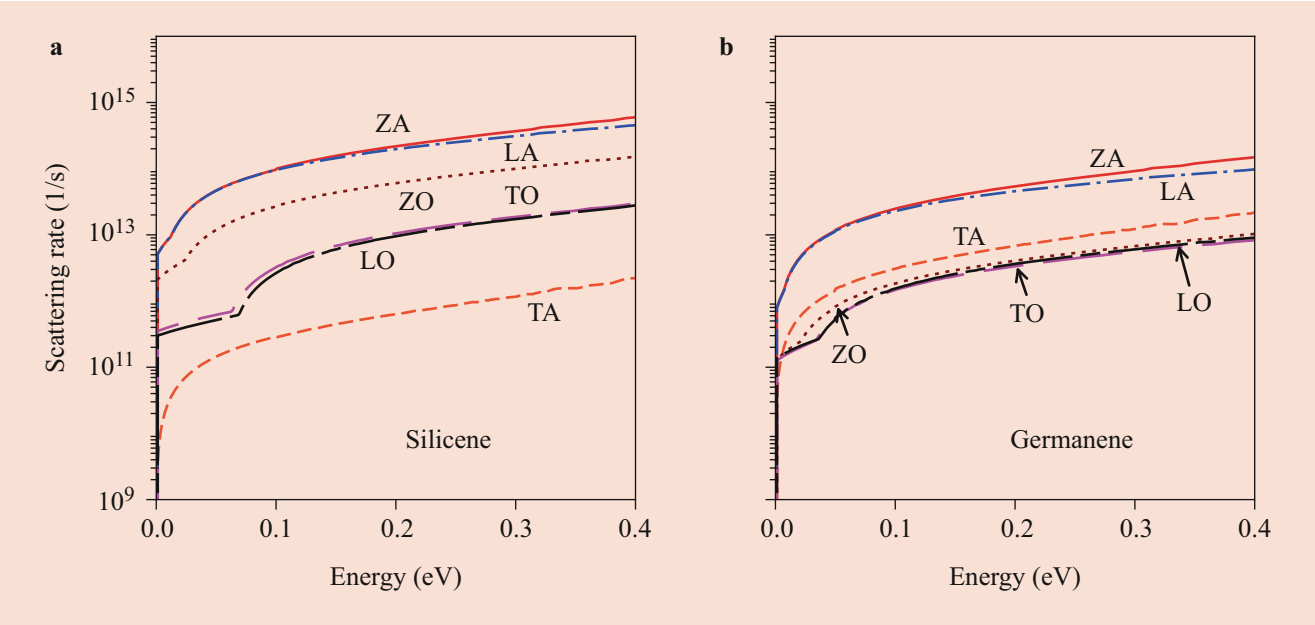

Fig. 42.23 Electron-phonon scattering rates for (**a**) silicene and (**b**) germanene per mode at 300 K, where the matrix elements are obtained from VASP

Table 42.6 Electron mobility in silicene and germanene in the [01] direction

	Silicene (germanene) ($cm^2V^{-1}s^{-1}$)
1 nm ZA phonon cutoff	$7.01 \times 10^2 (2.32 \times 10^3)$
Ignoring ZA phonons (intra- and intervalley)	$1.29 \times 10^3 (4.55 \times 10^3)$
Only intravalley with in-plane acoustic phonons	$4.3 \times 10^4 (2.6 \times 10^4)$
Only intervalley with acoustic phonons	$8.17 \times 10^2 (3.5 \times 10^3)$
Only optical phonons (intra- and intervalley)	$8.2 \times 10^3 (4.2 \times 10^4)$

After G. Gaddenane et al. [147], with permission from the American Institute of Physics ©2018 American Institute of Physics)

change of the charge density $e\delta\rho(\mathbf{r})$ when the external potential undergoes a small change, $\delta v_{\text{ext}}(\mathbf{r}')$, so that the electric polarizability (or "susceptibility") is $\chi(\mathbf{r},\mathbf{r}') = e\delta\rho(\mathbf{r})/\delta v_{\text{ext}}(\mathbf{r}')$. As an example, we first illustrate the independent-particle density-density response function $\chi^0(\mathbf{r},\mathbf{r}')$ of an armchair-edge graphene nanoribbon with a width given by seven atomic lines, here called a "7-aGNR." As mentioned above, in order to reduce the computational effort, we employ the local empirical pseudopotentials proposed by Kurokawa [181]. These pseudopotentials surprisingly yield the correct band structure of both sp^3-coordinated C in the face-center cubic phase(diamond) as well as sp^2-coordinated C, such as graphene [60]. The band structure of the ribbon has been calculated using a supercell size of 1.72 × 0.85 nm in the nonperiodic directions and an energy cutoff of 10 Rydberg, resulting in 2237 plane waves in the basis set. The static independent-particle polarizability matrix is then calculated as [180, 182, 183]:

$$\chi^0_{\mathbf{G}\mathbf{G}'}(\mathbf{q}) = \frac{4}{\Omega} \sum_{c,v,\mathbf{k}} \frac{\langle v,\mathbf{k}|e^{-i(\mathbf{q}+\mathbf{G})\cdot\mathbf{r}}|c,\mathbf{k}+\mathbf{q}\rangle\langle c,\mathbf{k}+\mathbf{q}|e^{i(\mathbf{q}+\mathbf{G}')\cdot\mathbf{r}'}|v,\mathbf{k}\rangle}{E^v_{\mathbf{k}} - E^c_{\mathbf{k}+\mathbf{q}}}, \tag{42.35}$$

using the eigenvalues $E^n_{\mathbf{k}}$ ($n = c, v$ for the conduction and valence bands, respectively) and eigenfunctions $|n,\mathbf{k}\rangle$ obtained from the calculation of the band structure. In Eq. (42.35), $\mathbf{G}$ and $\mathbf{G}'$ are reciprocal lattice vectors, $\mathbf{q}$ and $\mathbf{k}$ are the 2D vectors within the first Brillouin zone, and Ω denotes the crystal volume. In Eq. (42.35), the sum over the indices c and v denote the sum over all conduction and valence bands, respectively. The real-space susceptibility $\chi^0(\mathbf{r},\mathbf{r}')$ can be obtained by transforming $\chi^0_{\mathbf{G}\mathbf{G}'}(q_z \to 0)$:

$$\chi^0(\mathbf{r},\mathbf{r}') = \frac{1}{\Omega_{\text{cell}}} \sum_{\mathbf{G}\mathbf{G}'} e^{i\mathbf{G}\,\mathbf{r}} \chi^0_{\mathbf{G}\mathbf{G}'}(q_z \to 0) e^{-i\mathbf{G}'\mathbf{r}'}, \tag{42.36}$$

where Ω_{cell} is the volume of the supercell.

The screened response function, $P(\mathbf{r},\mathbf{r}')$, relates the induced charge, $e\rho_{\text{ind}}(\mathbf{r})$, to the total potential, $\varphi_{\text{tot}}(\mathbf{r})$, through:

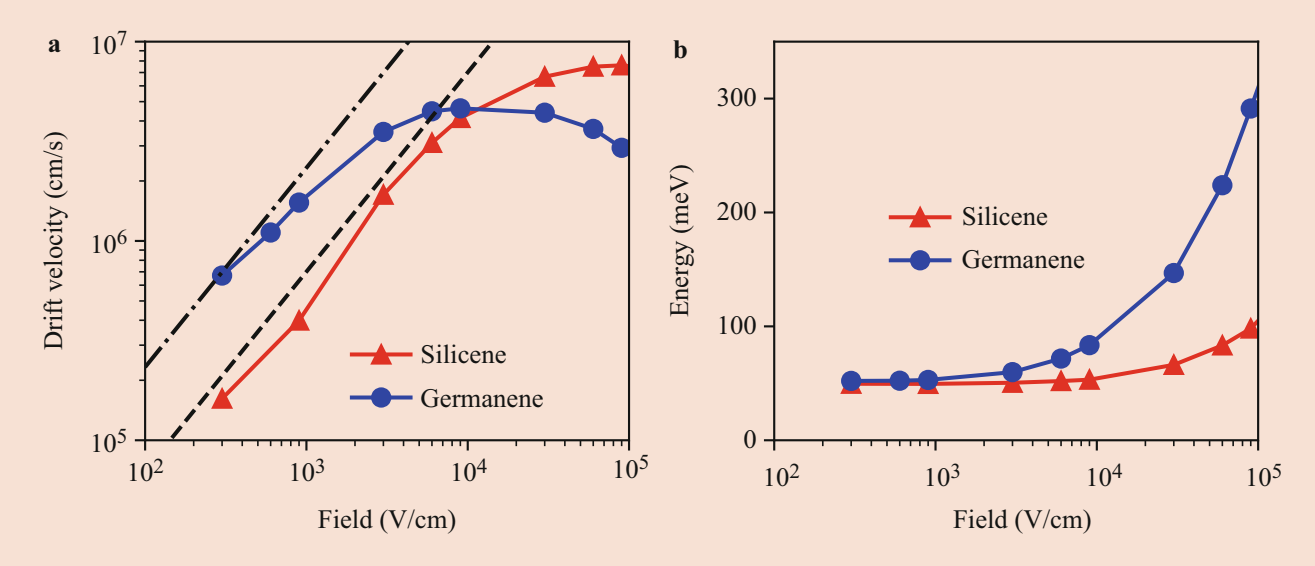

Fig. 42.24 (**a**) Drift velocity *vs* field and (**b**) average-energy *vs* field at 300 K for electrons in silicene and germanene

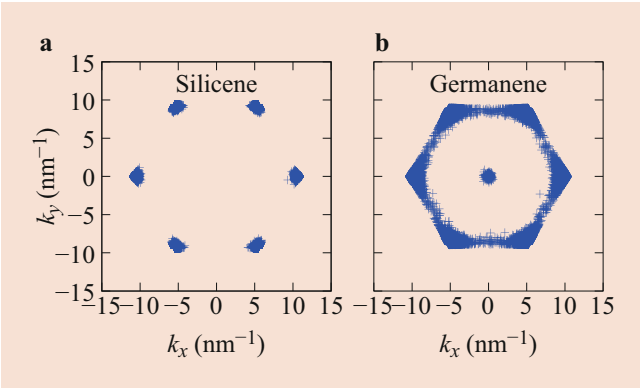

Fig. 42.25 Distribution of electrons in reciprocal space in (**a**) silicene and (**b**) germanene at a high field (≈10^5 V/cm) along the [01] direction

$$e\rho_{\text{ind}}(\mathbf{r}) = e^2 \int P(\mathbf{r},\mathbf{r}')\varphi_{\text{tot}}(\mathbf{r}')\mathrm{d}\mathbf{r}', \tag{42.37}$$

Within the random-phase approximation (RPA), $\chi^0(\mathbf{r},\mathbf{r}')$, obtainable as the Fourier-transform of the dielectric matrix, is $P(\mathbf{r}, \mathbf{r}')$. The function $\chi^0(\mathbf{r},\mathbf{r}')$, averaged along z, is shown in Fig. 42.26 for a perturbation at $\mathbf{r}'$, for $\mathbf{r}'$ is at the ribbon center (a) and at the bottom-left vacuum region (b), respectively.

Two important features of the density-density response function are its exponential spatial decay, like the electron density, and its scalar nature. The first feature enables us to employ a small supercell – as long as it is sufficiently large to guarantee the independence of the calculated band structure on its size – to study the dielectric response. The second feature allows us to avoid unwanted complexity in constructing the linear system of equations when solving the 'ordinary' Poisson equation with tensorial dielectric constants, as shown in the following.

42.5.2 Microscopic Poisson Equation

Of particular interest from the perspective of atomistic device simulations is the possibility of deriving a microscopic Poisson equation that accounts "exactly" for the position-dependent polarization of the system without having to employ any position-dependent "dielectric constant." This can be done by combining Gauss's law, $\nabla \cdot \mathcal{E}_{\text{tot}}(\mathbf{r}) = e\rho_{\text{tot}}(\mathbf{r})/\epsilon_0 = (e\rho_{\text{ext}}(\mathbf{r}) + e\rho_{\text{ind}}(\mathbf{r}))/\epsilon_0$, with the relation between the electric field and electrostatic potential, $\boldsymbol{E}_{\text{tot}}(\mathbf{r}) = -\nabla\varphi_{\text{tot}}$, in the Coulomb gauge and using Eq. (42.37), to express the induced charge as a function of the total potential:

$$\epsilon_0\nabla^2\varphi_{\text{tot}}(\mathbf{r}) + e^2 \int P(\mathbf{r},\mathbf{r}')\varphi_{\text{tot}}(\mathbf{r}')\mathrm{d}\mathbf{r}' = -e\rho_{\text{ext}}(\mathbf{r}), \tag{42.38}$$

where ϵ_0 is the vacuum permittivity, $\varphi_{\text{tot}}(\mathbf{r})$ is the total potential, and $e\rho_{\mathbf{ext}}(\mathbf{r})$ is the external charge. Equation (42.38) can be straightforwardly discretized and solved when Dirichlet/Neumann/periodic boundary conditions are applied. Assuming linear response and embracing the RPA, the solution of this microscopic Poisson equation with the polarizability $\chi^0(\mathbf{r},\mathbf{r}')$ – calculated using the procedure outlined above and either DFT of empirical pseudopotentials – provides the exact total microscopic potential for any arbitrary distribution of free charge.

In so doing, the total potential is obtained immediately, but separating the distinct contributions of the external potential

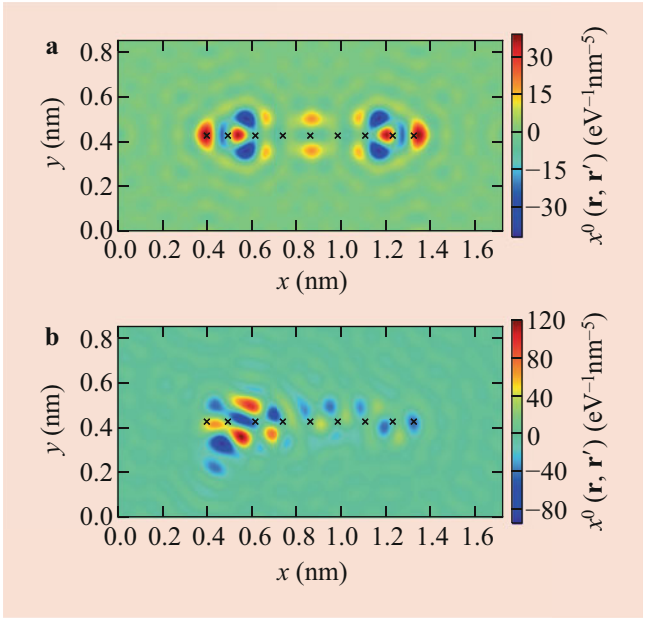

Fig. 42.26 The independent-particle density-density response function, $\chi^0(\mathbf{r},\mathbf{r}')$, of a 7-aGNR in response to a long-wavelength perturbing electric field $q_z \to 0$, (**a**) when the perturbation $\mathbf{r}'$ is at the ribbon center (*i.e.*, $\mathbf{r}' = (0.86\,\text{nm}, 0.43\,\text{nm})$), and (**b**) when the perturbation $\mathbf{r}'$ is at the bottom-left vacuum (*i.e.*, $\mathbf{r}' = (0.43\,\text{nm}, 0.21\,\text{nm})$). The microscopic distribution of the polarization charge can be observed. The seven carbon atoms in the center of the ribbon and the two terminating hydrogen atoms on the edges are indicated with the black cross symbols. (After J. Fang et al. [245], with permission from the American Physical Society ©2016 American Physical Society)

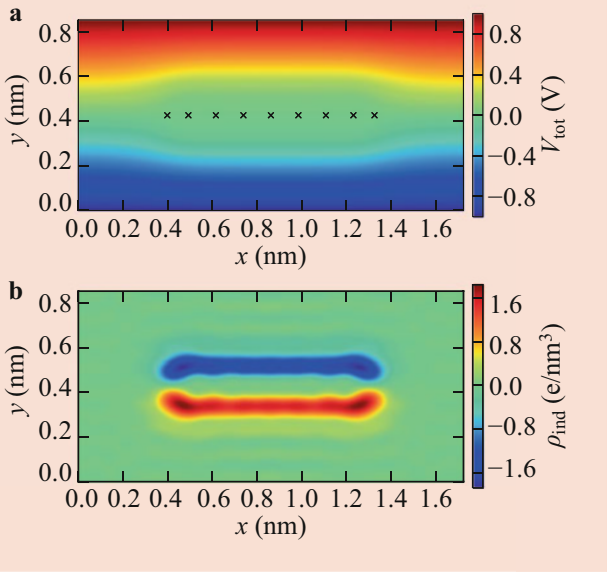

Fig. 42.27 The total potential (**a**) and the induced charge density (**b**) for a 'horizontal' parallel-plate capacitor when 1 V is applied to the top plate and −1 V to the bottom plate. In response to the external field, a dipole is formed. This counteracts the external electric field with a polarization field. (After J. Fang et al. [245], with permission from the American Physical Society ©2016 American Physical Society)

and of the induced (polarization) potential requires a brief discussion. Since we have assumed that the aGNR (or any other nanostructure) is embedded in vacuum, the polarization charge lies exclusively within the aGNR. This can be calculated using Eq. (42.37). Once this is known, the induced polarization potential can be obtained from:

$$\varphi_{\text{ind}}(\mathbf{r}) = e \int \frac{\rho_{\text{ind}}(\mathbf{r}')}{4\pi\epsilon_0|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}'. \tag{42.39}$$

In turn, having obtained the polarization potential, the applied external potential (*i.e.*, the bare unscreened perturbation) can be obtained from the difference between the total potential and the polarization potential. Finally, the external, polarization, and total electric fields can be calculated from the negative of the gradients of the corresponding potentials.

In two dimensions, averaging the charge distribution along the out-of-plane direction z, one should use the two-dimensional Green's function of the Poisson equation. Thus, the polarization potential is given by:

$$\varphi_{\text{ind}}(\mathbf{r}) = e \int \frac{\rho_{\text{ind}}(\mathbf{r}')\ln(|\mathbf{r}-\mathbf{r}'|/L)}{2\pi\epsilon_0}\mathrm{d}\mathbf{r}', \tag{42.40}$$

where L some arbitrary scaling length. In practice, to the integration over the singularity of the Green's function $\ln(|\mathbf{r}-\mathbf{r}'|/L)$, we can instead calculate the polarization potential by simulating the system using a larger region and Fourier-transforming the polarization charge to obtain $e\rho_{\text{ind}}(\mathbf{r}) \to e\rho_{\text{ind}}(\mathbf{q})$. Then, the polarization potential is finally obtained from $\varphi_{\text{ind}}(\mathbf{q}) = e\rho_{\text{ind}}(\mathbf{q})/(\epsilon_0|\mathbf{q}|^2) \to \varphi_{\text{ind}}(\mathbf{r})$.

42.5.3 Microscopic Dielectric Tensor of 1D Materials

To compute the microscopic dielectric tensor along the non-periodic directions of 1D materials, Eq. (42.38) can be used in the case of two nanocapacitors, a "horizontal" one with plates parallel to the aGNR surface and a "vertical" one with plates perpendicular to the aGNR surface. Since at $q_z \to 0$, the net polarization cannot be built to screen the external potential or electric field applied along the axial direction of the 1D materials, the axial dielectric constant is unity. For finite values of q_z, Eq. (42.38) can be applied to study the axial component of the dielectric tensor by assuming a periodic external (perturbing) potential or electric field and considering a nanocapacitor with length equal to the (spatial) period of the external perturbation. Here we restrict our attention to the simpler case of $q_z \to 0$.

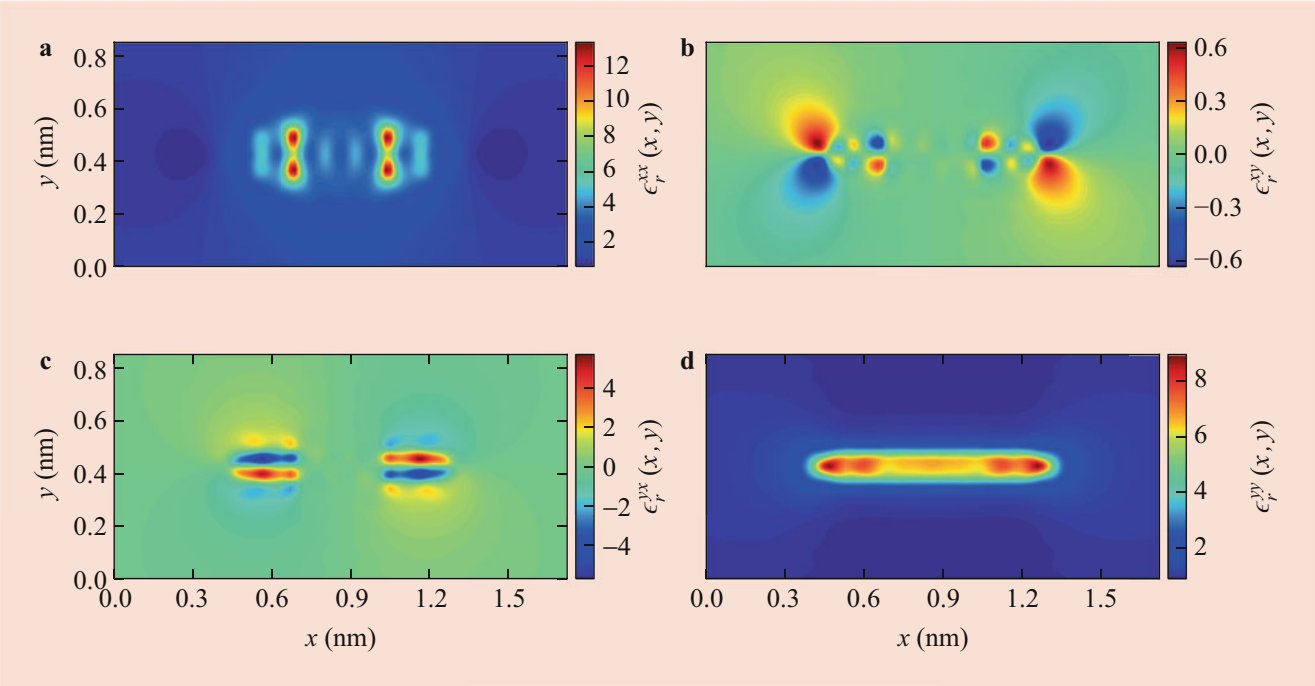

Fig. 42.28 The microscopic dielectric tensor of a 7-aGNR in vacuum. (**a**) and (**d**) show the diagonal components, and (**b**) and (**c**) show the off diagonal components. (After J. Fang et al. [245], with permission from the American Physical Society ©2016 American Physical Society)

The perturbation is defined by applying 1 V on the top plate and −1 V on the bottom plate of the horizontal nanocapacitor. Note that periodic boundary conditions are applied on the left and right boundaries and there are no free charges inside the capacitor. The spatial variation of the total potential and the induced charge, obtained by solving Eq. (42.38) in the two-dimensional case, are shown in Fig. 42.27. In the top frame, note the curvature of the potential distribution around the nanoribbon; in the bottom frame, one can clearly see the induced dipole. In the top frame, we can observe the curved potential distribution around the nanoribbon region; in the bottom frame, we can see the induced dipole. Although not shown, it is easy to obtain the potential and induced charge for the vertical nanocapacitor.

The microscopic external electric field and total electric field for the horizontal ($\boldsymbol{E}^{\text{hor}}_{\text{ext/tot}}$) and the vertical ($\boldsymbol{E}^{\text{ver}}_{\text{ext/tot}}$) capacitor can be easily derived having obtained $\varphi_{\text{tot}}(\mathbf{r})$ and $e\rho_{\text{ind}}(\mathbf{r})$. The microscopic dielectric tensor of a 1D nanostructure in the confined (x, y) plane (*i.e.*, the transverse dielectric tensor) is then evaluated as:

$$\begin{bmatrix} \epsilon_r^{xx}(\mathbf{r}) & \epsilon_r^{xy}(\mathbf{r}) \\ \epsilon_r^{yx}(\mathbf{r}) & \epsilon_r^{yy}(\mathbf{r}) \end{bmatrix} = \begin{bmatrix} \mathcal{E}^{\text{hor}}_{\text{ext},x}(\mathbf{r}) & \mathcal{E}^{\text{ver}}_{\text{ext},x}(\mathbf{r}) \\ \mathcal{E}^{\text{hor}}_{\text{ext},y}(\mathbf{r}) & \mathcal{E}^{\text{ver}}_{\text{ext},y}(\mathbf{r}) \end{bmatrix} \begin{bmatrix} \mathcal{E}^{\text{hor}}_{\text{tot},x}(\mathbf{r}) & \mathcal{E}^{\text{ver}}_{\text{tot},x}(\mathbf{r}) \\ \mathcal{E}^{\text{hor}}_{\text{tot},y}(\mathbf{r}) & \mathcal{E}^{\text{ver}}_{\text{tot},y}(\mathbf{r}) \end{bmatrix}^{-1}, \tag{42.41}$$

where $\mathcal{E}^{\text{hor/ver}}_{\text{ext/tot},x/y}(\mathbf{r})$ is the x or y component of the external/total electric field for the horizontal/vertical nanocapacitor and $\epsilon_r^{ij}(\mathbf{r})$ $(i,\ j = x,\ y)$ is a component of the dielectric tensor which indicates the dielectric response along the direction i when the perturbing electric field is applied along the direction j.

Microscopic Dielectric Tensor of a 7-aGNR

Using the empirical pseudopotentials of Ref. [181] for carbon and the terminating H atoms, we have used the method just outlined to calculate the microscopic dielectric tensor of a 7-aGNR. This is shown in Fig. 42.28. The anisotropy of the microscopic dielectric properties can be observed. Observing the distribution of both $\epsilon_r^{xx}(\mathbf{r})$ and $\epsilon_r^{yy}(\mathbf{r})$, the ribbon region exhibits a large microscopic dielectric constant whereas it approaches ϵ_0 in the vacuum region. Nevertheless, inside the ribbon, $\epsilon_r^{xx}(\mathbf{r})$ exhibits more pronounced microscopic oscillations compared to $\epsilon_r^{yy}(\mathbf{r})$. The off-diagonal elements of the microscopic dielectric tensor, $\epsilon_r^{xy}(\mathbf{r})$ and $\epsilon_r^{yx}(\mathbf{r})$, exhibit the inversion symmetry of the aGNR. Macroscopically, the off-diagonal elements of the microscopic dielectric tensor vanish. This is because x and y are two of the three principal axes of the nanosystem.

Ribbon-Width Dependence of the Dielectric Permittivity

We have simulated also a 3-aGNR, a 5-aGNR and a 6-aGNR. Using empirical pseudopotentials, we find for each of these ribbons a band gap of 1.19 eV, 0.43 eV, and 1.03 eV, respectively, in contrast to the band gap of 1.70 eV for the 7-aGNR. The variation of $\epsilon_r^{yy}(\mathbf{r})$ along the horizontal

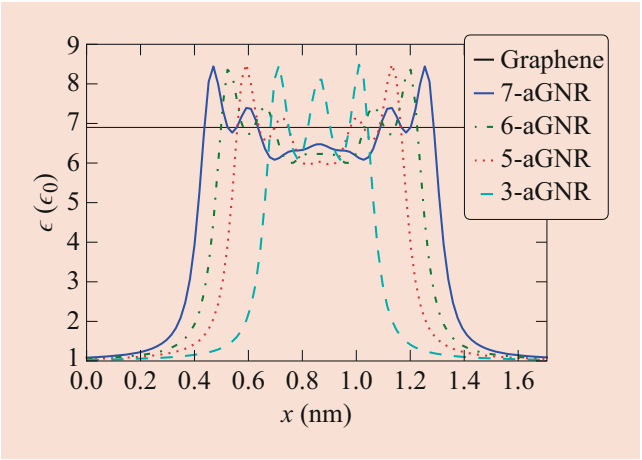

Fig. 42.29 Out-of-plane microscopic dielectric constant, $\epsilon_r^{yy}(\mathbf{r})$, in the horizontal plane for different ribbon widths. The local permittivity in the interior of all ribbons except for the 3-aGNR shows values close to 6 ϵ_0. The local permittivity at the edges of the ribbon shows similar oscillating peaks. The black horizontal straight line, $\epsilon = 6.9\epsilon_0$, indicates the macroscopic dielectric constant of graphene at the carbon-atom plane, as shown in Fig. 42.31. (After J. Fang et al. [245], with permission from the American Physical Society ©2016 American Physical Society)

plane of a 3-aGNR, a 5-aGNR, a 6-aGNR, and a 7-aGNR is plotted in Fig. 42.29. The permittivity in the center of all ribbons, except the 3-aGNR, is approximately 6 ϵ_0, and the permittivity at the edges of the ribbon shows similar peaks and valleys oscillating around $7\epsilon_0$. These features show that ribbon size barely affects the out-of-plane microscopic dielectric constant.

Microscopic Dielectric Tensor of a 3 × 3 Silicon Nanowire

To touch upon silicon, although only very briefly, in Fig. 42.30 we show results obtained for the *xx*-component of the dielectric tensor of a Si nanowire, $\epsilon_r^{xx}(\mathbf{r})$, following the same procedure and using the empirical local pseudopotentials of Ref. [184]. Given the small cross section of the nanowire (only 3 × 3 atoms) and the fact that it is free-standing (surrounded by vacuum, it is not surprising to see that the dielectric function inside the nanowire reaches only a small value, less than 4. This is the result of extremely small nanostructures inheriting the polarization (and, so, the dielectric constant) of the surrounding vacuum or bulk material.

42.5.4 Microscopic Dielectric Permittivity of 2D Materials

Similar to the study of aGNRs, we construct a nanocapacitor with graphene as dielectric and the capacitor plates are placed parallel to the graphene surface. The potential perturbation is applied by imposing a voltage on the plates and then

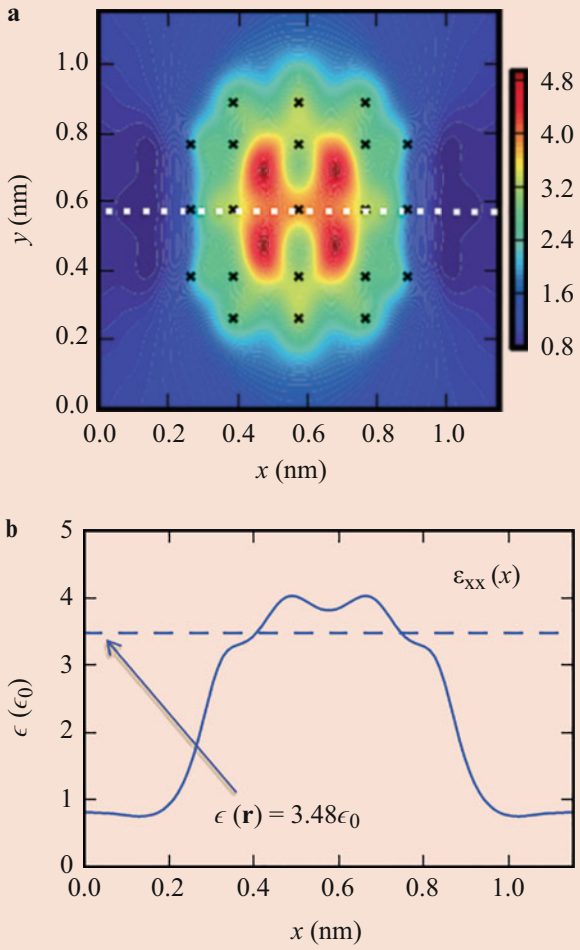

Fig. 42.30 (**a**) variation on the cross-sectional plane of the calculated diagonal *xx* component of the dielectric tensor of a small (3 × 3 atom in cross section) Si nanowire. (**b**) the same, but plotted along the dashed line in the left figure, showing how the maximum value of the dielectric constant in this very small nanostructure is affected by the surrounding medium, vacuum in this case. Note also the smooth transition between the semiconductor and the surrounding medium

we solve the microscopic Poisson equation. By solving the microscopic Poisson equation, Eq. (42.38), we obtain the induced charge density.

The induced charge density averaged on the (x, z) plane is shown in Fig. 42.31. The long-range oscillations of the induced charge are caused by local-field effects [171]. The polarization profile along y can be calculated by applying Gauss's law in 1D [185]. This is also shown in Fig. 42.31. The microscopic dielectric permittivity decays from 6.9 ϵ_0 in the carbon-atom plane to the vacuum permittivity within approximately 0.1 nm. This shows that the out-of-plane dielectric permittivity of the aGNRs resembles that of graphene. We also evaluate the capacitance per unit area of the graphene nanocapacitor as D/V, where D is the displacement field and V is the applied voltage. We find a capacitance of

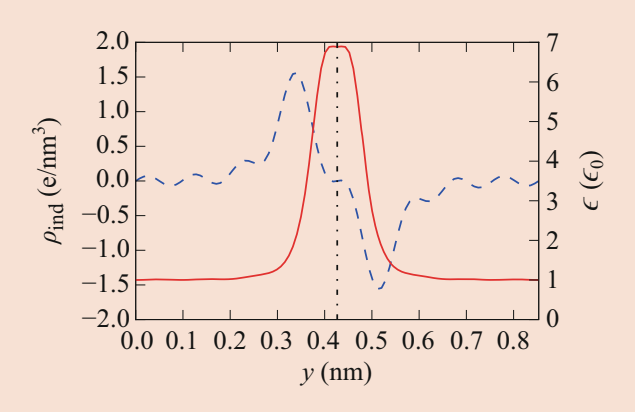

Fig. 42.31 Induced charge density (left y-axis, dashed blue line) when a voltage, $V = 2$ V, is applied to the graphene nanocapacitor and the microscopic dielectric constant of graphene along the direction perpendicular to the graphene plane (right y-axis, solid red line). In response to the potential perturbation, a dipole is formed across the graphene plane, as shown by the induced charge density. The microscopic dielectric permittivity exhibits a peak value of $6.9\epsilon_0$ on the carbon-atom plane and decays to the vacuum permittivity about 0.1 nm away from the carbon-atom plane, indicated by the dashed vertical line. (After J. Fang et al. [245], with permission from the American Physical Society ©2016 American Physical Society)

13.28 F/m^2. Equivalently, attributing an effective dielectric thickness, d, and a macroscopic dielectric constant, ϵ_{mac}, to graphene, the capacitance can also be calculated as $V/D = d/\epsilon_{mac} + (d_0 - d)/\epsilon_0$ (d_0 is the distance between the capacitor plates) since graphene and vacuum are connected in series. Assuming a macroscopic dielectric constant of $6.9\epsilon_0$, the effective dielectric thickness of graphene is about 0.22 nm. This corresponds roughly to the distance of the center of the respective induced charge layer comprising the dipole shown in Fig. 42.31.

42.5.5 Discussion

We have demonstrated that a direct solution of the microscopic Poisson equation incorporates all quantum effects on the electrostatics. This offers a physical-sound avenue for atomistic self-consistent quantum transport simulations in nanotransistors [186] without knowledge of the dielectric tensor of the nanosystems. This is different from the traditional treatment of the Poisson equation in atomistic device simulations reported by Guo et al. in Refs. [187, 188] and Fiori et al. in Ref. [189]. In these simulations the Poisson equation is solved with macroscopic empirical approaches, either using an arbitrarily assumed uniform dielectric permittivity throughout the entire devices or by defining interfaces as "straight ϵ-discontinuity lines," lines arbitrarily drawn among atoms. Thus, physical accuracy is not ensured.

42.6 Quantum Transport

In this final section, we deal with transport beyond the semiclassical limit. Other chapters in this volume discuss this issue in great detail from the perspective of the Wigner function formalism (Chap. 43 by P. Dollfus) and of the nonequilibrium Green's function formalism (Chap. 44 by S. Datta), as implemented using a tight-binding model for the electronic dispersion (Chap. 45 by G. Klimeck). Therefore, we give here only a brief introduction to the subject.

The discussion presented so far has been based implicitly on the idea that electronic transport can be described correctly using semiclassical models, the BTE in particular. However, as early as in 1950, doubts were raised regarding the suitability of such a model to deal with transport at electric fields and energies so large that the associated short electron scattering times render the electronic Bloch states an unacceptably poor approximation of the correct eigenstates of the total Hamiltonian (*i.e.*, that includes also the perturbation). Bardeen and Shockley considered this problem for the case of Si [190], concluding that a semiclassical approach is satisfactory in most cases of practical technological interest. However, the first full-band Monte Carlo study [50] was performed to study impact ionization in GaAs, a process that results in an electron lifetime, τ, as short as 1 fs. Capasso et al. [191] argued that in such cases collisional broadening renders the semiclassical BTE invalid, that is, the energy broadening of the electronic state, $\Delta E \sim \hbar/\tau$, becomes comparable to – or even exceeds – the energy itself of the state. This implies a failure of first-order perturbation theory and Fermi's golden rule. This problem had been already investigated in the context of high-field transport in polar insulators using Feynman path integrals [192]. However, the daunting nature of this formulation prompted, instead, the use of Monte Carlo simulations that account, somehow, for these "broadening" effects [193], vaguely in the spirit of the Barker and Ferry formulation [194]. However, Monte Carlo simulations that employ scattering rates computed beyond first-order perturbation theory soon proved to be affected by serious artifacts due to violations energy conservation. High-field transport was later studied by Jacoboni et al. [195, 196] using the concept of Wigner paths. However, the basic physical nature of this problem is so difficult that the use of *ab initio* methods in this context remains completely unexplored.

A second, and completely different, limitation of semiclassical transport stems, instead, from the ultra-fast dynamics of electrons coupled to elementary excitations of a crystal when stimulated, for example, by ultrashort laser pulses in pump/probe experiments. The eigenstates of the total Hamiltonian are now coupled modes, such as electron-phonon modes, and the semiconductor Bloch equations (SBE), essentially a density-matrix formulation handled by solving the

Heisenberg equations of motion, have been successfully used in the past (see, *e.g.*, Ref. [197] for a comprehensive review).

A third, and final, limitation of the BTE is the limitation that at present is raising the strongest concerns in devices scaled at the nanometer length. This limitation is caused by the small size of the structures that are used by the VLSI technology. Quantum-size (or confinement) effects, which historically originated from studies of the two-dimensional electron gas (2DEG) that is formed in Si inversion layers [198], does not present a particular problem: indeed, transport must be studied in a reduced dimensionality (much as we have seen here when dealing with 2D materials) but can still be treated semiclassically, as long as the length of the active layer (channel) of the device is much longer than the electron wavelength or phase-coherence length. However, in devices whose channels are as short as 10 nm or less, so dimensions comparable to the wavelength of the charge carriers and of their decoherence and scattering length, electrons (or holes) may traverse the active region almost coherently (ballistic transport), so that their full quantum mechanical behavior – neglected by the BTE and in what we wrote so far – must be included in any formulation of transport that we must use to study these devices. Tunneling is another genuine and important quantum mechanical effect that must be captured, since it affects small devices via leakage through thin gate oxides and source-to-drain tunneling and that may also be exploited not only in electrical-erasable programmable random-access memories (E^2PROM and flash-EPROM) but also in tFETs and interlayer tunneling between 2D materials [199]. While tunneling has been modeled using semiclassical expressions, this approach can fail for general nonuniform fields [200–202].

A varied set of methods have been developed to tackle the quantum mechanical description of electronic devices. This variety is caused by the many choices and approximation made:

1. The physics that is included in the (effective) Hamiltonian: Exchange and correlation, spin-orbit coupling, magnetism, etc. Similarly to the historical evolution of methods used to deal with semiclassical transport (as discussed in Sect. 42.2, empirical or semiempirical methods have been used at first, notably empirical tight-binding in the first computer program based on the nonequilibrium Green's function method, NEMO [203–205], empirical pseudopotentials [39, 186, 206, 207], or linear combination of atomic bands [208]. However, also in this case the progress made on numerical methods and hardware have begun to make it possible to consider first-principles approaches. Indeed empirical tight-binding has been replaced by its DFT counterpart [209, 210], and we have already mentioned approaches based on all-electron calculations [64, 65] and even earlier DFT itself [29].
2. The basis that is used to discretize the Hamiltonian: Linear combination of localized orbitals (LCAO) – as in many tight-binding studies [211], plane waves, Bloch waves, and Wannier functions. This choice affect also first-principles formulations, as we have seen before.
3. The representation of the nonequilibrium state, that is, the formulation of the quantum transport equations, such as single particle wavefunctions, Landauer-Büttiker formulation [212–214], density matrix [197, 215], Wigner functions [196,216,217], or nonequilibrium Green's functions (NEGF [218–220]). Even in the ballistic case, the quantum-transmitting boundary method (QTBM) [221] can be chosen in place of a (somewhat improperly termed but highly popular) "ballistic NEGF" approach.

One additional crucial issue is constituted by inelastic scattering, that is, collisions with scatterers with internal degrees of freedom, so that memory of the phase of the carriers is lost (phase decoherence). When using the Wigner formulation, inelastic processes are often included in an approximated way via a Boltzmann-like collisional integral, since the "correct" formulation [222] is numerically intractable. The NEGF formulation is equally daunting, unless the scattering processes are "diagonalized" in some *ad hoc* fashion (so, rendered local) or unless small systems are considered, such as molecules [33,34]. Nevertheless, this last method is arguably the method of choice, since, *in principle*, it is valid over the entire range of device dimensions, from long "semiclassical" channels to ultrashort "ballistic" devices. In particular, numerical difficulties notwithstanding, it can describe correctly the all-important intermediate regime, in which the device length is comparable to the other characteristic length-scales, namely, the electron wavelength, and the scattering/decoherence length associated with the various scattering processes, mainly, electron-phonon scattering, scattering with impurities or surface roughness.

In this section, we limit our discussion to length-scales short enough to render scattering processes a weak perturbation, starting from the ballistic limit, and extending in a natural way our methodology to include weak scattering processes. We employ plane waves since we consider them more suitable than localized orbitals to treat extended conduction states and we employ the simpler QTBM, rather than NEGF, because of its better numerical efficiency in the ballistic limit, a limit in which QTBM and NEGF are virtually identical from a physical perspective.

When considering *ab initio* transport within the density functional theory (DFT) framework, two options are available to approximate the Hamiltonian. The first option is to use the full self-consistent Kohn-Sham Hamiltonian, including exchange and correlation based on the nonequilibrium charge. However, since devices are large systems, self-consistently solving the Kohn-Sham Hamiltonian is com-

putationally expensive within the DFT framework. Since transport properties are only determined by electron states near the Fermi level, a second option is to use an effective low-energy Hamiltonian that is computationally less expensive. Such an effective Hamiltonian can be constructed from *ab initio* simulations of representative systems. A further benefit is that empirical data can supplement *ab initio* data in the construction of the effective Hamiltonian to correct for the deficiencies of DFT, such as underestimated band gaps and incorrect effective masses. Therefore, here we describe quantum electron transport within the pseudopotential approximation, using a plane-wave basis. However, the formulation can be easily generalized to first-principles methods. We first describe the ballistic transport formalism based on the extended states. We then detail the numerical approach based on envelope functions. Next, we introduce the addition of scattering using the Pauli Master Equation. Finally, we demonstrate our method by simulating highly scaled transistors based on graphene nanoribbons and silicon nanowires.

42.6.1 Ballistic Transport

In the ballistic limit, electron dynamics is described by the extended wavefunctions in the device and its infinitely long contacts. The extended wavefunctions are the solutions of the Schrödinger equation:

$$\left[-\frac{\hbar^2\nabla^2}{2m}+V_{\text{tot}}(\mathbf{r})\right]\psi_{\kappa\nu,E}(\mathbf{r})=E\psi_{\kappa\nu,E}(\mathbf{r})\,, \tag{42.42}$$

where E is the energy of the electron injected from contact κ and ν is a mode index. The potential energy $V_{\text{tot}}(\mathbf{r})$ captures all of the potential energy felt by an individual particle; this includes the ionic potential, the mean-field Hartree potential generated by the free charges, doping and electrostatic gates, as well as exchange and correlation contributions. In the contacts, the total potential is assumed to be lattice periodic, yielding Bloch wave solutions with a well-defined wave vector $\mathbf{k}_{\kappa\nu}$.

We assume that the device's contacts are connected to large equilibrium reservoirs, each at a fixed chemical potential μ_κ. When a bias is applied to the device (between contacts κ and κ'), it is driven out of equilibrium by a relative change in the Fermi level of the contacts, *i.e.*, $\mu_\kappa - \mu_{\kappa'} = V_{\text{bias}}$. To describe the statistics, we introduce the ballistic density matrix, which is diagonal in the basis of the extended states:

$$\rho^{(\text{bal})}_{\kappa\nu E,\kappa'\nu' E'}=\delta_{\kappa\kappa'}\delta_{\nu\nu'}\delta_{EE'}f_{\text{FD}}(E-\mu_\kappa)\,, \tag{42.43}$$

where the Fermi-Dirac distribution is given by

$$f_{\text{FD}}(E-\mu_\kappa)=\left[1-\exp\left(\frac{E-\mu_\kappa}{k_{\text{B}}T}\right)\right]^{-1}. \tag{42.44}$$

Using this density matrix, the expressions for electron density, as well as current density are readily obtained:

$$\rho^{(\text{bal})}(\mathbf{r})=\sum_{\kappa\nu}\int \text{d}E\left(\frac{\text{d}E_{\kappa\nu}}{\text{d}k}\right)^{-1} \times\left|\psi_{\kappa\nu,E}(\mathbf{r})\right|^2 f_{\text{FD}}(E-\mu_\kappa)\,, \tag{42.45}$$

$$\mathbf{J}^{(\text{bal})}(\mathbf{r})=\sum_{\kappa\nu}\frac{e\hbar}{m}\int \text{d}E\left(\frac{\text{d}E_{\kappa\nu}}{\text{d}k}\right)^{-1} \times \text{Im}[\psi_{\kappa\nu,E}(\mathbf{r})\nabla\psi_{\kappa\nu,E}(\mathbf{r})]f_{\text{FD}}(E-\mu_\kappa)\,, \tag{42.46}$$

where, since we have assumed that the injecting wavefunctions have been δ-normalized in their respective contacts, $(\text{d}E_{\kappa\nu}/\text{d}k)^{-1}$ is the density of states of mode ν contact κ.

42.6.2 Numerical Approach

In a numerical implementation, Eq. (42.42) needs to be discretized and the infinitely long contacts need to be truncated. In a periodic system, Eq. (42.42) is readily discretized on plane waves, $\psi_{\kappa\nu,E}=\sum_{\mathbf{G}}u_{\kappa\nu,E,G}e^{i\mathbf{G}\cdot\mathbf{r}}e^{i\mathbf{k}_{\kappa\nu,E}\cdot\mathbf{r}}$ using Bloch's theorem. Plane waves offer a mathematically complete basis that can be tuned to very high accuracy through the kinetic energy cutoff. By using the fast Fourier transform algorithm, plane waves have a relatively low computational cost and almost optimal scalability with system size. However, the application of bias and gate potentials breaks the periodic nature of the total potential in Eq. (42.42). This prevents the use of Bloch's theorem to express the electronic wavefunctions in the device. To circumvent this problem, the envelope function approach was developed [39, 186, 206]. More recently we developed a significantly more efficient method based on Bloch waves [223]. Once discretized, the truncation of the numerical domain is achieved by replacing the infinite contacts with a self-energy contribution, regardless of the chosen discretization.

While the Bloch wave method demonstrates significant progress in numerical efficiency, the envelope function has the benefit of conceptual clarity. For this reason, we highlight here the envelope function approach and its associated self-energies as an introduction to quantum transport simulations using pseudopotentials. We advise the interested reader to research advanced techniques, such as the Bloch wave-based method [223].

Envelope Functions

In the envelope-wavefunction approximation, we express the full electronic wavefunction at a given energy E as:

$$\psi_{\kappa\nu,E}(\mathbf{r}) = \sum_{\mathbf{G}} \phi_{\kappa\nu,E,\mathbf{G}}(\mathbf{r}) e^{i\mathbf{G}\cdot\mathbf{r}}, \tag{42.47}$$

where the envelope function in the periodic case $e^{i\mathbf{k}_{\kappa\nu,E}\cdot\mathbf{r}}$ is replaced by the more general envelope $\phi_{\kappa\nu,E,\mathbf{G}}$. The dependence of the envelope ϕ on $\mathbf{r}$ results indeed from the breaking of the periodicity caused by the applied bias and doping.

Using the envelope expansion in Eq. (42.47) in the Schrödinger equation (Eq. 42.42) yields an equation for the envelope functions

$$\sum_{\mathbf{G}'} \left\{ \left[\frac{\hbar^2}{2m}(-i\nabla + G)^2 + \bar{V}_{\text{tot}}(\mathbf{r}) \right] \delta_{\mathbf{G},\mathbf{G}'} + V_{\mathbf{G}-\mathbf{G}'} \right\} \times \phi_{\kappa\nu,E,\mathbf{G}}(\mathbf{r}) = E\phi_{\kappa\nu,E,\mathbf{G}}(\mathbf{r}) \tag{42.48}$$

where we have separated the total potential $V_{\text{tot}}(\mathbf{r}) = \bar{V}_{\text{tot}}(\mathbf{r}) + \sum_{\mathbf{G}} V_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}}$ into a slowly varying part $\bar{V}_{\text{tot}}(\mathbf{r})$ and the periodic lattice potential, captured by $V_{\mathbf{G}}$.

After discretization of the $\mathbf{r}$ coordinate, and using a finite difference scheme for the gradient, we obtain a sparse matrix equation:

$$\mathbf{H}\boldsymbol{\phi} = E\boldsymbol{\phi} \Leftrightarrow \begin{bmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \mathbf{T}^\dagger & \mathbf{D}_{i-1} & \mathbf{T} & 0 & 0 \cdot \\ \cdot & 0 & \mathbf{T}^\dagger & \mathbf{D}_i & \mathbf{T} & 0 \cdot \\ \cdot & 0 & 0 & \mathbf{T}^\dagger & \mathbf{D}_{i+1} & \mathbf{T} \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{bmatrix} \begin{bmatrix} \cdot \\ \boldsymbol{\phi}(\mathbf{r}_{i-1}) \\ \boldsymbol{\phi}(\mathbf{r}_i) \\ \boldsymbol{\phi}(\mathbf{r}_{i+1}) \\ \cdot g \end{bmatrix} = E \begin{bmatrix} \cdot \\ \boldsymbol{\phi}(\mathbf{r}_{i-1}) \\ \boldsymbol{\phi}(\mathbf{r}_i) \\ \boldsymbol{\phi}(\mathbf{r}_{i+1}) \\ \cdot \end{bmatrix}. \tag{42.49}$$

where the explicit matrix structure is given for the one-dimensional case, for which $\mathbf{D}_i$ and $\mathbf{T}$ are block matrices of size $(N_{\mathbf{G}} \times N_{\mathbf{G}})$ [186]. The vector containing the discretized envelope function contains sub-vectors of size $N_{\mathbf{G}}$:

$$\boldsymbol{\phi}(\mathbf{r}_i) = [\phi_{\mathbf{G}_1}(\mathbf{r}_i), \phi_{\mathbf{G}_2}(\mathbf{r}_i), \ldots, \phi_{\mathbf{G}_{N_{\mathbf{G}}}}(\mathbf{r}_i)]^\intercal . \tag{42.50}$$

Self Energies

In order to solve Eq. 42.49 numerically, we truncate it to the device region, *i.e.*:

$$\boldsymbol{\phi} = [\boldsymbol{\phi}(\mathbf{r}_1), \boldsymbol{\phi}(\mathbf{r}_2), \ldots, \boldsymbol{\phi}(\mathbf{r}_N)]^\intercal . \tag{42.51}$$

This necessitates the introduction of boundary conditions (the so-called quantum-transmitting boundary conditions) at the contacts that can inject and absorb waves. Since we have forced the potential in each contact to be periodic, the solutions in the contacts are Bloch waves. Specifically, for a given energy E, the envelope functions of the eigenmodes $\psi_\kappa^{(c)}$ of a contact κ located at $\mathbf{r}_{i_\kappa}$ are found, using Bloch's theorem, as:

$$\left[\mathbf{T}^\dagger e^{-ik_\kappa \Delta} + \mathbf{D}_{i_\kappa} + \mathbf{T} e^{ik_\kappa \Delta}\right] \boldsymbol{\phi}_\kappa^{(c)}(\mathbf{r}_{i_\kappa}) = E\boldsymbol{\phi}_\kappa^{(c)}(\mathbf{r}_{i_\kappa}), \tag{42.52}$$

where the Δ is distance between r_{i_κ} and $r_{i_\kappa - 1}$.

For each energy E, Eq. (42.52) admits $2N_{\mathbf{G}}$ solutions $(k_\kappa, \boldsymbol{\phi}_\kappa^{(c)})$. Classifying the contact solutions into incoming and outgoing modes, we assemble the "Bloch matrices," $\left[\boldsymbol{\phi}_\kappa^{(c)}\right]_{\text{in}}$ and $\left[\boldsymbol{\phi}_\kappa^{(c)}\right]_{\text{out}}$, containing the respective solutions as their columns. Using these Bloch matrices, we calculate the contact self-energies directly as:

$$[\boldsymbol{\Sigma}]_\kappa = \mathbf{T}' \left[\boldsymbol{\phi}_\kappa^{(c)}\right]_{\text{out}} \text{diag}\left[e^{ik_\kappa \Delta}\right]_{\text{out}} \left[\boldsymbol{\phi}_\kappa^{(c)}\right]_{\text{out}}^{-1}, \tag{42.53}$$

where $\text{diag}\left[e^{ik_\kappa \Delta}\right]_{\text{out}}$ is a diagonal matrix containing the phase factors of their respective solutions in the Bloch matrices and $\mathbf{T}'$ is either $\mathbf{T}$ or $\mathbf{T}^\dagger$ depending on the position of the contact. From right to left, the effect of the matrices in Eq. (42.53) is to (1) project the envelope at the edge onto the basis of contact solution, (2) propagate each solution one step (Δ) inside the contact, (3) reassemble the envelope function, and (4) apply the truncated part of the Hamiltonian. For a detailed derivation of the various parts, we refer the reader to Ref. [186].

With the definition of the self-energies $[\boldsymbol{\Sigma}]_\kappa$, the envelope functions ψ obey the following linear system of differential equations [186]:

$$(\mathbf{H} - E\mathbf{I} + [\boldsymbol{\Sigma}]_\kappa)\,\boldsymbol{\phi} = [\mathbf{r.h.s.}]_\kappa^{\text{inj}}, \tag{42.54}$$

where $\mathbf{I}$ is the identity matrix and $[\mathbf{r.h.s.}]_\kappa^{\text{inj}}$ is the contact injection from contact κ that decides which mode gets injected.

Self-Consistency

At a given bias, we solve Eq. (42.54) for all electron injection energies with a rough initial guess on the external potential and obtain their respective envelope functions and the spatial electronic wavefunctions. We calculate the carrier density using Eq. (42.45), summing over all the energy states with their corresponding thermal occupation set by the Fermi level of each contact. We then solve the (macroscopic or microscopic, see Sect. 42.5.2) Poisson equation, to update the Hartree potential and, if accounted for, update the exchange and correlation contributions. This procedure is repeated using Newton-Rhapson iteration until the root-mean-square potential-difference between two successive it-

erations is smaller than a preset convergence criterion. To accelerate convergence, we succesfully employed the direct inversion of the iterative subspace (DIIS) method, also known as Pulay mixing in the chemistry community [223]. After convergence, we calculate the current density from the final envelope functions.

42.6.3 Scattering—The Pauli Master Equation

In realistic small devices, the ballistic limit is rarely, if ever, achieved. To account for scattering in short devices where scattering is still relatively weak, we can use the Pauli Master equation approach [39, 224–226]. In this approach, we replace the noninteracting ballistic density matrix $\rho^{(\mathrm{bal})}$ with the density matrix ρ for the interacting system.

By invoking the Van Hove limit, Fischetti [225] showed that the time-dependence of the elements of the density matrix is given by:

$$\begin{aligned}\frac{\partial}{\partial t}\rho_{\kappa\nu E,\kappa'\nu'E'}(t) &= -\frac{i}{\hbar}(E-E')\rho_{\kappa\nu E,\kappa'\nu'E'}(t)\\ &- \sum_{\kappa''\nu''E''}\left[W_{\kappa''\nu''E'',\kappa\nu E} + W_{\kappa''\nu''E'',\kappa'\nu'E'}\right]\rho_{\kappa\nu E,\kappa'\nu'E'}(t)\\ &+ \sum_{\kappa''\nu''E''}\delta_{\kappa\nu E,\kappa'\nu'E'}W_{\kappa\nu E,\kappa''\nu''E''}\rho_{\kappa''\nu''E'',\kappa''\nu''E''}(t)\,. \quad (42.55)\end{aligned}$$

Thanks to the Van Hove limit, where we assume the scattering process completes much faster than the dynamics of the electrons themselves, we can ignore memory effects and phase information. The scattering rates $W(\kappa\nu E,\kappa'\nu'E')$ for a perturbing potential V' are then obtained using Fermi's golden rule, in much the same way as for the semiclassical Monte-Carlo approach:

$$W(\kappa\nu E,\kappa'\nu'E') = \frac{\left|\langle\kappa\nu E|V'|\kappa'\nu'E'\rangle\right|^2}{|E-E'|}\,. \quad (42.56)$$

When considering small devices, where electrons scatter only rarely before being absorbed by a contact, the off-diagonal parts of the density matrix are negligible and the Pauli Master equation reduces to:

$$\begin{aligned}&\frac{\partial}{\partial t}\rho_{\kappa\nu E,\kappa\nu E}(t)\\ &\quad= \sum_{\kappa'\nu'E'}\left[W_{\kappa\nu E,\kappa'\nu'E'}\rho_{\kappa'\nu'E',\kappa'\nu'E'}(t)\right.\\ &\qquad\left.- W_{\kappa'\nu'E',\kappa\nu E}\rho_{\kappa\nu E,\kappa\nu E}(t)\right]\,. \quad (42.57)\end{aligned}$$

To account for the exchange of particles through the contact reservoirs, Fischetti [224] introduced an empirical term:

$$\begin{aligned}&\left(\frac{\partial}{\partial t}\rho_{\kappa\nu E,\kappa\nu E}(t)\right)_{\mathrm{res}}\\ &\quad= |A_{\kappa\nu E}|^2\, v_{\kappa\nu E,\perp}\left[f_{\mathrm{FD}}(E-\mu_\kappa) - \rho_{\kappa\nu E,\kappa\nu E}(t)\right], \quad (42.58)\end{aligned}$$

where particles (waves) are injected from a contact κ that is in equilibrium with chemical potential μ_κ with a group velocity $v_{\kappa\nu E,\perp}$ normal to the contact. $A_{\kappa\nu E}$ is the normalization factor applied to the injected wavefunction such that $\int_\Omega \mathrm{d}^3 r|\psi_{\kappa\nu E}(\mathbf{r})|^2 = 1$, where Ω is the volume of the device.

For device transport we are mostly interested in the steady state. In this case, the injection from the contacts needs to balance the scattering, *i.e.*, the right-hand sides of Eqs. (42.57) and (42.58) must be equal. The resulting linear matrix equation can be solved very efficiently using existing linear algebra packages.

42.6.4 Example 1: Graphene Nanoribbon Transistors

To study transport through graphene nanoribbons, we use the empirical pseudopotentials from Ref. [181] with an energy cutoff of 15 Ry. The atoms have been positioned in a perfect sp^2 lattice, without relaxation of the hydrogen atom positions. We calculate the band structure of several armchair graphene nanoribbons (aGNR), shown in Fig. 42.32a. In the given energy range, 7-, 10-, 13-aGNRs show two conducting bands, whereas the 6-aGNR shows only one conducting band. Fischetti et al. have shown that the electron effective mass of aGNRs at the conduction band minimum oscillates, so that, for example, $m_6^* < m_7^* < m_{13}^* < m_{10}^*$, where m_n^* represents the effective mass of the n-aGNR [60]. Figure 42.32b shows the dispersion of the lowest conduction band for 3-, 6-, 9-, and 12-aGNRs, and it indicates that $m_{12}^* < m_9^* < m_6^* < m_3^*$ [60]. The difference of the effective mass can result in different transport behavior of each ribbon, especially in the subthreshold region of device operation, as we will discuss later.

Ribbons with different body widths exhibit different band gaps, as shown in Fig. 42.32c [199]. The $3n$-aGNRFETs and $(3n{+}1)$-aGNRFETs with different channel lengths and different ribbon widths are simulated to investigate their device performance. The $(3n{+}2)$-aGNRs are not of interest here, since their small band gap results in a very poor subthreshold leakage as a consequence of a high tunneling current.

Transport Characteristics of aGNRFETs

The I_{DS}-V_{GS} characteristics are presented in Fig. 42.33a,b. Clearly, transistors with different widths show different transfer characteristics. We show the ribbon width dependence of the current at a gate overdrive, V_{GS}-$V_{\mathrm{th}} = 0.25\,\mathrm{V}$, and subthreshold swing in Fig. 42.35.

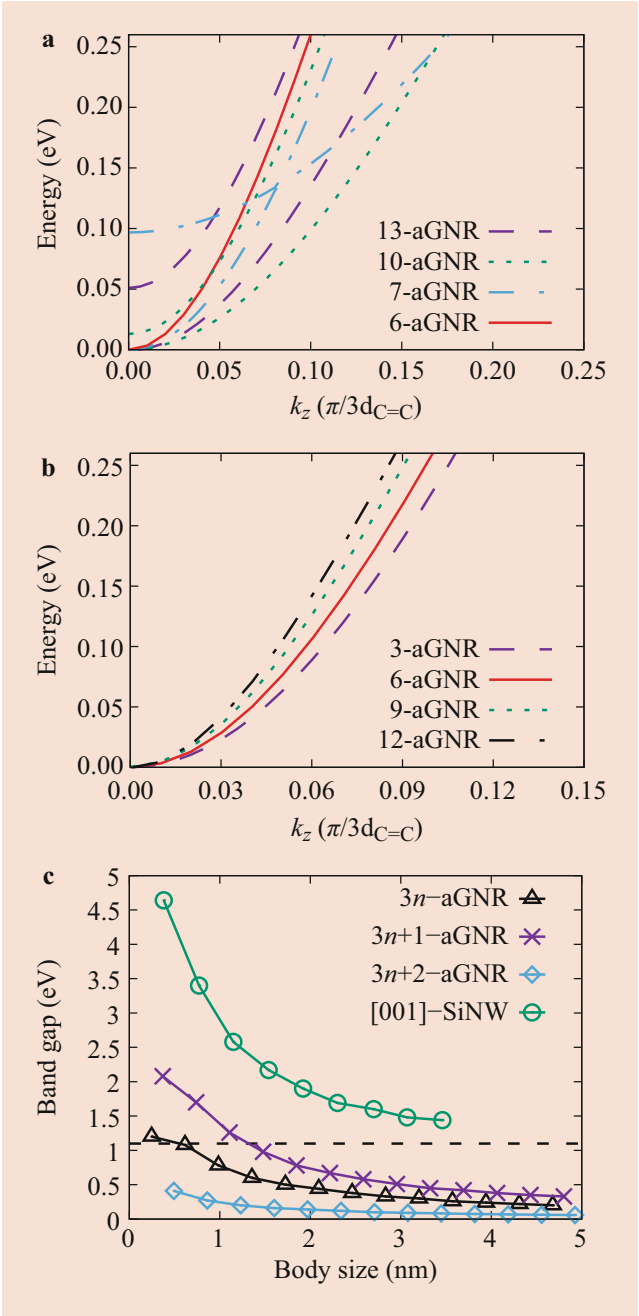

Fig. 42.32 (**a**, **b**) Conduction band dispersion of several aGNRs in a given energy range from E_{CBM}, the conduction band minimum, to $E_{CBM} + 10k_BT$ ($T = 300$ K). The energy of E_{CBM} is set as zero. (**c**) Body-size dependence of the band gap of aGNRs and [001]-oriented silicon nanowires. The horizontal dashed line indicates the band gap of bulk silicon, which is 1.1 eV. The index n is an integer which characterizes the ribbon width. The lines connecting the symbols are a guide to the eye. (After Ref. [206], with permission from IEEE)

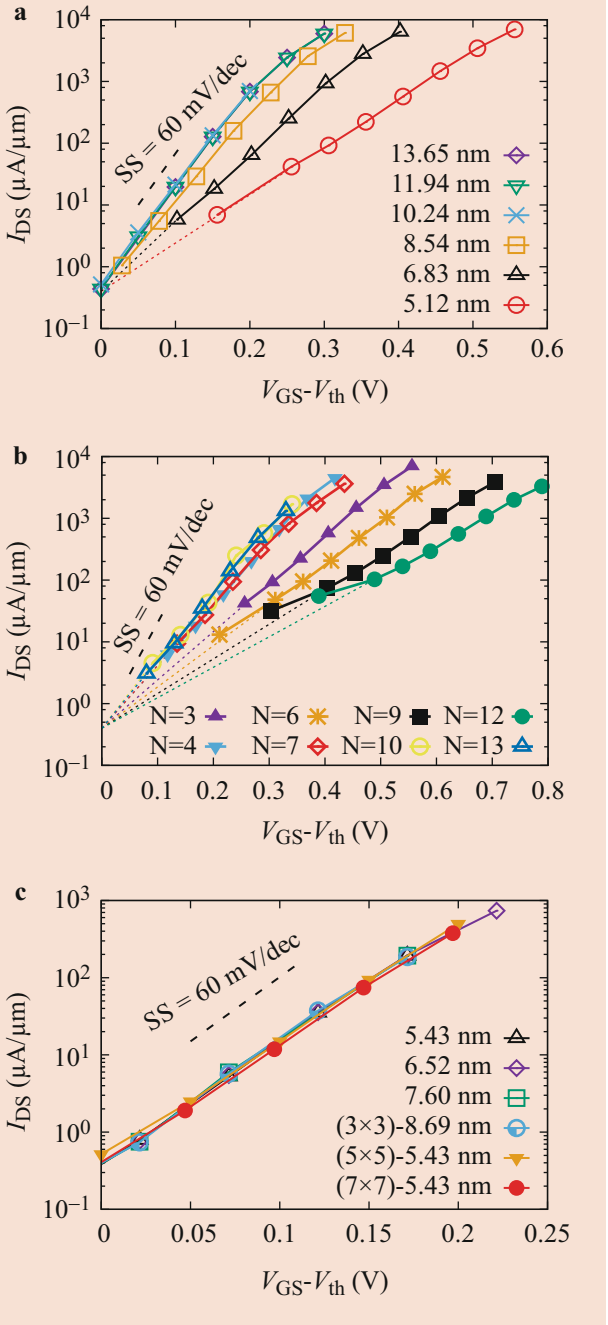

Fig. 42.33 (**a**) Gate-length dependence of transfer characteristics for 3-aGNRFETs at $V_{DS} = 0.1$ V (taken as representative of $V_{DD} = 0.4$ V, thanks to the saturation of the $I_{DS} - V_{DS}$ curves for $V_{DS} > 0.1$ V). The device gate length, L_G, ranges from 5.12 nm to 13.65 nm. (**b**) I_{DS}-V_{GS} transfer characteristics at $V_{DS} = 0.1$ V for aGNRFETs with the same gate length $L_G = 5.12$ nm and with different widths. (**c**) I_{DS}-V_{GS} transfer characteristics of four (3×3)-SiNWFETs with different gate lengths (from 5.43 nm to 8.69 nm) and of a (5×5)-SiNWFET and a (7×7)-SiNWFET both with a gate length of 5.43 nm, at $V_{DS} = 0.1$ V. The dotted lines extending to the threshold voltage have been obtained by extrapolating the current calculated at higher gate bias using the calculated subthreshold slope. The 60 mV/dec slope and the lines connecting the symbols are a guide to the eye. (After Ref. [206], with permission from IEEE)

Figure 42.32c illustrates the band gap of aGNRs with different body size (*i.e.*, ribbon width). For a ribbon wider than 5 nm, the band gap approaches the vanishing band gap of graphene. The band gap increases as the ribbon width de-

creases as a consequence of quantum confinement [227]. The band gap for a ribbon with a width about 4 nm is about 0.4 eV, which matches the experimental result reported in Ref. [228]. The gap of a 7-aGNR is also experimentally observed to be ∼1.8 eV [229]. These facts highlight the accuracy of band structure calculation based on empirical pseudopotentials, while maintaining computational efficiency. The 3-aGNRFETs with a body width $W_{body} = 0.25$ nm and a gate length L_G ranging from 5.12 nm (12 cells along z) to 13.65 nm (32 cells along z) are simulated. The source and the drain regions are both set as ∼6 nm, and we assume no gate-channel overlap. Both the source and the drain regions are doped as n-type with a density of 10^8 m^{-1}, and the channel region is doped as p-type with a density of 10^8 m^{-1}. Abrupt junctions are assumed. We use "vacuum" as a virtual gate insulator in the transport model. The size of "vacuum," t_{vac}, and its dielectric constant, ϵ, are related to the EOT as $t_{vac}/\epsilon = \text{EOT}/\epsilon_{SiO_2}$, where EOT is set as 0.43 nm and ϵ_{SiO_2} is the dielectric constant of silicon dioxide.

The current-voltage characteristics of these 3-aGNRFETs are shown in Fig. 42.33a. We define here the threshold voltage, V_{th}, as the gate bias at which the drain current reaches a preset value $I_{off} = 0.4\,\mu$A/μm. This definition allows us to compare various devices at the same I_{off} and the same gate overdrive $V_{GS} - V_{th} = 0.25$ V. Also we assume a power supply voltage $V_{DD} = 0.4$ V [1]. Since I_{DS} saturates for $V_{DS} > 0.1$ V, we shall consider the on-state at $V_{DS} = 0.1$ V as representative of the performance at $V_{DS} = V_{DD}$. When the gate length is larger than 10 nm, the current at a given bias is approximately independent of gate length. This is due to the assumption of ballistic transport. This is in contrast with "the linear model" or "the quadratic model" in traditional metal-oxide-semiconductor field-effect transistors (MOSFETs) according to which carriers can scatter within the device when traveling along the channel. Thus, increasing the device length will increase the channel resistance proportionally and reduce the current (*i.e.*, $I_{DS} \propto 1/L$) [230]. For devices with a gate length below 10 nm, the current decreases with a decrease of the gate length at the same given gate overdrive due to the significant quantum-mechanical source-to-drain tunneling effect that causes a very poor turn-off behavior and thus threshold voltage shift for devices with a ultrashort gate length [231].

This is shown as well in Fig. 42.34a which compares the current for devices with different channel lengths at a given gate overdrive, $V_{GS} - V_{th} = 0.25$ V. The current does not show a strong dependence on the channel length when it is above 10 nm, whereas it decreases by two orders of magnitude when the channel length is below 10 nm.

The subthreshold behavior is shown in Fig. 42.34b. The subthreshold swing reaches the ideal performance of 60 mV/dec for traditional MOSFETs [232] when $L_G > 10$ nm. However, a shorter-channel device presents a degraded subthreshold swing due to the source-to-drain tunneling. Thus, for a given power supply V_{DD}, the I_{on}/I_{off} current ratio decreases for a shorter device.

42.6.5 Example 2: Silicon Nanowire FETs

Gate-all-around SiNWFETs with square and smaller cross sections are simulated as well. The SiNWs are with axis along the [100] crystallographic (transport) direction and with {100} surfaces since this yields a high ballistic conductance (at least in large cross-section NWs, Ref. [40], Fig. 7.34) while retaining a transport mass that for small cross-section NWs is large enough [233] to minimize source-to-drain tunneling. The band gap of [001]-oriented SiNWs with a square cross section and different body sizes (*i.e.*, NW side lengths) is also shown in Fig. 42.32c. When the NW side length is larger than 3.5 nm, the band gap approaches the band gap of bulk silicon. The electron effective mass at the conduction band minimum is $1.94m_0$, $0.88m_0$, and $0.73m_0$, respectively, for (3×3) SiNW, (5×5) SiNW, and (7×7) SiNW. The (3×3) SiNWFETs with gate lengths ranging from 5.43 nm (10 cells along z) to 8.69 nm (16 cells along z) are simulated. All of these nanowires have three atomic layers along each side of the cross section and thus have a side length of 0.39 nm (Ref. [186], Fig. 3). The surfaces of the NWs are hydrogen-terminated. The current-voltage transfer characteristics of these devices are shown in Fig. 42.33c. The current is the same at a given V_{DS} and V_{GS} for all gate lengths, and thus they have the same threshold voltage. Thus, there is no appreciable source-to-drain tunneling for a (3 × 3) SiNWFET with a ∼5 nm gate length. Normalizing the current at $V_{GS} - V_{th} \approx 0.25$ V and $V_{DS} = 0.1$ V to the NW side length (footprint), the current density reaches around 1000 μA/μm, which satisfies the performance requirement for continued device scaling suggested by ITRS [146]. The subthreshold swing is 66 mV/decade and I_{on}/I_{off} ratio is $\sim 2 \times 10^3$.

In Fig. 42.34a we compare their performance with aGNRFETs in a similar range of gate lengths. It is obvious that SiNWFETs have a much larger current than aGNRFETs when the gate length is below 10 nm. Especially, at the 5 nm gate length, (3×3) SiNWFET shows a current ∼25 times larger than 3-aGNRFET.

Both a (5×5) SiNWFET and a (7 × 7) SiNWFET are simulated to investigate the body-size effect of NWs on the device performance. They both have a gate length of 5.43 nm and a side length of 0.78 nm and 1.17 nm. These large cross-section SiNWFETs show very similar current density with the (3 × 3) SiNWFETs at the same gate overdrive.

The current at a gate overdrive of 0.25 V and the subthreshold swing are illustrated in Fig. 42.35. In Fig. 42.34 we compare the performance of SiNWFETs with that of aGNRFETs at different body sizes. The SiNWFETs show a

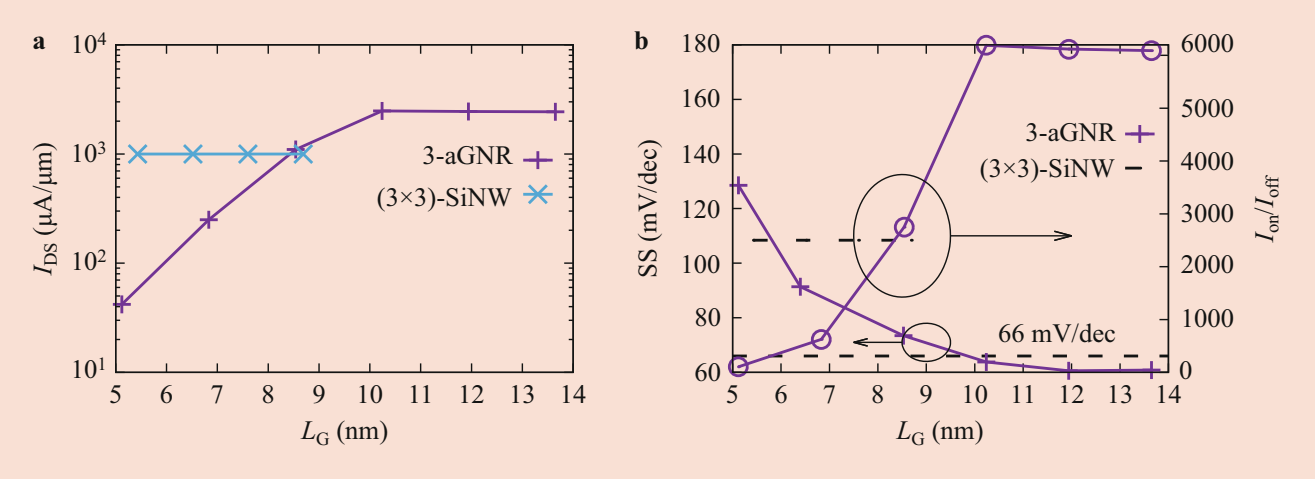

Fig. 42.34 (**a**) Drain-source current I_{DS} for 3-aGNRFETs and (3×3)-SiNWFETs with different L_G at $V_{DS} = 0.1$ V and $V_{GS} - V_{th} = 0.25$ V. (**b**) Subthreshold swing (SS) and I_{on}/I_{off} ratio as a function of L_G. The horizontal dashed line indicates the subthreshold swing, 66 mV/dec, for (3×3)-SiNWFETs in the given channel lengths. Lines connecting the symbols are a guide to the eye. (After Ref. [206], with permission from IEEE)

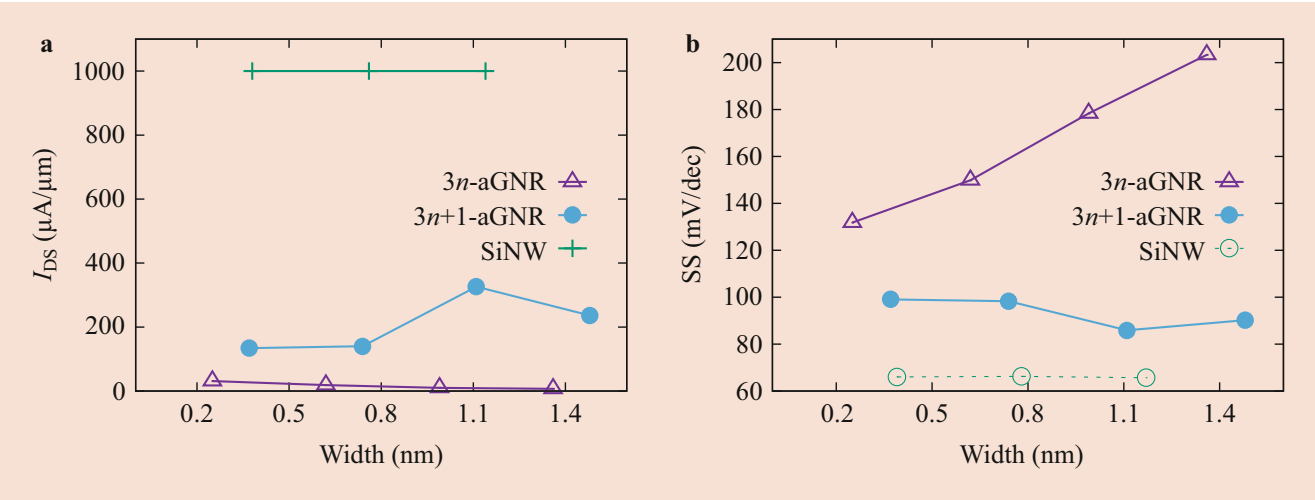

Fig. 42.35 (**a**) The current I_{DS} at $V_{DS} = 0.1$ V and $V_{GS} - V_{th} = 0.25$ V for aGNRFETs and SiNWFETs with different width and a similar gate length (~5 nm). (**b**) The SS as a function of width. The lines connecting the symbols are a guide to the eye. (After Ref. [206], with permission from IEEE)

current more than three times larger than aGNRFETs for the same gate length of 5 nm. To sum the studies shown above, SiNWFETs offer the avenue to scale transistors down to 5 nm channel lengths.

42.7 Conclusions and Outlook

So far, we have shown how DFT can be used to calculate electron-phonon scattering rates and transport properties of several bulk and two-dimensional materials. Comparing the power of these *ab initio* methods to what was possible as recently as 20 years ago (as discussed in Sect. 42.2), we can appreciate the enormous "cultural" value of the progress made. We must also express optimism about the possibility of investigating the transport properties of new materials without having to wait for expensive and time-consuming experiments that provide the information needed to assess the performance of devices based on these materials.

However, in a few occasions, we have also hinted at some uncertainty that still affects the accuracy and reliability of results obtained using *ab initio* methods. Broadly speaking, these difficulties originate from three causes: *(i)* the use of unsatisfactory approximations to calculate the carrier mobility and other transport characteristics, *(ii)* numerical "shortcuts" that reduce the computational efforts but introduce unwanted artifacts and errors, and *(iii)* intrinsic limitations of our knowledge of the basic physics.

(i) Regarding the accuracy and correctness of the formulations employed to compute transport characteristics, we have discussed in Ref. [97] how several results, labeled *ab initio*, rely on DFT calculations of the changes of the band structure under strain (the "proper" deformation potentials) to estimate the carrier mobility using oversimplified assumptions. To summarize what we wrote in Ref. [97] (and as also discussed in Refs. [234, 235]), these assumptions consists in the use of Takagi formula [236] to calculate the carrier mobility for a two-dimensional electron gas (2DEG):

$$\mu = \frac{e\hbar^3 C_{2D}}{k_B T m^* m_d E_1^2}, \tag{42.59}$$

where m^* and m_d are the conductivity and density-of-states effective masses, respectively, C_{2D} is the longitudinal or transverse elastic constant of the 2D material, and E_1 is the "proper" deformation potential mentioned above and calculated from the energy-shift, $\Delta E_{c,v}$, of the relevant band-edge (conduction for electron transport, valence for holes), under a relative change, $\Delta a/a_0$, of the lattice constant a_0:

$$E_1 = a_0 \frac{\Delta E_{c,v}}{\Delta a}. \tag{42.60}$$

This formula has been used to calculate extremely high values for the carrier mobility in silicene ($\approx 2 \times 10^5$ cm^2 V^{-1} s^{-1} for both electrons and holes [237]) and germanene ($\approx 6 \times 10^5$ cm^2 V^{-1} s^{-1} for both electrons and holes [238]), ignoring coupling to flexural acoustic modes [141]. Qiao et al. [137] have also used Eq. (42.59) to obtain an equally impressive electron and hole mobility in phosphorene. However, while approximately correct in the context of Si inversion layers, as originally intended by Takagi and coworkers, its validity should be considered carefully when extending it to other materials. Indeed, Eq. (42.59) accounts only for longitudinal phonons (unless the shear deformation potential is also accurately considered, as done in Ref. [144] for phosphorene), it ignores scattering with optical phonons, intervalley processes and ignores the anisotropy (*i.e.*, the dependence on the scattering angle) of the electron-phonon matrix element. This anisotropy is extremely important when estimating the carrier mobility, since it affects strongly the momentum relaxation rate. This has been shown even in bulk Si [36], strained bulk Si [239], and Si inversion layers [240]. Liao et al. [142] and Gaddemane et al. [97] have shown how this is also of paramount importance in monolayer phosphorene. Finally, Eq. (42.59) ignores effects that may result from the overlap integral of the initial and final wavefunctions, effects that are instead captured by the finite-displacement method or by DFPT. Therefore, the impressive values for the carrier mobility reported in Refs. [137, 237], among others, should be regarded as no more than extremely optimistic upper bounds.

We show in Table 42.7 (reproduced from Ref. [97]) the large discrepancies among the values of the electron mobility in phosphorene calculated using several different approximations or methods. As serious as the issue may be, paradoxically we should consider it a "minor problem," since reliable methods to calculate the electron mobility are available, such as the EPW computer package [77] and the by-now "conventional" full-band Monte Carlo simulations we have employed here.

(ii) Regarding numerical issues, we have also discussed in them in Ref. [97], and we have mentioned above in Sect. 42.4.1. These may be considered mundane issues, since the use of a sufficiently fine discretization of the Brillouin zone does not constitute an insurmountable conceptual obstacle. Even if today's hardware renders the task painful and (perhaps) impossible when dealing with high-energy transport, we are growing accustomed to ever-increasing computer resources, in terms of both speed and memory.

(iii) Much more fundamental are the reasons causing the dependence of the results on the choice of exchange-and-correlation functionals and even (very surprising to us) of the pseudopotentials used when performing *ab initio* calcula-

Table 42.8 Calculated electron mobility in monolayer WS_2

WTe_2	64	166	181	60	55

tions. In Sect. 42.4.3 we have already observed the surprising wide range of values for the calculated electron mobility in monolayer phosphorene that have been reported in the literature. Unfortunately, a similar puzzling observation can be made for monolayer TMDs. A typical example is provided by WS_2. As shown in Tables 42.8, the electron mobility calculated using DFT varies from a promising 767 cm^2/(Vs) to a disappointing 17 cm^2/(Vs). Indeed, different values are obtained when using different exchange and correlation functionals (PBE [94] or LDA [95]), different pseudopotentials ("standard solid-state pseudopotentials," SSSP [241] or "optimized norm-conserving," ONCV [242]) and depending on whether or not one accounts for the spin-orbit (SO) interaction.

The cause of this problem is twofold: first, the band structure of monolayer WS_2 shows conduction band minima at the six K symmetry points (the doubly degenerate K valleys) and local minima at a point along the Γ-K line (the sixfold degenerate Q valleys). The energy separation, ΔE_{KQ}, between these two sets of valleys obtained choosing different "flavors" of DFT using Quantum ESPRESSO [15, 16] varies between 22 and 210 meV. Since the K-Q intervalley scattering rates calculated using EPW [76] are quite strong, clearly different values of ΔE_{KQ} result in vastly different values of the mobility. In this case, we may blame the well-known inability of DFT – a ground-state theory thanks to the Hohenberg-Kohn theorems [243] – to reproduce the correct excitation spectrum with the accuracy required when performing transport calculations. However, in some sense, experimental information can guide us in choosing the proper combination of exchange-correlation functionals and pseudopotentials. In so doing, the problem is addressed very pragmatically, so that we have to accept some compromises in how we define the term "*ab initio*."

A similar problem affects our understanding of high-field electron transport in Si and GaN: regarding Si, Fig. 42.3 shows that DFT/EPW calculations yield peaks of the density of states at energies that are slightly smaller than those measured experimentally (and reproduced, by definition, by empirical pseudopotentials). This "compression" of the conduction bands results in a larger density of states that, in turn, results in scattering rates that are slightly larger than those predicted by rigid-(pseudo)ion calculations based on empirical pseudopotentials. Similarly, in GaN the energy of the satellite L-valleys computed from DFT seems to be inconsistent with some experimental data, as we have mentioned in Sect. 42.4.2. Ultimately and not surprisingly, the problem originates from the approximations that we must necessarily make in dealing with the exchange and correlation functionals that enter the Kohn-Sham equation. We should add, parenthetically, that accounting for the spin-orbit interaction still presents some fundamental issues.

Much more serious is the second cause of the broad range of calculated results. As shown in Table 42.9, even in materials in which intervalley scattering does not control transport, some differences are seen. If one may expect some dependence of the results on the choice made for the exchange-correlation functionals, more worrisome is the observation that even the choice made for the pseudopotentials matters. The situation is acceptable only in some particular cases, such as for MoS_2, but it remains generally unsatisfactory.

As a final important remark, we should note that results like those reported in Tables 42.8 and 42.9 have been obtained assuming free-standing 2D layers. Experiments are often performed on layers supported by insulating substrates, often also gated (occasionally supported *and* gated), and at a nonzero carrier density. Under these circumstances, dielectric screening by the dielectric environment (as reported for impurity scattering in Ref. [244]) and free-carrier screening may improve the mobility, whereas scattering with the hybrid plasmon/optical-phonon interface modes (often called "remote-phonon" scattering, somewhat improperly) may depress it. Therefore, comparison with experimental data should be made keeping these effects in mind.

If the choice of functionals and pseudopotential is an issue, using an all-electron method may solve the latter problem and employing the GW approximation may address the former issue. At present, such calculations are possible only in some particular cases (also employing the simpler G_0W_0 approximation). However, having already remarked how accustomed we have grown in witnessing the progress of numerical algorithms and computer hardware, we may speculate that in a not-too-distant future the term *ab initio*

will be considered synonymous of all-electron/GW, rather than DFT.

Acknowledgments We are grateful to Mr. Mohammad M. Khatami and Mr. Sanjay Gopalan for having provided the DFT results shown in Figs. 42.3 and 42.4 and in Tables 42.8 and 42.9, respectively.

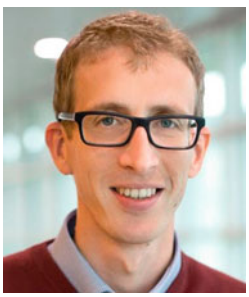
Massimo Fischetti (PhD from the University of California – Santa Barbara) has been at the IBM T. J. Watson Research Center (1983–2005) and at the University of Massachusetts – Amherst (2005–2010). He is now Texas Instruments Distinguished professor in Nanoelectronics at the University of Texas at Dallas. His interests focus on the theory of electron transport in solids.



William Vandenberghe received the M.Sc. degree (2007) and the Ph.D. degree (2012) from KU Leuven, Belgium. From 2012–2016, he was a research associate/scientist at the University of Texas at Dallas in the Department of Materials Science and Engineering. Dr. Vandenberghe was appointed assistant professor at UT Dallas in 2016 and promoted to Associate Professor in 2021. He studies electronic transport at the nanoscale using theoretical methods.

Maarten L. Van de Put received his PhD from the University of Antwerp in 2016, working at imec in Belgium. He joined the University of Texas at Dallas as a post-doctoral researcher. He currently works as a Research Scientist, focussing on the development of advanced modeling and simulation capabilities to study quantum transport in nanostructures and devices.

Gautam Gaddemane received his PhD from the University of Texas at Dallas in 2018. He has worked as a postdoctoral researcher at KU Leuven/imec, Belgium from 2019–2021. He is currently working as R & D Engineer in the TCAD group at imec, Belgium. His research interests include materials and device modeling using semi-classical and quantum approaches.

Jingtian Fang received his PhD from the University of Texas at Dallas in 2016. He worked at Vanderbilt University Department of Physics and Astronomy as postdoctoral scholar and Boston University Department of Electrical and Computer Engineering as postdoctoral research associate from 2016 to 2018. Currently he works in Synopsys, Inc. as senior application engineer.

Quantum Transport in the Phase Space, the Wigner Equation

Abstract

In this chapter, we present and discuss the primary features of the Wigner equation and the related Monte Carlo techniques which allow quantum simulations in the phase space. We start by introducing some of the main aspects of the quantum theory. Afterwards, we proceed with the tenets of the Schrödinger formalism. It allows us to revise the details of such approach and to fix the notation we will use throughout this chapter. Then, we introduce and discuss the important role Monte Carlo methods have played in the field of applied physics and present the latest developments in the field of time-dependent, multidimensional, many-body, and full quantum simulations in the Wigner formalism. Two main techniques will be discussed and illustrated by some typical examples: one technique based on the concept of quantum affinity and the other one based on the concept of signed particles.

Quantum mechanics · Wigner formulation · Quantum affinity · Signed particles · Monte Carlo methods

43.1 Why a Quantum Theory in the Phase Space?

Quantum mechanics was born from the necessity of explaining a series of experiments involving extremely small objects such as electrons, atoms, and molecules and which could not be approached in terms of classical mechanics. Puzzling concepts such as particle-wave duality and energy quantization were developed and utilized to describe physical observations for the first time. Since then, theoretical physicists have assembled a very successful set of rules which can explain and predict (impressively) the many ob-

served features of quantum systems. The modern approach to quantum mechanics was eventually made possible by the work of E. Schrödinger, completely describing quantum systems in terms of probability amplitudes or wave-functions (a revolutionary concept). A physical interpretation to this equation was provided, known as the standard or Copenhagen interpretation. This theory remains, to this day, the most rigorously tested theory in physics.

Right after the work of Schrödinger, other formulations and interpretations appeared, shedding a different light on different aspects of the theory. In this context, the work of E. Wigner stands out among the available (equivalent) alternatives as it is an intuitive approach which provides a direct connection between classical and quantum physics. In fact, it naturally creates a bridge with classical statistical mechanics which renders quantum mechanics a more natural theory: in this formulation, the description of quantum objects can completely be made in terms of quasi-distribution functions.

In spite of this intuitiveness, only recently we have observed a growing interest in the Wigner formulation of quantum mechanics. One plausible explanation is provided by the fact that the Wigner equation represents a challenging mathematical task, being a partial integro-differential equation where the unknown is a function defined over a $2 \times d \times n$ dimensional phase space, where d is the dimensionality of space ($d = 1, 2, 3$) and n is the number of involved particles or bodies (in this chapter, we use the terms body and particle interchangeably). Only very recently, Monte Carlo techniques have been designed which are capable of overcoming the many problems encountered with such model.

In this chapter, we focus on the Wigner equation and the related Monte Carlo techniques which allow quantum simulations in the phase space. Therefore, we start by introducing some of the main aspects of the quantum theory. Afterwards, we proceed with the tenets of the Schrödinger formalism. This is twofold. First, it allows us to revise the details of such approach, secondly it allows us to fix the notation we will use through this work. We, then, introduce and discuss the important role Monte Carlo methods have played in the field of applied physics and present the latest developments in the field of time-dependent, multidimensional, and full quantum simulations in the Wigner formalism. Two main techniques will be discussed: one based on the concept of *quantum affinity* and the other one based on the concept of *signed particles*. In the following, we suppose that the reader is familiar with the Schrödinger formulation of quantum mechanics.

43.2 An Introduction to Standard Quantum Mechanics

The time-dependent and time-independent Schrödinger equations are two linear partial differential equations which describe the state of a quantum system [1]. Both equations have played a crucial role in quantum mechanics and nowadays represent the standard approach. Several years after the appearance of Schödinger work, E. Wigner utilized one of these equations, the time-dependent one, as a starting point to create his own formalism [2]. Due to the importance it has gained during the years, in this section we briefly recall the tenets of the Schrödinger formulation. In the following, we adhere to the non-relativistic exposition of L.D. Landau [3].

The Born Rule A wave-function $\psi = \psi(\mathbf{x})$ completely describes a system. The probability of finding a particle around the position $\mathbf{x}$ in the interval $\mathrm{d}\mathbf{x}$ is given by its squared modulus $\psi^2(\mathbf{x})\mathrm{d}\mathbf{x}$. This heuristic rule is known as the Born rule [4]. In the general case, any other measurement can be predicted by a bilinear form:

$$\int \mathrm{d}\mathbf{x} \int \mathrm{d}\mathbf{x}' \psi(\mathbf{x}) \psi^*(\mathbf{x}') \phi\left(\mathbf{x}, \mathbf{x}'\right), \tag{43.1}$$

where the function $\phi = \phi(\mathbf{x}, \mathbf{x}')$ depends on the particular measurement performed. In particular, the probability of finding a particle at a certain given position is of the same form as (43.1) where $\phi(\mathbf{x}, \mathbf{x}') = 1$ for every $\mathbf{x}$ and $\mathbf{x}'$.

Principle of Superposition of States Given two valid wave-functions $\psi_1(\mathbf{x})$ and $\psi_2(\mathbf{x})$ for a system, and supposing that the state ψ_1 leads with certainty to a measurement $\mathbf{x}_1$ and the state ψ_2 leads with certainty to a measurement $\mathbf{x}_2$, then every linear combination of these two states $c_1\psi_1 + c_2\psi_2$ is an equivalently valid state for the given system (where c_1 and c_2 are two constants).

Operators For any physical quantity A, it is possible to construct an Hermitian (linear) mathematical operator $\hat{A}$ which eigenvalues a_n are the possible outcomes of the act of measurement of A [3]. The shape of the operator is determined by the particular measurement being performed. In the Schrödinger formalism, the only admissible operators are Hermitian ones.

The Momentum Operator In the Schrödinger formalism, the operator $\hat{p}$ corresponding to the momentum reads

$$\hat{p} = -i\hbar\nabla_{\mathbf{x}},$$

where i is the imaginary unit, $\hbar$ is the reduced Planck constant, and $\nabla_{\mathbf{x}} = \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)$.

The Hamiltonian Operator The Hamiltonian operator has the following mathematical expression:

$$\hat{H} = \frac{\hat{p}^2}{2m} + U(\mathbf{x}, t) = -\frac{\hbar^2}{2m}\nabla^2_{\mathbf{x}} + U(\mathbf{x}, t), \tag{43.2}$$

with m the mass of the particle and $U = U(\mathbf{x})$ the potential energy of the particle in an external field and the operator $\nabla^2_{\mathbf{x}} = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$.

The Time-Independent Schrödinger Equation The time-independent Schrödinger equation is an important milestone of quantum mechanics. It is an eigenproblem which eigenvalues represent the energy levels of a system. It describes quantum systems in the presence of a time-independent external field and reads:

$$\hat{H}\psi(\mathbf{x}) = E\psi(\mathbf{x}), \tag{43.3}$$

where $\hat{H}$ is the Hamiltonian operator of the system. Its solution formally reads as (E_n, ψ_n) for $n = 0, 1, 2, \ldots$, where the wave-functions ψ_n are also called stationary states. In particular, the function ψ_0 and the energy E_0 are known as the *ground state* function and energy, respectively. The reader should note that this equation implies the possibility for quantized energies.

The Time-Dependent Schrödinger Equation The evolution in time of the quantum state of a system is governed by the time-dependent Schrödinger equation which represents its most general description possible and reads

$$i\hbar\frac{\partial\psi(\mathbf{x}; t)}{\partial t} = \hat{H}\psi(\mathbf{x}; t). \tag{43.4}$$

The reader should note that, being a *linear* partial differential equation, the principle of superposition holds. This is a very peculiar characteristics which has no counterpart in classical mechanics.

43.3 Quantum Mechanics in the Phase Space

In his search for quantum corrections to classical thermodynamics, E. Wigner came up, in 1932, with a very peculiar, elegant, and intuitive formulation of quantum mechanics which involves familiar (classical) concepts such as the phase space and distribution functions [2]. We start this section with a focus on this formalism starting from the original work of Wigner and extending it to the case of mixed states. Afterwards, we proceed with the works of Moyal and Groenewold which provided firm mathematical foundations to this approach. These results eventually put the Wigner formalism on totally independent grounds. Finally, we conclude this section with a generalization of the single-body Wigner equation to the quantum many-body case and to systems of identical particles (with a particular attention to Fermions).

43.3.1 The Single-Body Problem

In this section, we describe the (single-body) formulation suggested by E. Wigner [2], which represents a peculiar and intuitive approach to quantum mechanics in the phase space. This is an important part of this chapter since it introduces many of the details related to the Wigner approach. The cases for the mixed states and for the many-body problem are directly connected to the pure state, single-body Wigner transport equation (WTE) presented in this section for coherent transport. Then, we introduce a simple approach frequently used to include scattering (dissipative) processes in the Wigner equation. It consists of using the Boltzmann collision operator for electron-phonon and electron-impurity interactions, which can be derived from the Wigner operator after a hierarchy of approximations.

The Single-Body Wigner Transport Equation

If one represents the state of a single-body quantum system by a wave-function $\psi(\mathbf{x}; t)$, it is possible to define the following transform:

$$f_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t) = \frac{1}{(\hbar\pi)^d}\int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x}'\psi^*(\mathbf{x}+\mathbf{x}'; t)\psi(\mathbf{x}-\mathbf{x}'; t)\mathrm{e}^{-\frac{2i}{\hbar}\mathbf{x}'\cdot\mathbf{p}}, \tag{43.5}$$

(where $d = 1, 2, 3$ is the dimension of the spatial domain). It can be shown that the function $f_{\mathrm{W}} = f_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t)$ is real but not positive definite [2]; therefore, it is not a distribution function

(since it should be positive definite to qualify as such). However, this function has a very interesting and convenient mathematical property: when integrated with respect to **p**, it returns the following quantity:

$$\int_{-\infty}^{+\infty} \mathrm{d}\mathbf{p} f_{\mathrm{W}}(\mathbf{x};\mathbf{p};t) = |\psi(\mathbf{x};t)|^2,$$

which represents the probability of finding a particle in a certain position. Moreover, when integrated with respect to **x**, it returns the probability for the particle to have a certain momentum, i.e.,

$$\int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x} f_{\mathrm{W}}(\mathbf{x};\mathbf{p};t) = \left| \int \mathrm{d}\mathbf{x} \psi(\mathbf{x};t) \mathrm{e}^{-\frac{i}{\hbar}\mathbf{x}\cdot\mathbf{p}} \right|^2.$$

Therefore, it is possible to calculate the space-dependent and space-independent expectation values, respectively $\bar{A}(\mathbf{x})$ and $< A >$, of any macroscopic variable defined as a function of coordinates and momenta $A = A(\mathbf{x};\mathbf{p})$, i.e.,

$$\bar{A}(\mathbf{x}) = \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{p} A(\mathbf{x};\mathbf{p}) f_{\mathrm{W}}(\mathbf{x};\mathbf{p};t), \tag{43.6}$$

and

$$< A >= \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x} \bar{A}(\mathbf{x}) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x}\mathrm{d}\mathbf{p} A(\mathbf{x};\mathbf{p}) f_{\mathrm{W}}(\mathbf{x};\mathbf{p}).$$

It immediately follows that, in practice, one can still use the function f_{W} for the calculation of the variables $< A >$ and $\bar{A}(\mathbf{x})$ of a given macroscopic function $A(\mathbf{x};\mathbf{p})$ in spite of the fact that the function f_{W} is a quasi-distribution function. The reader should note, though, that the quantity $f_{\mathrm{W}}(\mathbf{x};\mathbf{p};t)$ cannot be interpreted as a probability for position and momentum of a particle simultaneously.

Now, knowing that the dynamics of a wave-function $\psi(\mathbf{x};t)$ is given by Eq. (43.4), and by making use of definition (43.5), it becomes possible to derive the time-dependent evolution equation for the quasi-distribution function $f_{\mathrm{W}}(\mathbf{x};\mathbf{p};t)$. In fact, the time derivative of the function $f_{\mathrm{W}}(\mathbf{x};\mathbf{p};t)$ [2] reads

$$\begin{aligned}
&\frac{\partial f_{\mathrm{W}}}{\partial t}(\mathbf{x};\mathbf{p};t) \\
&= \frac{1}{(\hbar\pi)^d} \frac{\partial}{\partial t} \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x}' \psi^*(\mathbf{x}+\mathbf{x}';t)\psi(\mathbf{x}-\mathbf{x}';t)\mathrm{e}^{\frac{2i}{\hbar}\mathbf{x}'\cdot\mathbf{p}} \\
&= \frac{1}{(\hbar\pi)^d} \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x}' \mathrm{e}^{\frac{2i}{\hbar}\mathbf{x}'\cdot\mathbf{p}} \left[\frac{\partial \psi^*}{\partial t}(\mathbf{x}+\mathbf{x}';t)\psi(\mathbf{x}-\mathbf{x}';t) \right. \\
&\quad \left. + \psi^*(\mathbf{x}+\mathbf{x}';t) \frac{\partial \psi}{\partial t}(\mathbf{x}-\mathbf{x}';t) \right],
\end{aligned} \tag{43.7}$$

where

$$\begin{aligned}
&\frac{\partial \psi}{\partial t}(\mathbf{x}-\mathbf{x}';t) \\
&= \frac{1}{i\hbar} \left[-\frac{\hbar^2 \nabla^2_{\mathbf{x}} \psi(\mathbf{x}-\mathbf{x}';t)}{2m} + U(\mathbf{x}-\mathbf{x}';t)\psi(\mathbf{x}-\mathbf{x}';t) \right].
\end{aligned} \tag{43.8}$$

Moreover, by using the complex conjugate of (43.4) one readily obtains

$$\begin{aligned}
&\frac{\partial \psi^*}{\partial t}(\mathbf{x}+\mathbf{x}';t) \\
&= \frac{1}{i\hbar} \left[\frac{\hbar^2 \nabla^2_{\mathbf{x}} \psi^*(\mathbf{x}+\mathbf{x}';t)}{2m} - U(\mathbf{x}+\mathbf{x}';t)\psi^*(\mathbf{x}+\mathbf{x}';t) \right].
\end{aligned} \tag{43.9}$$

By substituting (43.8) and (43.9) into (43.7), replacing the differentiations with respect to **x** by differentiations with respect to $\mathbf{x}'$, and performing partial integrations for the terms containing the operator $\nabla^2_{\mathbf{x}}$, one obtains

$$\begin{aligned}
\frac{\partial f_{\mathrm{W}}}{\partial t}(\mathbf{x};\mathbf{p};t) &= \frac{1}{(\hbar\pi)^d} \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{x}' \mathrm{e}^{\frac{2i}{\hbar}\mathbf{x}'\cdot\mathbf{p}} \\
&\cdot \left\{ \frac{\mathbf{p}}{m} \left[-\nabla_{\mathbf{x}'} \psi^*(\mathbf{x}+\mathbf{x}';t)\psi(\mathbf{x}-\mathbf{x}';t) \right. \right. \\
&\quad \left. + \nabla_{\mathbf{x}'} \psi(\mathbf{x}-\mathbf{x}';t)\psi^*(\mathbf{x}+\mathbf{x}';t) \right] + \psi^*(\mathbf{x}+\mathbf{x}';t) \\
&\quad \left. \times \psi(\mathbf{x}-\mathbf{x}';t) \left[U(\mathbf{x}+\mathbf{x}';t) - U(\mathbf{x}-\mathbf{x}';t) \right] \right\}.
\end{aligned} \tag{43.10}$$

Finally, by replacing the differentiations with respect to $\mathbf{x}'$ back to **x**, one obtains the Wigner equation in the ballistic (collisionless) approximation:

$$\frac{\partial f_{\mathrm{W}}}{\partial t} + \frac{\mathbf{p}}{m} \cdot \nabla_{\mathbf{x}} f_{\mathrm{W}} = \int_{-\infty}^{+\infty} \mathrm{d}\mathbf{p}' V_{\mathrm{W}}(\mathbf{x};\mathbf{p}';t) f_{\mathrm{W}}(\mathbf{x};\mathbf{p}+\mathbf{p}';t), \tag{43.11}$$

with

$$\begin{aligned}
V_{\mathrm{W}}(\mathbf{x};\mathbf{p};t) &= \frac{i}{\pi^d \hbar^{d+1}} \int \mathrm{d}\mathbf{x}' \mathrm{e}^{-\left(\frac{i}{\hbar}\right)\mathbf{x}'\cdot\mathbf{p}} \\
&\quad \times \left[U\left(\mathbf{x}+\frac{\mathbf{x}'}{2};t\right) - U\left(\mathbf{x}-\frac{\mathbf{x}'}{2};t\right) \right],
\end{aligned} \tag{43.12}$$

known as the Wigner kernel, or potential, and where the function $U = U(\mathbf{x};t)$ can vary with time.

Equation (43.11) is known as the *Wigner equation*, or Wigner transport equation (WTE), and describes the dynamics of a single particle in the presence of an external potential expressed by the function $U(\mathbf{x};t)$. This equation will be the main focus of this chapter and has, in the phase-space formalism, the same place as the Schrödinger equation

(43.4) has in the standard formalism (in fact, they are mathematically equivalent). It represents a statistical approach to quantum mechanics, although not in a classical sense (f_W is not necessarily crypto-deterministic [5]). Moreover, in this rather different context, the emergence of classical mechanics can be easily explained [2].

Mixed States In practical experiments, one cannot always know which quantum state is being manipulated (e.g., in systems with a random preparation history). In this case, the pure state approach governed by Eq. (43.4) does not apply any longer, and the concept of density matrix becomes more suitable. It is possible to show, though, that the evolution equation for the Wigner function f_W remains unchanged. The interested reader is invited to read [6] for more details.

Scattering Effects: The Wigner-Boltzmann Transport Equation (WBTE)

The Wigner function approach allows to handle, in a natural way, open-boundary systems. Early works have investigated the theoretical and numerical properties of the coherent Wigner equation, appropriate for ballistic transport [7, 8]. However, in the real world of nanoelectronic devices, one cannot neglect the important role of decoherent and dissipative processes.

Dissipative interactions have been approached by means of phenomenological models based on the relaxation time approximation [9] and also by introducing an actual Boltzmann-like collision operator [10, 11]. It raised a fundamental question: Can the classical Boltzmann scattering operator and the quantum Wigner-potential operator reside in a common equation? The answer is not trivial: derivations from first principles and analysis of the assumptions and approximations have been provided only quite recently for interactions with ionized impurities [12] and with phonons [13], with two different approaches. The full derivation is beyond the scope of this chapter. We just summarized below the main steps.

Consider for instance the short-range Coulomb potential created by an ionized impurity $e^2 \exp(-\beta |\mathbf{r} - \mathbf{r}_i|)/4\pi E |\mathbf{r} - \mathbf{r}_i|$, where E is the semiconductor permittivity and β is the screening factor in the static screening approximation. The demonstration starts with the derivation of the Wigner potential associated with this Coulomb potential, from which a quantum evolution term is derived. After some tedious but straightforward calculations, considering a large number of dopants and within the fast collision approximation, the electron-impurity collision term finally takes exactly the same form as commonly derived for the Boltzmann collision operator with continuous doping density [14].

The semi-classical phonon collision is derived from the equation for the generalized Wigner function [15]. Along with the electron coordinates, the function depends on the occupation number of the phonon states in the system. We are actually interested in the electron, or reduced, Wigner function. It is obtained from the generalized Wigner function by a trace over the phonon coordinates. A closed equation for the reduced Wigner function can be derived after a hierarchy of approximations, which includes the weak scattering limit and assumes that the phonon system is in equilibrium [14]. The approximations only concern the interaction with phonons, while the potential operator remains exact. The Wigner-Boltzmann electron-phonon scattering operator is obtained after a classical limit in the phonon term, leading to the instantaneous and local Boltzmann operator.

It follows that, under some conditions, the collision term widely used in the Boltzmann transport equation (BTE) can also be used in the Wigner transport equation. It is a strong result and one of the main advantages of the Wigner function with regard to device modeling. All the knowledge acquired in the treatment of scattering in semi-classical transport can still be reused for quantum transport in the Wigner formalism. It makes it possible to study new problems such as scattering-induced decoherence and the transition from quantum to semi-classical transport regimes. The Wigner transport equation including the Boltzmann collision term is usually called the Wigner-Boltzmann transport equation (WBTE) [16]. As an extension of (43.11), it writes, finally

$$\frac{\partial f_W}{\partial t}(\mathbf{r}, \mathbf{p}, t) + \frac{\mathbf{p}}{m} \cdot \nabla_{\mathbf{x}} f_W(\mathbf{r}, \mathbf{p}, t) = Qf_W(\mathbf{r}, \mathbf{p}, t) + Cf_W(\mathbf{r}, \mathbf{p}, t) \tag{43.13}$$

where the Boltzmann collision term derives from the transition probabilities per unit of time $s_i(\mathbf{p}, \mathbf{p}')$ of each scattering process calculated in the first order perturbation theory of the Fermi golden rule [17], i.e.,

$$Cf_W(\mathbf{r}, \mathbf{p}, t) = \sum_i \int \mathrm{d}\mathbf{p}' \left[s_i(\mathbf{p}, \mathbf{p}') f_W(\mathbf{r}, \mathbf{p}', t) - s_i(\mathbf{p}', \mathbf{p}) f_W(\mathbf{r}, \mathbf{p}, t) \right]. \tag{43.14}$$

In the right hand side of (43.13), the quantum evolution term due to the potential U is given by

$$Qf_W(\mathbf{r}, \mathbf{p}, t) = \int \mathrm{d}\mathbf{p}' V_W(\mathbf{x}, \mathbf{p}', t) f_W(\mathbf{x}, \mathbf{p} + \mathbf{p}', t) \tag{43.15}$$

where the non-local effects of the potential appear in the Wigner potential V_W defined in (43.12).

This Wigner-Boltzmann approach of scattering cannot take into account quantum collision effects like collisional broadening and intra-collisional field effect related to the finite duration of the scattering processes. At this point, we should mention the Wigner paths method developed by Jacoboni's group at the University of Modena. This particle simulation technique makes it possible to go beyond the Wigner-Boltzmann equation since it can solve exactly

the Wigner equation without approximation on the electron/phonon coupling [15, 18–23]. It is based on the integral form of the Wigner equation and on a Neumann expansion of the Wigner function. Then, a subtle evolution of particle affinities and wave vectors is performed by following paths induced by the Wigner potential and phonon scattering. It is a rich tool for fundamental physics investigation but difficult to implement for device simulation.

Surprisingly, one of the most important results obtained using the Wigner paths technique is the fact that quantum collision effects play a reduced role inside devices, which tends to reinforce the validity of the Wigner-Boltzmann approach [24]. Indeed, the multiple collision processes tend to average the advanced effect of collisions, i.e., citing Bertoni: "multiple collisions reduce collisional broadening and contribute to understanding the success of the semiclassical approximation," which may explain the successful use of the Fermi golden rule beyond its expected theoretical limit.

43.3.2 The Many-Body Problem

We now introduce and discuss the time-dependent quantum many-body problem. At a first glance, the Wigner formulation does not seem to introduce any particular advantage over other approaches. In fact, the mathematics involved becomes incredibly complicated. Thanks to the Monte Carlo techniques nowadays available, though, this formalism brings a broad range of possibilities which would be hardly imaginable in other contexts.

We show now that one can define a many-body quasi-distribution function and that an evolution equation exists just as for the well-known single-body problem. For clarity, we first describe the problem in the Schrödinger formalism. Afterwards, we introduce the many-body Wigner equation. We conclude with a discussion on systems of indistinguishable particles in the phase space.

The dynamics of a system consisting of n interacting particles is described by a time-dependent Schrödinger equation similar to (43.4). The space of configurations now consists of the coordinates of n particles and reads

$$\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n), \tag{43.16}$$

where $\mathbf{x}_i = (x_i, y_i, z_i)$ are the spatial coordinates of the i-th particle, for $i = 1, 2, \ldots, n$, and the wave-function becomes a function of the n-body configuration space. Moreover, the many-body time-dependent Schrödinger equation reads

$$i\hbar \frac{\partial \psi}{\partial t}(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n; t) = \hat{H}\psi(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n; t), \tag{43.17}$$

where the Hamiltonian operator $\hat{H}$ reads

$$\begin{aligned}\hat{H} &= \hat{H}(\hat{\mathbf{x}}_1, \hat{\mathbf{x}}_2, \ldots, \hat{\mathbf{x}}_n; \hat{\mathbf{p}}_1, \hat{\mathbf{p}}_2, \ldots, \hat{\mathbf{p}}_n) \\ &= -\sum_{i=1}^{n} \frac{\hat{\mathbf{p}}_i^2}{2m} + U(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n; t),\end{aligned} \tag{43.18}$$

with $\hat{\mathbf{x}}_i = (\hat{x}_i, \hat{y}_i, \hat{z}_i)$ and $\hat{\mathbf{p}}_i = -i\hbar\nabla_i = -i\hbar\left(\frac{\partial}{\partial x_i}, \frac{\partial}{\partial y_i}, \frac{\partial}{\partial z_i}\right)$, the position and momentum operators for the i-th particle respectively.

43.3.3 The Many-Body Liouville von Neumann Equation

In order to describe the dynamics of a many-body system, the Liouville von Neumann equation is modified accordingly to take into account the new shape of the configuration space and thus reads

$$\begin{aligned}&\frac{\partial \rho}{\partial t}(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n) \\ &= \frac{1}{i\hbar}\left[H(\hat{\mathbf{x}}_1, \hat{\mathbf{x}}_2, \ldots, \hat{\mathbf{x}}_n; \hat{\mathbf{p}}_1, \hat{\mathbf{p}}_2, \ldots, \hat{\mathbf{p}}_n), \rho(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)\right],\end{aligned} \tag{43.19}$$

This can be considered as a generalization of the single-body Liouville von Neumann equation with the operator $\hat{H}$. It is important to note that, despite the mathematical structure of Eq. (43.19) is practically the same as the corresponding single-body equation, it is mathematically much more challenging, even when approached numerically. The same difficulty applies to the many-body Schrödinger equation. In fact, both models are defined over a $(n \cdot d)-$dimensional configuration space.

The Many-Body Wigner Equation

In the Wigner formulation as well, it is possible to follow the dynamics of a quantum system consisting of n interacting particles (or bodies) by means of a quasi-distribution function $f_W = f_W(\mathbf{x}; \mathbf{p}; t)$, where the phase space is now a $2 \cdot n \cdot d-$dimensional space $(\mathbf{x}; \mathbf{p}) = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n; \mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_n)$, and where $\mathbf{x}_i$ and $\mathbf{p}_i$ have the usual meaning. In the same way, it is possible to define the Wigner quasi-distribution function for the pure and mixed quantum states of a system of n particles. Indeed, the pure state Wigner function now reads:

$$\begin{aligned}f_W(\mathbf{x}; \mathbf{p}; t) = \frac{1}{(\hbar\pi)^{d \cdot n}} \int d\mathbf{x}' e^{-\frac{i}{\hbar}\sum_{k=1}^{n} \mathbf{x}'_k \cdot \mathbf{p}_k} \\ \times \Psi\left(\mathbf{x} + \frac{\mathbf{x}'}{2}; t\right) \Psi^*\left(\mathbf{x} - \frac{\mathbf{x}'}{2}; t\right),\end{aligned} \tag{43.20}$$

where $\Psi = \Psi(\mathbf{x}; t)$ is a Schrödinger many-body pure state, $\int d\mathbf{x}' = \int d\mathbf{x}'_1 \int d\mathbf{x}'_2 \ldots \int d\mathbf{x}'_n$, and $(\mathbf{x} \pm \frac{\mathbf{x}'}{2}) = (\mathbf{x}_1 \pm \frac{\mathbf{x}'_1}{2}, \mathbf{x}_2 \pm$

$\frac{\mathbf{x}'_2}{2}, \ldots, \mathbf{x}_n \pm \frac{\mathbf{x}'_n}{2}; t)$. Analogously, a definition can be given in the case of mixed states described by a many-body density matrix $\rho = \rho(\mathbf{x}; \mathbf{y}; t)$

$$f_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t) = \frac{1}{(\hbar\pi)^{d\cdot n}} \int \mathrm{d}\mathbf{x}' \mathrm{e}^{-\frac{i}{\hbar}\sum_{k=1}^{n} \mathbf{x}'_k \cdot \mathbf{p}_k} \rho\left(\mathbf{x} + \frac{\mathbf{x}'}{2}; \mathbf{x} - \frac{\mathbf{x}'}{2}; t\right). \tag{43.21}$$

If one applies the mathematical transform (43.20) to the many-body Schrödinger equation (43.17), one easily obtains the corresponding time-dependent many-body Wigner equation:

$$\frac{\partial f_{\mathrm{W}}}{\partial t}(\mathbf{x}; \mathbf{p}; t) + \sum_{k=1}^{n} \frac{\mathbf{p}_k}{m_k} \cdot \nabla_{\mathbf{x}_k} f_{\mathrm{W}} = \int \mathrm{d}\mathbf{p} f_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t) V_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t), \tag{43.22}$$

where $\int \mathrm{d}\mathbf{p} = \int \mathrm{d}\mathbf{p}_1 \int \mathrm{d}\mathbf{p}_2 \ldots \int \mathrm{d}\mathbf{p}_n$, m_k is the mass of the k-th particle, or body, and the many-body Wigner kernel $V_{\mathrm{W}} = V_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t)$ now reads

$$V_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t) = \frac{i}{\pi^{dn}\hbar^{dn+1}} \int \mathrm{d}\mathbf{x}' \mathrm{e}^{-\left(\frac{2i}{\hbar}\right)\sum_{k=1}^{n} \mathbf{x}'_k \cdot \mathbf{p}_k} \times \left[U(\mathbf{x} + \frac{\mathbf{x}'}{2}; t) - U(\mathbf{x} + \frac{\mathbf{x}'}{2}; t)\right]. \tag{43.23}$$

The function $U = U(\mathbf{x}; t) = U(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ represents the potential acting over the n bodies and, in general, it can vary in time.

Indistinguishable Fermions

A very interesting case consists of systems made of *indistinguishable Fermions*. In this section, we follow the work of Schram et al. [6]. Previously, we have shown that by applying the transform (43.21) to the many-body Liouville von Neumann equation (43.19), it is possible to obtain the many-body Wigner equation (43.22). The reader should note that no assumption has been made on the symmetry properties of the system [6].

Now, in the standard formalism, indistinguishable Fermions are described by antisymmetric wave-functions, which reads

$$\Psi(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_i, \ldots, \mathbf{x}_j, \ldots, \mathbf{x}_n; t) = -\Psi(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_j, \ldots, \mathbf{x}_i, \ldots, \mathbf{x}_n; t), \tag{43.24}$$

and, by taking into account the antisymmetric nature of the system, it is possible to define a (many-body) Weyl map for Fermions

$$f^{-}_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t) = \frac{1}{(\hbar\pi)^{d\cdot n}} \int \mathrm{d}\mathbf{x}' \mathrm{e}^{-\frac{i}{\hbar}\sum_{k=1}^{n} \mathbf{x}'_k \cdot \mathbf{p}_k} \times \Psi^{-}\left(\mathbf{x}_1 + \frac{\mathbf{x}'_1}{2}, \ldots, \mathbf{x}_n + \frac{\mathbf{x}'_n}{2}; t\right) \times \Psi^{-*}\left(\mathbf{x}_1 - \frac{\mathbf{x}'_1}{2}, \ldots, \mathbf{x}_n - \frac{\mathbf{x}'_n}{2}; t\right), \tag{43.25}$$

(the case for mixed states is similarly obtained in [6]). One can, thus, show that the many-body Wigner equation for indistinguishable Fermions is, again, Eq. (43.22) [6, 25]. This readily comes from the application of the transform (43.21)–(43.19) which does not depend on the symmetry of the system. Therefore, this proves that the Wigner formalism is already adapted to treat the case of antisymmetric systems [6]. This means, in particular, that the Pauli exclusion principle is directly embedded into the Wigner formalism without any *ad hoc* trick.

Consequently, the antisymmetric properties of a quantum system are defined through its initial conditions. In practice, when in presence of Fermions, one starts from a Slater determinant at time $t = 0$:

$$\Psi^{-}(\mathbf{x}_1, \ldots, \mathbf{x}_n) = \frac{1}{\sqrt{n!}} \begin{vmatrix} \phi_1(\mathbf{x}_1) & \phi_2(\mathbf{x}_1) & \ldots & \phi_n(\mathbf{x}_1) \\ \phi_1(\mathbf{x}_2) & \phi_2(\mathbf{x}_2) & \ldots & \phi_n(\mathbf{x}_2) \\ \ldots & \ldots & \ldots & \ldots \\ \phi_1(\mathbf{x}_n) & \phi_2(\mathbf{x}_n) & \ldots & \phi_n(\mathbf{x}_n) \end{vmatrix}. \tag{43.26}$$

It can be shown that this is equivalent to express the initial Wigner function as a sum of reduced single-particle Wigner functions and a number of integral terms [26, 27]. This process couples the involved Fermions together, in agreement with the fact that the corresponding initial Wigner function cannot be expressed as multiplications of independent wave packets.

43.3.4 The Moyal Mathematical Formalization

An important contribution to put the Wigner approach on solid mathematical foundations came from J. Moyal in 1949 who published a brilliant work on whether the phase-space approach was a proper statistical theory. In this attempt, he managed to merge the works of E. Wigner [2], J. von Neumann [28], H. Weyl [29], and H. Groenewold [30] in an elegant and firm mathematical framework [5]. In turn, this provides a way to connect classical mechanics to quantum mechanics, allowing a natural comparison between these very different theories. Furthermore, this work allows to avoid the use of operators for observables, a concept which, somehow, has always puzzled physicists. Below, we introduce the theory for the one-dimensional space, being the generalization to higher-dimensional spaces trivial.

43.3.5 The Weyl Map and the Equations of Motion

The Weyl map M_{W}, also known as the Wigner-Weyl transform, represents a fundamental mathematical tool in this context. It essentially is an isomorphism from the space of linear operators $\hat{A}$ to the space of functions $A(x; p)$ provided with a product $\cdot$ and a commutator $[.,.]$ defined over the phase space with a non-commutative product $*$, known as the Groenewold product [30], and bracket $[.,.]_{\mathrm{M}}$, known as the Moyal bracket [5]:

$$\left(\hat{A}\left(\hat{x};\hat{p}\right), \cdot, [.,.]\right) \rightarrow \left(A(x;p), *, [.,.]_{\mathrm{M}}\right).$$

Given a quantum operator $\hat{A} = \hat{A}\left(\hat{x};\hat{p}\right)$, expressed in terms of the position and momentum operators $\hat{x}$ and $\hat{p}$, the Weyl map is mathematically defined as

$$M_{\mathrm{W}}\left(\hat{A}\right)(x;p) = A(x;p) = \frac{\hbar}{2\pi}\int \mathrm{d}\xi \int \mathrm{d}\eta \mathrm{Tr}\left[\hat{A}\left(\hat{x};\hat{p}\right)\mathrm{e}^{i(\xi\hat{x}+\eta\hat{p})}\right]\mathrm{e}^{-i(\xi x+\eta p)}, \tag{43.27}$$

where Tr[.] is the trace of an operator and the exponential of an operator is defined as $e^{\hat{X}} = \sum_{l=0}^{+\infty}\frac{1}{l!}\hat{X}^l$. The Wigner mapping is invertible [31]. The Groenewold $*$-product and Moyal bracket $[.,.]$ can be defined in terms of the Weyl map: given two operators $\hat{A}$ and $\hat{B}$ which corresponding Weyl transforms are the functions $A = A(x; p)$ and $B = B(x; p)$ one has:

$$A * B = M_{\mathrm{W}}\left(\hat{A},\hat{B}\right) \tag{43.28}$$

$$[A,B]_{\mathrm{M}} = \frac{1}{i\hbar}(A*B - B*A) = \frac{1}{i\hbar}M_{\mathrm{W}}\left(\left[\hat{A},\hat{B}\right]\right). \tag{43.29}$$

According to the above mathematical definitions, the Wigner quasi-distribution function can now be defined as the Weyl transform of the density matrix operator multiplied by a normalization factor; in other words,

$$f_{\mathrm{W}}(x;p;t) = \frac{1}{2\pi\hbar}M_{\mathrm{W}}\left(\hat{\rho}(t)\right). \tag{43.30}$$

In the case of pure states, one can show that [31]

$$f_{\mathrm{W}}(x;p;t) = \frac{1}{2\pi}\int \mathrm{d}y\psi^*\left(x+\frac{\hbar y}{2};t\right)\psi\left(x-\frac{\hbar y}{2};t\right)\mathrm{e}^{-iyp} = \frac{1}{\hbar\pi}\int \mathrm{d}x'\psi^*(x+x';t)\psi(x-x';t)\mathrm{e}^{-\frac{2i}{\hbar}x'\cdot p},$$

which is equivalent to formula (43.5). As expected, one can show that the function $f_{\mathrm{W}}(x; p; t)$ is square integrable, normalized, and real, but not positive defined.

The Evolution Equations One can now obtain the time-dependent evolution equation for the Wigner function $f_{\mathrm{W}}(x; p; t)$. By supposing that the wave-function $\psi(x; t)$ is a solution of the Schrödinger equation (43.4), one can show that the function f_{W} obeys the following evolution equation:

$$\frac{\partial f_{\mathrm{W}}(x;p;t)}{\partial t} = [H, f_{\mathrm{W}}(x;p;t)]_{\mathrm{M}}, \tag{43.31}$$

which corresponds to the single-body Wigner equation in the Moyal formalism, and it is equivalent to Eq. (43.11). In this formulation of quantum mechanics, this is the equivalent to the time-dependent Schrödinger equation (43.4).

43.3.6 Admissible States in Phase Space

More recently, Tatarskii [7] and Dias and Prata [31] have provided a mathematically and physically sound definition of admissible states in the phase-space formulation of quantum mechanics, along with their conditions and properties for both pure and mixed states. This helps to define what properties a phase-space function must have in order to be a valid description of a quantum state. It also shows that the Wigner formalism can be defined completely independently from the Schrödinger formulation.

43.4 Monte Carlo Methods to Simulate the Single-Body Wigner Equation

Monte Carlo methods provide approximations of the solution of a given computational problem by exploiting random processes. In other words, such methods are capable of computing statistical estimates for any linear functional of the solution by performing random sampling of a certain random variable whose mathematical expectation is the desired functional [32]. In practice, this class of numerical methods reduces a given problem to the approximation of some mathematical expectation. They are well known to represent powerful tools when it comes to solve problems in mathematics, physics, and engineering where the deterministic methods hopelessly break down since their strength consists in not requiring any additional regularity of the solution. Moreover, it is always possible to control the accuracy of the solution in terms of the probability error, a very important feature to control the correctness of a solution. Another important advantage of these methods consists in their high efficiency in dealing with very large computational problems such as multidimensional integration, very large linear systems, partial integro-differential equations in highly dimensional spaces, etc. Finally, they are extremely efficient on parallel processors and parallel machines, a very interesting feature

due to the availability of modern hardware such as multi-core CPUs and GPUs.

The year 1949 is generally considered to be the official birthday of the Monte Carlo method in the Physics community [33], but it is fair to note that much earlier applications can be found in the scientific literature; see, for example, the work of the French mathematician Georges-Louis Leclerc in 1777 (L'aiguille de Buffon, the Buffon's needle) [34]. As pointed out by Marquis Pierre-Simon de Laplace in 1886, his approach can be utilized to compute the value of the number π, in other words the first Monte Carlo method to evaluate the number π. With the advent of modern computational resources based on electronics, intensive applications eventually started to be developed in the context of the Manhattan project (Los Alamos, USA), by J. von Neumann, E. Fermi, G. Kahn, and S.M. Ulam. The legend says that the name *Monte Carlo* was eventually suggested by N. Metropolis in honor of Ulam's uncle who was a well-known gambler. Nowadays, Monte Carlo algorithms exist to solve a plethora of different computational problems, and it would be practically impossible to specify an even barely complete list.

Nowadays, Monte Carlo methods can be divided into two main classes: (1) Monte Carlo simulations and (2) Monte Carlo numerical methods. The first one represents a class of algorithms which directly simulate physical processes by miming the corresponding physical laws, e.g., the very well-known Boltzmann Monte Carlo method for the simulation of electron transport in semiconductor devices [35]. The second class, instead, exploits stochastic numerical algorithms for the resolution of computational problems such as linear systems, eigenproblems, evaluation of multidimensional integrals, etc. and does not represent the focus of this chapter. The interested reader is invited to refer to works such as [36].

It should be mentioned that some works dedicated to the direct solution of the Wigner or Wigner-Boltzmann equation for device simulation have been successfully achieved, but either using the ballistic approximation [37], using a simplified relaxation time approximation to incorporate scattering [38], or using a more rigorous Boltzmann collision operator but limited to elastic acoustic phonon scattering and surface roughness scattering [39].

In this section, we focus on two different Monte Carlo methods for the time-dependent solution of the Wigner equation. Recently, several techniques to solve this very complex problem have been suggested, developed, and validated very successfully, one being based on the concept of *particle quantum affinity* [40–43] (inspired by the pioneering works [44, 45]) and the other being based on the concept of *signed particles* [46, 47]. Their equivalence has been investigated in [48] and is out of the scope of this chapter.

As for the subject of Sects. 43.4.1, 43.4.2, 43.4.3, and 43.4.4, the interested reader may find a more extended treatment in [43], pp. 71–86.

43.4.1 The Affinity Method

Principles This method is actually strongly inspired by, and extrapolated from, the traditional Monte Carlo method for solving the Boltzmann transport equation (BTE) that proved to be very efficient in simulating semiconductor devices. In the case of the single-body BTE, classical particles are simply described as Dirac excitations of the form

$$f_j(\mathbf{r}, \mathbf{p}, t) = \delta(\mathbf{r} - \mathbf{r}_j)\delta(\mathbf{p} - \mathbf{p}_j), \tag{43.32}$$

and the Boltzmann distribution function is just a sum of such particles.

Since it can take negative values, it may look nonsensical to represent the Wigner function with particles which cannot have a "negative presence." Classically, electrons either do or do not exist. To solve this apparent inconsistency with a view to developing a statistical particle approach to the solution of the WTE or the WBTE, it is necessary to give simulated particles the strange property to carry negative contributions. With this in mind, it has been suggested that the Wigner function be described as a sum of Dirac excitations of the form [41]

$$f_j(\mathbf{r}, \mathbf{p}, t) = \delta(\mathbf{r} - \mathbf{r}_j)\delta(\mathbf{p} - \mathbf{p}_j)A_j(t) \tag{43.33}$$

which are still localized in the phase space but weighted by an amplitude, usually called "affinity." This amplitude was not necessary to consider for the solution of the BTE since the Boltzmann function is always positive, but it is required to reconstruct the Wigner function which can take negative values. Accordingly, this amplitude may be negative too. The particle amplitudes will contain all the information on the quantum state of the electron system. Consistently with the Heisenberg inequalities, such excitations, which we will call pseudo-particles, cannot represent physical particles. They are just to be considered as mathematical tools for the solution of the WBTE. The advantage of this formulation is that the evolution of these excitations follows simple equations. In the signed particle technique, the affinity can just take integer values, either $+1$ or -1, but in the present "affinity" approach, it can take real values and evolves continuously. In this approach, initially suggested by Shifren, Ringhofer, and Ferry [49], the interpretation of the quantum evolution term is different from that of the signed particle technique. This term does not generate here some events determined by an MC technique, but it is considered to act continuously on the particle affinity at each time step. Only the collision term is assumed to generate random events, as in Boltzmann simulation.

43.4.2 Affinity Evolution and Monte Carlo Algorithm

The method is thus very similar to the Boltzmann Monte Carlo technique [17]. The main change consists in adding at each time step the update of the Wigner function and of the particle affinities. In a mesh of the phase-space $M(x, k)$, the quantum evolution term Qf_{W}, i.e., the right-hand side of the Wigner equation (43.11), induces the change of the affinity of particles in the mesh according to

$$\sum_{i\in M(x,p)} \frac{\mathrm{d}A_i}{\mathrm{d}t} = Qf_{\mathrm{W}}(x,p) = \int \mathrm{d}p' V_{\mathrm{W}}(x,p',t) f_{\mathrm{W}}(x,p-p',t), \tag{43.34}$$

which means that at each time step the affinity of all pseudo-particles in a mesh of the phase space is updated as a function of Qf_{W}. The simple idea on which is based this quantum Monte Carlo simulation now appears clearly. During a time step, the real and momentum space coordinates of pseudo-particles evolve as in conventional MC simulation. In other words, if the potential has been separated in slowly and rapidly varying parts, i.e., $U(\mathbf{r}) = U_{\mathrm{slow}}(\mathbf{r}) + U_{\mathrm{rapid}}(\mathbf{r})$ the coordinates of the j-th obey, in the effective mass approximation,

$$\begin{aligned} \frac{\mathrm{d}\mathbf{r}_j}{\mathrm{d}t} &= \frac{\mathbf{p}_j}{m} \\ \frac{\mathrm{d}\mathbf{p}_j}{\mathrm{d}t} &= -\nabla_{\mathbf{r}} U_{\mathrm{slow}}(\mathbf{r}) \end{aligned} \tag{43.35}$$

If the whole potential is included in the quantum evolution term, i.e., $U_{\mathrm{slow}}(\mathbf{r}) = 0$, the momentum of each particle is constant during a free flight and can take a new value only after scattering.

In the semi-classical limit, i.e., if the full potential is treated as a slowly varying quantity $U(\mathbf{r}) = U_{\mathrm{slow}}(\mathbf{r})$, the quantum evolution term Qf_{W} is zero, and the particle affinity is constant. The method turns out to be equivalent to the semi-classical Monte Carlo simulation. It should be noted that the strong similarity and even compatibility of this technique with the conventional MC solution of the BTE is one of its highest advantage. In summary, the Monte Carlo technique for solving the WBTE consists here of describing statistically the motion of each pseudo-particle as a succession of free flights interrupted by instantaneous scattering events. Prior to the simulation, the scattering rates are evaluated as function of energy and stored in a lookup table. The duration of free flights is randomly selected from the total scattering rate. The computation of free-flight duration is simplified by introducing a fictitious "self-scattering," the rate of which is adjusted to make the total scattering rate energy-independent. During a free flight the particle coordinates evolve according to classical laws (43.35), while its affinity is adjusted according to (43.34). At the end of a free flight, the scattering process responsible for the free flight interruption is randomly selected on the basis of the scattering rate of each possible mechanism according to the carrier state. Once the scattering mechanism is known, the final state can be selected according to the angular dependence of the scattering rate. The details of the derivation of various types of scattering rates in the first-order perturbation theory and of the random selection procedure may be found in many textbooks, e.g., in [17, 50].

In the case of device simulation self-consistently coupled to Poisson's equation, the ensemble Monte Carlo simulation consists of simultaneously simulating the time behavior of a large number of particles during very small time steps (typically 0.1–10.0 femtoseconds (fs) depending on the timescales of relevant phenomena, such as the dielectric relaxation time and plasma frequency). The Poisson equation is solved at the end of each time step with updated carrier density distribution and, possibly, new electrostatic potential at contacts. The Wigner kernel and the quantum evolution term Qf_{W} are updated as well.

43.4.3 Conservation of Affinity and Pseudo-Particle Injection

One of the most important difficulties in this MC method lies in the fact that even a particle with zero affinity may gain finite affinity through the quantum evolution term Qf_{W} according to (43.34). It means that if there is no particle in a particular region of the phase space where the affinity should evolve, a significant error may occur with possible non-conservation of charge since the contribution of each particle to the total charge in the device is weighted by its affinity. This problem is very important for device simulation and should be fixed by implementing an appropriate algorithm to inject particles of convenient affinity.

The technique proposed in [51] has proved to give good results. It can be described as follows. After each time step, the quantum evolution term $Qf_{\mathrm{W}}(\mathbf{x}, \mathbf{p})$ is calculated in the full phase space. If in a mesh $M(\mathbf{x}, \mathbf{k})$ of the phase space, even inside the device, the quantity $|Qf_{\mathrm{W}}(\mathbf{x}, \mathbf{p})|$ is finite, or greater than a threshold value, a pseudo-particle of zero affinity is injected in the mesh.

This injection procedure must come in addition to the injection of particles at Ohmic contacts, as commonly done in semi-classical device simulation, for which the only condition of particle injection is the neutrality of real-space cells adjacent to the Ohmic contacts. After each time step, if particles are missing in some "Ohmic" cells with respect to the charge neutrality, the appropriate number of carriers (of affinity equal to 1) is injected in these cells to recover the neutrality. Assuming these "Ohmic" regions to be in

thermal equilibrium, an equilibrium distribution is used to randomly select their momentum components. In this way, the consistence between the distribution of potential and the average number and distribution of particles in the device is reached. Obviously, this condition of particle injection should still be used in quantum simulation of Ohmic contacts within the Wigner equation if the transport in the contact region is assumed to be essentially semi-classical.

In summary, in the case of WBTE simulation, it is necessary to combine the "semi-classical injection" of particles of 1 affinity at Ohmic contacts to guarantee the electrical neutrality near the contacts and the "quantum injection" of pseudo-particles of 0 affinity in all regions of the phase space where particles are missing and Qf_W takes significant values. Though it works well, the disadvantage of this "quantum injection" is that it is demanding in terms of CPU time, because of the large number of pseudo-particles required to fill the phase space for a good evaluation of the Wigner function.

Other numerical issues regarding the discretization schemes and the calculation of the Wigner kernel must be carefully considered. They are beyond the scope of this book chapter but are discussed in details in [43]. Additionally, important considerations regarding the boundary conditions [52,53] and the way to carefully incorporate scattering in the Wigner formalism [54,55] have been recently discussed.

43.4.4 Basic Validation for Typical Cases

It has been verified that this affinity technique of Wigner MC simulation is able to reproduce quantum mechanical effects accurately. It consisted in simulating the interaction of a ballistic Gaussian wave packet with a tunnel barrier, without any scattering term [43]. Such a simple situation without collision term can be solved easily from the time-dependent Schrödinger equation. In the probability density plotted in Fig. 43.1, a good agreement is shown between the particle approach of the WTE and the solution of the Schrödinger equation at time $t = 80$ ps after the starting of the interaction, when we see clearly the separation between transmitted and reflected wave packets. In particular, the oscillations of the wave-function are very well reproduced. This shows that the method can accurately model the existence of space correlations and interferences. However, it should be noted that some particle noise inherent in the method remains visible.

It has been shown also that semi-classical transport can be very well reproduced by using the quantum evolution term Qf_W to describe the effect of a slowly variable potential. A simple GaAs $N^+/N/N^+$ structure was considered, with N^+ regions doped to $10^{18}\,cm^{-3}$ and the 50 nm-long central region doped to $10^{16}\,cm^{-3}$. No quantum effects are expected to occur in such a structure. The conduction band structure

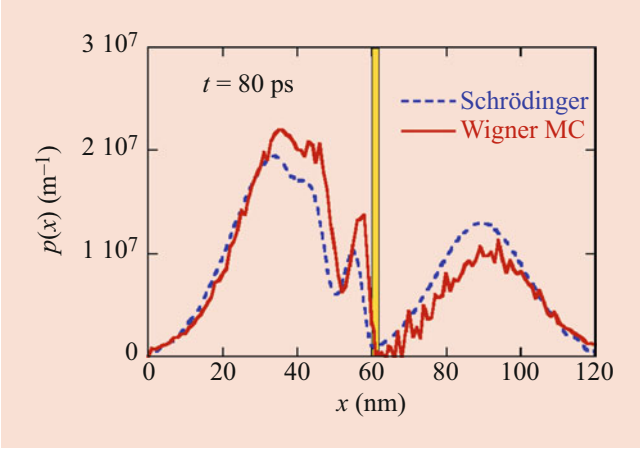

Fig. 43.1 Probability density resulting from the coherent interaction of a wave packet coming from the left with a square tunneling barrier at $t = 80$ ps after the starting of interaction, obtained from both Schrödinger equation and Wigner Monte Carlo simulation

was limited to the Γ valley with an effective mass of 0.6 m_0. The scattering mechanisms included in the collision term of the transport equation were interactions with acoustic phonons, polar optical phonons, and ionized impurities, at room temperature. The transport simulation was self-consistently coupled with the 1D Poisson equation. It was performed using both the semi-classical and the quantum MC models. In the latter case, the Poisson potential was fully included in the quantum evolution term, which means that the electron momentum is constant during free flights and may change only when the electron is scattered by a phonon or an impurity. After each time step, the Wigner potential associated with the Poisson potential is recalculated, and the affinity of particles is updated according to (43.34).

As expected, the I-V characteristics plotted in Fig. 43.2 are identical for semi-classical and quantum treatment of the potential. The results are superimposed on three orders of magnitude of current and voltage. It clearly shows that in semi-classical situation, i.e., for slowly varying potential, the semi-classical evolution of momentums and the quantum evolution of affinities are fully equivalent, though these two treatments are mathematically strongly different.

43.4.5 Application of the Affinity Method to Electronic Devices: The Resonant Tunneling Diode

Conveniently, coupled to the 1D or 2D Poisson equation within a self-consistent procedure, the affinity method described in Sect. 43.4.1 for solving the Wigner-Boltzmann transport equation has been successfully applied to a wide range of nanoelectronic devices or quantum problems, like the resonant tunneling diode (RTD) [51,56], silicon double-

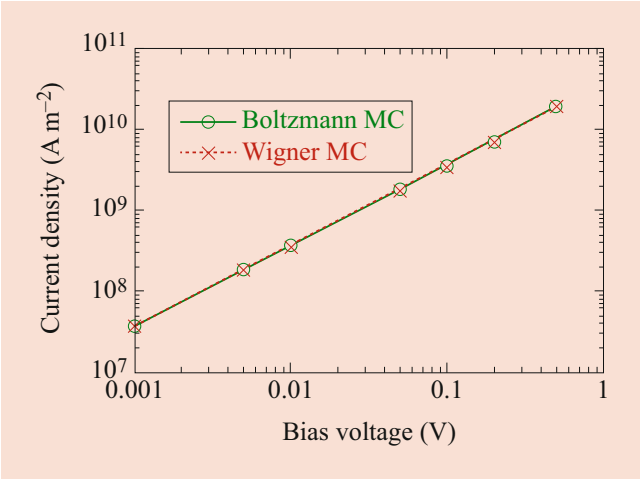

Fig. 43.2 Current-voltage characteristics for a 50 nm/50 nm/50 nm $N^+/N/N^+$ GaAs structure using semi-classical and quantum Wigner Monte Carlo simulation, including phonon and ionized impurity scattering. (After [43], with permission from Querlioz and Dollfus)

gate MOSFET [57, 58], the CNT-FET [59], GaAs/GaAlAs superlattices [60], or the phonon-induced decoherence effects [61].

Here, we restrict the discussion to the RTD that is certainly the simplest device operating at room temperature in which the wave-like behavior of electrons plays a prominent role. The operation of this device is based on the control of tunneling through the resonant state of a quantum well, e.g., GaAs, coupled to two leads via tunnel barriers, e.g., AlGaAs [62]. It results in a negative differential resistance (NDR) in the I-V characteristics. After the first experimental demonstration of this behavior at low temperature [63] and at room temperature [64], the RTD has been the subject of intense research both for its high potential of applications and for fundamental quantum device physics.

The NDR of the I-V characteristics may be used indeed for many electronic applications indeed [65], and for most of them, the peak-to-valley ratio (PVR) IP/IV of this characteristics is an important figure of merit. The RTD is often made of a GaAs quantum well with AlGaAs tunnel barriers, but other materials offering higher tunnel barriers, e.g., InGaAs or InAs quantum well between AlAs barriers, may be used to enhance the PVR up to 14 or even 30 at room temperature [66, 67]. Another important feature of the RTD comes from the very short lifetime of the quasi-bound states, which is the typical time constant associated with the operation of this tunneling device. If other transit times and parasitics are well controlled, the RTD may potentially operate in the THz regime.

Some typical results obtained on this device are presented here and we briefly discuss the physics of decoherence induced by electron-phonon scattering.

43.4.6 Electrical Characteristics

The simulated GaAs/GaAlAs RTD consists of a 5 nm-thick quantum well sandwiched between two AlGaAs barriers 0.3 eV high and 3 nm wide (Fig. 43.3). The quantum well, the barriers, and 9.5 nm-thick buffer regions surrounding the barriers are slightly doped to $10^{16}\,\mathrm{cm}^{-3}$. The 50 nm-long access regions are doped to $10^{18}\,\mathrm{cm}^{-3}$. Simulation was made at room temperature, including scattering with polar optical phonons, acoustic phonons and ionized impurities, for a single Γ valley with effective mass of 0.06 m_0. The Wigner-Boltzmann Monte Carlo (WBMC) algorithm was self-consistently coupled with the 1D Poisson equation.

In the current-voltage characteristics plotted in Fig. 43.4, the result obtained by including scattering (circles, solid line) is compared with that obtained from ballistic simulation, i.e., with scattering mechanisms artificially deactivated (squares, solid line). The curve obtained with scattering rates artificially multiplied by 5 (diamonds, dashed line) will be considered later, in the study of decoherence. It is clearly shown here that scattering effects significantly reduce the peak-to-valley ratio. We observe both a reduction of the peak current and an enhancement of the valley current. The latter effect is expected. In the valley regime where the coherent current is small, scattering induces an additional uncoherent path that generates an additional contribution to the current. In resonance (peak current) regime, when scattering is included a potential drop appears in the emitter region while the conduction band is flat in the ballistic case (see Fig. 43.5). This potential drop and the effect of inelastic scattering tend to induce an energy spreading of electrons, which reduces the fraction of electrons satisfying the resonant condition through the double barrier. It thus contributes to the suppression of current peak at the resonance, as observed in Fig. 43.4. It is thus essential to properly consider scattering mechanisms and self-consistence for room-temperature simulation of RTDs.

It should be noted that the peak-to-valley ratio obtained from such simulation for typical GaAlAs/GaAs RTDs at room temperature and 77 K has been found in good agreement with experimental data [51], which suggests this MC technique is actually able to provide realistic results for nanodevices exhibiting quantum transport effects with significant rates of scattering.

It is very instructive to examine the phase-space cartography of the Wigner function displayed in Fig. 43.6. Near the contacts, i.e., for $x < 40$ nm and $x > 120$ nm, the Wigner function appears to be very close to a displaced Maxwellian function, which is the signature of semi-classical transport regime in these regions. In contrast, the situation is very different in the quantum well. For the resonant state, i.e., $V = 0.3$ V (Fig. 43.6a), we can see between the barriers (schematized by vertical dashed lines) a peak (a spot) centered on $k =$

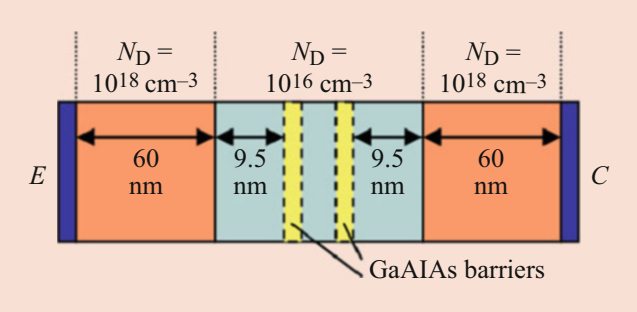

Fig. 43.3 Schematic cross-section of the simulated resonant tunneling diode. The GaAlAs barriers and the GaAs quantum well are 3 nm- and 5 nm-thick, respectively. (After [43], with permission from Querlioz and Dollfus)

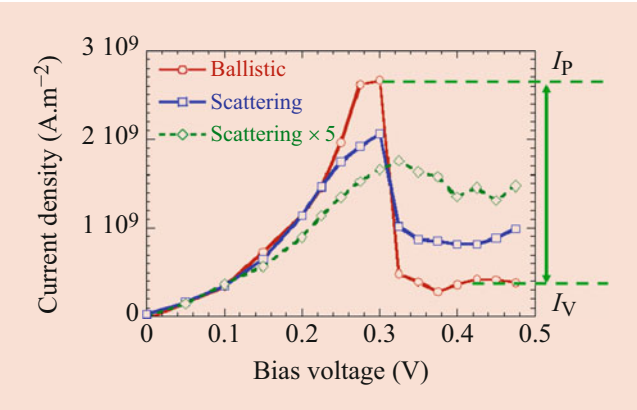

Fig. 43.4 I-V characteristics for the RTD obtained from WBMC simulation, with scattering artificially deactivated (circles), with standard scattering (squares), and with scattering rates artificially multiplied by 5 (diamonds). (After [43], with permission from Querlioz and Dollfus)

0 similar to that obtained for the Wigner function associated with the first energy level of a square quantum well. This peak is due to the contribution of electrons crossing the double-barrier through the resonant state in the well. For a non-resonant state (Fig. 43.6b), this peak vanishes and becomes almost invisible. It should also be noted that, in both cases, the oscillations of the Wigner function give rise to negative values in small regions of the phase space (dark blue areas), which is the signature of quantum coherence.

43.4.7 Decoherence and Quantum/ Semiclassical Transition

Let us come back to Fig. 43.6a that shows the Wigner function of the RTD operating at peak voltage ($V = 0.3$ V). In a large part of access regions ($x < 30$ nm and $x > 120$ nm), the transport is essentially semi-classical, and the Wigner function matches very well a semi-classical distribution function represented by a displaced Maxwellian function. In the

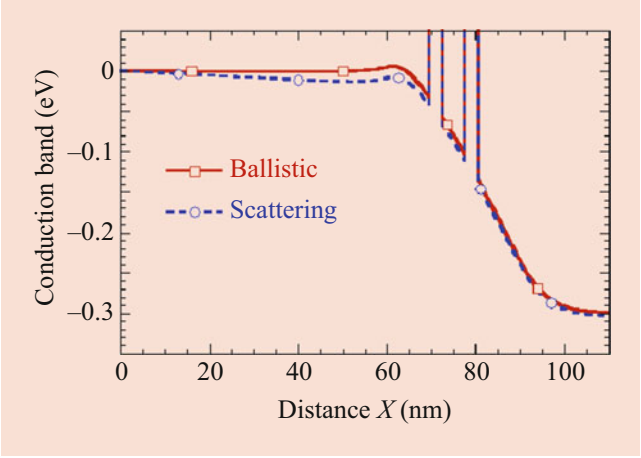

Fig. 43.5 Conduction band profile obtained by Wigner simulation, at resonance ($V = 0.3$ V), from either ballistic simulation (solid line) or including scattering (dashed line). (After [43], with permission from Querlioz and Dollfus)

overall active region of the device, oscillations of the Wigner function reveal the presence of spatial coherence. Hence, there is apparently a transition between coherent quantum and semi-classical regions within the device. To understand better this behavior and the de-coherence effect, it is insightful to analyze the density matrix (obtained by inverse Fourier transform of the Wigner function) for different strengths of electron-phonon scattering.

Accordingly, the density matrix is displayed in Fig. 43.7a–c for the same scattering situations, as in the I-V characteristics of Fig. 43.4. In Fig. 43.7a, the transport is fully ballistic in the active region, i.e., phonon scattering has been artificially switched off. In Fig. 43.7b, standard scattering rates were used as for the Wigner function plotted in Fig. 43.6. In Fig. 43.7c, phonon scattering rates have been artificially multiplied by five.

In Fig. 43.7a (ballistic case), a strong coherence is observed between electrons in the quantum well and in the emitter region. The amplitude of all off-diagonal elements is significant, even between collector and emitter regions, which is a clear indication of a fully coherent system. When considering standard scattering rates, the off-diagonal elements strongly reduce. When phonon scattering rates are artificially multiplied by five, the off-diagonal elements of the density matrix vanish, i.e., the coherence between electrons on the left and right side almost disappears. The tunneling process through the double barrier is thus no longer fully resonant. Electrons can be seen as entering and leaving the quasi-bound state via two distinct processes, with the possibility of energy exchange with the lattice through electron-phonon scattering. This illustrates the well-known coherent versus sequential tunneling regimes.

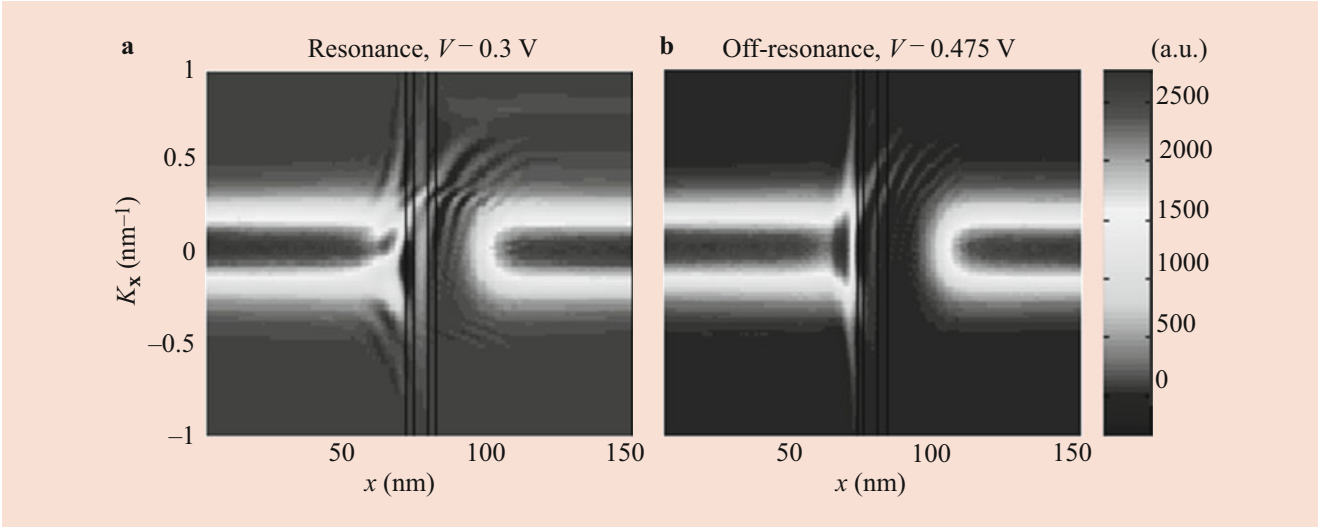

Fig. 43.6 Cartography in phase space of the Wigner function computed (**a**) for a resonant state ($V = 0.3$ V) and (**b**) a non-resonant state ($V = 0.475$ V). (After [43], with permission from Querlioz and Dollfus)

This transition between coherent and sequential tunneling regimes manifests itself in the current-voltage characteristics of the RTD plotted in Fig. 43.4 for the three scattering situations. Phonon scattering tends to suppress the resonant tunneling peak, while the valley current increases to such a point that the negative differential conductance effect almost disappears. The device tends to behave as two incoherent tunneling resistances connected in series for which a semi-classical-type description could be accurate enough.

More advanced considerations about the quantum to semi-classical transition may be found in [61].

43.4.8 The Signed Particle Method

In this section, we describe and discuss the signed particle Monte Carlo (MC) method which is based on the iterative Monte Carlo methods for the resolution of linear and non-linear systems of equations described in [36, 68] and which allows quantitative, time-dependent, multidimensional, single, and many-body simulations of quantum systems [16, 46, 47].

This method has shown to be a surprisingly powerful tool and has been applied to the simulation of quantum single-body problems in technologically relevant situations [69, 70] and even extended to time-dependent quantum many-body problems in the framework of density functional theory [71]. It has also been generalized to the ab initio simulations of strongly correlated many-body problems [72]. Finally, it has inspired a new formulation of quantum mechanics [73]. This is the first time that the Wigner formalism can be applied to such class of very computationally demanding problems and has the potential to profoundly impact the fields of electronics, physics, and chemistry.

The applications shown at the end of this chapter could not be fully understood without a comprehension of this section. Therefore, below, we start by going through the mathematical details of the theory. Furthermore, the interested reader can find an implementation of the Wigner MC method based on signed particles at [74]. The reader is advised to download the source code and study it for a faster, and more intuitive, comprehension of this approach.

Semi-Discrete Phase Space We have already seen that, in the Wigner formulation, any quantum system consisting of one particle, or body, is (completely) described by a quasi-distribution function defined over the phase-space $f_{\mathrm{W}}(\mathbf{x}; \mathbf{p}; t)$ which evolves in time according to Eq. (43.11). Therefore, our main goal consists in reconstructing this function for any given time of interest. To achieve this goal, the starting point is represented by the reformulation of the Wigner equation in a semi-discrete phase space with a continuous spatial variable $\mathbf{x}$ and a discretized momentum $\mathbf{p}$, with step $\Delta\mathbf{p} = \frac{\hbar\pi}{L_{\mathrm{C}}}$, where L_{C} is a free parameter, sometimes refered to as the coherence or cut-off length (a study on the dependence of the accuracy of a solution in function of L_{C} has been presented in [75]). In the semi-discrete momentum space, the Wigner equation now reads

$$\frac{\partial f_{\mathrm{W}}}{\partial t} + \frac{\hbar}{m}\frac{\mathbf{M}\Delta\mathbf{p}}{\hbar} \cdot \nabla_{\mathbf{x}} f_{\mathrm{W}} = \sum_{M'=-\infty}^{+\infty} V_{\mathrm{W}}(\mathbf{x}; \mathbf{M}'; t) f_{\mathrm{W}}(\mathbf{x}; \mathbf{M} - \mathbf{M}'; t), \qquad (43.36)$$

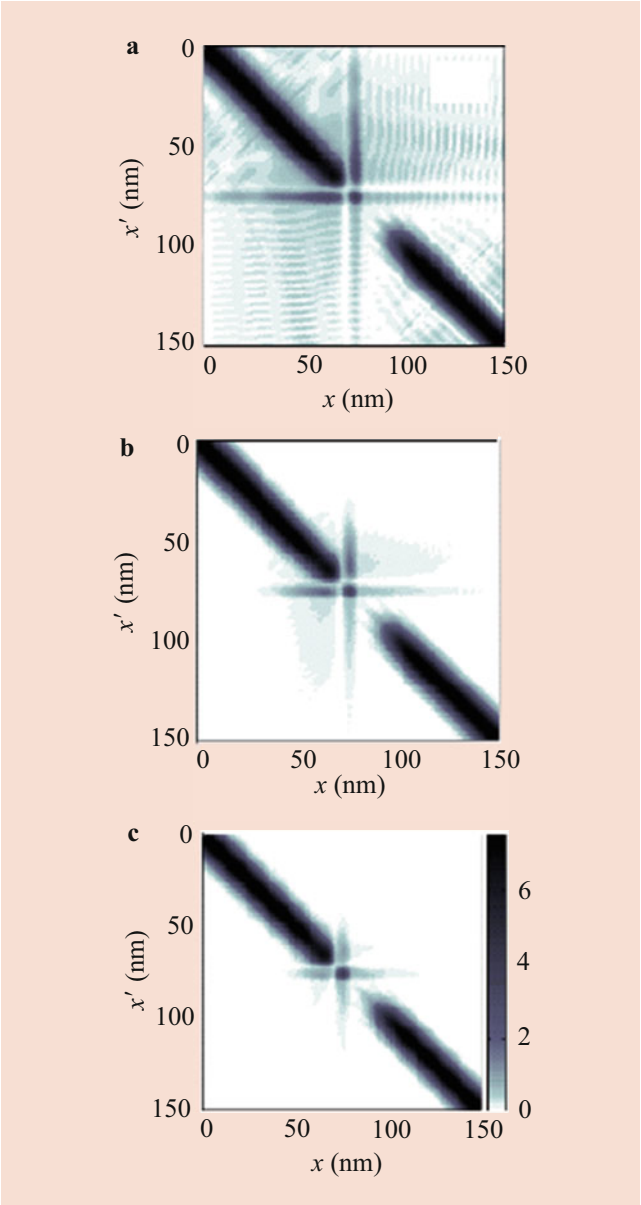

Fig. 43.7 Density matrix of a RTD operating at peak voltage for three cases: (**a**) no scattering, (**b**) standard phonon scattering rates, (**c**) standard rates multiplied by 5

where, for convenience, we use the notation $f_{\mathrm{W}}(\mathbf{x};\mathbf{M};t) = f_{\mathrm{W}}(\mathbf{x};\mathbf{M}\Delta\mathbf{p};t)$, with $\mathbf{M} = (M_1,\ldots,M_d)$ a set of integers with d elements, and $\mathbf{M}\Delta\mathbf{p} = (M_1\Delta p_1,\ldots,M_d\Delta p_d)$. Knowing the Wigner distribution function, it is possible to evaluate the expectation value $\langle A\rangle(t)$ of some generic physical quantity, described by a phase-space function, or $c-$number, $A = A(x;k)$ at a given time t. Therefore, the main computational problem becomes the calculation of the inner product (A, f_{W}) with the solution of (43.11). It can be shown that this task can be reformulated by exploiting the solution of the adjoint equation. In particular, we first obtain an integral form of (43.11) and then its corresponding adjoint equation.

Integral Formulation The semi-discrete Wigner equation (43.36) can be reformulated in an integral form. First, one defines a function γ as

$$\gamma(\mathbf{x}) = \sum_{\mathbf{M}=-\infty}^{\infty} V_{\mathrm{w}}^{+}(\mathbf{x};\mathbf{M}) = \sum_{\mathbf{M}=-\infty}^{\infty} V_{\mathrm{w}}^{-}(\mathbf{x};\mathbf{M}), \qquad (43.37)$$

where V_{w}^{+} is the positive part of V_{w}, i.e., it gives V_{W} if $V_{\mathrm{w}} > 0$ and 0 otherwise, and V_{w}^{-} is the negative part defined similarly (the equality was initially proven in [16] and afterwards in [46] and in [47]). In the stationary case, the Wigner potential is antisymmetric. It is clear that if $V_{\mathrm{w}}^{+}(x,-m) = 0$, then $V_{\mathrm{w}}^{-}(x,-m) \neq 0$ and, moreover, $V_{\mathrm{w}}^{-}(x,-m) = V_{\mathrm{w}}^{+}(x,m)$. Thus, the Eq. (43.22) can be rewritten by adding and substracting the term $\gamma(x(t'))$.

Let us, now, denote by Γ the following expression:

$$\Gamma(\mathbf{x}(t'),\mathbf{M},\mathbf{M}') = V_{\mathrm{w}}^{+}(\mathbf{x}(t');\mathbf{M}-\mathbf{M}') - V_{\mathrm{w}}^{+}(\mathbf{x}(t');\\ -(\mathbf{M}-\mathbf{M}')) + \gamma(\mathbf{x}(t'))\delta_{\mathbf{M},\mathbf{M}'}. \qquad (43.38)$$

For the sake of simplicity, we assume the evolution of an initial condition $f_i(x,m)$ starts at time 0. A common inclusion of both boundary and initial conditions, which formally resembles the free term of the Boltzmann integral equation, is performed, and by integration over the interval $(0,t)$, one recovers the following equation:

$$\begin{aligned} &f_{\mathrm{W}}(\mathbf{x};\mathbf{M};t) - \mathrm{e}^{-\int_0^t \gamma(\mathbf{x}(y))\mathrm{d}y} f_i(\mathbf{x}(0);\mathbf{M}) \\ &= \int_0^t \mathrm{d}t' \sum_{\mathbf{M}'=-\infty}^{\infty} f_{\mathrm{W}}(\mathbf{x}(t');\mathbf{M}';t')\Gamma(\mathbf{x}(t'),\mathbf{M},\mathbf{M}')\mathrm{e}^{-\int_{t'}^t \gamma(\mathbf{x}(y))\mathrm{d}y} \\ &= \int_0^{\infty} \mathrm{d}t' \sum_{\mathbf{M}'}^{\infty} \int \mathrm{d}x' f_{\mathrm{W}}(\mathbf{x}';\mathbf{M}';t')\Gamma(\mathbf{x}',\mathbf{M},\mathbf{M}') \\ &\quad \times \mathrm{e}^{-\int_{t'}^t \gamma(\mathbf{x}(y))\mathrm{d}y}\theta(t-t')\delta(\mathbf{x}'-\mathbf{x}(t'))\theta_{\mathrm{D}}(\mathbf{x}'), \end{aligned} \qquad (43.39)$$

where, to ensure the appearance of the variables $Q = (\mathbf{x},\mathbf{M},t)$ and $Q' = (\mathbf{x}',\mathbf{M}',t')$, the kernel has been augmented by the functions θ and δ which leave the value of the integral unchanged. In particular, the function θ_D keeps the integration within the simulation domain. In the same way, the expectation value of the physical quantity A at time τ is augmented and now reads

$$\langle A\rangle(\tau) = \int \mathrm{d}t \int \mathrm{d}\mathbf{x} \sum_{\mathbf{M}=-\infty}^{\infty} f_{\mathrm{W}}(\mathbf{x};\mathbf{M};t)A(\mathbf{x};\mathbf{M})\delta(t-\tau)$$
$$= \int \mathrm{d}Q f_{\mathrm{W}}(Q)A_{\tau}(Q), \tag{43.40}$$

(note the implicit definition of the symbol $A_{\tau}(Q)$).

Adjoint Equation The expectation value (43.40) can be rewritten by introducing the adjoint equation of (43.39) which has a solution g and a free term g_0 determined below:

$$f(Q) = \int \mathrm{d}Q' K(Q,Q')f(Q') + f_i(Q),$$
$$g(Q') = \int \mathrm{d}Q K(Q,Q')g(Q) + g_0(Q').$$

The first equation is multiplied by $g(Q)$ and integrated over Q, while the second equation is multiplied by $f(Q')$ and integrated over Q'. By subtracting the two equations, then one obtains

$$\int \mathrm{d}Q f_i(Q)g(Q) = \int \mathrm{d}Q' g_0(Q')f(Q')$$
$$\int \mathrm{d}Q' f_i(Q')g(Q') = \int \mathrm{d}Q g_0(Q)f(Q),$$

where the dummy variables have been exchanged for a more convenient comparison with (43.40). From this, one can show that

$$g_0(Q) = A_{\tau}(Q);$$
$$\langle A\rangle = \int_0^{\infty} \mathrm{d}t' \int \mathrm{d}\mathbf{x}' \sum_{\mathbf{M}'=-\infty}^{\infty} f_i(\mathbf{x}';\mathbf{M}')\mathrm{e}^{-\int_0^{t'}\gamma(\mathbf{X}'(y))\mathrm{d}y}$$
$$\times\, g(\mathbf{x}';\mathbf{M}';t'), \tag{43.41}$$

where $\mathbf{x}'(y)$ is the trajectory initialized by $(\mathbf{x}',\mathbf{M}',t')$, and $\mathbf{x}(0) = \mathbf{x}'$. Therefore, the adjoint equation (obtained by integration on the unprimed variables) reads

$$g(\mathbf{x}';\mathbf{M}';t')$$
$$= A_{\tau}(\mathbf{x}',\mathbf{M}',t') + \int_0^{\infty} \mathrm{d}t \sum_{\mathbf{M}=-\infty}^{\infty} \int \mathrm{d}\mathbf{x} g(\mathbf{x};\mathbf{M};t)\Gamma$$
$$\times\, (\mathbf{x}',\mathbf{M},\mathbf{M}')\mathrm{e}^{-\int_{t'}^{t}\gamma(\mathbf{x}(y))\mathrm{d}y}\theta(t-t')\delta(\mathbf{x}'-\mathbf{x}(t'))\theta_{\mathrm{D}}(\mathbf{x}'). \tag{43.42}$$

Now, we revert the parametrization of the fieldless trajectory and, therefore, $(\mathbf{x}(t') = \mathbf{x}'', \mathbf{M}, t')$ initialize the trajectory, and the variable $\mathbf{x} = \mathbf{x}(t)$ becomes the time-dependent variable. Consequently, the spatial coordinates for the function g become $\mathbf{x}'(t)$, and one has

$$g(\mathbf{x}';\mathbf{M}';t') = A_{\tau}(\mathbf{x}',\mathbf{M}',t')$$
$$+ \int_{t'}^{\infty} \mathrm{d}t \sum_{\mathbf{M}=-\infty}^{\infty} g(\mathbf{x}'(t);\mathbf{M};t)\Gamma(\mathbf{x}',\mathbf{M},\mathbf{M}')$$
$$\times\, \mathrm{e}^{-\int_{t'}^{t}\gamma(\mathbf{X}'(y))\mathrm{d}y}\theta_D(\mathbf{x}'). \tag{43.43}$$

In the same manner, one can reformulate Eq. (43.41) with the initialization changing from $(\mathbf{x}',\mathbf{M}',t')$ to $(\mathbf{x}_i = \mathbf{x}'(0),\mathbf{M}',0)$:

$$\mathbf{x}'(y) = \mathbf{x}_i(y) = \mathbf{x}_i + \frac{\mathbf{M}'\Delta\mathbf{p}}{m}y;\ \ \mathbf{x}' = \mathbf{x}'(t') = \mathbf{x}_i(t');$$
$$\mathrm{d}\mathbf{x}' = \mathrm{d}\mathbf{x}_i \tag{43.44}$$

$$\langle A\rangle = \int_0^{\infty} \mathrm{d}t' \int \mathrm{d}\mathbf{x}_i$$
$$\times \sum_{\mathbf{M}'=-\infty}^{\infty} f_i(\mathbf{x}_i;\mathbf{M}')\mathrm{e}^{-\int_0^{t'}\gamma(\mathbf{x}_i(y))\mathrm{d}y} g(\mathbf{x}_i(t');\mathbf{M}';t'). \tag{43.45}$$

Signed Particles in Practice Finally, by iterating consecutively (43.43) into (43.45), one can depict the numerical method based on signed particles. In fact, if one starts from the zero-th order term

$$< A >_0 (\tau) = \int_0^{\infty} \mathrm{d}t' \int \mathrm{d}\mathbf{x}_i$$
$$\sum_{\mathbf{M}'=-\infty}^{\infty} f_i(\mathbf{x}_i;\mathbf{M}')\mathrm{e}^{-\int_0^{t'}\gamma(\mathbf{x}_i(y))\mathrm{d}y} A(\mathbf{x}_i(t');\mathbf{M}')\delta(t'-\tau), \tag{43.46}$$

and applies the Monte Carlo theory for the computation of integrals, it is possible to interpret part of the integrand as the product of conditional probabilities. In practice, by assuming that f_i is normalized to unity, one generates a set of random points $(\mathbf{x}_i,\mathbf{M}')$ at time 0 which initialize the particle trajectories $\mathbf{x}_i(y)$. In this context, the above exponent provides the probability for a particle to remain over the trajectory given that the change of trajectory rate is expressed by the function γ. Thus, this probability filters out these particles, such that the randomly generated change of trajectory time is less than τ. If the particle stays in the trajectory until time τ, then it contributes to $< A >_0 (\tau)$ with a value equal to the rest of the integrand; in other words, $f_i(\mathbf{x}_i;\mathbf{M}')A(\mathbf{x}_i(\tau),\mathbf{M}')$. Otherwise, particles which have experienced a change of trajectory do not provide any kind of contribution. Therefore,

$< A >_0 (\tau)$ is estimated by averaging over the set of N initialized particles.

Similarly, the first-order term of the iteration term is obtained by replacing the term $g(\mathbf{x}_i(t'); \mathbf{M}'; t')$ in (43.45) by the kernel of (43.44) specifically rewritten; in other words, in (43.44), we substitute $\mathbf{x}'$ with $\mathbf{x}_1 = \mathbf{x}_i(t')$. In this case, the trajectory in the exponent is now initialized by the values $(\mathbf{x}_1, \mathbf{M}, t')$:

$$
\begin{aligned}
&< A >_1 (\tau) \\
&= \int_0^\infty \mathrm{d}t' \int \mathrm{d}\mathbf{x}_i \sum_{\mathbf{M}'=-\infty}^{\infty} f_i(\mathbf{x}_i; \mathbf{M}') \mathrm{e}^{-\int_0^{t'} \gamma(\mathbf{x}_i(y))\mathrm{d}y} \times \int_{t'}^\infty \mathrm{d}t \\
&\quad \times \sum_{\mathbf{M}=-\infty}^{\infty} g((\mathbf{x}_1(t); \mathbf{M}; t) \Gamma(\mathbf{x}_1, \mathbf{M}, \mathbf{M}') \mathrm{e}^{-\int_{t'}^{t} \gamma(\mathbf{x}_1(y))\mathrm{d}y} \theta_\mathrm{D}(\mathbf{x}_1).
\end{aligned}
$$

We then substitute the function $g(\mathbf{x}_1(t); \mathbf{M}; t)$ with the free term of (43.44) at point $A(\mathbf{x}_1(t), \mathbf{M}, t)\delta(t - \tau)$, and finally, we augment the equation by completing some of the probabilities enclosed in curly brackets. By partially reordering some of the terms, one obtains

$$
\begin{aligned}
&< A >_1 (\tau) = \int_0^\infty \mathrm{d}t' \int \mathrm{d}\mathbf{x}_i \\
&\times \sum_{\mathbf{M}'=-\infty}^{\infty} f_i(\mathbf{x}_i; \mathbf{M}') \left\{ \gamma(\mathbf{x}_i(t')) \mathrm{e}^{-\int_0^{t'} \gamma(\mathbf{x}_i(y))\mathrm{d}y} \right\} \theta_\mathrm{D}(\mathbf{x}_1) \int_{t'}^\infty \mathrm{d}t \\
&\times \sum_{\mathbf{M}=-\infty}^{\infty} \left\{ \frac{\Gamma(\mathbf{x}_1, \mathbf{M}, \mathbf{M}')}{\gamma(\mathbf{x}_i(t'))} \right\} \left\{ \mathrm{e}^{-\int_{t'}^{t} \gamma(\mathbf{x}_1(y))\mathrm{d}y} \right\} \\
&A(\mathbf{x}_1(t), \mathbf{M}, t)\delta(t - \tau).
\end{aligned}
$$

In a similar fashion, it is possible to give a purely Monte Carlo interpretation to this process: a particle is considered to be initialized at $(\mathbf{x}_i, \mathbf{M}', 0)$, which follows the trajectory until time t', i.e., the time when the particle changes its coordinates in the phase space. The time t' is then provided by the probability density in the first curly brackets since the enclosed term, if integrated over the time interval $(0, \infty)$, returns the unity. Moreover, the exponent can be interpreted as the probability of a particle staying in the same trajectory until time t', while $\gamma(\mathbf{x}_i(t'))\mathrm{d}t'$ can be interpreted as the probability to leave that trajectory during the interval $(t', t' + \mathrm{d}t')$. Its new phase-space coordinates now become $(\mathbf{x}_1 = \mathbf{x}_i(t'), \mathbf{M}')$ at t' and the evolution continues (as long as the particle remains in the simulation domain, otherwise its contribution is identically zero). The term in the next curly bracket becomes a source of change for the momentum, from $\mathbf{M}'$ to $\mathbf{M}$, at the spatial point $\mathbf{x}_1$ and at the time of scattering t'. Thus, at time t' the particle initializes the trajectory $(\mathbf{x}_1, \mathbf{M})$ and, with a probability provided by the exponent in the last curly brackets, remains on the same trajectory until time τ. In particular, t is set to τ by the δ function provided that $t' < \tau$; otherwise its contribution is zero. We note, however, that in this particular case the particle still has a contribution to the zero-th iteration term.

In other words, one can utilize the kernel of (43.44) to construct a transition probability for the numerical Monte Carlo trajectories which consist of pieces of fieldless Newton trajectories linked by a change of the momentum from $\mathbf{M}$ to $\mathbf{M}'$ according to Γ. These can be seen as particles being affected by events which change their phase-space coordinates, and the exponent in the formulas gives the probability that a particle remains on its trajectory with a changing rate equal to γ.

If a particle does not go under a trajectory changing event until time τ, then it contributes to $< A >_0 (\tau)$, and its contribution is equal to $f_i(\mathbf{x}_i; \mathbf{M}')g(\mathbf{x}_i(\tau); \mathbf{M}')$. If a particle goes under a trajectory event, then it contributes to a next term of the expansion. In fact, one could show that a particle contributes to one and only one term of this expansion, and the macroscopic value $< A > (t)$ is estimated by averaging over a set of N particles. Thus, we have seen that it is possible to depict a Monte Carlo algorithm for the ballistic, single-body, semi-discrete Wigner equation (43.36) where, after any free flight, an initial particle creates a pair of new particles with opposite signs and momentum offset (around the initial momentum), which are equal to $+\mathbf{L}$ and $-\mathbf{L}$, and where $\mathbf{L} = \mathbf{M} - \mathbf{M}'$. The initial particle and the two newly created ones represent three contributive terms of the series.

43.5 Monte Carlo Methods to Simulate the Many-Body Wigner Equation

The simulation of quantum many-body systems is an important problem which touches many practical aspects of our everyday life such as the design of chemical reactions, new materials, and electronics. It also represents, unfortunately, a complex task which requires immense computational resources. Therefore, it is not surprising to see that the first attempt to simplify the quantum many-body problem appeared very early, precisely in 1926, as a method to find the electronic structure in terms of a one-electron ground-state density $\rho(\mathbf{x})$ [76, 77].

In this section, we focus on two possible generalizations of the Wigner MC methods based on signed particles discussed previously, i.e., (1) the generalization to the density functional theory and (2) the generalization of the method for first-principle simulations of quantum systems.

43.5.1 The Density Functional Theory

This first approach to the quantum many-body problem, today known as the Thomas-Fermi theory, unfortunately introduces too many oversimplifications to be of any realistic use but represents an important result anyway since it has provided the foundations for the development of very advanced methods such as the density functional theory (DFT). Later on, Slater was the first one to introduce the combination of the ideas of Thomas and Fermi with Hartree's orbital method [78, 79], introducing the new (revolutionary) concept of a local exchange potential. Afterwards, the Hohenberg-Kohn theorem proved that, at least in principle, an exact method using the one-electron ground-state density $\rho(\mathbf{x})$ [80] could be developed and the Kohn-Sham system was introduced right after for the case of homogeneous electron gases [81]. The time-dependent counterpart of the Hohenberg-Kohn theorem appeared much later, in 1984, when Runge and Gross presented their theorem [82] (the reader should note, though, that this theorem only guarantees the validity of the time-dependent Kohn-Sham system for the calculations of the ground-state, nothing is proved for the excited states [83]). Nowadays, the DFT method is the most popular tool in quantum chemistry [84] and is being utilized by a growing number of different communities such as, for instance, the field of nanoelectronics. Therefore, in this section, we focus on the first extension to the many-body problem based on the signed particle Wigner MC method. This section is based on the work described in [71].

The DFT approach relies on the fact that computing the wave-function of a single-electron Schrödinger equation is relatively simple (at least numerically). In practice, the many-body problem is reduced to a system of coupled single-electron equations, known as the Kohn-Sham system, and effects such as electron-electron interaction are described in terms of the so-called density functional. This is the essence of both time-independent and time-dependent approaches in DFT [81, 82]. Although the exact mathematical expression for the density functional is usually unknown for systems of practical interest, this simplification allows the simulation of many-body problems in acceptable computational times. In spite of these limitations, practitioners can now choose among a huge number of functionals which work at least at a qualitative level; see, for example [81, 85, 86].

In standard quantum mechanics, the time-dependent dynamics of a many-body system is described by the many-body Schrödinger equation which reads

$$i\hbar\frac{\partial}{\partial t}\Psi = \hat{H}\Psi. \tag{43.47}$$

The unknown is represented by the wave-function $\Psi = \Psi(\mathbf{x}_1, \ldots, \mathbf{x}_n)$, which is a complex valued function, and the Hamiltonian $\hat{H}$ accounts for the various forces involved in the problem (e.g., see formula (43.19)). Resolving equation (43.47) is a formidable, see daunting, mathematical problem even when it is approached by numerical techniques. A great help in this context comes from the time-dependent Kohn-Sham system which reduces the difficulties involved in (43.47) by orders of magnitude and, therefore, allows practical (although qualitative) simulations of many-body systems. As a matter of fact, this problem becomes a much simpler set of n single-body Schrödinger equations coupled to each other by means of an effective density functional $v_{\text{eff}} = v_{\text{eff}}(\mathbf{x})$ [84]. The reader should note, again, that there is no unique way to express the density functional (e.g., [81, 85, 86]).

Finally, the time-dependent Kohn-Sham system reads ($i = 1 \ldots n$)

$$i\hbar\frac{\partial \Phi_i}{\partial t}(\mathbf{x}, t) = \left(-\frac{\hbar^2\nabla^2}{2m_i} + U_{\text{eff}}(\mathbf{x})\right)\Phi_i(\mathbf{x}, t) \tag{43.48}$$

which can be utilized to compute the one-electron density:

$$\rho(\mathbf{x}) = \sum_i |\Phi_i(\mathbf{x})|^2, \tag{43.49}$$

where the sum is performed over the states below the Fermi energy.

43.5.2 The *Wigner* Density Functional Theory

It is relatively easy to see that if one applies the Wigner-Weyl transform (43.27) to every equation of the system (43.48), one readily obtains a new time-dependent Kohn-Sham system which is now defined in terms of n single-body Wigner equations. Such a system reads

$$\frac{\partial f_w^i}{\partial t} + \frac{\mathbf{p}}{m_i}\cdot\nabla_{\mathbf{x}} f_w^i = Q\left[f_w^i\right], \tag{43.50}$$

where the Wigner kernel is a functional of the effective potential, i.e.,

$$V_{\text{w}}(\mathbf{x}, \mathbf{p}, t) = \frac{i}{(2\pi)^d\hbar^{d+1}}\int \mathrm{d}\mathbf{x}' \mathrm{e}^{-i\frac{\mathbf{p}\mathbf{x}'}{\hbar}} \times \left(U_{\text{eff}}\left(\mathbf{x} + \frac{\mathbf{x}'}{2}, t\right) - U_{\text{eff}}\left(\mathbf{x} - \frac{\mathbf{x}'}{2}, t\right)\right). \tag{43.51}$$

Thus, in this new context, the quantum many-body problem consists in solving the set of coupled equations (43.50). Obviously, this system is affected by the very same problems of standard DFT, e.g., the choice of the exchange-correlation potential is not unique, there is no guarantee that the excited states are correct, etc., and, if applied to a computational

quantum problem, it will provide the same answers provided by the standard DFT. Nevertheless, two important advantages appear in this new model. First, the Wigner formalism is based on the concept of a quasi-distribution function and, as such, offers a much more intuitive representation of the simulated system. Second, the Wigner MC method, based on signed particles, is known to be embarrassingly parallelizable [36, 68].

43.5.3 The Wigner Monte Carlo Method for Many-Body Systems

Traditionally, ab initio simulations, based on first principles of quantum mechanics, are known to be incredibly difficult to perform as they require an immense amount of computational power.

Although they are complex, it is important to find ways to simulate such systems, since they allow the simulation of so-called *strongly correlated* systems, which are relevant in both applied physics and chemistry. In this section, we briefly describe the first-principle many-body Wigner MC method based on signed particles which was suggested in [72]. Many details are skipped since it would be out of the scope of this chapter, and the interested reader is kindly invited to read [72] and [25] for more information.

First of all, as done previously for the single-body Wigner equation, the many-body Wigner equation needs to be rewritten in a semi-discrete phase space where the spatial coordinates $\mathbf{x}$ keep on being continuous while the space of momenta is discretized. In such context, the momentum $\mathbf{p}$ is expressed as multiples of the quantity $\Delta\mathbf{p} = \frac{\hbar\pi}{L_C}$, where L_C is the usual cut-off or coherence parameter encountered previously. It is possible to show that the semi-discrete many-body Wigner equation reads

$$\frac{\partial f_W}{\partial t}(\mathbf{x};\mathbf{M};t) + \sum_{k=1}^{n} \frac{\mathbf{M}_k \Delta\mathbf{p}}{m_k} \cdot \nabla_{\mathbf{x}_k} f_W = \sum_{\mathbf{M}=-\infty}^{+\infty} f_W(\mathbf{x};\mathbf{M};t) V_W(\mathbf{x};\mathbf{M};t), \tag{43.52}$$

with $\mathbf{M} = (\mathbf{M}_1, \mathbf{M}_2, \ldots, \mathbf{M}_n)$, $\sum_{\mathbf{M}=-\infty}^{+\infty} = \sum_{\mathbf{M}_1=-\infty}^{+\infty} \sum_{\mathbf{M}_2=-\infty}^{+\infty} \cdots \sum_{\mathbf{M}_n=-\infty}^{+\infty}$, and

$$V_W(\mathbf{x};\mathbf{M};t) = \frac{i}{\pi^{dn}\hbar^{dn+1}} \int \mathrm{d}\mathbf{x}' \mathrm{e}^{-\left(\frac{2i}{\hbar}\right)\sum_{k=1}^{n} \mathbf{x}'_k \cdot \mathbf{M}_k \Delta\mathbf{p}} \times \left[V\left(\mathbf{x} + \frac{\mathbf{x}'}{2}; t\right) - V\left(\mathbf{x} + \frac{\mathbf{x}'}{2}; t\right) \right].$$

Note that, now, the momentum of the i-th particle is represented by a set of d integers $\mathbf{M}_i = (M_1^i, \ldots, M_d^i)$ and $\mathbf{M}_i \Delta\mathbf{p} = (M_1^i \Delta p_1, \ldots, M_d^i \Delta p_d)$ where $\Delta\mathbf{p} = (\Delta p_1, \ldots, \Delta p_d)$.

At this point, it is possible to rewrite Eq. (43.52) in an integral form by defining the (many-body) function γ which now reads:

$$\gamma(\mathbf{x}) = \sum_{\mathbf{M}=-\infty}^{\infty} V_W^+(\mathbf{x};\mathbf{M}), \tag{43.53}$$

where V_W^+ has the usual meaning generalized in the many-body context. Then, the Eq. (43.52) can be rewritten by adding and substracting the term $\gamma(\mathbf{x})$. Similarly, the function Γ can be generalized to this new context and now reads

$$\Gamma(\mathbf{x};\mathbf{M};\mathbf{M}') = V_W^+(\mathbf{x};\mathbf{M}-\mathbf{M}') - V_W^+(\mathbf{x};-(\mathbf{M}-\mathbf{M}')) + \gamma(\mathbf{x})\delta_{\mathbf{M},\mathbf{M}'}. \tag{43.54}$$

If one follows the same strategy employed for the single-body Wigner equation, it is possible to rewrite the semi-discrete many-body Wigner equation in the form of a Fredholm integral equation of second kind:

$$f_W(\mathbf{x};\mathbf{M};t) - \mathrm{e}^{-\int_0^t \gamma(\mathbf{x}(y))\mathrm{d}y} f_i(\mathbf{x}(0);\mathbf{M}) = \int_0^\infty \mathrm{d}t' \sum_{\mathbf{M}'=-\infty}^{+\infty} \int \mathrm{d}\mathbf{x}' f_W(\mathbf{x}';\mathbf{M}';t')\Gamma(\mathbf{x}';\mathbf{M};\mathbf{M}') \times \mathrm{e}^{-\int_{t'}^t \gamma(\mathbf{x}(y))\mathrm{d}y} \theta(t-t')\delta(\mathbf{x}'-\mathbf{x}(t'))\theta_D(\mathbf{x}'). \tag{43.55}$$

43.5.4 Signed Particle Method

At this point, it is easy to see that the equations so far recovered are in the same shape as the ones obtained for the single-particle Wigner MC method. This suggests that we can simply follow the same procedure and express the expectation value of a variable as a Liouville von Neumann series. This eventually allows to depict a signed particle MC method for the many-body Wigner equation.

In the very same way as for the single-body problem, it is possible to show that the expansion of $\langle A \rangle$ branches and the total value is given by the sum of all branches. We can, thus, equivalently talk in terms of three appearing particles even for the many-body Wigner Monte Carlo method. The reader should note, though, that in this new context, by *particle* one now means a mathematical point defined in a *nd*-dimensional phase space, i.e.,

$$\frac{\Gamma(\mathbf{x};\mathbf{M};\mathbf{M}')}{\gamma(\mathbf{x})} = \left\{ \frac{V_W^+(\mathbf{x},\mathbf{M}-\mathbf{M}')}{\gamma(\mathbf{x})} \right\} - \left\{ \frac{V_W^-(\mathbf{x},\mathbf{M}-\mathbf{M}')}{\gamma(\mathbf{x})} \right\} + \left\{ \delta_{\mathbf{M},\mathbf{M}'} \right\}. \tag{43.56}$$

It is, therefore, possible to depict a Monte Carlo method which is based, again, on signed particles but, this time,

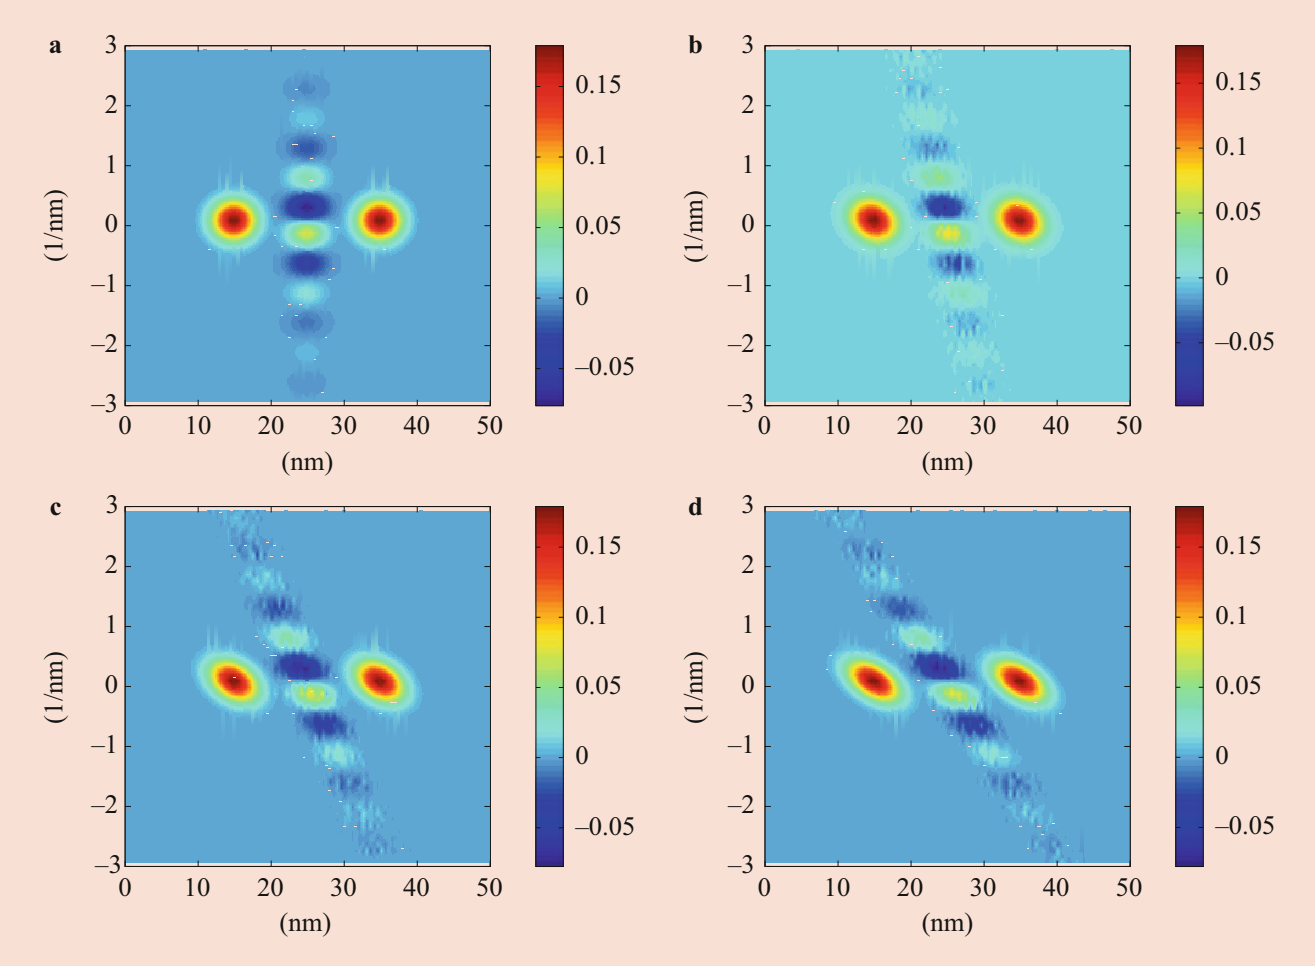

Fig. 43.8 Evolution of an entangled two-body system. The quasi-distribution function in the reduced phase space are shown at times 0 fs, 1 fs, 2 fs and 3 fs respectively (**a** to **c**, **a** to **b**). As expected, the entanglement oscillations rotates during the simulation

within the many-body context. According to the last term above, as for the one-body case, an initial parent particle generates a couple of new signed particles with the first two probabilities, i.e., the first many-body momentum state is generated $\mathbf{M} - \mathbf{M}' = \mathbf{L}$ with probability

$$\frac{V_{\mathrm{W}}^{+}(\mathbf{x}, \mathbf{L})}{\gamma(\mathbf{x})},$$

and with the same probability, another value is generated, say $\mathbf{L}'$, for the second state $\mathbf{M}' - \mathbf{M} = \mathbf{L}'$. In other words, the term $\Gamma(\mathbf{x}; \mathbf{M}; \mathbf{M}')$ allows to depict a Monte Carlo algorithm for the integration of the many-body semi-discrete Wigner equation (43.52). After any free flight, the initial particle creates two new particles with opposite signs and momentum offset, around the initial momentum, equal to $+\mathbf{L}$ and $-\mathbf{L}$ with $\mathbf{L} = \mathbf{M} - \mathbf{M}'$. The initial particle and the created couple represent three contributive terms to the many-body Liouville-Neumann series. Therefore, the solution of the many-body problem is constructed by an ensemble of fieldless Newtonian particles which are *independent* from each other. As an example, Fig. 43.8 shows the evolution of a two-body system consisting of two wave packets being entangled (represented by the oscillations between the two packets).

43.6 Neural Networks to Compute the Kernel

The computation of the (highly dimensional) Wigner kernel (43.12) can represent a serious bottleneck for the simulation of quantum systems, especially in the presence of time-dependent potentials which, in practice, amounts to the computation of such function at every time step. In this situation, its numerical computation becomes not only time consuming but also memory demanding. Mainly, two approaches are utilized in this case: a deterministic one, e.g., based on the finite element method, and a stochastic one, e.g., the sampling Monte Carlo method.

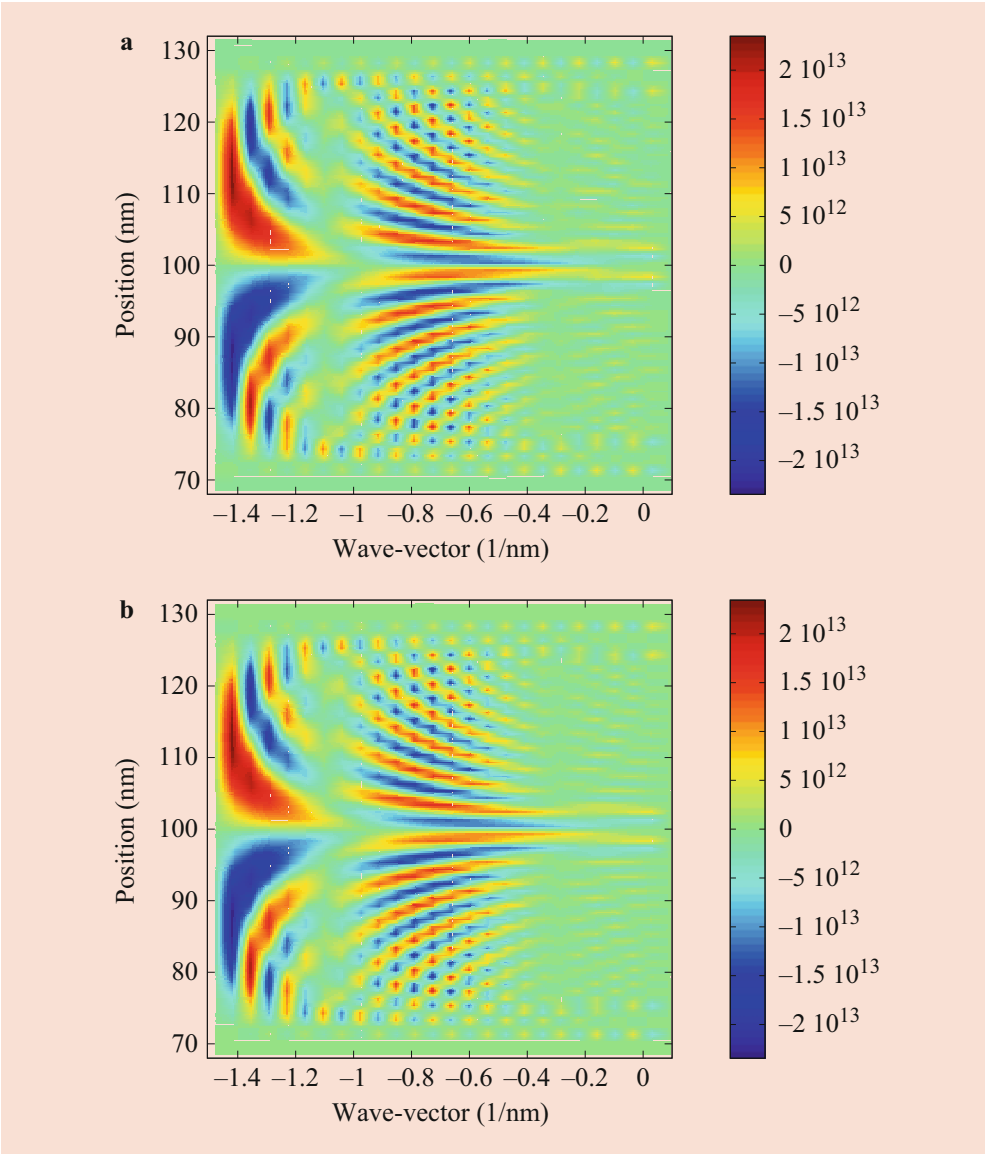

Fig. 43.9 Quantum one-body problem in the presence of a double barrier: (**a**) Wigner kernel computed by a finite difference method, (**b**) Wigner kernel computed by a trained neural network. A very good agreement is clearly achieved

Finite Difference Approaches Any finite difference integration, or quadrature, method is based on the evaluation of the integrand over a series of points defined within the integration interval which are, usually, equidistant (in other words, a discretized space). A well-known example is represented by the trapezoidal rule, which can be considered the archetypal of the numerical integration methods, and the Simpson rule [87]. Other methods exist, based on different weighted summations of the integrand evaluated over the cells of the discretized space. It is well known that the accuracy of these methods quickly degrades with the increase of the dimensionality of the integrand. Therefore, in this context, the only way to keep the accuracy is by increasing the number of evaluations of the integrand function [87]. Eventually, this amounts to a consistent number of evaluations which greatly slow down the computation of the integral along with an increase of the amount of memory involved in the process. One way to escape the increase of sampling points, while still being accurate, is by recurring to the use of Monte Carlo techniques.

Monte Carlo Approaches The main idea behind any Monte Carlo quadrature technique is simple and consists in supposing that the integrand $f(x)$ can be written as the product of two functions, say $f(x) = h(x)p(x)$, where $p = p(x)$ is a given function with certain convenient properties. It can be

mathematically proved that the computational complexity of such methods is linear [32]. The main drawbacks of such approach consists in the fact that the accuracy depends on what one knows about the integrand function $f = f(x)$. In fact, the integral can be evaluated only when a certain amount of information is available. Moreover, if the function $f(x)$ is rapidly oscillating, then the convergence usually tends to become very slow [87] and the amount of memory needed to perform such computation can increase very rapidly with the dimensionality of the problem at hand, which can represent a serious drawback in the case of the simulation of many-body quantum problems.

A Neural Network Approach In the last few years, artificial neural networks have been applied to broader sets of applications with immense success. For instance, they have been utilized, with impressive results, to the recognition of individual objects in photographs, to the problem of speech recognition, etc. In particular, they have shown to excel in tasks where information is complex and voluminous [88]. Inspired by these recent achievements, it seems more than reasonable to investigate whether they could provide advantages over the standard methods described above. It turns out that the answer is positive. As a matter of fact, artificial neural networks have been developed which are capable of accurately computing the Wigner kernel, when provided with a potential defined over the configuration space, with insignificant memory resources and at faster computational times [89].

In this particular and rather novel context, the main effort consists in the optimization of two antagonist objectives, i.e., the computational accuracy and speed. This can be achieved by selecting the appropriate network architecture. In [89], the search space of architectures has been restricted to feedforward neural networks, mainly motivated by their simplicity while still being able to capture global interactions between the inputs. Although one might end up with a relevant number of parameters, a speedup about 18 times faster has been achieved (compared to the simplest finite difference quadrature methods). Moreover, this approach easily allows efficient parallelization schemes on graphical processing units (GPUs), without any effort, with the use of modern deep learning libraries. In fact, within this approach, most of the computations consist of matrix multiplications. As an example, Fig. 43.9 shows the Wigner kernel corresponding to a double barrier potential computed by a finite difference method (left) and by a trained neural network (right). No difference is visible to the naked eye.

Abstract

The nonequilibrium Green function (NEGF) method was established in the 1960s through the classic work of Schwinger, Kadanoff, Baym, Keldysh, and others using many-body perturbation theory (MBPT) and the diagrammatic theory for nonequilibrium processes. Much of the literature is based on the original MBPT-based approach, and this makes it inaccessible to those unfamiliar with advanced quantum statistical mechanics. We obtain the NEGF equations directly from a one-electron Schrödinger equation using relatively elementary arguments. These equations have been used to discuss many problems of great interest such as quantized conductance, (integer) quantum Hall effect, Anderson localization, resonant tunneling, and spin transport without a systematic treatment of many-body effects. But it goes beyond purely coherent transport allowing us to include phase-breaking interactions (both momentum-relaxing and momentum-conserving as well as spin-conserving and spin-relaxing) within a self-consistent Born approximation. We believe that the scope and utility of the NEGF equations transcend the MBPT-based approach originally used to derive it. NEGF teaches us how to combine quantum dynamics with "contacts" much as Boltzmann taught us how to combine classical dynamics with "contacts," using the word "contacts" in a broad figurative sense to denote all kinds of entropy-driven processes. We believe that this approach to "contact-ing" the Schrödinger equation should be of broad interest to anyone working on device physics or nonequilibrium statistical mechanics in general.

44.1 Introduction

The nonequilibrium Green function (NEGF) method was pioneered in the 1960s by the classic work of Martin, Schwinger [1], Kadanoff, Baym [2], Keldysh [3], and others, which have been discussed in many review articles such as Danielewicz [4] and Mahan [5]. After the advent of mesoscopic physics in the 1980s, this method was combined with the Landauer approach (see [6–8]), and this "NEGF-Landauer method" has been widely used in the field of nanoelectronics for device modeling and technology development (see [9–23] as a small subset of a vast literature). The chapter by Klimeck and Boykin in this volume provides an introduction to state-of-the-art quantum transport simulation tools based on this method. The present chapter is intended to serve a complementary purpose, namely, to introduce the conceptual underpinnings of NEGF and to answer some frequently asked questions regarding them.

The iconic device in modern electronics is the field effect transistor (FET), billions of which are a part of every smartphone. An oversimplified sketch of an FET is shown in Fig. 44.1 consisting of an active region marked the *channel* sandwiched between two highly conductive regions labeled the *source* and the *drain*. An FET also has a third terminal (not shown) which can be used to control the resistance $R = V/I$ of the channel, but we will not get into such "details." We will focus just on the problem of calculating the steady-state charge current I for a given voltage V taking *quantum* effects into account.

Quantum mechanical descriptions usually start from a Hamiltonian matrix $\mathbf{H}$ whose eigenvalues give us the allowed energy levels. However, if we treat the structure like a closed system described just by an $\mathbf{H}$, an applied voltage will cause opposite charges to pile up in the source and drain, and we will have a capacitor and not a resistor. What makes it a resistor is the external battery that continually takes electrons out of the drain and inserts electrons back into the source to maintain an electrochemical potential difference: $\mu_1 - \mu_2 = qV$.

One way to describe such an open system is to describe the two contacts denoted 1 and 2 through self-energy functions $\mathbf{\Sigma}_{1,2}$, $\mathbf{\Sigma}^{\text{in}}_{1,2}$. The first of these $\mathbf{\Sigma}_{1,2}$ has a Hermitian part that modifies the Hamiltonian and an anti-Hermitian part that represents the rate at which electrons escape from the channel. The second of these $\mathbf{\Sigma}^{\text{in}}_{1,2}$ represents the inflow of the electrons into the channel from the contacts. In addition to these physical contacts, there are abstract "contacts" representing the interactions of the electrons with the lattice and with other electrons as they traverse the channel, and these are described the self-energy functions $\mathbf{\Sigma}_0$, $\mathbf{\Sigma}^{\text{in}}_0$. To apply the NEGF method to a given problem, there are two steps:

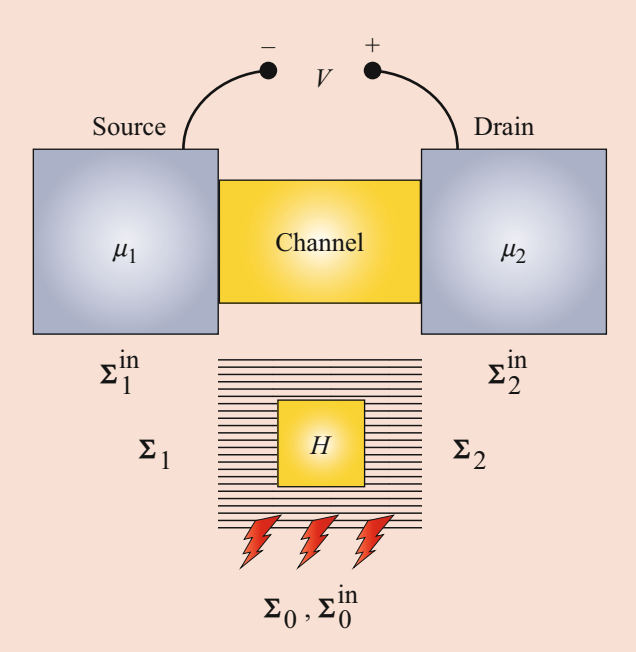

Fig. 44.1 A resistor: Physical structure comprising a channel with two contacts, labeled source and drain. In the nonequilibrium Green function (NEGF) method, the channel is described by a Hamiltonian $\mathbf{H}$, while its connection to the "contacts" is described by the self-energy functions $\mathbf{\Sigma}$, $\mathbf{\Sigma}^{\text{in}}$: subscripts 1 and 2 denote the physical contacts labeled source and drain, while the subscript 0 represents abstract contacts like the phonon bath

1. Identify the appropriate Hamiltonian $\mathbf{H}$ and self-energy functions $\mathbf{\Sigma}_m$, $\mathbf{\Sigma}^{\text{in}}_m$
2. Use these in the NEGF Eqs. (44.1–44.3) summarized in Sect. 44.2 to calculate quantities of interest like current, electron density, or density of states.

The NEGF method is commonly viewed as an esoteric tool accessible only to a small group of specialists. To quote from two popular books [24, 25]:

> …In this respect, the most difficult topic is probably the non-equilibrium Green's function formalism of Chapter 4 …

> …Because of my aim of avoiding too heavy formalism I have chosen not to describe non-equilibrium Green's function approaches to transport phenomena. Courses detailing these approaches usually spend half the time on the formalism, finding the poles of the various Green's functions, and figuring out analytic continuations and so on …

Both books are pedagogically outstanding, and we cite them only to stress that NEGF is considered difficult even by the foremost practitioners in the field. And the reason is that the traditional discussion of NEGF is based on many-body perturbation theory (MBPT) which takes many semesters of advanced quantum mechanics to master.

However, as we have often noted [26], the only aspect of NEGF that really requires MBPT is in writing down the self-energy functions $\mathbf{\Sigma}_0$, $\mathbf{\Sigma}_0^{\text{in}}$ describing interactions within the channel. Everything else can be accomplished without the use of MBPT, including deriving the NEGF Eqs. (44.1–44.3) and writing down the noninteracting channel Hamiltonian $\mathbf{H}$ along with the self-energy functions for the physical contacts $\mathbf{\Sigma}_{1,2}$ and $\mathbf{\Sigma}_{1,2}^{\text{in}}$. This is the approach one of us has used in all his books starting from Chapter 8 of [27] and later in [28] and Part B of [29]. The recent book by Ghosh [30] is unique in describing both our approach and the MBPT-based one along with special non-perturbative approaches.

44.1.1 Decoupling NEGF from MBPT

Why is the standard treatment so heavily dependent on MBPT? We believe the reason is historical. Until 1990 it was common to regard the physical contacts as an unimportant detail and view the channel interactions as the essential physics. And so the original papers in the field dating back to the 1960s described the resistance in terms of $\mathbf{\Sigma}_0$, $\mathbf{\Sigma}_0^{\text{in}}$ and never even considered the $\mathbf{\Sigma}_{1,2}$, $\mathbf{\Sigma}_{1,2}^{\text{in}}$ describing the physical contacts.

What changed around 1990 was the widespread experimental measurement of the resistance of *ballistic conductors* where electrons zip through the channel like bullets with little or no interactions making $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{\text{in}}$ negligible. Do such conductors have a resistance? The experimental answer was a resounding *yes* (For example, [31] is one of the first experiments that established the fundamental limits of conductance in such ballistic conductors. Later, scientists have even measured the resistance of a single molecule [32]!). A current I flowing through a nonzero resistance R must generate a heat I^2R. Heat is generated when energetic electrons give up some of their energy to the lattice making the atoms jiggle, which manifests itself as an increase in temperature.

But if there are no interactions in the channel, then how can heat be generated? The answer is that the heat is generated within the contacts (Fig. 44.2a) which is not surprising since a bullet heats up the material it hits and not the medium it flies through. A corollary of this observation is that although any resistance R is accompanied by the generation of I^2R heat, the heating need not occur exactly where the resistance is caused.

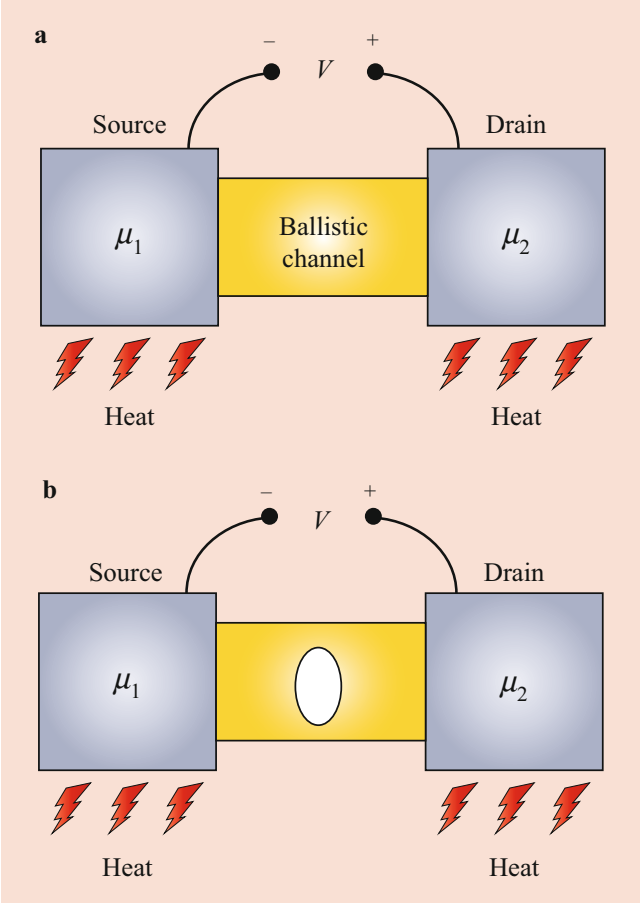

Fig. 44.2 (**a**) In a ballistic conductor, the resistance arises from the channel-contact interfaces, but the heating occurs deeper in the contacts. (**b**) A ballistic conductor with a hole further accentuates the spatial separation between the microscopic cause of resistance and the resulting generation of heat

For example, in the ballistic conductor, the resistance is caused by the channel-contact interfaces, while the heating could occur away from the interface. This separation of the resistance R and its heat I^2R is even more stark if we consider a ballistic conductor with a hole in the middle (Fig. 44.2b). We would expect the hole to cause a large increase in resistance by obstructing the flow of electrons. But it does not have the *internal degrees of freedom* needed to get heated which must still occur far away somewhere in the contacts (An experimental observation that supports this viewpoint is current transport through carbon nanotubes. Despite being extremely small in diameter and volume, carbon nanotubes can carry enormous amounts of current, and if there were any significant energy dissipation within the channel, they could not get rid of such excessive heat and would burn up.).

However, pre-1990, it was not common to talk of resistance in a model without explicitly including interactions and dissipation in the channel (Though device engineers had started to recognize that momentum and energy relaxation

lengths could be very different in late 1980s. See, for example, [33].). Indeed much of the work on quantum transport was based on the Kubo formula which equates resistance to dissipation and then relates it to noise through the fluctuation-dissipation theorem. This is a powerful approach to linear response problems, but it tends to create the impression that the origin of resistance is energy relaxation rather than momentum relaxation. But it now seems clear that resistance is caused by momentum exchange, and the resulting energy exchange need not occur at the same location. It is possible to create a zero-order model for resistance without including any $\mathbf{\Sigma}_0$ or $\mathbf{\Sigma}_0^{\text{in}}$, and this approach at least has enormous pedagogical value.

The NEGF Eqs. (44.1–44.3) obtained in the next section from elementary quantum mechanics are the *same* as those obtained in the classic paper by Keldysh using MBPT [3]. The difference is that we obtain them considering only the physical contacts described by $\mathbf{\Sigma}_{1,2}$ and $\mathbf{\Sigma}_{1,2}^{\text{in}}$, while the classic treatment considers only the many-body interactions described by $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{\text{in}}$. Our approach makes it accessible to a much wider audience, and for over a decade, we have been teaching the NEGF equations to advanced undergraduate and beginning graduate students, both on campus and online.

We believe the utility of this approach goes beyond the purely pedagogical. It decouples the NEGF Eqs. (44.1–44.3) from MBPT, thus clearing the path for alternative approaches to $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{\text{in}}$ including non-perturbative methods as well as phenomenological approaches. In this chapter we will present a simple example of the latter.

44.1.2 Outline

In Sect. 44.2 we will briefly summarize the NEGF equations followed by a brief outline of their derivation from the one-electron Schrödinger equation in Sect. 44.3. In Sect. 44.4 we present toy examples to give the reader a feeling for how the method is applied. Corresponding Python codes are also included for interested readers. We end in Sect. 44.5 with answers to a few commonly asked questions. For more detailed examples and discussions, we refer the reader to Chapter 8 of [27,28], and Part B of [29].

44.2 NEGF Equations

There are three NEGF equations as described below:

1. First is the equation for the quantum *density of states* (times 2π) (Note that the quantum density of states is generally a dense matrix of size $N \times N$ for a lattice size of N ($2N \times 2N$ if electron spin is included). Its diagonal entries correspond to the classical local density of states, but off-diagonal elements also contain useful information. For example, when the quantum density of states is multiplied by Pauli spin matrices, the diagonal elements provide local density of states *for a particular spin* as we show later by an example in Sect. 44.4.6. The matrix nature of $\mathbf{A}$ and $\mathbf{G}^{\text{n}}$ compared to their classical counterparts that are of size $N \times 1$ is due to the quantum generalization of these quantities.):

$$\mathbf{A} = i\left[\mathbf{G}^{\text{R}} - \mathbf{G}^{\text{A}}\right]$$

where the advanced Green function $\mathbf{G}^{\text{A}}$ is the Hermitian conjugate of the retarded Green function $\mathbf{G}^{\text{R}}$ given by ($\mathbf{\Sigma} = \mathbf{\Sigma}_0 + \mathbf{\Sigma}_1 + \mathbf{\Sigma}_2$):

$$\mathbf{G}^{\text{R}} = [E\mathbf{I} - \mathbf{H} - \mathbf{\Sigma}]^{-1} \tag{44.1}$$

2. Next is the equation for the quantum *electron density* (times 2π) per unit energy:

$$\mathbf{G}^{\text{n}} = \mathbf{G}^{\text{R}}\,\mathbf{\Sigma}^{\text{in}}\,\mathbf{G}^{\text{A}} \tag{44.2}$$

3. And finally the current per unit energy $\tilde{I}_m$ at contact m is given by:

$$\tilde{I}_m = \frac{q}{h}\,\text{Trace}\left[\mathbf{\Sigma}_m^{\text{in}}\mathbf{A} - \mathbf{\Gamma}_m\,\mathbf{G}^{\text{n}}\right] \tag{44.3}$$

where $\mathbf{\Gamma}_m = i\left[\mathbf{\Sigma}_m - \mathbf{\Sigma}_m^{\dagger}\right]$.

We use a notation that is slightly different from that used in the conventional literature because it helps provide a physical picture for different quantities. For example, we use $\mathbf{G}^{\text{n}}$ instead of the traditional $-i\mathbf{G}^{<}$ because $\mathbf{G}^{\text{n}}$ represents a matrix version of the *electron density*. The correspondences are summarized in a table to help the reader translate our equations as needed (Table 44.1).

Table 44.1 NEGF symbols used in this chapter and their counterpart in the literature

Conventional symbol	Physical interpretation	Symbol used in this book
$-i\mathbf{G}^{<}$	Matrix electron density	$\mathbf{G}^{\text{n}}$
$+i\mathbf{G}^{>}$	Matrix hole density	$\mathbf{G}^{\text{p}}$
$-i\mathbf{\Sigma}^{<}$	In-scattering function	$\mathbf{\Sigma}^{\text{in}}$
$+i\mathbf{\Sigma}^{>}$	Out-scattering function	$\mathbf{\Sigma}^{\text{out}}$

44.3 NEGF Equations from One-Electron Schrödinger Equation

Let us briefly indicate how the NEGF Eqs. (44.1–44.3) are obtained directly from the one-electron Schrödinger equation $E\,\boldsymbol{\psi} = \mathbf{H}\,\boldsymbol{\psi}$. The first step is to incorporate the effect of the *open boundary conditions* imposed by the contacts through

two additional terms:

$$E\,\boldsymbol{\psi} \;=\; \mathbf{H}\,\boldsymbol{\psi} \;+\; \underbrace{\boldsymbol{\Sigma}\,\boldsymbol{\psi}}_{\text{Outflow}} \;+\; \underbrace{\mathbf{s}}_{\text{Inflow}} \tag{44.4}$$

Note that the modification of the Schrödinger equation by the $\boldsymbol{\Sigma}$ and the $\mathbf{s}$ terms leads to a conceptually different viewpoint of energy. Instead of being the resonant energies of a given system described by $\mathbf{H}$, energy now becomes an independent variable related to the incoming electrons from the contacts that excite the channel (see Chapter 8 of [28] for a detailed discussion).

44.3.1 NEGF Eqs. (44.1) and (44.2)

From Eq. (44.4) we write the wave function as

$$\boldsymbol{\psi} \;=\; [E\mathbf{I} - \mathbf{H} - \boldsymbol{\Sigma}]^{-1}\,\mathbf{s} \;=\; \mathbf{G}^{\mathrm{R}}\,\mathbf{s}$$

making use of the definition of $\mathbf{G}^{\mathrm{R}}$ from NEGF Eq. (44.1). Note that $\boldsymbol{\Sigma}$ is non-Hermitian so that $E\mathbf{I} - \mathbf{H} - \boldsymbol{\Sigma}$ is not singular for any real value of E and has a well-defined inverse $\mathbf{G}^{\mathrm{R}}$.

Since different sources "$\mathbf{s}$" are incoherent, we cannot superpose the resulting $\boldsymbol{\psi}$s from multiple sources. So we define bilinear quantities that *can* be superposed:

$$\underbrace{\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger}}_{\mathbf{G}^{\mathrm{n}}/(2\pi)} \;=\; \mathbf{G}^{\mathrm{R}}\;\underbrace{\mathbf{s}\mathbf{s}^{\dagger}}_{\boldsymbol{\Sigma}^{\mathrm{in}}/(2\pi)}\;\mathbf{G}^{\mathrm{A}}$$

giving us NEGF Eq. (44.2).

In our description $\boldsymbol{\psi}$ is the one-electron wave function whose square gives the probability of finding an electron. When averaged over all electrons in an ensemble, it gives the electron density. More generally $\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger}$ is a matrix whose diagonal elements give the probabilities, and the off-diagonal elements give the correlations. For a more formal justification using field operators, the reader can check the Appendix in [28].

Note that $\mathbf{s}\mathbf{s}^{\dagger}$ reflects the availability of electrons at a given energy in the contacts which fill the available states in the channel giving rise to $\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger}$. Fermi functions are invoked only in the contacts and not in the channel.

44.3.2 NEGF Eq. (44.3)

Starting from the time-dependent version of the modified Schrödinger equation, Eq. (44.4):

$$i\hbar\,\frac{\mathrm{d}}{\mathrm{d}t}\,\boldsymbol{\psi} \;=\; [\mathbf{H}+\boldsymbol{\Sigma}]\,\boldsymbol{\psi} \;+\; \mathbf{s}$$

and its conjugate transpose (noting that $\mathbf{H}$ is a Hermitian matrix):

$$-\,i\hbar\,\frac{\mathrm{d}}{\mathrm{d}t}\,\boldsymbol{\psi}^{\dagger} \;=\; \boldsymbol{\psi}^{\dagger}\,[\mathbf{H}+\boldsymbol{\Sigma}^{\dagger}] \;+\; \mathbf{s}^{\dagger}$$

and making use of the relations:

$$\boldsymbol{\psi} \;=\; \mathbf{G}^{\mathrm{R}}\,\mathbf{s} \quad\text{and}\quad \boldsymbol{\psi}^{\dagger} \;=\; \mathbf{s}^{\dagger}\,\mathbf{G}^{\mathrm{A}},$$

we can write:

$$\begin{aligned} i\hbar\,\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger} &= \left(i\hbar\,\frac{\mathrm{d}}{\mathrm{d}t}\,\boldsymbol{\psi}\right)\boldsymbol{\psi}^{\dagger} \;+\; \boldsymbol{\psi}\left(i\hbar\,\frac{\mathrm{d}}{\mathrm{d}t}\,\boldsymbol{\psi}^{\dagger}\right) \\ &= ([\mathbf{H}+\boldsymbol{\Sigma}]\,\boldsymbol{\psi}+\mathbf{s})\,\boldsymbol{\psi}^{\dagger} - \boldsymbol{\psi}\left(\boldsymbol{\psi}^{\dagger}\,[\mathbf{H}+\boldsymbol{\Sigma}^{\dagger}] + \mathbf{s}^{\dagger}\right) \\ &= \left[(\mathbf{H}+\boldsymbol{\Sigma})\,\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger} - \boldsymbol{\psi}\boldsymbol{\psi}^{\dagger}(\mathbf{H}+\boldsymbol{\Sigma}^{\dagger})\right] \\ &\quad + \left[\mathbf{s}\mathbf{s}^{\dagger}\mathbf{G}^{\mathrm{A}} - \mathbf{G}^{\mathrm{R}}\mathbf{s}\mathbf{s}^{\dagger}\right] \end{aligned}$$

Making use of:

$$2\pi\,\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger} \;=\; \mathbf{G}^{\mathrm{n}} \quad\text{and}\quad 2\pi\,\mathbf{s}\mathbf{s}^{\dagger} \;=\; \boldsymbol{\Sigma}_{\mathrm{in}}$$

we can write:

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger} \;=\; \frac{[\mathbf{H}\mathbf{G}^{\mathrm{n}} - \mathbf{G}^{\mathrm{n}}\mathbf{H}]+[\boldsymbol{\Sigma}\mathbf{G}^{\mathrm{n}} - \mathbf{G}^{\mathrm{n}}\boldsymbol{\Sigma}^{\dagger}]+[\boldsymbol{\Sigma}^{\mathrm{in}}\mathbf{G}^{\mathrm{A}} - \mathbf{G}^{\mathrm{R}}\boldsymbol{\Sigma}^{\mathrm{in}}]}{i\,2\pi\hbar}. \tag{44.5}$$

We can interpret $\boldsymbol{\psi}\boldsymbol{\psi}^{\dagger}$ as the number operator so that its derivative represents the current operator. To find the change of any quantity A, we can multiply by the corresponding operator $\mathbf{A}_{\mathrm{op}}$ and take the trace to obtain:

$$\begin{aligned} \frac{\mathrm{d}A}{\mathrm{d}t} = -\frac{i}{\hbar}\mathrm{Trace}([\mathbf{H}\mathbf{G}^{\mathrm{n}} - \mathbf{G}^{\mathrm{n}}\mathbf{H}]\mathbf{A}_{\mathrm{op}} + [\boldsymbol{\Sigma}\mathbf{G}^{\mathrm{n}} - \mathbf{G}^{\mathrm{n}}\boldsymbol{\Sigma}^{\dagger}]\mathbf{A}_{\mathrm{op}} \\ + [\boldsymbol{\Sigma}^{\mathrm{in}}\mathbf{G}^{\mathrm{A}} - \mathbf{G}^{\mathrm{R}}\boldsymbol{\Sigma}^{\mathrm{in}}]\mathbf{A}_{\mathrm{op}}) \end{aligned}$$

The first term represents the change in the quantity A inside the channel due to the action of the Hamiltonian $\mathbf{H}$, while the last two terms represent the "*A current*" injected from the terminals. We can define the terminal current operator $\mathbf{I}_{\mathrm{op}}$ as:

$$\mathbf{I}_{\mathrm{op}} = -\frac{i}{h}\;\left([\boldsymbol{\Sigma}\boldsymbol{G}^{\mathrm{n}} - \mathbf{G}^{\mathrm{n}}\boldsymbol{\Sigma}^{\dagger}] \;+\; [\boldsymbol{\Sigma}^{\mathrm{in}}\mathbf{G}^{\mathrm{A}} - \mathbf{G}^{\mathrm{R}}\boldsymbol{\Sigma}^{\mathrm{in}}]\right) \tag{44.6}$$

such that the "*A current*" can be obtained from the trace of $\mathbf{A}_{\mathrm{op}}\mathbf{I}_{\mathrm{op}}$.

If we are interested only in the charge current, then we need the trace of $\mathbf{I}_{\text{op}}$ since the charge operator is an identity matrix (times the electronic charge). Noting that Trace [**AB**] = Trace [**BA**], we can write:

$$\text{Trace}\,[\mathbf{I}_{\text{op}}] \;=\; \frac{1}{h}\,\text{Trace}\left[\mathbf{\Sigma}^{\text{in}}\mathbf{A} - \mathbf{\Gamma}\mathbf{G}^{\text{n}}\right].$$

Both the left- and the right-hand sides of this equation are zero, since we are discussing steady-state charge transport with no time variation. But the terms on the left can be separated into two parts, one associated with contact 1 and one with contact 2. They tell us the currents at contacts 1 and 2, respectively, and the fact that they add up to zero is simply a statement of *Kirchhoff's law* for steady-state currents in circuits (Note that Eq. (44.6) can also be used to obtain terminal *spin* currents if both sides of the equation are multiplied by Pauli spin matrices corresponding to a desired spin direction. In this case however, the standard Kirchhoff's laws for charge transport may not hold, but it is still possible to design "spin circuits" that obey Kirchhoff's laws [34].). With this in mind, we can write for the current at contact m ($m = 1, 2$):

$$\tilde{I}_m \;=\; \frac{q}{h}\,\text{Trace}\left(\mathbf{\Sigma}_m^{\text{in}}\mathbf{A} \;-\; \mathbf{\Gamma}_m\,\mathbf{G}^{\text{n}}\right)$$

as stated in NEGF Eq. (44.3).

44.4 A Simple Example

In this section we will outline the application of the NEGF Eqs. (44.1) and (44.2) to a simple example centered around a one-dimensional conductor with a barrier U and connected to two contacts with Fermi functions $f_1(E) = 1$ and $f_2(E) = 0$ (Fig. 44.3). The reader can consult Part B of [29] for more details.

44.4.1 Hamiltonian H

We describe the 1D channel using a simple tight-binding Hamiltonian **H** with ε on the diagonal and t on the upper and lower diagonals, as shown pictorially in Fig. 44.4. This leads to a dispersion relation of the form:

$$E(k) \;=\; \varepsilon + 2t\cos(ka) \qquad (44.7a)$$

This cosine dispersion can approximate a parabolic one:

$$E \;=\; E_{\text{c}} + \frac{\hbar^2 k^2}{2m} \qquad (44.7b)$$

if we choose:

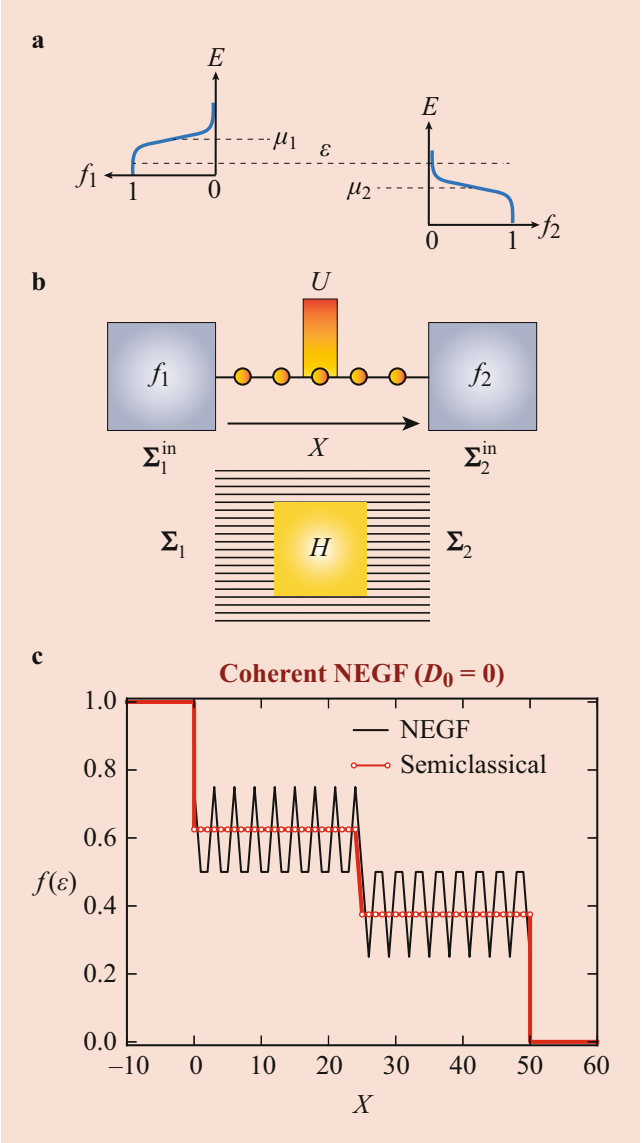

Fig. 44.3 (**a**) A simple one-dimensional conductor with a barrier U and connected to two contacts with Fermi functions $f_1(E) = 1$ and $f_2(E) = 0$. (**b**) To analyze it using the NEGF Eqs. (44.1) and (44.2), we need the **H** to describe the channel and the **Σ**s to describe the physical contacts. Interactions in the channel are ignored in this example ($D_0 = 0$). (**c**) Plot of the occupation factor across the channel

$$E_{\text{c}} \;=\; \varepsilon + 2t \qquad (44.8a)$$

$$\text{and} \qquad -t \equiv t_0 \equiv \frac{\hbar^2}{2ma^2}. \qquad (44.8b)$$

44.4.2 Self-Energy Due to Contacts

The self-energy function for each contact has only one nonzero element corresponding to the point that is connected to that contact:

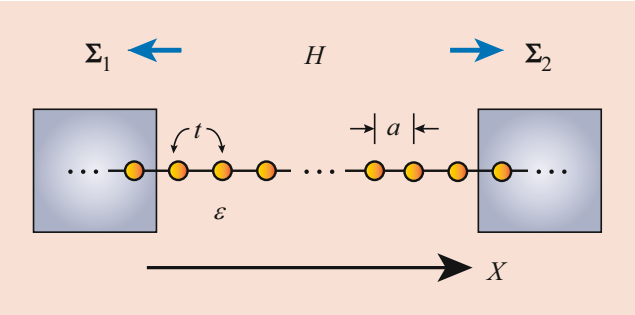

Fig. 44.4 For the one-dimensional examples discussed in this chapter, we use the 1D Hamiltonian shown with on-site elements ε and nearest neighbor coupling t

$$\boldsymbol{\Sigma}_1 = \begin{bmatrix} te^{ika} & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix}, \quad \boldsymbol{\Sigma}_2 = \begin{bmatrix} 0 & \cdots & 0 & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & 0 & te^{ika} \end{bmatrix}$$

44.4.3 Inscattering from Contacts

The inscattering functions are given simply by the broadening functions times the corresponding occupation factor:

$$\boldsymbol{\Sigma}_1^{\text{in}} = \boldsymbol{\Gamma}_1 f_1 \quad \text{and} \quad \boldsymbol{\Sigma}_2^{\text{in}} = \boldsymbol{\Gamma}_2 f_2 \tag{44.9}$$

where the broadening functions are obtained from $\boldsymbol{\Gamma}_{1,2} = i[\boldsymbol{\Sigma}_{1,2} - \boldsymbol{\Sigma}_{1,2}^\dagger]$:

$$\boldsymbol{\Gamma_1} = \frac{\hbar v}{a} \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix}, \quad \boldsymbol{\Gamma_2} = \frac{\hbar v}{a} \begin{bmatrix} 0 & \cdots & 0 & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & 0 & 0 \\ 0 & \cdots & 0 & 0 & 1 \end{bmatrix}$$

noting that the velocity $v = \mathrm{d}E/(\hbar \mathrm{d}k)$ which from the dispersion relation Eq. (44.7a) equals $-2at/\hbar \sin(ka)$.

Given these matrices it is straightforward to use the NEGF Eqs. (44.1) and (44.2) to evaluate the "electron density" $\mathbf{G}^{\text{n}}/2\pi$ and the "density of states" $\mathbf{A}/2\pi$ from which we can obtain the ℓ-th element of the occupation factor

$$f_\ell = \frac{G^{\text{n}}_{\ell,\ell}}{A_{\ell,\ell}}$$

which is plotted in Fig. 44.3. Note that the NEGF occupation factor shows oscillations due to quantum interference around the average values expected from a semiclassical picture. The semiclassical curve is based on three localized resistors in series, one each at the two interfaces and one at the barrier:

$$\frac{R}{h/q^2} = \underbrace{\frac{1}{2}}_{\text{Channel-source interface}} + \underbrace{\frac{1-T}{T}}_{\text{Barrier}} + \underbrace{\frac{1}{2}}_{\text{Channel-drain interface}} \tag{44.10}$$

where T is the transmission probability through the barrier given by:

$$T(E) = \frac{(\hbar v/a)^2}{U^2 + (\hbar v/a)^2} \tag{44.11}$$

This is a standard result that can be obtained from scattering theory on a discrete lattice [28]; next we will show how the NEGF equations lead to the same result.

44.4.4 Current

If we are not interested in the spatial variation of quantities like the occupation factor but are only interested in the current that flows for a given voltage, we can simply let the channel represent one point and treat the rest as contacts. This makes all matrices collapse to (1×1) reducing them to just numbers:

$$H = \varepsilon + U$$

$$\boldsymbol{\Sigma}_1(E) = te^{+ika} = \boldsymbol{\Sigma}_2(E) \quad \text{where } ka = \cos^{-1}\left(\frac{E-\varepsilon}{2t}\right)$$

$$\boldsymbol{\Sigma}(E) = \boldsymbol{\Sigma}_1(E) + \boldsymbol{\Sigma}_2(E) = 2te^{+ika}$$

$$\boldsymbol{\Gamma}_1 = \frac{\hbar v}{a} = \boldsymbol{\Gamma}_2$$

$$\boldsymbol{\Sigma}_1^{\text{in}} = \boldsymbol{\Gamma}_1 f_1, \quad \boldsymbol{\Sigma}_2^{\text{in}} = \boldsymbol{\Gamma}_2 f_2 \quad \text{and} \quad \boldsymbol{\Sigma}^{\text{in}} = \boldsymbol{\Gamma}_1 f_1 + \boldsymbol{\Gamma}_2 f_2$$

Now we do not need a computer to evaluate the NEGF Eqs. (44.1–44.3). We can just do it by hand. First we calculate G^{R} from Eq. (44.1):

$$\begin{aligned} G^{\text{R}}(E) &= \frac{1}{E - (\varepsilon + U) - 2te^{ika}} \\ &= \frac{1}{-U - i2t\,\sin(ka)} \\ &= \frac{1}{-U + i\hbar v/a} \end{aligned}$$

so that:

$$\begin{aligned} G^{\text{A}}(E) &= \frac{1}{-U - i\hbar v/a} \\ A(E) &= \frac{2\hbar v/a}{U^2 + (\hbar v/a)^2} \end{aligned}$$

Next from Eq. (44.2):

$$G^{\text{n}} = \frac{\hbar v/a}{U^2 + (\hbar v/a)^2}(f_1 + f_2)$$

so that from Eq. (44.3):

$$\tilde{I}(E) = \frac{q}{h}\frac{(\hbar v/a)^2}{U^2+(\hbar v/a)^2}\left(2f_1 - \overline{f_1+f_2}\right)$$
$$= \frac{q}{h}\underbrace{\frac{(\hbar v/a)^2}{U^2+(\hbar v/a)^2}}_{T(E)}\left(f_1 - f_2\right)$$

The quantity $T(E)$ represents the transmission probability through the barrier U. Integrating $\tilde{I}$(E) we get the total current. The quantity $T(E)$ is the same as the semiclassical transmission that was shown in Eq. (44.11).

44.4.5 Dephasing Interactions

What we have done so far represents coherent transport with no interactions in the channel. In this limit, the results could also have been obtained from the scattering theory of transport, sometimes referred to as the Landauer-Büttiker formalism. The NEGF method provides a convenient way to get the same results. However, the NEGF method also allows us to include channel interactions through the self-energy functions $\mathbf{\Sigma}_0$, $\mathbf{\Sigma}_0^{\text{in}}$.

It is important to include these interactions because the purely coherent model predicts quantum interference effects like the oscillations in Fig. 44.3 which are usually not seen experimentally except at extremely low temperatures. The reason is that the phase of individual electrons is destroyed by the random scattering potential it sees due to the other electrons. Such electron-electron interactions normally do not lead to any overall loss of momentum from the system of electrons and so have little effect on the mobility or the current. But they do lead to dephasing which suppresses the coherent oscillations. Dephasing may also arise from other sources such as electron-phonon interactions [35]. However, they usually cause momentum relaxation as well, thereby affecting the resistance. We specifically mention electron-electron interaction because it can cause dephasing without having any first-order effect on the resistance. Resistance typically becomes temperature independent around 10 K, once phonons have frozen out. But electron-electron interactions continue to cause dephasing, and it usually takes much lower temperatures to see interference effects.

The classic NEGF provides definite prescriptions for including all such effects from first principles starting from a microscopic Hamiltonian using MBPT as described in many available references. Here we will use a phenomenological approach that incorporates dephasing in terms of a single parameter D_0 which can be adjusted to reflect experimental dephasing times:

$$\mathbf{\Sigma}_0 = D_0\,\mathbf{G}^{\text{R}} \tag{44.12a}$$
$$\mathbf{\Sigma}_0^{\text{in}} = D_0\,\mathbf{G}^{\text{n}} \tag{44.12b}$$

Note that we now need to solve Eqs. (44.1) and (44.2) self-consistently since the same quantity appears on both the left- and right-hand sides:

$$\mathbf{G}^{\text{R}} = \left[E\mathbf{I} - \mathbf{H}[\mathbf{\Sigma_1} - \mathbf{\Sigma_2} - D_0\mathbf{G}^{\text{R}}\right]^{-1} \tag{44.13a}$$
$$\mathbf{G}^{\text{n}} = \mathbf{G}^{\text{R}}\,[\mathbf{\Sigma}_1^{\text{in}} + \mathbf{\Sigma}_2^{\text{in}} + D_0\mathbf{G}^{\text{n}}\,]\mathbf{G}^{\text{A}} \tag{44.13b}$$

The self-consistent calculation is straightforward to implement numerically, and a Python code is provided for readers interested in reproducing the results shown in Figs. 44.3 and 44.5. Note that the results for pure dephasing agree well with the simple semiclassical model based on series resistors (Eq. 44.10) as described earlier. Figure 44.5 also shows results for a slightly different model of interactions which relaxes both phase and momentum leading to a linear drop in the occupation factor across the channel like an ohmic resistor. In this slightly different model, the diagonal elements of $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{\text{in}}$ are the same as before, but all off-diagonal elements are set to zero [36, 37].

Intuitively, we can justify the pure phase relaxation model by thinking of it as distributed "Büttiker probes" that take electrons out of the channel and reinject them back into it to break their phase coherence [38]. But because the electron density ($\mathbf{G}^{\text{n}}$) is preserved *exactly* by constant multiplication, no property other than phase is relaxed. In contrast, just keeping the diagonal elements of the $\mathbf{G}^{\text{n}}$ in the real space representation breaks momentum in addition to phase since the reinjected electrons have no definite momentum and can flow in any direction. This intuition allows an immediate extension to spin-preserving but momentum-relaxing $\mathbf{\Sigma}_0$ as follows: supposing we express $\mathbf{H}$, $\mathbf{G}^{\text{n}}$ and lead $\mathbf{\Sigma}$s in $2N \times 2N$ matrices for a lattice of N points, following the same principle, we could write down a spin-conserving but momentum- and phase-relaxing $\mathbf{\Sigma}_0$ as:

$$\mathbf{\Sigma}_0 = \begin{bmatrix} \begin{bmatrix}1&1\\1&1\end{bmatrix} & 0 & \cdots\cdots & 0 \\ 0 & \begin{bmatrix}1&1\\1&1\end{bmatrix} & 0 \cdots & 0 \\ \vdots & \vdots & \vdots\ddots & \vdots \\ 0 & 0 & \cdots\cdots & \begin{bmatrix}1&1\\1&1\end{bmatrix} \end{bmatrix},$$

where the 2×2 blocks in each lattice point preserve spin information but phase and momentum are relaxed. Indeed, using this principle, we can write down $\mathbf{\Sigma}_0$s that can preserve information within *any* unit cell with B basis functions by having $B \times B$ blocks of all 1s that preserve local correlations

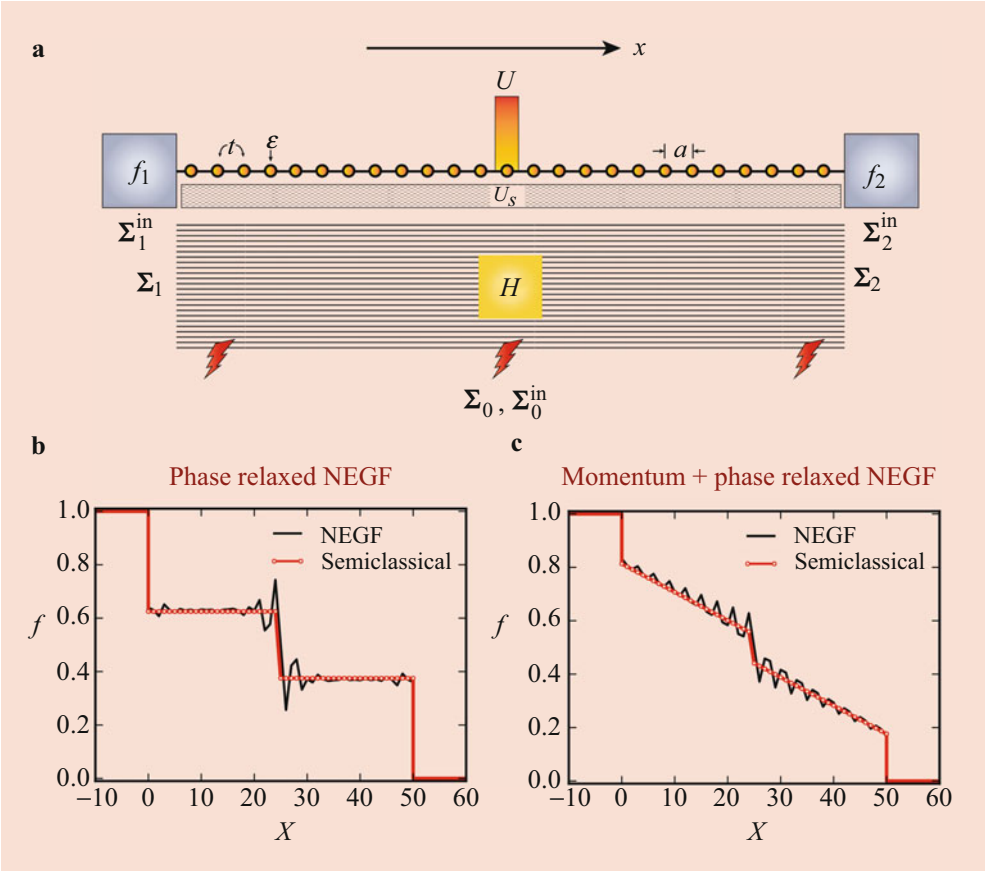

Fig. 44.5 (**a**) Same problem as in Fig. 44.3 but we now include the effect of a random potential U_S. (**b**) The effect of the random potential is incorporated through $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{in}$ where the magnitude of scattering, D_0, is $0.09\, t_0^2$. (**c**) Plot of occupation factor across channel for phase-relaxing scattering. (**d**) Plot of occupation factor across channel for phase- and momentum-relaxing scattering

in $\mathbf{G}^n$. In the next subsection, we show an example of spin-conserving dephasing in the context of spin transport.

44.4.6 Diffusive Spin Transport Using NEGF

Spin electronics or spintronics that combine spin transport with magnetics has attracted much attention in recent years [39]. Of particular interest are the so-called high spin-orbit materials such as Rashba channels or interfaces [40–43] as well as topological insulators [44] or heavy metals with high spin-orbit coupling [45,46]. NEGF allows a natural extension to incorporate spin transport in the tight-binding framework which makes the Hamiltonian for a lattice of N points a $2N \times 2N$ matrix. For example, consider a channel with a Rashba spin-orbit interaction that is described by the Hamiltonian:

$$\mathbf{H} = \mathbf{H}_0 + \eta\, (\boldsymbol{\sigma}_x k_y - \boldsymbol{\sigma}_y k_x) \tag{44.14}$$

where $\mathbf{H}_0$ represents the usual effective mass Hamiltonian, η is the Rashba coefficient, and $\boldsymbol{\sigma}$s are Pauli spin matrices. We can think of the Rashba interaction as an effective magnetic field that depends on the momentum of an electron if we associate $|\eta \mathbf{k}|$ as the magnitude of the effective magnetic field. Indeed, injecting x directed spins by using ferromagnetic contacts with momentum $(\pm k_x)$ can cause periodic oscillations of their spin, since these electrons would feel an effective magnetic field in the y direction. This effect was initially proposed in [47] and experimentally confirmed in [48], followed later by full demonstrations including the contacts [49–51].

Here, our purpose is to simply show how the NEGF formalism can be useful in modeling this effect in the presence of *momentum, phase, and spin* relaxations in a toy model. Figure 44.6a shows an NEGF simulation of 1D wire with Rashba spin-orbit coupling, attached to two ferromagnetic leads that point in the x direction. The left lead is an x-directed ferromagnet that injects x-spins in the channel. In the presence of momentum and phase relaxation, the chemical potential for charge goes steadily down as in Fig. 44.5. We can calculate the corresponding *spin* potentials by:

$$f_\ell^{x,y,z} = \frac{\text{Trace}\left[\mathbf{G}^n_{\ell,\ell}\, \boldsymbol{\sigma}_{x,y,z}\right]}{\text{Trace}\left[\mathbf{A}_{\ell,\ell}\right]}$$

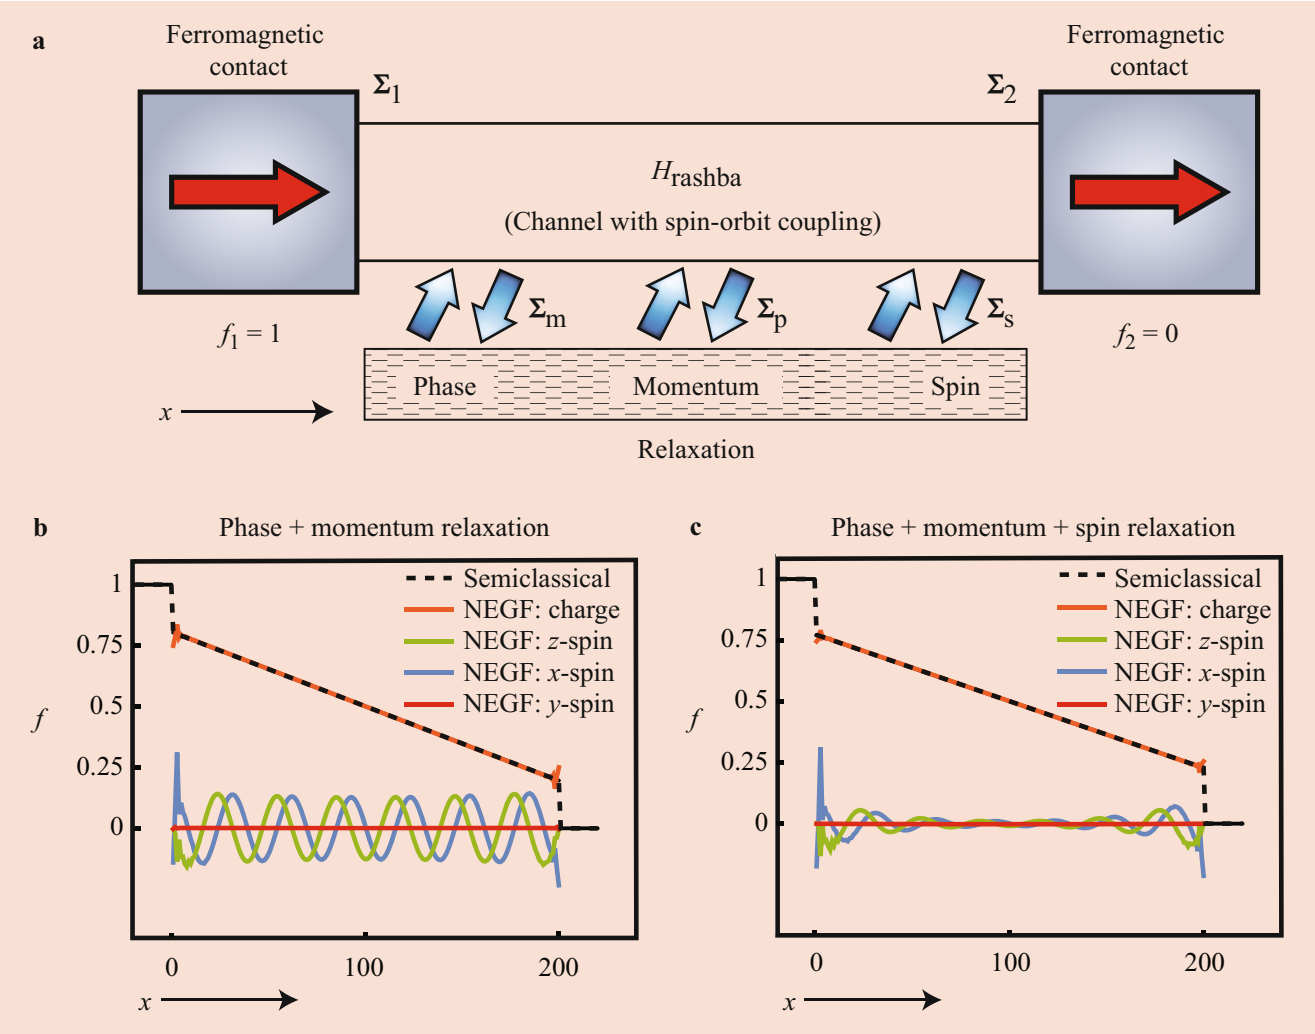

Fig. 44.6 (**a**) Rashba channel with ferromagnetic leads. Phase, momentum, and spin relaxation can be introduced to the system independently. (**b**) Spin precession is possible when $+x$-spins are injected to the channel even in the presence of phase and momentum relaxation. (**c**) Adding spin relaxation attenuates spin precession. (Python code available at the end of the article)

where "Trace" indicates tracing the 2×2 blocks of $\mathbf{G}^{\text{n}}$ and $\mathbf{A}$ at lattice point ℓ and $\boldsymbol{\sigma}$s are 2×2 Pauli spin matrices. Interestingly, if there is little to no spin relaxation, we see that the x-spins rotate in the channel even in the presence of high momentum and phase relaxation due to the effective magnetic field that is exerted on the x-spins by the Rashba channel. In practice, however, momentum relaxation in high spin-orbit materials is known to give rise to strong spin relaxation through the Elliott-Yafet [52] mechanism. Our purpose is simply to show that it is possible to include spin relaxation *independently* of momentum relaxation. This allows us to flexibly choose phase, momentum, and spin relaxation rates to match experimentally measured quantities when modeling real experiments. As discussed in [37], a possible spin flip relaxation model, $\boldsymbol{\Sigma}_0^{\text{sf}}$ can be written as:

$$\boldsymbol{\Sigma}^{\text{sf}}_{0,i,j} = D_0(\boldsymbol{\sigma}_x \mathbf{G}^{\text{n}}_{i,j} \boldsymbol{\sigma}_x + \boldsymbol{\sigma}_y \mathbf{G}^{\text{n}}_{i,j} \boldsymbol{\sigma}_y + \boldsymbol{\sigma}_z \mathbf{G}^{\text{n}}_{i,j} \boldsymbol{\sigma}_z) \qquad (44.15)$$

where the $\boldsymbol{\Sigma}_0^{\text{sf}}$ acts on all 2×2 subblocks of the $\mathbf{G}^{\text{n}}$ matrix that are labeled $\mathbf{G}^{\text{n}}_{i,j}$. By multiplying the terms out, we can easily see the effect of this dephasing is to reinject an electron *with an opposite spin* back to the channel that relaxes spin. In Fig. 44.6c we show how a pure spin relaxation model can be added in addition to momentum and phase breaking to reduce the spin signals in the channel.

44.4.7 Application to Superconducting Devices

An important application of the NEGF method is to devices where one of the contacts or the channel is superconducting. This is of great current interest due to the excitement surrounding the search for Majorana bound states (MBS) or equivalently Majorana zero modes (MZM) in Rashba

nanowire systems in proximity with superconductors [53–57]. It would take us too far afield to discuss the significant conceptual extensions needed for these problems, and so we will refer interested readers to a couple of old papers [58,59] and some recent ones [60–62].

44.5 Frequently Asked Questions

44.5.1 Shouldn't We Also Consider the Poisson Equation for Modeling Real Devices?

Yes. Earlier we mentioned the role of electron-electron interactions in causing dephasing which can be included through the anti-Hermitian part of the self-energy function $\mathbf{\Sigma}_0$. A far more important effect of electron-electron interactions is manifested through the Hermitian part of $\mathbf{\Sigma}_0$ which effectively modifies the Hamiltonian $\mathbf{H}$. The most important part of $\mathbf{\Sigma}_0$ is just the Coulomb potential U arising from the electron density $\mathbf{G}^n/2\pi$ and can be obtained by solving the Poisson equation and is often called the Hartree term. In addition there are more subtle contributions to $\mathbf{\Sigma}_0$ generally referred to as exchange and correlation effects which subtract from the Hartree term, see, for example, Chapter 2 of [28].

Since $\mathbf{\Sigma}_0$ depends on $\mathbf{G}^n$, this requires a self-consistent calculation: we start by assuming $\mathbf{\Sigma}_0 = 0$, use Eqs. (44.1) and (44.2) to calculate $\mathbf{G}^n$, use $\mathbf{G}^n$ to calculate $\mathbf{\Sigma}_0 = 0$, recalculate $\mathbf{G}^n$ from Eqs. (44.1) and (44.2), and so on till the results converge. This requirement for an iterative solution makes it much more difficult to calculate the energy levels even for helium which has two electrons compared to hydrogen which has only one electron and hence no electron-electron interactions.

Two more points to note. Firstly, in device simulations, it is common to use the Hamiltonian $\mathbf{H}$ from semiempirical methods that already include the $\mathbf{\Sigma}_0$ for a uniform channel material in equilibrium. As such it is necessary to include *only* the *change* in $\mathbf{\Sigma}_0$ when the channel is driven out of equilibrium by the applied bias. Secondly, this correction is not important for low applied voltages but plays a very significant role at high voltages. Indeed one can say that the saturation current for transistors is largely controlled by the Hartree term, making it primarily an electrostatically controlled device.

44.5.2 Can You Arbitrarily Designate the Ends as Contacts?

Designating a region as a contact implies that there is a significant increase in the number of conducting channels due to an increase in width and/or in the density of states. When analyzing a given structure, it is important to scrutinize the results carefully, to make sure that the assumed contacts are indeed functioning as nearly ideal reservoirs.

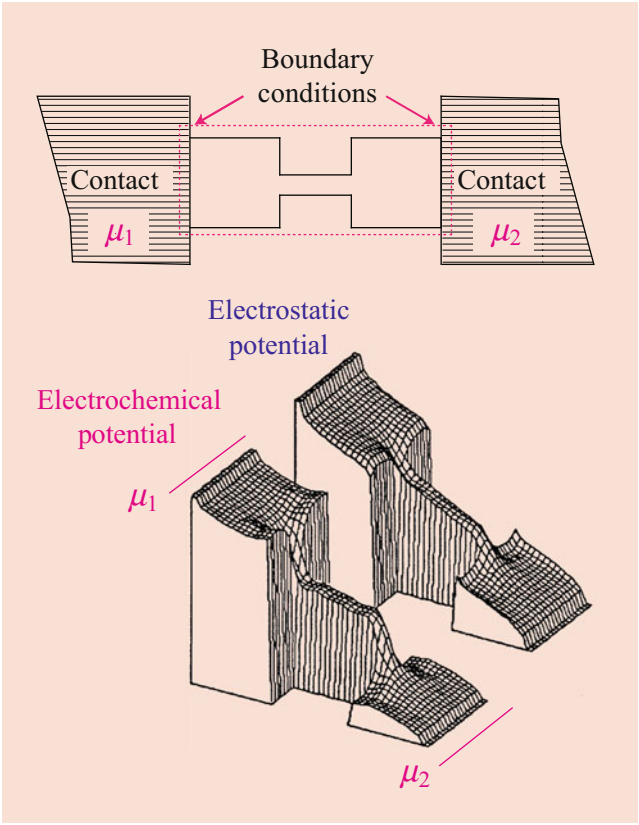

Fig. 44.7 A wide-narrow-wide ballistic constriction where the contacts are imposed inside the widest region. A numerical simulation with phase scattering shows the 2D profile of electrochemical and electrostatic potentials. (Reprinted Fig. 27b of [7] with permission from Michael et al. Copyright (1991) by the American Physical Society)

For example, Fig. 44.7 is an excerpt from an old paper showing a wide-narrow-wide structure (see Fig. 27a of [7]). We impose the contact boundary conditions inside the widest region as shown. Note the sharp drops in the occupation factor (or electrochemical potential) at the narrow-wide interfaces due to the interface resistance. The electrostatic potential is obtained by convolving the electrochemical potential with a screening function as explained in the paper (Fig. 27b of [7]). Note also the small drops where the wide regions meet the contacts indicating a small interface resistance.

One could save computation time by imposing the contact in the wide region rather than in the widest region. This may or may not be acceptable depending on how conductive the wide region is relative to the narrow region. A related phenomenon called the "source-starvation" effect where contact-like wide regions are driven out of equilibrium has been discussed in the context of ballistic nanotransistors [63].

44.5.3 Does NEGF Give the Correct Coherent and Semiclassical Limits?

Yes, with small dephasing, it matches the scattering theory for coherent transport, also called the Landauer-Büttiker formalism. With sufficient dephasing, it reproduces results from the semiclassical Boltzmann method, thus providing a bridge from quantum to semiclassical transport. The example presented earlier shows how the NEGF result for coherent transport includes oscillations around the Boltzmann result, which damp out when dephasing is included. Many such examples are included in [29] essentially as homework problems that are easily reproduced.

44.5.4 How Is This Related to the Kubo Formalism?

The Kubo formalism is a linear response theory based on small perturbations close to equilibrium. Many of the problems in modern nanoelectronics require a framework that can handle transport far from equilibrium. The results from NEGF agree with the Kubo formalism in the linear response regime close to equilibrium.

Isn't It a Problem to Have Separate Electrochemical Potentials in a Single System?

On the contrary, we would argue that current flow requires separate electrochemical potentials, just as the flow of heat requires separate temperatures. There is nothing fundamentally wrong with invoking two large reservoirs held at two different electrochemical potentials and/or temperatures connected by a nanoscale conductor.

Doesn't the Kubo Formula Use a Single Electrochemical Potential?

Yes, the Kubo formalism calculates an equilibrium quantity, namely, the noise, and relates it to the linear transport coefficients through the fluctuation-dissipation theorem. But this only works for transport close to equilibrium and is not possible in general. NEGF on the other hand addresses the nonequilibrium problem directly. Like the Boltzmann equation, NEGF too permits the use of separate electrochemical potentials as boundary conditions.

Can't You Have Equilibrium Currents with a Single Electrochemical Potential?

Yes, but these are distinct from the transport currents we are discussing. For example, in the quantum Hall regime, there are circulating edge currents which involve all electrons and not just the ones with energies close to μ. But these are normally not measured with external probes.

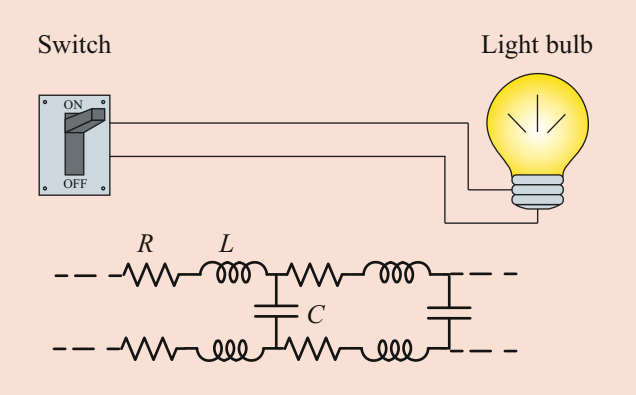

Fig. 44.8 When we turn the switch on, a signal propagates to the light bulb which can be described by a distributed *RLC* model. The capacitance *C* and the inductance *L* are determined primarily by electrostatics and magnetostatics, respectively

44.5.5 Isn't the Flow of Electricity Essentially a Many-Body Process?

As undergraduates we learn that current flow, at least in metals, is a many-body interacting process: when we turn the switch on, a signal propagates to the light bulb at the speed of light. One electron pushes the next electron, which pushes the next electron and so on. If we had to wait for an electron to transmit from the switch to the bulb, it would take far too long. And so it might seem futile to describe current flow without invoking many-body interactions. However, we believe that while signal propagation cannot be analyzed without interactions, the low-frequency resistance can be (Fig. 44.8).

This signal propagation can be described quantitatively by a distributed *RLC* model [64] (For a spin generalization of similar ideas, see [65].). The *L*s and *C*s in this model have a transport component but usually represent primarily the interactions, and the velocity is given by $1/\sqrt{LC}$. However, these parameters are not involved in determining the steady-state or *dc* current since at low frequencies the *L*s appear as short circuits and the *C*s are open circuits. The low-frequency resistance *R* can be understood at least approximately without invoking interactions.

This observation appears to apply to quantum transport as well. For example, in 1985 Richard Webb and collaborators from IBM reported [66] the Aharonov-Bohm (AB) effect in metallic rings with a period described quite well by the one-electron theory without interactions, as if we were talking about AB paths in vacuum! The one-electron picture works so well possibly because there is a Landau-style (We mean Landau, not Landauer!) dressed quasiparticle that "actually" moves from left to right. We have some mental pictures of what such a quasi-electron looks like, but we are not aware of any serious discussions along these lines.

Are Many-Body Effects Irrelevant in Transport Experiments?

That is not at all what we mean. Our point is that many-body effects are fairly obvious at high frequencies starting with the well-known fact that signals travel at the speed of light and not at the speed of electrons. By contrast their role at low frequencies are more subtle, like Coulomb blockade and the Kondo effect. More recently experiments on graphene have revealed intriguing evidence of collective motion [67].

In a volume published on the occasion of the 50th anniversary of *Anderson localization*, Phil Anderson commented "…What might be of modern interest is the channel concept which is so important in localization theory. The transport properties at low frequencies can be reduced to a sum over one dimensional channels."

Note the qualification *low frequencies*. Transmission of an electron from the left to the right contact is essential only for steady-state charge transport. High-frequency currents can flow capacitively without end-to-end transfer of electrons. Also, experiments have revealed that spins can be transported across insulators by magnons without the actual transmission of electrons (See, for example, [68,69] for possible practical applications of such pure spin conductors).

Would NEGF Be Suitable for Describing Such Effects?

NEGF provides a clear prescription for including arbitrary interactions to any desired order in perturbation theory. But some effects may require us to go beyond MBPT: perhaps a non-perturbative approach or a different perturbation parameter. Single-electron charging effects provide a good example [70].

44.5.6 How Can We Teach NEGF Without Advanced Quantum Statistical Mechanics?

The NEGF Eqs. (44.1) and (44.2) are essentially the same as Eqs. (75)–(77) of L. V. Keldysh [3], which is one of the seminal papers on the NEGF method that obtained these equations using MBPT and established the "diagram technique for nonequilibrium processes" for calculating the self-energy functions $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{\text{in}}$. Much of the literature is based on the original MBPT-based approach, and this makes it inaccessible to those unfamiliar with advanced quantum statistical mechanics.

We obtain the NEGF equations directly from a one-electron Schrödinger equation using relatively elementary arguments. These equations have been used to discuss many problems of great interest like quantized conductance, (integer) quantum Hall effect, Anderson localization, resonant tunneling, and spin transport without a systematic treatment of many-body effects. But it goes beyond purely coherent transport allowing us to include phase-breaking interactions (both momentum-relaxing and momentum-conserving) within a self-consistent Born approximation.

The NEGF equations provide a unified framework for such problems, spanning a wide range of materials and phenomena all the way from molecular to ballistic to diffusive transport, and have been widely adopted by the nanoelectronics community for device analysis and design.

44.5.7 But Is This the Real NEGF?

- The answer is NO, if we associate NEGF with the MBPT commonly used to obtain $\mathbf{\Sigma}_0$ and $\mathbf{\Sigma}_0^{\text{in}}$ appearing in Eqs. (44.1–44.3).
- The answer is YES, if we associate NEGF with Eqs. (44.1–44.3) irrespective of how the $\mathbf{\Sigma}$s are obtained.

Which answer we choose is clearly a matter of perspective, but the second viewpoint seems more in keeping with semiclassical transport theory, where the (steady-state) Boltzmann approach is identified with the equation:

$$\boldsymbol{v} \cdot \nabla f + \mathbf{F} \cdot \nabla_p f = S_{\text{op}} f$$

and NOT with the evaluation of the scattering operator S_{op} which is analogous to the $\mathbf{\Sigma}$s in NEGF. While the concept of the collision integral involved in S_{op} was well-known, the quantitative details of its evaluation has evolved significantly since the days of Boltzmann. Similarly, totally new approaches that go beyond many-body perturbation theory (MBPT) for evaluating the $\mathbf{\Sigma}$s have been and will be developed as we apply NEGF to newer problems.

44.5.8 Contacting Schrödinger

In summary, we feel that the scope and utility of the NEGF equations Eqs. (44.1–44.3) transcend the MBPT-based approach originally used to derive it. NEGF teaches us how to combine quantum dynamics with "contacts" much as Boltzmann taught us how to combine classical dynamics with "contacts," using the word "contacts" in a broad figurative sense to denote all kinds of entropy-driven processes. There are many problems of fundamental and applied significance that can be simulated straightforwardly within the NEGF method without a first principle treatment of many-body effects which in any case would be perturbative in nature. This includes novel phenomena like the (integer) quantum Hall effect as well as new devices like magnetic tunnel junctions. As such, we feel that this elegant framework for "contacting" the Schrödinger equation should be of broad interest to anyone working on device physics or nonequilibrium statistical mechanics in general.

Python codes for Figs. 44.3 and 44.5

```
# This code illustrates how to perform NEGF calculations on a simple
# 1D device with one scatterer in the middle of the channel region.

Kerem Y. Camsari is Assistant Professor at the University of California, Santa Barbara, since July 2020. He received his Ph.D degree in 2015 from Purdue University where he continued as a postdoctoral researcher until 2020. His research interests are in the areas of nanoelectronics, spintronics, and magnetism that enable new types of domain-specific circuits and architectures.

Shuvro Chowdhury received his B.Sc and M.Sc in Electrical and Electronic Engineering from Bangladesh University of Engineering and Technology, Bangladesh. He is currently pursuing his Ph.D in Electrical and Computer Engineering at Purdue University under the supervision of Professor Supriyo Datta. His research interest includes simulation and modeling of nanoelectronic devices and probabilistic and quantum computing.

Supriyo Datta started his career in ultrasonics, then worked on nanodevices and most recently on probabilistic computing. The approach to quantum transport pioneered by his group has been widely adopted in the field of nanoelectronics. He is also known for innovative theoretical proposals that have inspired new fields of research including molecular thermoelectricity, negative capacitance devices, and spintronics.

Tight-Binding Models, Their Applications to Device Modeling, and Deployment to a Global Community

Abstract

Tight-binding has become the state-of-the-art for realistically sized nanoscale device modeling. It has been implemented by multiple advanced device modeling research groups in conjunction with multiple quantum transport methodologies. Industry has begun to adopt some of the advanced codes and is beginning to implement company internal versions. Commercial software vendors are adopting the methodologies and are beginning to deploy the approaches into their commercial TCAD products. Intense software development combining tight-binding with the non-equilibrium Green's function (NEGF) approach and quantum transmitting boundary method (QTBM) for quantum transport began in 1994 at Texas Instruments. Acceptance of NEGF and tight-binding began with wider adoption in about 2004. The past 25 years have resulted in many model advancements, numerical technology development, and physics exploration that is by far too large to be covered here comprehensively. We start by setting forth the requirements for realistic modeling of extended

nanoscale devices (Sects. 45.1 and 45.2), which include a full quantum mechanical treatment, atomistic interface treatments, atomistic representations of crystal symmetries, polarization, strain, and bond directions, and embedding into macroscopic fields such as electromagnetic potentials and long-range strain. We then proceed to describe the essential definitions and features for empirical tight-binding (Sect. 45.3). Sections 45.4, 45.5, and 45.6 address numerical issues of tight-binding in terms of transfer matrices, Green's functions, and parallel scaling. Section 45.7 is dedicated to several applications around quantum dots and nanowires. We highlight million-atom quantum dot simulations and focus on carrier transport though silicon nanowires. We demonstrate how effective masses and bandgaps become design parameters at the nanoscale, how heavy masses are desirable for end-of-roadmap transistors, and how coherent transport assumptions break down. The nanowire simulations can be duplicated by everyone on nanoHUB.org. Section 45.8 highlights the widespread use of tight-binding within nanoHUB applications. Section 45.9 concludes this chapter.

45.1 Nanodevice Characteristics

Nanodevices by definition have extremely small active regions, so small that the number of atoms is, as a practical matter, countable. The small size has consequences for nanodevice physics; thus, these devices operate far differently than traditional semiconductor devices. The most important aspects of nanodevice physics that follow from their small size are: (1) length scales smaller than the electron wavelength; (2) a much higher surface-area-to-volume ratio, necessitating detailed surface modeling; (3) the importance of crystal orientation, rendering continuum models as invalid; (4) the interaction of long-range Coulomb potentials and strain fields with short-range quantum confinement. These physical consequences of the exceptionally small nanodevice size determine the requirements for modeling nanodevices.

Prototypical nanodevices, listed roughly in order of historical technical developments, are the resonant tunneling diode (RTD), quantum dots (QDs), and modern nanoFETs. The RTD consists of 1D vertically stacked, nanoscaled layers and can be considered the first room temperature quantum device geared up for electronic circuits. The RTD has, however, never found widespread technical adoption owing to a variety of technical issues. Although no longer really technically relevant, RTDs offer a wonderful utility to study and understand the intricacies of quantum transport in simple 1D geometries that become even more complicated in 3D. QDs confine electrons in 3D to nanoscale dimensions, are sometimes called artificial atoms, and they have found utility in optical applications. Because of the 3D confinement, they offer an extraordinarily clear view of the interplay between geometry and band-structure effects on optical interactions in these artificial atoms. Nano-scaled field effect transistors (nanoFETs) are ubiquitous and literally in everyone's pocket inside modern smart phones, and certainly in our laptops and notebooks. Understanding and optimizing carrier transport in such highly sophisticated 3D geometries is complex and still undergoing extensive research and development. We next briefly summarize the dimensions of these three prototypical devices.

The central part of a typical RTD heterostructure consists of two barriers measuring 3–5 nm thick surrounding a quantum well measuring 3–5 nm thick. The material system is typically GaAs/AlGaAs or InGaAs/InAlAs for the well/barrier. The central region of the RTD is typically undoped and surrounded by 10–30 nm of undoped spacer layers to reduce ionized dopant scattering near the central quantum device. This undoped region is surrounded by heavily, degenerately doped regions, so that under forward (reverse) bias electron reservoirs form adjacent to the emitter (collector) barriers. These long, heavily doped regions eventually terminate in quasi-ohmic metal contacts. The overall semiconductor device that needs to be modeled for quantitative agreement with experiment is typically 100–200 nm long in the growth direction. This length represents a surprisingly small atomic count: 8 atoms in one dimension roughly occupy 1 nm in length. Thus, a device measuring 128 nm long corresponds to a one-dimensional string of around 1000 atoms. For an RTD, the most critical consequences of small size manifest as:

1. Electron confinement to a 5 nm quantum well is clearly significantly smaller than the phase coherence length of about 50 nm for typical GaAs or InGaAs at room temperature [1].
2. The cross section of the RTD is typically defined by mesas that are of the order of 1–100 μm and therefore effectively infinite. The mesa surface is designed to play no role. The heterostructure, however, needs to be treated in atomistic detail and the surfaces as such define the device.
3. Typical RTDs have been grown in III–V material systems in the [100] direction. Substrate orientation has not played a very critical role in these typical electron devices, but does play a role in understanding hole transport, owing to the anisotropy of the valence bands.

The long-range effects of the electrostatic potentials in the semiconductor do, however, play a critical role, and a multi-scale approach to the modeling of the central 15-nm-long RTD connected to 100-nm-long semiconductor regions is critical.

In self-assembled QDs, the dot materials provide the confinement. These QDs are typically of the size of 10–30 nm in the lateral dimension and around 5–10 nm in height. These dots are typically embedded in a buffer material that confines the electrons to the QDs and passivates any open surfaces. A typical QD/buffer/substrate material system is InGaAs/InAlAs/GaAs. The typically used Stranski–Krastanov growth mode [2] ensures that the overall structure is virtually defect free, even though complex 3D geometries in the form of (capped) pyramids or domes are formed. QDs can also be realized via electrostatic confinement. This class of QD typically consists of a 1D heterostructure that confines electrons in one dimension and electrostatic 2D gates that confine electrons in the lateral dimensions. This 2D lateral confinement is limited in its down-scaling by lithography and processing technology and is typically larger than the self-assembled QDs. Typical material systems are the III–V and column IV semiconductor families. Yet another structurally different QD is one formed by an individual impurity such as P embedded in Si.

Typical self-assembled QDs have 50,000–300,000 atoms. For example, typical dome-shaped QDs have dimensions of $5 \times 30 \times 30$ nm^3 corresponding to roughly 200,000 atoms. The electron and hole wavefunction and the eigenstates are not completely confined to just the central QD but leak out, or "feel" the buffer layers. The typical electronic structure domain size is around 1–4 million atoms and the strain domain must be even larger, as discussed further below. Electron states in a single P impurity have a very shallow binding energy below the conduction band and the wavefunction spreads out to a space of $30 \times 30 \times 30$ nm^3 corresponding to about 1.7 million atoms. These total atom numbers start to be large, but are still computationally feasible. Typically, these geometries have one dimension that is significantly smaller than the other two – generally the growth direction and electron are confined to less than 5 nm, making the geometry look similar to an RTD in that aspect. The physical consequences of the small QD size are:

1. Electron confinement of 5–30 nm is of the order of the electron wavelength in typical semiconductors and this length scale is smaller than typical decoherence lengths, even at room temperature. Modeling therefore requires a quantum mechanical treatment.
2. QDs are strongly influenced by the details of the heterostructures that confine them, and have high surface-area-to-volume ratios. The treatment of the interfaces is thus critical.
3. Crystal symmetry plays a critical role in any of the three described QDs in terms of the intricate details of optical polarization effects [3], as well as valley splitting in indirect-gap band-structure materials such as Si [4].
4. Self-assembled QDs form by differences in the lattice constants of the constituent materials and are subject to significant long-range strain. The strain can reach 20–30 nm down into the substrate and it must be managed in the design [5] of overlayer growth. Gated QDs and also gated impurity dots are embedded in long-range fields that extend tens to hundreds of nanometers. These long-range, classical fields must be coupled to the detailed central device models.

Field effect transistors (FETs) have evolved from planar to full 3D geometries. The core active material is some form of strained Si connected to SiGe contacts with sophisticated 3D gate stacks. A modern finFET looks a little bit like an old RTD (oriented vertically), except that the current flows in the plane/fin. The Si/Ge transistors are strained and subject to large electric fields. Many of the principles of operation of RTDs and QDs translate to modern finFETs. Today's commercially widespread "old" nano-FETs dating back to 2011 are 3D geometries that already have channel widths as small as 8 nm or 59 atoms and channel heights that are about 3 or 4 times larger [6–8]. The active device cross section has only around 1000 atoms. Channel lengths have been decreasing from nominally 22 nm in 2012 [6, 7] to around 7 nm in 2016 [8]. The centrally active device may be well-described by 100,000 to 1 million atoms. The physical consequences of ultra-scaling finFETs are:

1. Quantum mechanical treatment is required because the confinement within a finFET is of the order of the electron wavelength and smaller than the electron coherence length, as with an RTD.
2. Device performance is determined by interface details of the finFET or nanowire FET geometry in terms of shape and interface roughness; these effects must be included in the device model.
3. Crystal orientation has a profound effect on device performance. It has been a critical transistor device design parameter since the 90-nm transistor node [9], where Texas Instruments was able to avoid the very costly SiGe-based stressors employed by Intel [10]. A simple 45° rotation of the wafer/device provided the needed performance boost for PMOS transistors. This invention was motivated by observations derived from orientation effects in NEMO-modeled QDs. The rotated substrate approach is standard technology today, indicating the continued critical importance of crystal orientation.
4. Alternative materials beyond the traditional Si have been introduced into 3D device geometries. Intel introduced

SiGe in source/drain for strain-engineering the Si channel in 2002 [10] in their 90-nm node. The 7-nm channel transistor introduced by IBM, GLOBAL FOUNDRIES, and Samsung in 2016 features SiGe channels [8]. These new materials must be rapidly included in the modeling suite.

5. NanoFETs are strained by design [6–8, 10] to improve performance and are subject to electrostatic fields to control carrier flow. This classical long-range physics must be coupled to local, relatively small central devices.

45.2 Nanodevice Modeling Approaches

Thus, nanoscale feature size and its consequences are common across a broad range of devices: RTDs, QDs, and nanoFETs. Models for these devices must accurately take into account the quantum mechanical nature of the electrons, surface and substrate effects, and long-range Coulomb potentials and strains. *Taken together, these characteristics point to a basis that is fundamentally atomistic, localized (involving as few as possible neighbors), and transferrable.*

This conclusion to use an atomistic basis was, however, not obvious to most researchers involved with quantum device modeling over the past 30 years. The principal focus of the modeling community that studies quantum devices or nanodevices as we call them today had been on the quantum mechanical aspects of the modeling. This focus was natural, as nanostructure dimensions within the range 5–30 nm are of the length scale of the electron wavelength and significantly smaller than the coherence length. It was clear even then that only quantum mechanical models would work, but quantum mechanical models differ widely in the basis sets used for the electronic states.

At the most basic level, single-(quasi) electron models fall into one of two broad categories: (1) those that explicitly include the potential due to the atoms and (2) continuum models. Continuum models, called envelope-function or effective-mass approaches, deal with electrons (holes) in a single conduction (valence) band. Materials differences are incorporated only in terms of bandgaps and effective masses (inverse band curvatures). In these models, carriers in the conduction and valence bands are different quasiparticles. These models treat the crystalline environment as a continuum; the potential due to the atoms does not appear beyond the effective masses and energy gaps. The basis states are plane waves or decaying exponentials. In addition, these models are valid for energies only near the band edges. In a periodic crystal these models do not account for nonparabolic bands (unless they are empirically expanded ad hoc) and are useful only for wavevectors near the band extrema. The **k•p** method is a multi-band continuum approach, and has similar drawbacks (and is traditionally plagued by numerical stability issues). Chapter ▸ 45, by Baccarani and Reggiani is dedicated to the **k•p** method.

Beyond their deficiencies for periodic crystals, continuum approaches are completely unsuited to nanodevice modeling in other ways that relate to realistic device representations. They cannot model surface effects and cannot account for differences in substrate orientation, both of which are critically important. In addition, multi-band effects, such as valley splitting in Si and the Rashba and Dresselhaus effects, can only be included crudely via ad hoc specifically empirically fitted parameters. There is no predictive value in models that must use such ad hoc parameters. Effects critical to realistic device models such as atomistic interfaces and their roughness, 3D geometry effects that impose nontrivial strain fields, alloy disorder, alloy grading, and full-band representations cannot in general be included in continuum models, unless they are highly calibrated through ad hoc methods.

Although the traditional device modeling community pursues efforts that scale their large device models down toward small nano-devices, there is another community, originating in material science, that pushes their models up from a few atoms toward devices. This materials science (MS) approach has some commonality with electrical engineering (EE). At the nanometer scale, the distinction between material and device vanishes and the two approaches meet. MS brings the knowledge of the placement of atoms and the electronic ground state to the common problem. EE brings approaches to quantum transport under highly non-equilibrium conditions with the need for atomistic material resolution.

Myriad atomistic structure methods can be found in the area of material science [12]. The methods can be roughly

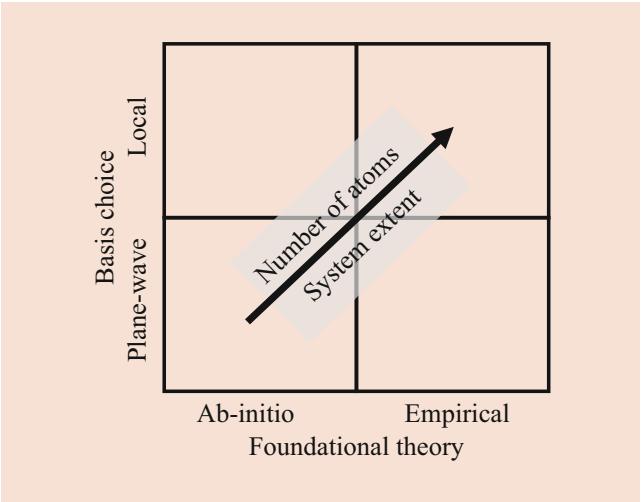

Fig. 45.1 Conceptual layout for the choice of foundational electronic structure theories and choice of basis sets. Empirical theories with localized basis sets generally scale to larger and realistically extended system sizes. Industry is now using non-equilibrium Green's function in NEMO5, utilizing empirical tight binding to design real devices [11]

distinguished into a 2 × 2 table, with one axis representing basis sets (plane waves versus local orbitals) [13, 14] and the other axis fundamental theory (ab initio versus empirical) [15, 16] (Fig. 45.1). Plane waves are appealing because they offer a quantifiable path to improve accuracy by adding more waves and are very efficient for modeling perfectly periodic crystals. However, plane waves are not well suited to modeling typical nanodevices, which are finite, with electrical contacts, and not periodic. Therefore, local orbitals are preferable, and computationally less expensive, for realistically extended device modeling. True industrial design and exploration require hundreds and thousands of simulation runs with reasonable accuracy, rather than representations of a few hero simulations.

Fundamental many-electron correlated methods based on perturbation theory [17], the quantum Monte Carlo method [18], or the GW approach [19] offer intellectual appeal, but can only predict electronic structure for very small systems (around 100 atoms). Empirical methods lose some fundamental claim to correctness but do much better in terms of incorporating correct bulk bandgaps and masses via their Hamiltonian parameters and can be scaled up to larger system sizes. Almost all ab initio and quantum chemistry codes treat closed systems close to or at equilibrium; that excludes the far-from-equilibrium irreversible electron transport needed to solve our problem. Beyond these considerations, the standards for sufficient accuracy in bulk band-structure calculations are very different in MS and EE.

Accuracy of bandgaps and masses must be significantly greater in EE than in MS. In MS ground state properties are usually the focus, and gaps off by 200 meV and masses within a factor of 2 are sufficient. In contrast, the interest in EE is on the upper valence bands and the conduction bands; gaps and band offsets need to be within about 10 meV and masses within 5%.

Forming and breaking bonds versus *stable systems:* MS is primarily concerned with the formation and establishment of the material systems and their equilibrium conditions. Realistic semiconductor devices must have stable bonds and transport characteristics are determined by the valence electrons only. Therefore, full ab initio methods are not necessary to simulate current/spin flow. Approximate methods that resolve the physics of the valence electrons with stable bonds are appropriate (and computationally feasible) for large systems.

Empirical orthogonal tight-binding (ETB) ($sp^3\ s^*$ and $sp^3\ d^5\ s^*$) is one of the oldest and conceptually simplest atomistic material descriptions available. The 'empirical' refers to fitting the Hamiltonian matrix elements to bulk band structures. ETB has proven to be scalable to very large system sizes and valid for standard semiconductor electronic structure and transport simulations under high bias current conditions [20–33]. ETB lacks an explicit basis and projection methods are needed to compute Coulomb matrix elements [34]. ETB treats the atomic positions as inputs. NEMO3D bases the positioning of the atoms on a valence force field [25, 26, 35].

The empirical tight-binding method is often questioned with regard to its accuracy of nearest-neighbor assumptions and the overall fitting process and the lack of explicit basis sets. As such many researchers prefer more fundamental approaches based on density functional theory (DFT). We reiterate here that to us the most accurate effective mass and bandgap representation that can be experimentally verified at room temperature, as well as the computational efficiency, outweigh the limitations. Typical DFT approaches that can scale up to device levels in general deliver 0K band structure with bandgaps and masses that are inaccurate.

In 2015, Intel began integrating empirical tight binding embodied in the NEMO5 implementation into their TCAD model stream. In 2019, Intel announced the integration of NEMO5 publicly at the International Electron Devices Meeting for accurate and calibrated device exploration and design [11].

45.3 Empirical Tight-Binding Method

45.3.1 Bases for the Hamiltonian

Tight-binding methods (or more specifically semi-empirical tight-binding methods) are ideally suited to nanodevice simulations. With a relatively small basis of usually no more than 20 orbitals per atom (when spin–orbit interaction is included) the bands of the device materials within the relevant energy range can be accurately reproduced throughout the Brillouin zone. Surface and interface parameters can be fit to special structures. The limited range of interactions, especially for nearest-neighbor models, allows for highly efficient device electronic structure and transport calculations. These characteristics are all highly desirable for nanodevice modeling.

The modern use of tight-binding for crystalline electronic structure calculations begins with the work of Slater and Koster [36]. The tight-binding method traditionally uses an orthonormal basis of atomic-like orbitals centered on the atoms of the crystal, with the orbitals having a limited range of interaction. Most applications are semi-empirical tight-binding, in which the orbitals do not have explicit spatial representations and are instead defined through their Hamiltonian parameters [36], although explicit, non-orthogonal, basis sets can be used, such as with the closely related extended Hückel theory [37]. In orthogonal tight-binding, there is no unique method for generating orthonormal atomic-like orbitals from true atomic orbitals, but the Löwdin orthogonalization [38] is one of the most useful. A very significant advantage of this method is that the resulting orthonormal orbitals, though no longer possessing full atomic symmetry,

nevertheless transform, as would their atomic antecedents under the symmetry operations of the crystal, and remain generally localized. For semi-empirical tight-binding models, the mere existence of such a basis is sufficient for most device modeling applications, as explicit wavefunctions are not needed most of the time.

Tight-binding bases are specified by their orbital compositions and the range of interaction. Nearest-neighbor models are best suited to nanostructures and nanodevices, which generally have a high proportion of surfaces or interfaces. In nanodevices it is often computationally preferable to use a nearest-neighbor model with a larger basis versus a smaller basis of more extended orbitals. A limited range of interactions also results in a more computationally efficient calculation. The basis set chosen must accurately reproduce the energy gaps and effective masses of all bands within the relevant energy range for the bulk materials. The earliest models for semiconductors employed an sp^3 basis (one s- and three p-orbitals per atom, doubled when the spin–orbit interaction is included), but proved unable to accurately reproduce the conduction bands. Vogl et al. [39] significantly improved conduction-band reproduction along the [100] directions by adding an excited s-like (s^*) orbital to the basis ($sp^3\ s^*$). Still, problems in the conduction band remained. Most problematic was the inability of the nearest-neighbor $sp^3\ s^*$ model to accurately reproduce the X-valley transverse effective mass. Two remedies for this deficiency were developed: (1) within the $sp^3\ s^*$ basis, extending the range of interaction to second-nearest neighbors [40]; or (2) retaining nearest-neighbor interactions with a basis including d-orbitals, the $sp^3\ d^5\ s^*$ basis proposed by Jancu et al. [41]. The nearest-neighbor $sp^3\ d^5\ s^*$ basis is usually preferred for nanodevices owing to its minimal range of interaction.

The parameters of tight-binding Hamiltonians are referred to as Slater–Koster [36] parameters and are characterized as two- and three-center integrals. The two-center integrals include only potentials centered on the two atoms of the orbitals involved in the matrix element; three-center integrals include the effects of potentials on other atoms as well. Most nanoelectronic-device, tight-binding models restrict interactions to nearest neighbors, so that the two-center approximation is justified. An example of one such matrix element in silicon or germanium is that between an s-orbital at the origin and a p_x-orbital at $\mathbf{d}$:

$$\langle s; \mathbf{0}| \hat{H} |x; \mathbf{d}\rangle = lV_{sp\sigma}. \tag{45.1}$$

In Eq. (45.1) l denotes the x-direction cosine for the vector $\mathbf{d}$. $V_{sp\sigma}$ is the Slater–Koster [35] parameter for this type of matrix element. Cyclic permutations of coordinates and direction cosines give the remaining two matrix elements for p_y- and p_z-orbitals. In compound semiconductors such as GaAs there are separate parameters for the s-orbital on the anion and the p_x-orbital on the cation ($V_{sapc\sigma}$) and vice-versa ($V_{scpa\sigma}$). The atomic locations are fixed by the crystal structure and lattice constant; the Slater–Koster parameters are determined via a fitting process.

Tight-binding basis states take different forms depending on the number of confined dimensions; in the nonconfined dimensions they obey the appropriate form of Bloch's theorem. In bulk 3D materials the basis states for the perfect crystal Hamiltonian are:

$$|\omega; l; \mathbf{k}\rangle = \frac{1}{\sqrt{N}} \sum_{j=1}^{N} \exp\left[i\mathbf{k}_j \cdot \left(\mathbf{R}_j + \mathbf{d}_l\right)\right] |\omega; \mathbf{R}_j + \mathbf{d}_l\rangle. \tag{45.2}$$

In Eq. (45.2) ω denotes the orbital type (s-, p_x-, etc., including spin where appropriate), $\mathbf{R}_j$ the location of the j-th primitive cell, $\mathbf{d}_l$ the location relative to the cell origin of the l-th atom in the primitive cell (for polyatomic primitive cells), $\mathbf{k}$ the wavevector (crystal momentum), and N the number of primitive cells. These states obey Bloch's theorem in three dimensions. Superlattice basis states are formally the same as expressed in Eq. (45.2), except that $\mathbf{R}_j$ denotes the supercell location, N the number of supercells, and $\mathbf{d}_l$ the location relative to the supercell origin of the l-th atom. (For a supercell of N_c primitive cells with N_a atoms per primitive cell, there are $N_c N_a$ different $\mathbf{d}_l$.) Basis states for a two-dimensional material such as graphene are constructed analogously, except that the wavevector and primitive cell vectors are two-dimensional. Basis states for nanowires are constructed, as are 3D superlattice states, except that there is translational symmetry in only one direction and thus only a one-dimensional wavevector.

Three-dimensional materials with confinement or broken translational symmetry in one or more dimensions require different basis states. In layered structures with only planar translational symmetry, the basis states are Bloch sums in the plane:

$$\left|\omega; l; L; \mathbf{k}_{\|}\right\rangle = \frac{1}{\sqrt{N_{\|}}} \sum_{j=1}^{N_{\|}} \exp\left[i\mathbf{k}_{\|} \cdot \left(\mathbf{R}_{j\|}(L) + \boldsymbol{d}_{l\|}\right)\right] \Big| \omega; L; \boldsymbol{R}_{j\|}(L) + \boldsymbol{d}_{l\|} \Big\rangle. \tag{45.3}$$

In Eq. (45.3) the subscript '||' denotes a vector in the plane, and L the layer index. A layer is usually defined as a grouping of one or more atomic planes so that there are only nearest-neighbor couplings between layers. Note that the bulk primitive cell origin may be offset depending on the layer index.

45.3.2 Parameter Fitting

The fitting process for three-dimensional materials begins with the perfect crystal Hamiltonian in the tight-binding basis of Eq. (45.2). Perfect 2D Hamiltonians are constructed analogously. The eigenvalues and eigenvectors of the Hamiltonian depend on the parameters and thus are used to fit them so that the relevant effective masses and energy gaps reproduce those of the bands within the relevant energy range. Until very recently, gaps and masses were the only targets used in the fitting process; the values for these targets are taken from ab initio calculations or experimental results. At high symmetry points there may be analytic formulas for some gaps and masses in terms of the parameters [40, 42–44]. These expressions are most useful for the band fitting process when the dependencies on the parameters are clear, meaning that in practice the Hamiltonian matrix $\underline{\mathbf{H}}(\mathbf{k})$ should be analytically block diagonalizable, with some of the blocks being of dimension 1 or 2. (Analytic solutions are always possible for up to quartic equations and thus the eigenvalues and eigenvectors of matrices up to 4×4, but the complicated solutions to quartic and cubic equations generally obscure parameter dependences.) Expressions for inverse effective masses (band curvatures) are possible once the Hamiltonian eigenvalues and eigenvectors are found at the $\mathbf{k}$-point of interest. The expression for the inverse effective mass is different from the standard formula found in solid-state textbooks owing to the incompleteness of the basis set [45, 46]. The issue of incompleteness and its consequences are discussed in Sects. 45.3.4, 45.3.5, 45.3.6, and 45.3.7 below.

Although analytic gap and mass formulas help in the fitting process, in practice, iterative computer algorithms are almost always used. Computational optimization is needed when fitting mass and gap targets that are not at high-symmetry points. Klimeck et al. [47] introduced genetic algorithms for global optimization in a very high dimensional space to the tight-binding parameter fitting problem. This genetic algorithm employs user-assigned weights for targets and from them computes a fitness function in each step. Then, random mutations of the current parameter set are generated and the one with the best overall fitness is preserved as the parent for the next mutation step. The algorithm terminates when a solution with acceptable fitness is found. Although fitting algorithms such as this are essential for parameter determination, there remains the possibility that the best solution might not be found. Sometimes very different parameter sets can reproduce the targeted gaps and masses to nearly the same accuracy. However, they may well differ in their wavefunction quality. The analytical expressions for bandgaps and effective masses discussed above are extremely helpful as they serve as additional constraints to the problem solution and guide the high-dimensional fitting problem to convergence.

To address the fundamental wavefunction variations for different parameter sets a new fitting method has been developed that includes matches to ab initio wavefunctions in addition to gaps and masses in the fitting process. Tan et al. [48–50] use DFT wavefunctions to construct real-space tight-binding wavefunctions. A low-rank approximate DFT Hamiltonian is then transformed into the tight-binding basis using the transformation between the DFT and tight-binding wavefunctions. The tight-binding Hamiltonian is iteratively improved by comparing gaps, masses, and wavefunctions at high-symmetry points with DFT results. Including wavefunction fitting removes much of the uncertainty about whether the true best fit has been found.

The work of Tan et al. [49, 50] on mapping tight-binding parameters from DFT calculations also helps to answer the question of the extent of interactions needed (nearest neighbor, second-nearest neighbor, etc.) to accurately reproduce semiconductor band structures. Heuristically, it has been observed that similar accuracy can be achieved with smaller basis sets and more distant neighbor interactions or larger basis sets and shorter range interactions. For example, comparable accuracy in common semiconductors (Si, Ge, and III–Vs) can be achieved with either the 2NN $sp^3\ s^*$ model or the NN $sp^3\ d^5\ s^*$ model. Tan et al. [49, 50] show that the DFT-mapped NN $sp^3\ d^5\ s^*$ model can achieve excellent accuracy for common semiconductor materials. The fact that the parameters in their model are derived from DFT calculations, including, critically, DFT wavefunctions, supports the utility and applicability of the NN $sp^3\ d^5\ s^*$ model.

45.3.3 Strain

Strains displace the atoms of a crystal from their ideal positions and can be either regular or irregular. Regular strains affect all primitive cells identically, and occur in strained layer superlattices (GaAs/InAs, Si/Ge, etc.) or when external strains are applied. Irregular strains affect differing primitive cells differently and occur in random alloys or in the presence of defects, for example, as well as in geometry variations in two- or three dimensions. Both types affect the electronic structure of the material by altering the Hamiltonian in terms of both its potentials and its basis states. Changes appear in both the neighboring-atom and onsite Hamiltonian matrix elements. The most obvious change is in the relative positions (distances and orientations) of the potentials centered on the two atoms involved in a two-center integral. The second, less obvious change, is to the orbitals themselves. Recall that orthonormal basis sets are generally constructed from non-orthogonal bases using Löwdin's procedure [38]. In the Löwdin method, an orthonormal set $\{|\varphi_j\rangle; j = 1, \ldots, N\}$ is constructed from a non-orthogonal set (e.g., atomic orbitals)

$\{|\eta_j\rangle; j = 1, \ldots, N\}$ using the square root of the overlap matrix:

$$|\varphi_j\rangle = \sum_{m=1}^{N} \left[\underline{\mathbf{S}}^{-1/2}\right]_{m,j} |\eta_m\rangle\,, \quad [\underline{\mathbf{S}}]_{m,n} = \langle\eta_m|\eta_n\rangle\,. \tag{45.4}$$

Displacing the atoms, and thus the non-orthogonal orbitals centered on them, changes the overlap matrix elements and thus the orthonormal basis of the Hamiltonian.

Both types of changes are incorporated into the neighboring-atom matrix elements (generally two-center integrals) via a power-law scaling relation. This scaling is referred to as the Generalized Harrison's Law. Harrison [43] fit the bands of a simple cubic crystal to the free-electron bands at $k = 0$ and $k = \pi/a$, which requires the s-s and s-p matrix elements to vary as d^{-2}, where d is the nearest-neighbor distance. The generalization allows for the power to vary with the bond type ($ss\sigma$, $sp\sigma$, $pd\pi$, etc.):

$$V_{\mathrm{ab}\gamma}(d) = V^{(0)}_{\mathrm{ab}\gamma}\left(\frac{d_0}{d}\right)^{\eta_{\mathrm{ab}\gamma}}. \tag{45.5}$$

In Eq. (45.5) $V^{(0)}_{\mathrm{ab}\gamma}$ is the ideal-crystal, two-center integral between orbitals a, and b (s, p, d, etc.) with bond type γ (σ, π, δ, etc.); d_0 is the ideal distance between the atoms and d the actual distance; and $\eta_{\mathrm{ab}\gamma}$ the scaling exponent (nominally 2). The exponents are fit in a process similar to the two-center integrals in order to reproduce the gaps and masses as functions of strain, using as targets either ab initio calculations or experimental results.

The issue of scaling the onsite matrix elements under strain is somewhat subtler. Although it is tempting to think of the onsite parameters as being atomic orbital energies, Eq. (45.4) and consideration of the crystalline environment make it clear that this cannot be the case. From Eq. (45.4) it is clear that the onsite terms are affected by the Löwdin orthogonalization [38]. These terms are likewise affected by the neighboring atom potentials. In a free atom there is no p_x-p_y Hamiltonian matrix element owing to the spherical symmetry of the atomic potential. In diamond or zincblende this term vanishes as well owing to symmetry: nearest neighbors are located at $(a/4)(1,1,1)$, $(a/4)(-1,-1,1)$, $(a/4)(1,-1,-1)$, $(a/4)(-1,1,-1)$. Under uniaxial [110] strain, however, the first two ($z > 0$) neighbors are at one common distance from the central atom whereas the second two ($z < 0$) are at a different common distance, leading to an incomplete cancellation of their effects. As a result, onsite matrix elements absent from the ideal crystal Hamiltonian can appear under some strain conditions.

Within the context of the $sp^3\,d^5\,s^*$ basis [41] four different approaches to the strain treatment of the onsite matrix elements have been proposed. Jancu et al. [41] scale only the onsite d parameters for regular strains, the only new parameter being the d-state shear parameter. In order to treat randomly varying strains, such as one finds in a random alloy, adjustments computed separately for each neighboring atom, and summed over neighbors to find the complete shift, have been proposed [50–53]. The implementation of each of these methods is sufficiently involved that the reader is referred to the original references for the details. Briefly, however, the differences between them are that Niquet et al. [51] include both neighboring atom potential and Löwdin renormalization effects into a pair of parameters for each type of onsite matrix element. These adjustments are relatively simple to calculate, but because both effects are bundled together into each matrix element, establishing physically meaningful limits on the strain parameters is difficult. Boykin et al. first included Löwdin renormalization [38] shifts only [52], and then added nearest-neighbor potential effects (for p- and d-orbitals only) later [53]. Although this approach is more complicated to implement, it does have the advantage of allowing physical limits on the parameters arising from the two separate effects to be determined [52, 53]. The most recent approach is the DFT-mapped method of Tan et al. [50], which reduces uncertainty in the parameter values. This method takes into account changes in neighboring atom potentials, but has the largest number of strain parameters of the methods discussed here.

45.3.4 Consequences of Discreteness and Incompleteness

Perhaps the least well understood and least appreciated properties of tight-binding models are their discreteness and incompleteness. Actually, any finite model is incomplete, and any model implemented on a computer is discrete. Even large-basis models, such as the linearized augmented plane wave method, are incomplete and the incompleteness must be properly taken into account [54]. The consequence of incompleteness is that many familiar relations from continuous quantum mechanics must be modified, because steps in their derivation assumed a complete basis. Not surprisingly, incompleteness is most readily seen in connection with the matrix elements of the momentum operator, which has a real-space representation: $\hat{p}^{(x)} = -i\hbar\partial/\partial x$, etc. Faithful representation of the derivative operator in a real-space basis implies an infinitesimal spatial resolution, which is clearly impossible in any finite basis. The momentum operator can only be exactly represented (for the included states) in a purely plane-wave basis, because plane waves are momentum eigenfunctions. Beyond this difficulty, commutators of the momentum operator are problematic in any finite basis. Graf and Vogl [45] point out that in any finite basis the position and momentum matrices no longer satisfy the commutator: $\left[\underline{\mathbf{r}}^{(\alpha)}, \underline{\mathbf{p}}^{(\beta)}\right] \neq i\hbar\underline{\boldsymbol{\delta}}_{\alpha,\beta}$. The reason is that for

any finite matrices $\underline{\mathbf{M}}$, $\underline{\mathbf{N}}$, trace $\left(\underline{\mathbf{MN}}\right)$ = trace $\left(\underline{\mathbf{NM}}\right)$, so that the trace of the commutator is zero. Because these operators and commutators appear in many different formulas, the consequences of incompleteness are far-reaching.

45.3.5 Effective-Mass Formula

The effective mass formula found in nearly all solid-state physics texts is incorrect and must be modified in an incomplete basis, because the leading term comes from the position–momentum commutator. Graf and Vogl [45] and Boykin [46] derive the correct formula (Boykin [46] also includes modifications for degenerate bands), which agrees exactly with the effective mass as calculated from the band curvature $\partial^2 E_n(\mathbf{k})/\partial k^{(\alpha)}\,\partial k^{(\beta)}$. The inverse effective mass tensor for a nondegenerate band state $|n,\mathbf{k}\rangle$ is [45, 46]:

$$\left[\frac{1}{m^*}(\mathbf{k})\right]_{\alpha,\beta} = \frac{-i}{m_0\hbar}\langle n,\mathbf{k}|\left[\hat{r}^{(\alpha)},\hat{p}^{(\beta)}\right]|n,\mathbf{k}\rangle + \frac{1}{m_0^2}\sum_{j\neq n}\frac{\langle n,\mathbf{k}|\hat{p}^{(\alpha)}|j,\mathbf{k}\rangle\langle j,\mathbf{k}|\hat{p}^{(\beta)}|n,\mathbf{k}\rangle + \langle n,\mathbf{k}|\hat{p}^{(\beta)}|j,\mathbf{k}\rangle\langle j,\mathbf{k}|\hat{p}^{(\alpha)}|n,\mathbf{k}\rangle}{E_n(\mathbf{k}) - E_j(\mathbf{k})} \tag{45.6}$$

In Eq. (45.6) the sum runs over all states j in the finite basis. In terms of the Hamiltonian matrix, these matrices and commutators are [46]:

$$\frac{\hbar}{m_0}\underline{\mathbf{p}}^{(\alpha)}(\mathbf{k}) = \frac{\partial\underline{\mathbf{H}}(\mathbf{k})}{\partial k^{(\alpha)}}, \quad \underline{\mathbf{p}}^{(\alpha)}(\mathbf{k}) = \frac{m_0}{i\hbar}\left[\underline{\mathbf{r}}^{(\alpha)},\underline{\mathbf{H}}\right](\mathbf{k}), \tag{45.7}$$

$$\frac{-i\hbar}{m_0}\left[\underline{\mathbf{r}}^{(\alpha)},\underline{\mathbf{p}}^{(\beta)}\right](\mathbf{k}) = \frac{\partial^2\underline{\mathbf{H}}(\mathbf{k})}{\partial k^{(\alpha)}\partial k^{(\beta)}}. \tag{45.8}$$

Note in particular Eq. (45.8), which is not (up to constants) $\underline{\boldsymbol{\delta}}_{\alpha,\beta}$. We remark that so long as the spin-orbit Hamiltonian $\underline{\mathbf{H}}_{so}$ has only same-atom couplings, as in Chadi's prescription [55], and the position operator is diagonal (see Sect. 45.3.7 below), $\left[\underline{\mathbf{r}}^{(\alpha)},\underline{\mathbf{H}}_{so}\right] = \underline{\mathbf{0}}$. As a result, the momentum and velocity matrices are proportional.

45.3.6 Localized-Orbital Representations

One cannot simply calculate localized-orbital position and momentum matrix elements as one does in atomic physics. The existence of discrete translational symmetry in an ideal crystal imposes a discrete real-space grid, which puts constraints on the position and momentum matrices. First, these matrices must be consistent with the band velocities and effective masses of the tight-binding model itself, see Eqs. (45.6–45.8) above. Calculating momentum matrix elements using the continuous-space momentum operator fails the consistency test [56]. Second, the formalism must be gauge invariant, which in an arbitrary localized-orbital basis requires commuting position matrices [56]. In an arbitrary basis the only guaranteed gauge-invariant definition of the position matrix is diagonal:

$$\langle\gamma;\mathbf{R}_m+\mathbf{d}_n|\,\hat{r}^{(\alpha)}\,|\omega;\mathbf{R}_j+\mathbf{d}_l\rangle = \delta_{\gamma,\omega}\delta_{m,j}\delta_{n,l}\left(\mathbf{R}_j^{(\alpha)}+\mathbf{d}_l^{(\alpha)}\right) \tag{45.9}$$

These position matrices commute [45, 56, 57] and, from the states Eq. (45.2), also satisfy the consistency tests, Eqs. (45.6–45.8).

The momentum matrices must therefore be calculated using the position operator:

$$\hat{p}^{(\alpha)} = \frac{m_0}{i\hbar}\left[\hat{r}^{(\alpha)},\hat{H}\right] \tag{45.10}$$

$$\begin{aligned}&\langle\gamma;\mathbf{R}_m+\mathbf{d}_n|\,\hat{p}^{(\alpha)}\,|\omega;\mathbf{R}_j+\mathbf{d}_l\rangle\\ &\quad= \frac{-im_0}{\hbar}\left(\mathbf{R}_m^{(\alpha)}+\mathbf{d}_n^{(\alpha)}-\mathbf{R}_j^{(\alpha)}-\mathbf{d}_l^{(\alpha)}\right)\\ &\quad\langle\gamma;\mathbf{R}_m+\mathbf{d}_n|\,\hat{H}\,|\omega;\mathbf{R}_j+\mathbf{d}_l\rangle.\end{aligned} \tag{45.11}$$

Using the diagonal form of the position operator therefore results in no same-atom position or momentum matrix elements (in an orthonormal basis). Same-atom, different-orbital position matrix elements generally result in noncommuting position matrices, thus violating gauge invariance: the only exception is for unusual, restricted bases. Foreman [58] has shown that gauge invariance with intra-atomic position matrix elements requires unconventional basis choices, for example, in cubic crystals: s^1, $s^1\,p^3\,d^2$, $s^1\,p^3\,d^3\,f^1$, or $s^1\,p^3\,d^5\,f^3$. Conventional bases, such as sp^3, $sp^3\,s^*$, and $s^1\,p^3\,d^5\,s^*$ are ruled out. Therefore, in an arbitrary basis, gauge invariance and consistency are only guaranteed with diagonal position matrices.

45.3.7 Electromagnetic Coupling Hamiltonian

In continuous quantum mechanics the vector potential couples into the Hamiltonian via the momentum operator. Because the discrete, finite-basis expression should become the continuous-space expression in the limit of a complete basis, the vector potential should enter with the momentum operator in tight-binding as well. A further requirement is that the expression be gauge invariant. The matrix elements of the tight-binding Hamiltonian with a vector potential are given by the Peierls substitution [59], which weights the

Hamiltonian matrix elements with a phase (called the Peierls phase) [45, 56, 57]:

$$\left\langle \gamma; \mathbf{R}_{m,n} \right| \hat{H}^{(\mathbf{A})} \left| \omega; \mathbf{R}_{j,l} \right\rangle = \exp\left[-\frac{ie}{\hbar} \int_{\mathbf{R}_{j,l}}^{\mathbf{R}_{m,n}} \mathbf{A}\left(\mathbf{s}, t\right) \cdot d\mathbf{s} \right] \left\langle \gamma; \mathbf{R}_{m,n} \right| \hat{H}^{(0)} \left| \omega; \mathbf{R}_{j,l} \right\rangle . \tag{45.12}$$

In Eq. (45.12) $\hat{H}^{(\mathbf{A})}$ $\left(\hat{H}^{(0)}\right)$ denotes the Hamiltonian with (without) vector potential $\mathbf{A}$, and $\mathbf{R}_{a,b} = \mathbf{R}_a + \mathbf{d}_b$ the position of atom b (for polyatomic unit cells) in unit cell a. Equation (45.12) is manifestly gauge invariant, but requires further justification on two points: (1) Its relationship to the minimal coupling Hamiltonian of continuous quantum mechanics, and (2) the path to be taken in the Peierls integral. Concerning the latter point, Graf and Vogl [45] propose the straight-line path connecting the two atoms. This choice is clearly the simplest and most natural, especially for nearest-neighbor models. It is also reasonable in view of the discrete nature of the model. If additionally, one uses the trapezoidal rule for the integral, which is in fact exact for linear $\mathbf{A}$ (e.g., a uniform $\mathbf{B}$-field as in $\mathbf{A} = (\mathbf{B}_0 \times \mathbf{r})/2$), the result bears a striking resemblance to the minimal-coupling Hamiltonian:

$$\begin{aligned} &\left\langle \gamma; \mathbf{R}_{m,n} \right| \hat{H}^{(\mathbf{A})} \left| \omega; \mathbf{R}_{j,l} \right\rangle \\ &\quad = \exp\left[-\frac{ie}{2\hbar} \left(\mathbf{R}_{m,n} - \mathbf{R}_{j,l}\right) \left[\mathbf{A}\left(\mathbf{R}_{m,n}, t\right) + \mathbf{A}\left(\mathbf{R}_{j,l}, t\right) \right] \right] \\ &\quad \left\langle \gamma; \mathbf{R}_{m,n} \right| \hat{H}^{(0)} \left| \omega; \mathbf{R}_{j,l} \right\rangle \end{aligned} \tag{45.13}$$

In particular, note that an expansion of the exponential to first order in $\mathbf{A}$ gives for the first-order term the average of the momentum matrix element, Eq. (45.11), times $\mathbf{A}$ evaluated on the two atomic sites. The full power series for the exponential gives matrix elements of multiple commutators of the position and Hamiltonian. Thus, there are solid physical reasons for favoring the straight-line path.

More formally, Boykin [60] has shown that in the continuous $\{|\mathbf{r}\rangle\}$ basis, the matrix elements

$$\left\langle \mathbf{r} \right| \hat{H}^{(\mathbf{A})} \left| \mathbf{r}' \right\rangle = \exp\left[-\frac{ie}{\hbar} \int_{\mathbf{r}'}^{\mathbf{r}} \mathbf{A}\left(\mathbf{s}, t\right) \cdot d\mathbf{s} \right] \left\langle \mathbf{r} \right| \hat{H}^{(0)} \left| \mathbf{r}' \right\rangle \tag{45.14}$$

result in the usual minimal-coupling Schrödinger equation:

$$\left\langle \mathbf{r} \right| \hat{H}^{(\mathbf{A})} \left| \psi(t) \right\rangle = \frac{1}{2m} \left[\hat{\mathbf{p}} + e\mathbf{A}\left(\mathbf{r}, t\right) \right]^2 \psi\left(\mathbf{r}, t\right) . \tag{45.15}$$

Note the analogy of Eqs. (45.14) to (45.12). In Eq. (45.14) it is critical to realize that the continuous-space basis matrix elements are generalized functions. In the continuous $\{|\mathbf{r}\rangle\}$ basis the path is immaterial, as one might expect. In addition, Boykin et al. [57] derive Eq. (45.12) in a different way. Using a multiple-commutator expansion and diagonal position operators (Eq. 45.9), they obtain an infinite series in terms of the momentum operator and the vector potential. In a complete basis the series terminates at second order in the vector potential, resulting in the usual minimal coupling Hamiltonian. Furthermore, they show that when the straight-line path between the two atoms is used in the Peierls integral in Eq. (45.12), the multiple commutator series and the Peierls substitution give the same matrix elements. Thus, when one uses diagonal (i.e., commuting) position matrices and takes into account the incomplete basis, the vector potential is accommodated by weighting the Hamiltonian matrix elements by the Peierls phase.

External, scalar potentials are handled consistently with the diagonal form of the position matrices, Eq. (45.9). The applied scalar potential, $U(\mathbf{r})$, can be expanded in a Taylor series in the position operators, so that its matrix elements are:

$$\left\langle \gamma; \mathbf{R}_{m,n} \right| \hat{U}\left(\mathbf{r}\right) \left| \omega; \mathbf{R}_{j,l} \right\rangle = \delta_{\gamma,\omega} \delta_{m,j} \delta_{n,l} U\left(\mathbf{R}_{j,l}\right) . \tag{45.16}$$

This prescription for the scalar potential also satisfies gauge invariance [45, 56, 57].

45.4 Interfaces and Transport

45.4.1 Complex Bands

The complex bands are the evanescent surface/interface modes of a crystal [61–67]; they come in growing/decaying pairs. These surface/interface states are used in constructing the open boundary conditions of planar devices, such as nanowire transistors, or resonant tunneling diodes (RTDs). They also determine the confinement, as with barriers in RTDs or the cladding of a QD. In RTDs, for example, the confinement determines the sharpness of the resonances and thus greatly affects the current-voltage characteristics. In a QD it determines the wavefunction leakage out of the dot. The complex bands are found by imposing periodic boundary conditions only in the plane of the surface/interface, using basis states of Eq. (45.3); one or more atomic planes are grouped together into layers, so that there are only nearest-layer couplings. The resulting Hamiltonian sub-matrices are defined as:

$$\left[\underline{\mathbf{H}}_{(L',L)} \right]_{(\omega' l', \omega l)} = \left\langle \omega'; l'; L'; \boldsymbol{k}_{\parallel} \left| \hat{H} \right| \omega; l; L; \boldsymbol{k}_{\parallel} \right\rangle . \tag{45.17}$$

The total state is:

$$\left|\psi\left(\boldsymbol{k}_{\parallel}\right)\right\rangle = \sum\nolimits_{\omega',l',L'} C_{L'}^{\omega',l'} \left|\omega';l';L';\boldsymbol{k}_{\parallel}\right\rangle. \tag{45.18}$$

The Schrödinger equation therefore has rows:

$$\underline{\mathbf{H}}_{(L-1,L)}^{\dagger}\mathbf{C}_{L-1} + \left[\underline{\mathbf{H}}_{(L,L)} - \underline{\mathbf{1}}E\right]\mathbf{C}_{L} + \underline{\mathbf{H}}_{(L,L+1)}\mathbf{C}_{L+1} = \underline{\mathbf{0}}. \tag{45.19}$$

In Eq. (45.19) $\mathbf{C}_L$ is the vector of all coefficients for layer L; in bulk, $\underline{\mathbf{H}}_{(L-1,L)} = \underline{\mathbf{H}}_{(L,L+1)}$.

The propagation equation is found by introducing $\mathbf{C}_L = \mathbf{C}_L$ along with Eq. (45.19):

$$\begin{bmatrix} \underline{\mathbf{H}}_{(L,L+1)} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{1}} \end{bmatrix} \begin{bmatrix} \mathbf{C}_{L+1} \\ \mathbf{C}_{L} \end{bmatrix} = \begin{bmatrix} -\left(\underline{\mathbf{H}}_{(L,L)} - \underline{\mathbf{1}}E\right) & -\underline{\mathbf{H}}_{(L,L+1)}^{\dagger} \\ \underline{\mathbf{1}} & \underline{\mathbf{0}} \end{bmatrix} \begin{bmatrix} \mathbf{C}_{L} \\ \mathbf{C}_{L-1} \end{bmatrix}. \tag{45.20}$$

The traditional way of solving Eq. (45.20) is to multiply by the inverse of the left-hand matrix to generate a transfer matrix:

$$\underline{\mathbf{M}}_{(L+1,L)} = \begin{bmatrix} \underline{\mathbf{H}}_{(L,L+1)} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{1}} \end{bmatrix}^{-1} \begin{bmatrix} -\left(\underline{\mathbf{H}}_{(L,L)} - \underline{\mathbf{1}}E\right) & -\underline{\mathbf{H}}_{(L,L+1)}^{\dagger} \\ \underline{\mathbf{1}} & \underline{\mathbf{0}} \end{bmatrix};$$
$$\begin{bmatrix} \mathbf{C}_{L+1} \\ \mathbf{C}_{L} \end{bmatrix} = \underline{\mathbf{M}}_{(L+1,L)} \begin{bmatrix} \mathbf{C}_{L} \\ \mathbf{C}_{L-1} \end{bmatrix}. \tag{45.21}$$

Setting $\mathbf{C}_{L+1} = \lambda_{+}\mathbf{C}_{L}$ gives an ordinary eigenvalue equation for the transfer matrix. Its eigenstates are the surface states for the crystal and they can be propagating or growing/decaying.

Although this equation is intuitively satisfying, it unfortunately has a severe problem: it might not exist. For certain parameter sets or simply values of $\boldsymbol{k}_{\parallel}$ the left- and/or right-hand matrices in Eq. (45.20) become singular and the transfer matrix does not exist [65, 66]. The alternative, and most numerically stable way of finding the surface states is to solve either the forward $\mathbf{C}_{L+1} = \lambda_{+}\mathbf{C}_{L}$ or reverse $\mathbf{C}_{L-1} = \lambda_{-}\mathbf{C}_{L}$ propagation problem as a generalized eigenproblem [65]; an ordinary eigenproblem with a shift strategy can also be used [67]. The forward generalized eigenproblem is:

$$\lambda_{+}\begin{bmatrix} \underline{\mathbf{H}}_{(L,L+1)} & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{1}} \end{bmatrix} \begin{bmatrix} \mathbf{C}_{L} \\ \mathbf{C}_{L-1} \end{bmatrix} = \begin{bmatrix} -\left(\underline{\mathbf{H}}_{(L,L)} - \underline{\mathbf{1}}E\right) & -\underline{\mathbf{H}}_{(L,L+1)}^{\dagger} \\ \underline{\mathbf{1}} & \underline{\mathbf{0}} \end{bmatrix} \begin{bmatrix} \mathbf{C}_{L} \\ \mathbf{C}_{L-1} \end{bmatrix} \tag{45.22}$$

The eigenvalues come in pairs $\left(\lambda_{\pm}, \lambda_{\pm}^{*}\right)$ and eigenvalues $\lambda_{\pm} \neq 0$ come in pairs $\left(\lambda_{\pm}, 1/\lambda_{\pm}^{*}\right)$; for every m-fold $\lambda_{+} = 0$, there is likewise an m-fold $\lambda_{-} = 0$ [65]. Thus, for every immediately decaying state there is an immediately growing one; for every forward-propagating state there is a reverse-propagating one. The nonzero eigenvalues $\lambda_{\pm} \neq 0$ are conveniently written as $\exp[ik_{\perp}a_{\perp}]$, where $k_{\perp}$ is the wavevector normal to the surface and is in general complex (real for Bloch states) and $a_{\perp}$ is the layer thickness. The forward or reverse generalized eigenproblem therefore yields wavevectors $k_{\perp}(E, \boldsymbol{k}_{\parallel})$.

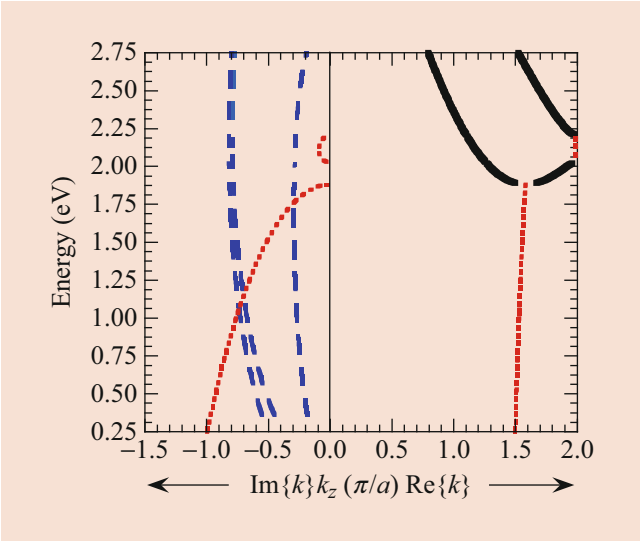

Fig. 45.2 The complex bands [65] of AlAs calculated using the parameter set of Schulman and Chang [63]. All three types of bands are present: real (solid black lines), imaginary (dashed blue lines), and complex (dotted red lines), which have wavevectors with both real and imaginary parts

An example of complex band structure is plotted in Fig. 45.2, part of the AlAs complex bands [65] for the [001] surface, calculated using the sp^3s^* parameter set given in Schulman and Chang [63]. In Fig. 45.2 *a* is the face-centered cubic conventional unit cube edge. The real bands are plotted with black solid lines; purely imaginary bands with blue dashed lines; and the real and imaginary parts of complex bands are plotted with red dotted lines. Real bands and real parts of complex bands are plotted for $k_z > 0$ only; imaginary bands and imaginary parts of complex bands are plotted for $k_z < 0$ only. The imaginary bands connect the valence band maxima (degenerate heavy/light hole and split-off hole) with conduction band minima. The lowest X-valley minimum occurs at $k_z \approx 1.5\pi/a$, so that at the Brillouin zone face the lowest conduction band has a shallow local maximum. This maximum is connected to the minimum of the next lowest band by a small complex band between around 2.0 and 2.2 eV with $\mathrm{Re}\{k_z\} \approx 2\pi/a$ (i.e., at the zone face). Another complex band begins off the X-valley minimum.

We conclude this subsection on complex bands with a brief discussion on a closely related issue: interface parameter determination. The inter-layer coupling matrices in Eq. (45.21) incorporate the interface treatment scheme. As a first step, the onsite terms of one material are uniformly

shifted relative to the other to incorporate the correct valence band offset. The interface handling for common anion or cation interfaces (e.g., GaAs/AlAs) traditionally averages the onsite parameters of the common atom and retains the nearest-neighbor couplings appropriate to the bulk materials. In the GaAs/AlAs interface example, the onsite As parameters are an average of the As onsite terms for GaAs and AlAs. The As/Ga couplings are those of GaAs and the As/Al couplings are those of AlAs. This method generally works well in practice but lacks a sound theoretical footing. To address this shortcoming, Tan et al. [50] recently introduced an environment-dependent, transferrable tight-binding model with parameters mapped from DFT (including input from DFT wavefunctions). The onsite parameters include terms dependent on the nearest neighbors to a given atom, as well as transferrable inter-atomic couplings, and therefore remove the uncertainty of interface treatment. Tan et al. [50] validate their approach by comparing tight-binding superlattice bands with those calculated with DFT and find good agreement.

45.4.2 Transmission Calculations with Transfer Matrices: Numerical Stability

Wavefunction-based transport calculations involve injecting propagating state(s) into a device and calculating the reflection and transmission coefficients (probabilities), and are thus open systems. The energy is continuous, not quantized, and the boundary conditions on the terminal wavefunction coefficients come from the complex band structure calculations discussed above. Mathematically, in a direct transmission calculation, this results in an $\underline{\mathbf{A}}\mathbf{x} = \mathbf{b}$ problem at each energy, with the inhomogeneous vector representing the open-system boundary conditions.

The transfer matrix Eq. (45.21) is a conceptually simple way of calculating the wavefunction in a layered device or structure such as an RTD, superlattice, or nanowire. Its structure is similar to that of the transfer matrix used to calculate the transmission through an RTD in the envelope function (i.e., effective mass) model [68], or to propagate electromagnetic waves through layered dielectrics. Because of its success in envelope function modeling of RTDs, the transfer matrix was the method first applied in early tight-binding models of these devices in the late 1970s/early 1980s. For a structure with boundaries at layers 0 and $(N+1)$, the wavefunction coefficients were calculated as:

$$\begin{bmatrix} \mathbf{C}_{N+1} \\ \mathbf{C}_N \end{bmatrix} = \prod_{L=0}^{N-1} \underline{\mathbf{M}}_{(L+1,L)} \begin{bmatrix} \mathbf{C}_1 \\ \mathbf{C}_0 \end{bmatrix}. \tag{45.23}$$

The boundary conditions applied on the layer 0 side include only a forward-propagating state and reflected reverse-propagating and reverse-decaying states; those on the layer $(N+1)$ side include only transmitted forward-propagating and forward-decaying states.

This procedure often worked for very thin structures, but once the number of transfer matrices exceeded around 20 or so, the calculation rapidly became severely inaccurate [69]. The sum of reflection and transmission probabilities, which *must* be unity, would instead turn out to be much higher, often in the range $10^2 - 10^6$. As a result, tight-binding models were not used to model realistic devices, which have long space-charge regions.

The cause of the instability is easily seen in the AlAs complex band plot of Fig. 45.2. Notice that the lowest conduction-band states (in the X-valleys) appear at around 1.90 eV (lowest black solid line). In addition to these purely propagating states, at the same energy, there are also three imaginary bands (blue dashed lines) connecting valence-band maxima to conduction-band minima at the zone center; these states grow and decay. Generally, then, there are evanescent (growing/decaying) states at the same energy as propagating states, and that is the source of the numerical problem. Products of transfer matrices can even be problematic in single-band models owing to accumulated round-off errors, but it generally takes many more than in the multi-band case, where there are evanescent and propagating states at the same energy.

The boundary conditions result from accurate, but still finite-precision, numerical calculations of the eigenvectors in Eq. (45.22), whether via an ordinary (transfer-matrix) or generalized eigenproblem. Thus, the boundary condition vectors will be corrupted with tiny amounts of other, disallowed eigenvectors; namely, those that grow in forward propagation; at a given energy, these evanescent states are generally present with propagating states. At each subsequent transfer-matrix multiplication, these initially small, erroneous eigenvectors grow in magnitude, and the growth is exponential. It does not take many transfer-matrix multiplications before the corrupt growing eigenvectors overwhelm the true eigenvectors, leading to a catastrophic failure of the calculation [69, 70]. In principle, this sort of failure can occur in an envelope-function calculation, but it requires extraordinarily thick barrier regions because each material supports only a single pair of states, propagating or evanescent, at a given energy.

45.4.3 Direct Transmission Methods

The numerical instabilities discussed above prevented multi-band tight-binding models from being used to model realistic aperiodic structures and devices for around a decade. Then, in the late 1980s–early 1990s, a series of solutions to the problem were developed [69, 71, 72]. Although the three methods differ in their details, they all recast the transmission problem as a large, sparse, matrix equation. This

reformulation into a large, sparse linear system is the key to preventing corruption of the true eigenvectors by erroneous growing eigenvectors. The renormalization method [72] was initially used for superlattice electronic structure calculations (thus with periodic, as opposed to open-system, boundary conditions). The first numerically stable resonant-tunneling diode calculations were those of Boykin et al. [69, 73], which included long, realistically sized space-charge layers. They divided the device into segments of a few layers over which wavefunction propagation using transfer-matrices was still accurate. The result is a large, sparse, linear system consisting of many small transfer-matrix problems, although the dimension is considerably smaller than the Hamiltonian with open-system boundary conditions. The next year, Ting et al. [71] published a similar method, in which they solve the $\underline{\underline{\mathbf{A}}}\mathbf{x} = \mathbf{b}$ problem resulting from the Hamiltonian with open-system boundary conditions directly. The large, sparse, linear system is larger than that of Boykin et al. [69] but avoids transfer matrices and their products.

The methods of Boykin et al. [69] and Ting et al. [71] work well for structures that have periodicity in the plane normal to the transport or quantization axis, such as RTDs and quantum wells. However, they can be costly for nanowires that have finite cross-sections, because the resulting layer-basis now consists of perhaps dozens of atoms (versus as few as two), each with many (often 20) orbitals. The layer matrices in Eq. (45.19) are therefore very large, which for a general basis and nanowire orientation can significantly slow the computation. However, for a nearest-neighbor basis and for [100]- and [111]-oriented nanowires in zincblende/diamond materials, these matrices are very sparse because each atomic plane contains atoms belonging to only one of the two face-centered-cubic sublattices, so there are no same-plane interatomic couplings. In 2008, Boykin et al. [74, 75] published an optimized renormalization method [72] to exploit this sparsity.

The optimized method [74, 75] is easily illustrated for the case of a [100]-oriented NW in diamond or zincblende. In these nanowires, four atomic planes make up a layer (i.e., a primitive cell for a perfect nanowire). In terms of layer matrices and vectors, the Schrödinger equation for a wire of L layers is written as [74]:

$$\begin{bmatrix} \underline{\underline{\mathbf{H}}}_{1,1} + \underline{\underline{\mathbf{\Sigma}}}_1 - \underline{\underline{1}}E & \underline{\underline{\mathbf{H}}}_{1,2} & \underline{\underline{\mathbf{0}}} & \cdots & \underline{\underline{\mathbf{0}}} \\ \underline{\underline{\mathbf{H}}}_{1,2}^{\dagger} & \underline{\underline{\mathbf{H}}}_{2,2} - \underline{\underline{1}}E & \underline{\underline{\mathbf{H}}}_{2,3} & \underline{\underline{\mathbf{0}}} & \underline{\underline{\mathbf{0}}} \\ \underline{\underline{\mathbf{0}}} & \ddots & \ddots & \ddots & \underline{\underline{\mathbf{0}}} \\ \vdots & \ddots & \ddots & \ddots & \underline{\underline{\mathbf{H}}}_{L-1,L} \\ \underline{\underline{\mathbf{0}}} & \cdots & \underline{\underline{\mathbf{0}}} & \underline{\underline{\mathbf{H}}}_{L-1,L}^{\dagger} & \underline{\underline{\mathbf{H}}}_{L,L} + \underline{\underline{\mathbf{\Sigma}}}_L - \underline{\underline{1}}E \end{bmatrix} \begin{bmatrix} \vec{\mathbf{C}}_1 \\ \vec{\mathbf{C}}_2 \\ \vdots \\ \vdots \\ \vec{\mathbf{C}}_L \end{bmatrix} = \begin{bmatrix} \vec{\mathbf{V}}_I \\ \vec{\mathbf{0}} \\ \vdots \\ \vdots \\ \vec{\mathbf{0}} \end{bmatrix}, \tag{45.24}$$

where the self-energies $\underline{\underline{\mathbf{\Sigma}}}_1$, $\underline{\underline{\mathbf{\Sigma}}}_L$ couple the emitter in Eq. (45.1) and collector (L) layers to the semi-infinite contact regions (unbiased nanowire), the vectors $\vec{\mathbf{C}}_j$ are the j-th layer orbital coefficients, and the injection into the emitter is the vector $\vec{\boldsymbol{V}}_I$.

As mentioned above, the layer matrices in Eq. (45.24) are themselves sparse: layers l and $(l+1)$ are only coupled by the last atomic plane of l and the first atomic plane of $(l+1)$. This means that the nanowire can be very efficiently treated one atomic plane at a time; the renormalization method [72] is ideally suited to the task. Renormalization decouples one plane from its neighbors and then re-couples the surrounding planes; no other planes are altered. Decoupling such a plane is accomplished as follows [74]:

$$H = M_{L,p}^{-1} \tilde{H} M_{R,p}^{-1}, \tag{45.25}$$

$$H = \begin{bmatrix} \ddots & \ddots & & & \\ \ddots & \underline{\underline{\mathbf{H}}}_{p-1,p-1} - \underline{\underline{1}}E & \underline{\underline{\mathbf{H}}}_{p-1,p} & \underline{\underline{\mathbf{0}}} & \\ \underline{\underline{\mathbf{0}}} & \underline{\underline{\mathbf{H}}}_{p-1,p}^{\dagger} & \underline{\underline{\mathbf{H}}}_{p,p} - \underline{\underline{1}}E & \underline{\underline{\mathbf{H}}}_{p,p+1} & \\ & & \underline{\underline{\mathbf{H}}}_{p,p+1}^{\dagger} & \underline{\underline{\mathbf{H}}}_{p+1,p+1} - \underline{\underline{1}}E & \underline{\underline{\mathbf{H}}}_{p+1,p+2} \\ & & & \ddots & \ddots & \ddots \end{bmatrix}, \tag{45.26}$$

$$\tilde{H} = \begin{bmatrix} \ddots & \ddots & & & \\ \ddots & \hat{\underline{\underline{\mathbf{H}}}}_{p-1,p-1} - \underline{\underline{1}}E & \underline{\underline{\mathbf{0}}} & \hat{\underline{\underline{\mathbf{H}}}}_{p-1,p+1} & \\ \underline{\underline{\mathbf{0}}} & \underline{\underline{\mathbf{0}}} & \underline{\underline{\mathbf{H}}}_{p,p} - \underline{\underline{1}}E & \underline{\underline{\mathbf{0}}} & \\ & \hat{\underline{\underline{\mathbf{H}}}}_{p-1,p+1}^{\dagger} & \underline{\underline{\mathbf{0}}} & \hat{\underline{\underline{\mathbf{H}}}}_{p+1,p+1} - \underline{\underline{1}}E & \underline{\underline{\mathbf{H}}}_{p+1,p+2} \\ & & & \ddots & \ddots \end{bmatrix}, \tag{45.27}$$

$$M_{L,p}^{-1} = \begin{bmatrix} \ddots & \underline{\mathbf{0}} & \ddots & \cdots & \\ \ddots & \underline{\mathbf{1}} & \underline{\mathbf{X}}_p^\dagger & \underline{\mathbf{0}} & \ddots \\ \ddots & \underline{\mathbf{0}} & \underline{\mathbf{1}} & \underline{\mathbf{0}} & \ddots \\ \vdots & \underline{\mathbf{0}} & \underline{\mathbf{Y}}_p^\dagger & \underline{\mathbf{1}} & \ddots \\ \vdots & \ddots & \ddots & \underline{\mathbf{0}} & \ddots \end{bmatrix}, \quad M_{R,p}^{-1} = \left(M_{L,p}^{-1}\right)^\dagger, \tag{45.28}$$

$$\underline{\mathbf{X}}_p = \left(\underline{\mathbf{H}}_{p,p} - \underline{\mathbf{1}}E\right)^{-1} \underline{\mathbf{H}}_{p-1,p}^\dagger, \quad \underline{\mathbf{Y}}_p = \left(\underline{\mathbf{H}}_{p,p} - \underline{\mathbf{1}}E\right)^{-1} \underline{\mathbf{H}}_{p,p+1}, \tag{45.29}$$

$$\begin{aligned} \hat{\underline{\mathbf{H}}}_{p-1,p+1} &= -\underline{\mathbf{H}}_{p-1,p}\underline{\mathbf{Y}}_p, \quad \hat{\underline{\mathbf{H}}}_{p-1,p-1} \\ &= \underline{\mathbf{H}}_{p-1,p-1} - \underline{\mathbf{H}}_{p-1,p}\underline{\mathbf{X}}_p, \quad \hat{\underline{\mathbf{H}}}_{p+1,p+1} \\ &= \underline{\mathbf{H}}_{p+1,p+1} - \underline{\mathbf{H}}_{p,p+1}^\dagger \underline{\mathbf{Y}}_p. \end{aligned} \tag{45.30}$$

Clearly, each plane is decoupled only once. Also, no complicated inversions are required for the decoupling matrices M:

$$M_{L,p} = \begin{bmatrix} \ddots & \underline{\mathbf{0}} & \ddots & \cdots & \\ \ddots & \underline{\mathbf{1}} & -\underline{\mathbf{X}}_p^\dagger & \underline{\mathbf{0}} & \ddots \\ \ddots & \underline{\mathbf{0}} & \underline{\mathbf{1}} & \underline{\mathbf{0}} & \ddots \\ \vdots & \underline{\mathbf{0}} & -\underline{\mathbf{Y}}_p^\dagger & \underline{\mathbf{1}} & \ddots \\ \vdots & \ddots & \ddots & \underline{\mathbf{0}} & \ddots \end{bmatrix}, \quad M_{R,p} = M_{L,p}^\dagger. \tag{45.31}$$

The matrices $\underline{\mathbf{X}}_p$, $\underline{\mathbf{Y}}_p$ and the inverses $\hat{\underline{\mathbf{H}}}_{p,p}^{-1}$ for later wavefunction reconstruction. The emitter and collector layers require a somewhat different, but not overly complicated, treatment because the open-system boundary conditions make them non-Hermitian [74].

The method becomes highly efficient when the decoupling proceeds by *alternating* interior atomic planes. In the initial step, inverting the diagonal blocks is trivial in the no-spin-orbit case and nearly trivial in the spin-orbit case. The interplane coupling matrices are themselves very sparse, so that in the initial step one-half of the nanowire is decoupled with trivial inversions and sparse-matrix multiplies. Subsequent steps use the alternating-plane method as well, and savings accrue in the second step (decoupling a further one-fourth of the NW), which requires a mixture of sparse- and full-matrix operations. Only the last fourth of the NW requires full-matrix operations. The computational efficiency improvement can be substantial [74, 75].

45.4.4 DFT-TB and Nanodevice Modeling

In the foregoing treatment we have concentrated on the empirical tight-binding approach for two important reasons: (1) It allows for efficient full-band structure transport calculations; (2) It has an orthonormal basis. The second point might seem an unusual one to make, but density functional theory tight-binding (DFT-TB) approaches [76–78] have non-orthogonal bases. From a purely electronic structure perspective the ab initio nature of DFT-TB is attractive [77]; however, device modeling involves more than electronic structure. As seen above, the calculation of currents and electromagnetic coupling involves the position and momentum operators and dealing with these in a non-orthogonal basis is problematic to say the least. In fact, all of the considerable formalism presented above appears very different in a non-orthogonal basis. Even including a scalar potential in a gauge-invariant manner is not easy. The overlap matrix, its inverse, and very often its square root and/or inverse square root are required for even simple calculations [79, 80]. These are the same size as the Hamiltonian: very large for any realistic nanodevice. Obtaining the exact non-orthogonal basis expressions from their orthonormal basis forms is very costly, although in some cases a first-order approximation will work [80]. Nevertheless, the cost involved (especially if a first-order approximation is insufficient) negates most of the advantages of tight-binding.

Sections 45.7.2, 45.7.3, 45.7.4, 45.7.5, 45.7.6, and 45.7.7 describe in detail the critical physics of nanowire transport based on our orthogonal empirical tight-binding with two very different transport models. The conclusion there is that the accurate modeling of the effective masses and the bandgaps is of utmost importance for silicon nanowires. The full charge self-consistency is important in the context of the overall nanowire charge and the details of the potential profile in 3D. These aspects can be handled using our method without the presence of an atomistic wavefunction basis. As discussed above, the passivation of dangling bonds can also be handled without an explicit basis. Although our method and its parameters are empirical and although more fundamental methods are appealing, we need to keep in mind the critical requirements of modeling realistic devices.

45.5 Transport with Green Functions

The numerical instability of transfer matrices can also be totally avoided by using a completely different Ansatz to compute transmission and transport: the non-equilibrium Green's Function (NEGF) approach. This approach is based on the formulation of an explicit, real-space representation of the whole device in a (sparse) Hamiltonian. The discussion

of the NEGF approach is beyond the scope of this book chapter. The foundational theory for NEGF was developed in the 1960s by Kadanoff and Baym [81] and Keldysh [82], but it remained confined to the physics literature. Bertoncini et al. [83] and Datta [84] took NEGF from an esoteric physics approach to a useful tool in electrical engineering by placing quantum transport simulations on a solid theoretical footing in the early 1990s. Datta refined the essential description of the methodology into very good introductions to NEGF for engineers in the early 2000s [85–87] and published a series of well received text books [88–90]. The latest two books [91, 92] accompany two self-paced study courses in nanoHUB-U [93, 94]. In Chapter ▶47, Datta provides an overview of NEGF.

The NEMO code developed at Texas Instruments to model resonant tunneling diodes provided the first tight-binding implementation within NEGF [20, 95]. The concept of an impulse response at every site inside the device eliminates the transfer matrix issue altogether. However, the computation of the open boundary conditions of the infinite contact layer is still battling similar issues depending on the detailed approach. Bowen provided a solution to the wavefunction-based quantum transmitting boundary method (QTBM)-based conditions [67, 96] in the case of singular coupling matrices [97]. Completely stable iterative surface green function treatments have been developed [98] and refined to a point of geometrically fast convergence [99].

The perception in the field of quantum transport is that the strength of the NEGF is derived from foundational physics principles and offers the fundamentally solid capability to include incoherent scattering. Yet most researchers in the field shy away from actually treating incoherent scattering owing to the high computational burden and use NEGF in a purely coherent, ballistic approach. Relatively few full implementations of incoherent scattering in NEGF for quantum transport with generally applicable device modeling considerations have been reported overall. NEMO1D, with its representation of local and nonlocal, inelastic optical phonon scattering in 1D RTDs [100], OMEN with inelastic phonon scattering [101, 102], and NEMO5 with nonlocal scattering [103], showed that this can be done, but also how computationally intensive the effort is.

Most researchers implement NEGF for its foundational physics principles and numerical stability in a purely coherent model without scattering self-energies. In that framework one can ask if there are other approaches that are equivalent. In this "coherent NEGF" context Bowen [94] demonstrated that the coherent wavefunction approach based on QTBM [67, 96] is in its physical content equivalent to the coherent NEGF approach. For 1D RTD devices Bowen showed that the NEGF is delivering results faster than the QTBM. Luisier showed that the QTBM is computationally less intensive than the NEGF approach in 2D and 3D systems [104].

It is the opinion of these authors that the real strength of the NEGF approach is the treatment of the open boundary conditions and their influence in broadening the interior quantum states, which provide finite lifetimes. This concept can now be conveyed to undergraduate students in EE by Datta's books [91, 92] and courses [93, 94]. Such general boundary conditions enable the treatment of complex, irregular contacts that inject carriers from scattering-broadened quasi-bound states [105] formed in quantum wells, geometrically L-shaped contacts, superlattice energy filters [106], and generally shaped [107] and disordered [107, 108] contacts. Such contact treatment includes an empirical broadening that compiles together scattering mechanisms of any sort. The empirical broadening parameter is typically chosen [20, 105] to be around 6.6 meV, equivalent to a scattering time of 0.1 ps. The parameter must be chosen to be energy dependent to avoid filling the gap with artificial states and so that it can be mapped to Urbach tails [103]. Recently, such broadening has been shown to be specifically critical in geometries such as heterostructure tunnel FETs (TFETs) that typically contain quasi-bound states confined close to the tunneling region owing to heterostructure design [109] or traps [110]. With the assumption of a local quasi-Fermi level in the contact regions one can easily link the NEGF approach with drift diffusion in sophisticated, quantum-state-dominated contact regions in 1D [111] and 2D/3D [112] to enable truly multi-scale transport modeling that ranges from ab initio-based atomistic representations to realistic device domains that extend hundreds of nanometers [105, 111, 112]. The use of tight-binding enables the multi-scale modeling of long-range, spatially dependent strain, or piezo-electric effects [3, 5, 25–28] and electron–nucleus interactions [29]. Chapter ▶11 by Meinerzhagen and Jungemann is dedicated to the multi-scale modeling approaches. Chapter ▶33 by Seabaugh and Paletti and Chapter ▶41 by Reggiani et al. discuss TFETs in detail in analytical and **k•p** approaches. Tight-binding approaches are used in He et al., Ameen et al., and Long et al. [109–111] and the extensive references therein.

45.6 Large-Scale Numerical Aspects

45.6.1 Hamiltonian Matrix Structures and Scaling for Closed Systems

One critical application-oriented advantage of the nearest-neighbor orthogonal tight-binding model is its very sparse matrix representation. The valence electrons of each atom are represented with a number of orbitals, where typical choices are s, sp^3, $sp^3\ s^*$, or $sp^3\ d^5\ s^*$ with 1, 4, 5, and 10 orbitals respectively, which ultimately determine the per-atom matrix size. If spin is explicitly included, which is typically necessary for most applications, then the number of orbitals simply

doubles. Each atom forms a well-structured block matrix that is coupled with the same block size to any neighboring atom (typically 4 in Si/Ge and III–V semiconductors). The on-site block matrix elements are diagonal only with a few off-diagonal terms coupling up and down spin through spin–orbit interaction. The block matrices coupling neighboring atoms are typically close to full, but couple only the same spin. Spin-up and spin-down coupling blocks are typically identical, unless modified by an external magnetic field. Rather, general Hamiltonian matrix construction algorithms were implemented early in the NEMO1D work [20]. The NEMO5 [113, 114] implementation was further generalized to include any number of orbitals such as *f*, which resulted in a rather rapid incorporation of piezoelectric materials such as SmSe and SmTe [115].

The specific block matrix Hamiltonian structure offers significant opportunities for computational optimization with regard to: (1) optimized Hamiltonian construction (pre-compiled Slater–Koster tables); (2) memory storage requirement reductions (number of stored elements and real/complex custom storage); (3) optimized matrix–vector multiplications; and (4) short integer-based pointers to address individual atoms. With these optimizations it was possible in NEMO3D to compute million-atom electronic structures in the year 1999 on the first Beowulf cluster computers built at Caltech/NASA/JPL [31, 32, 116]. Further optimized matrix–vector optimizations based on Intel-specific SSE instruction sets enabled scaling to 50 million atoms, which roughly corresponds to a chunk of semiconductor measuring $100 \times 100 \times 100\ \text{nm}^3$.

Figure 45.3 shows the excellent scaling on a moderate size cluster of 2008 [3]. The compute time represents the end-to-end computing time including set-up and output for four conduction band and four valence band states of an InAs QD embedded in GaAs. The fixed-size InAs QD is in the middle of the simulation domain and the GaAs buffer size is increased in this numerical experiment to demonstrate several key aspects of NEMO3D and its algorithms: (a) that the eigenenergies and eigenstates should be independent of the GaAs buffer size as long as the buffer is large enough; (b) that the calculation of interior eigenvalues remains stable regardless of the system size; (c) that memory requirements remain under control even in such large system sizes (special data structures and addressing schemes had to be developed to minimize storage and avoid duplicate storage on the distributed MPI-based algorithms); (d) that parallel scaling performance remains linear with system size. MPI communication requirements increase with the number of cores and with the number of atoms at each MPI parallel overlap region. The required times increase from 28.3 h per million atoms on eight cores to 83 h per million atoms on 128 cores. As the overall system size increases, more cores must be used to fit the overall computation into memory.

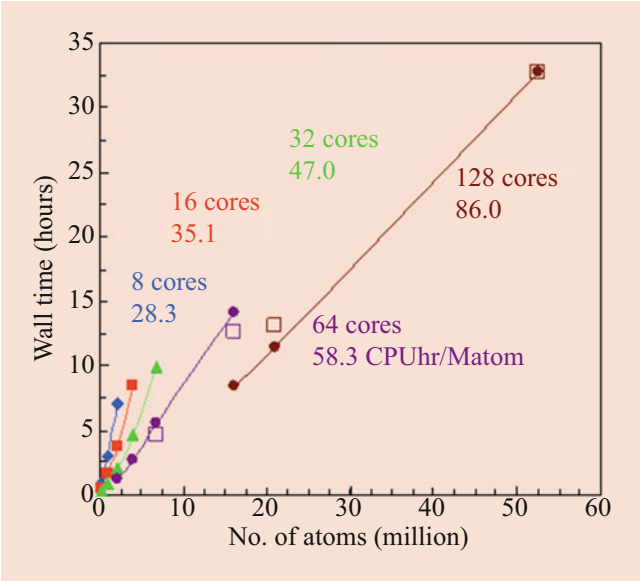

Fig. 45.3 Wall clock time versus number of atoms for end-to-end computations of the electronic structure of a quantum dot, for various numbers of cores on the PU/Woodcrest cluster. Listed next to the number of cores are the CPU h/million atoms needed in the simulation. (From Ahmed et al. [3] Fig. 45.10a)

45.6.2 Scaling Issues with Open Boundary Conditions

Scaling electronic structure calculations to multiple millions of atoms has been critical for the study of QDs and single shallow impurities such as or P in Si as discussed below. In these problems the system is considered to be closed and the eigenvalues are real (even though the Hamiltonian is in general complex). The introduction of open boundary conditions turns the Hamiltonian system into a non-Hermitian system. Any atom inside a unit cell that is connected to a semi-infinite lead is part of a full boundary condition sub-matrix that is completely full. Typical unit cells of a 2.1-nm Si nanowire cross section with transport in the [100], [110], and [111] crystal directions are depicted in Fig. 45.4 below. Numerical inversion stability in double precision limits such matrix sizes to typically dimension 2000 to 10,000. With a typical number of 20 orbitals only 100 to 500 atoms can be in open system boundary condition. Ignoring spin or ignoring *d* orbitals can result in a $\times 2$ or $\times 10$ increase in allowed atoms in the open surface. Either way the open cross sections in nanowires can barely reach 5–10 nm in diameter.

The NEGF method has now been established as the state-of-the-art in quantum transport modeling. The retarded Green's function is the inverse of the open system non-Hermitian Hamiltonian, is for realistic systems computationally prohibitively expensive, and is in almost all cases really not needed. The first and last columns of

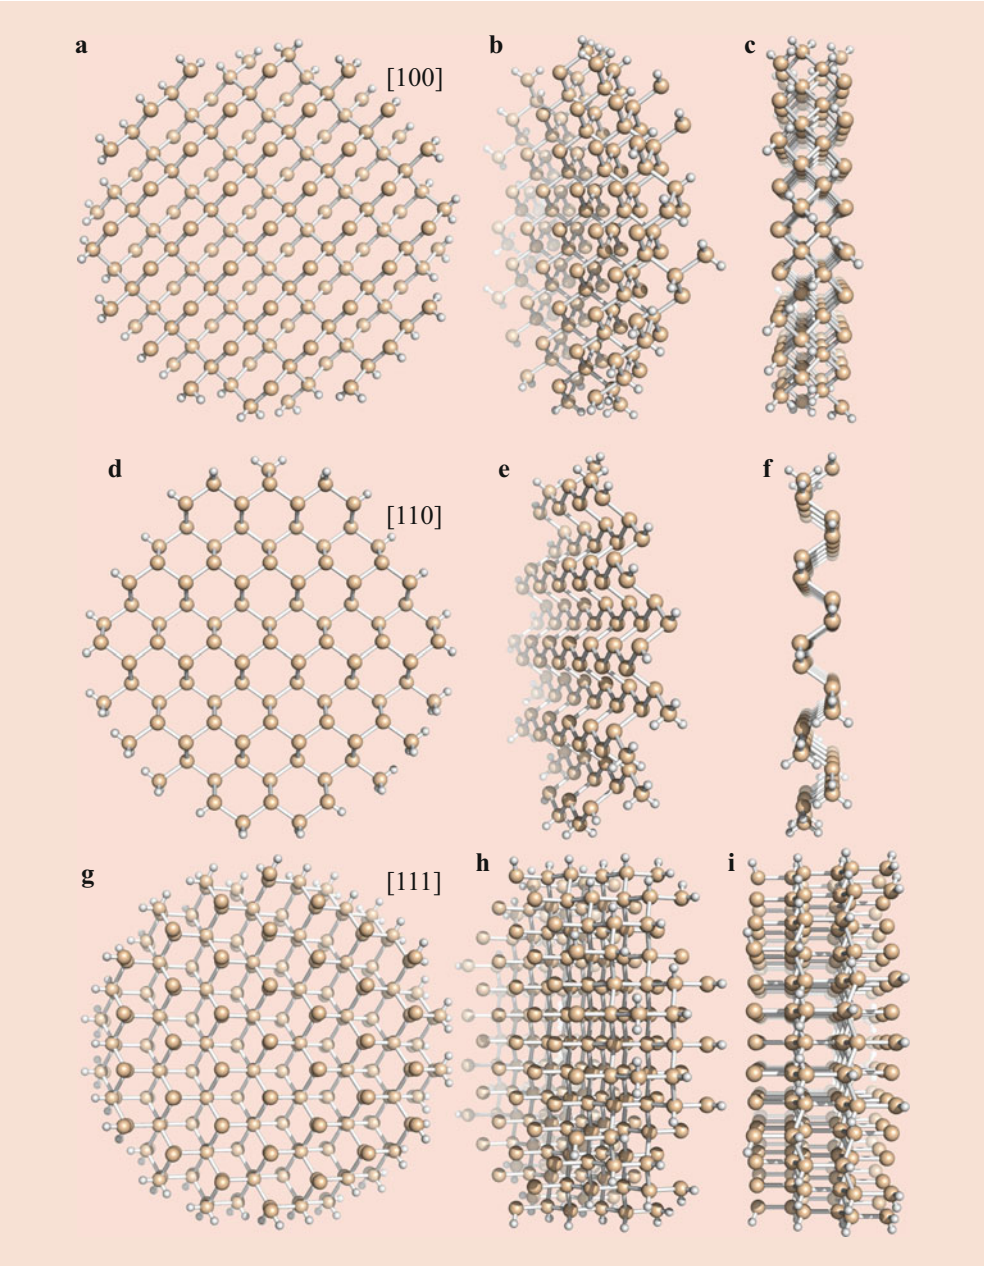

Fig. 45.4 Unit cells of three nanowires measuring 2.5 nm thick with transport in three different crystal directions [100], [110], and [111]. The full cross sections are shown in **a, d, g**, a tilted side view in **b, e, h** and a side view of the repeated cell in **c, f, i**. (The images were created with *Band Structure Lab* on nanoHUB [117])

the off-diagonal matrix elements are needed to compute the charge injection from the left and the right ends of the device. The diagonals represent the local density of states in the system and are needed if some sort of physics-based decoherence or scattering is included in the model [95, 105]. The Hamiltonian of the open system remains sparse, as described above, except for the block of atoms at the contacts that create a full-matrix sub-block. This sub-block is determined by the number of atoms in the contact regions, such as source and drain, that are modeled as infinite leads.

The size of the cross section scales the computational load in the number of atoms in the open surface in $O[(NB)^3]$, where N is the number of atoms in the repeated boundary cell and B is the number of orbitals in the basis (per atom). The length of the nanowire in terms of number of layers (L) enters the scaling of the computation basically linearly $O[L(NB)^3]$ in the typical recursive Green's function (RGF) algorithm [95]. The RGF remains the fastest general-purpose algorithm to compute the diagonals and selected off-diagonals of the system's Green's function, which is effectively the inverse

of the open-system Hamiltonian. Algorithm enhancements to reduce the cubic scaling dependence $O[L(NB)^3]$ to lower order, reduce the layer coupling, decompose the blocks, and to enable efficient parallelization have been developed over the years [72, 74, 75, 118–123].

The computational load can also be reduced by compressing the real-space basis in the cross section into modes [124]. This approach works very well for effective mass models and has been applied extensively [125, 126]. This basis transformation enables reduced computation times and increased cross-section sizes. The tool *nanowire* [127] on nanoHUB.org allows anyone to visualize the modes and explore larger cross-section devices interactively. The mode space method, however, has serious issues in multi-band (**k•p**) and atomistic basis sets, where the quantization in the cross section couples different orbitals. Careful construction of the mode space can be performed for **k•p** models [128–131]. The use of mode space representations in real space tight-binding models has been limited to carbon nanotubes and graphene, where simple p_z-orbitals were used for each atom [132–134]. (A 1D π-coupled chain is mathematically identical to a 1D s-orbital chain.) The mode approach has been shown to be extremely challenging if not impossible to implement systematically for atomistic highly coupled tight-binding approaches [135]. A related reduced-order method not requiring explicit eigenstates has been demonstrated for effective-mass models [136]. Relatively recently Mil'nikov et al. developed a methodology [137] that eliminates spurious eigenvalues in a specific energy window. This method has been used for nanowire metal–oxide–semiconductor field-effect transistors (MOSFETs) [137] and Tunnel FETs [138]. The method was further used in non-orthogonal DFT methods [139] and 2D ultra-thin body (UTB) devices [140]. The Mil'nikov method has been further automated and stabilized such that larger cross sections can be considered and implemented in NEMO5 [141].

If only coherent transport is considered and no quasi-bound, lead-decoupled states exist in the device, then fully atomistic implementations of wavefunction-based approaches such as the QTBM [67, 96] and optimized renormalization [74, 75] can scale significantly better than $O[L(NB)^3]$ owing to the usage of highly optimized linear solvers. For UTB transistors this method has been shown to be at least $\times 4$ faster than NEGF in the highly optimized and parallelized OMEN code [104].

45.6.3 Quantum Transport: Parallel Computing Scaling

With the QTBM or the NEGF the computational cost of quantum transport under high bias is so intense that large supercomputers can be utilized efficiently, if the transport algorithms are implemented efficiently. The art of parallel computing is to maximize the number of computing cores, to keep them busy computing, and to reduce the communication between nodes as much as possible. Communication can be minimized by the design and grouping of independent computing tasks. In an ideal world one would write a scientific program and a compiler would understand the levels of parallelism and distribute the computational load automatically. This has been a dream for a long time and still has not reached practical utility beyond shared memory use in a single CPU with OpenMP for real application programs. Many mathematical libraries use the shared memory OpenMP or threaded paradigm for parallelization within a single chip to about 24 or 64 cores. The message passing interface (MPI) paradigm requires the explicit design and programming of messages between cores or groups of cores. Such programming requires careful design, intense testing, and fine tuning. OMEN was designed to have four or even five levels of parallelism. At the highest level are independent groups of bias points that do not need to communicate at all until assembly of the final I–V curve. The next two levels parallelize the internal transport kernels of momentum (k) and energy (E) integrals. The (outer) k-integral requires the evaluation of (inner) E-integrals for fixed k. At the lowest level a transport kernel needs to be solved as a function of (E,k). That kernel consists of the computation of the open boundary conditions in source and drain and then the subsequent QTBM or NEGF transport equation solution. In the QTBM this requires an eigenvalue solution for the boundary conditions and a solution of a linear system of equations. Each of these can utilize standard libraries that have been parallelized in MPI or even OpenMP, or a combination of both. The dual-level MPI + OpenMP parallelization has not really delivered better computational performance within OMEN than the pure MPI parallelization. Within the four-level parallelization OMEN scaled almost perfectly to over 220,000 computational cores [75, 104]. In an ideal world of so-called strong scaling, one would divide the compute time by two if the number of computational cores is doubled. This strong scaling results in a straight line of reduced compute time on a logarithmic scale. OMEN delivers almost perfect strong scaling as depicted in Fig. 45.5. Running for 1 h on 221,400 cores corresponds to about 25.3 years compute time on a single CPU. The OMEN implementation was recognized with the Gordon Bell Prize Honorable Mention as the first Engineering Code running at the peta-scale in 2011.

45.6.4 Surface Passivation

The strength of empirical tight-binding methods is the valence electron bonding electronic structure representation within an atomistic representation of the physical geometry.

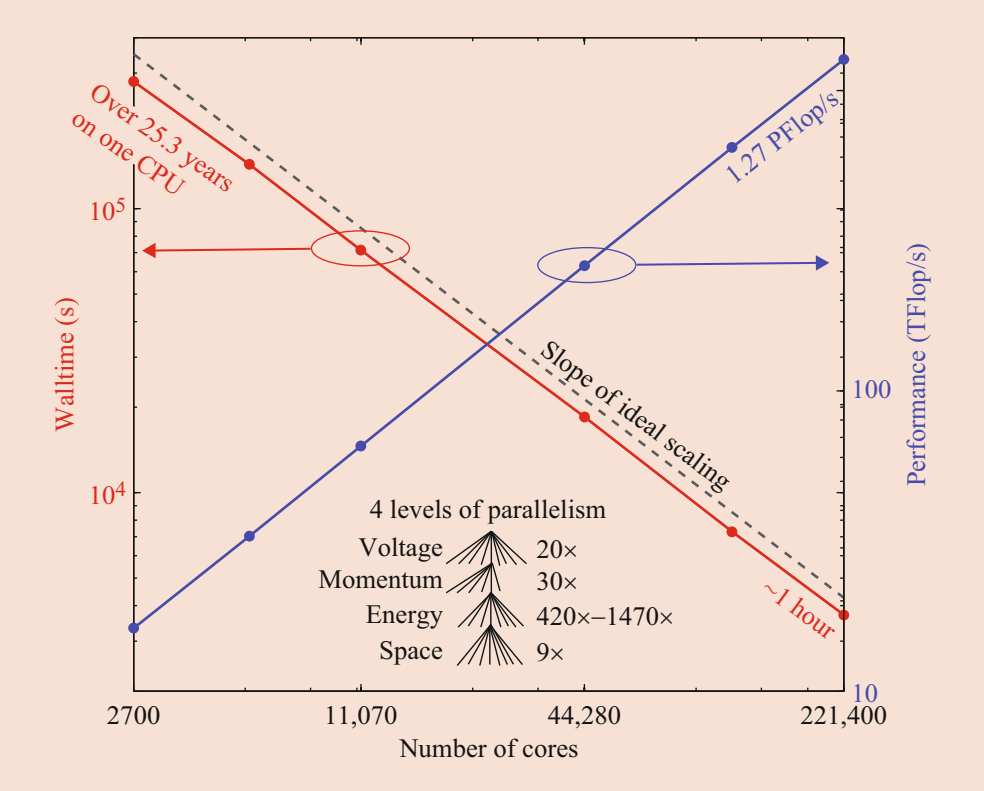

Fig. 45.5 OMEN parallel compute times for an ultra-thin body transistor as a function of the number of computational cores on a logarithmic scale. The dashed line indicates the slope of perfectly strong scaling. Also indicated on the right axis is the computational throughput in tera floating point operations per second. OMEN was the first engineering code to reach the peta-scale [104]

This representation lends itself very well to the numerical description of nanoscale structures. There is, however, one critical pitfall that needs special attention owing to finite size structures: dangling bonds. Here, we cover just some of the numerical aspects [142]. The physical interpretation and mapping to DFT are discussed in references Tan et al. and Lee et al. [49, 143].

For the NEMO team this issue of dangling bonds first emerged in the NEMO3D work, where InAs QDs embedded in a GaAs matrix were to be simulated. A finite amount of GaAs buffer layer needs to be included to properly model the wavefunction penetration into the buffer layer and to include the effects of spatial distortion to built-in strain. A periodic boundary condition would create a 3D array of QDs that would result in band structure and not in discrete states. Furthermore, such a periodic boundary condition requires the boundary surfaces to be perfectly flat and periodic, which is typically not the case in the strained and bulged systems. The simulation domain needs to be finite. If the simulation domain is simply terminated, then something really interesting can be numerically "observed" in the computed eigenspectrum of this finite system: eigenstates localized at the surfaces and edges emerge in the simulation domain with eigen-energies distributed across the whole energy spectrum, including the nominal band edge. These surface states are in this case of course an artifact due to the numerical requirement of a finite simulation domain. Naïve attempts to shift the onsite matrix element energies up or down to push the surface states out of the bandgap failed to achieve any generally reliable solution. Lee et al. [142] developed a numerical methodology for the typical $sp^3\ s^*$ and $sp^3\ d^5\ s^*$ models through a basis transformation into the direction of the dangling bonds and adding an adjustable energy shift to that bond energy. This method results in a very robust and stable method of eliminating the effects of the dangling bonds and has been highly adopted and cited in the literature.

Other, non-embedded, nanostructures actually do have exposed surfaces that require a physical and corresponding numerical passivation. The passivation method in Huang et al. [142] has found very wide use in the field to manage the surface states that naturally emerge in the tight-binding calculations. Twelve years later, the NEMO5 team generalized this passivation method [143] and linked it to chemical bonding. For the very thinnest active regions, however, explicit hydrogen passivation is often the most accurate method. Explicit passivation parameters have been determined by mapping ab initio wavefunctions and bands to tight-binding Hamiltonians [49]. We note here that in tight-binding meaningful surface

states emerge naturally. As such, this basis set naturally captures topological surface states [144] without any ad hoc parameters that are required in continuum basis sets.

45.7 Applications

45.7.1 Quantum Dots: Closed Systems

Quantum dots (QDs) enable designers to custom-create optical transitions at specific wavelengths or confine electrons at specific spatial locations with specific energies. Therefore, QDs are sometimes also called "artificial atoms." These systems are studied very widely in the literature. To highlight the enabling capabilities of tight-binding we just highlight a few QD applications here [145].

Figure 45.6 depicts in a graphically appealing way an InAs QD on an InAs wetting layer on a GasAs substrate, capped by an InGaAs capping layer. With such carefully engineered designs one can achieve optical emission at 1.5 μm for optical communication. A detailed description of the required modeling and the understanding of the design space is given in Usman et al. [5].

A typical dome-shaped QD of 20 nm in diameter and 5 nm in height might nominally only contain around 100,000 atoms. However, such QDs are formed by significant crystal lattice mismatches in the GaAs and InAs system via the Stranski–Krastanov growth method [2]. As such, these systems have a significant built-in strain that reaches far beneath the QD into the substrate. Cutting off the finite, closed system simulation domain too small results in significantly false eigenvalues with variations in conduction band states of over 150 meV and valence band states over 40 meV, underestimating the gap by over 20% [116]. Figure 45.7, taken from Ahmed et al. [3] shows that eigenvalue convergence and proper state polarization significantly depend on the size of the simulation domain. In Fig. 45.7b, the substrate is extended down to 50 nm underneath the QD. Eigenstate tuning can be controlled by the capping layer as indicated in Fig. 45.7b.

45.7.2 Nanowire Electronic Structure: Quasi-Periodic in 1D and Closed Systems in 2D

Nanowires as depicted in Fig. 45.8 are of significant technical relevance for transistor scaling at the end of Moore's law. The last generations of CMOS-based transistors in the so-called 5-nm node might be vertical stacks of such nanowires or nanosheets with wrap-around gate control. The following sections provide an overview of how empirical tight binding can deliver fundamental and quantitative insights into the performance of nanowires. We start from a very "simple" top-of-the-barrier model for a long nanowire, compare it with a sophisticated full transport model, and then explore the limitations of these transport models as the gate lengths are reduced. The two transport models vary significantly in a variety of aspects: (1) Use of a semiclassical dispersion versus full quantum transport, and (2) the treatment of charge in the nanowires: only the full quantum transport model considers full charge self-consistency. Somewhat surprisingly, these models deliver virtually identical results for long nanowires. These performance results show how critical the details of the band structure are versus the charge details in the wire and the surface. For short wires the accurate representation of the band structure is just as critical for effects of tunneling. Without the accurate representation of bandgaps and

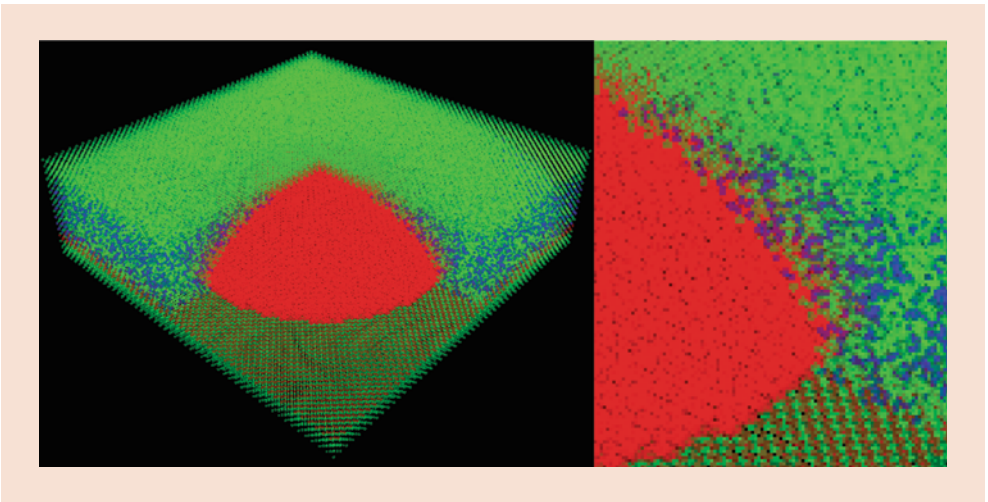

Fig. 45.6 Dome-shaped InAs QD measuring 20 nm in diameter and 5 nm tall embedded in an AlGaAs buffer layer grown on top of a GaAs substrate [5]. Image is also accessible on nanoHUB [146]

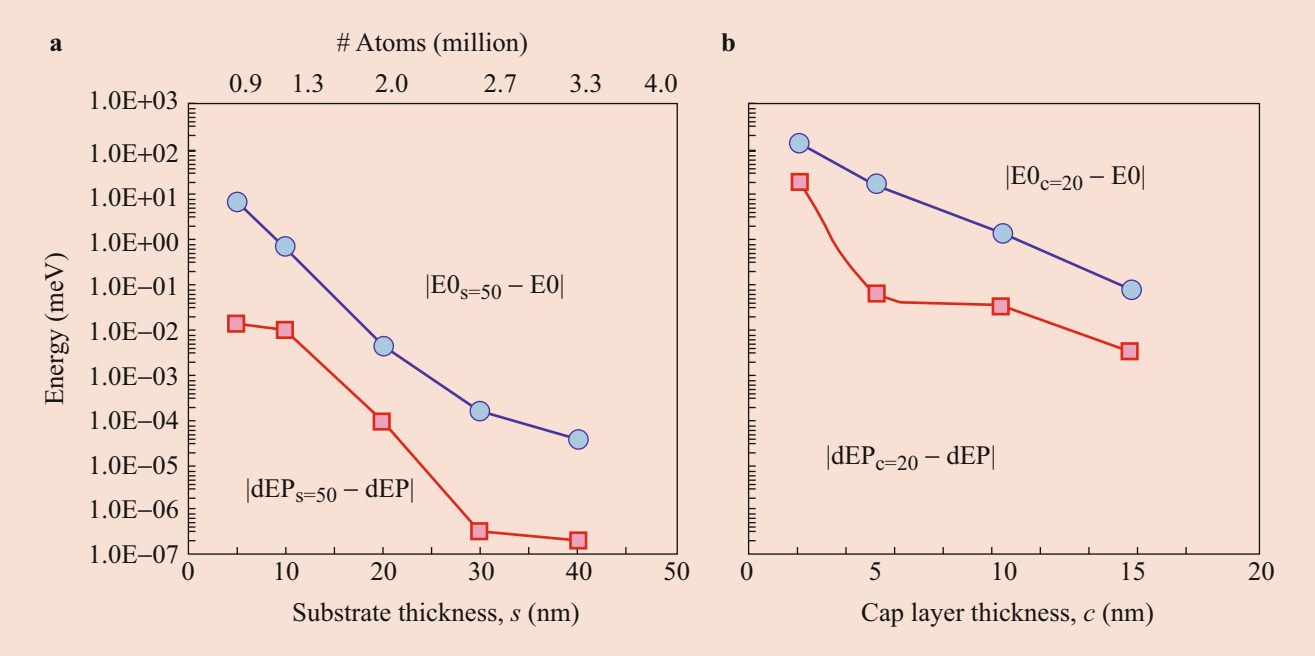

Fig. 45.7 (**a**) Substrate layer thickness dependence of the conduction band minimum and the P level splitting. Other structural parameters remain constant ($h = 5.65$ nm, $d = 11.3$ nm, $c = 10$ nm, and $D = 31.3$ nm). (**b**) The impact of cap layer thickness (with substrate, $s = 30$ nm and other structural parameters remaining the same). Lanczos convergence tolerance $= 1 \times 10^{-7}$. The changes in both these quantities are calculated with respect to the largest s (50 nm) and c (20 nm) respectively. (From Ahmed et al. [3])

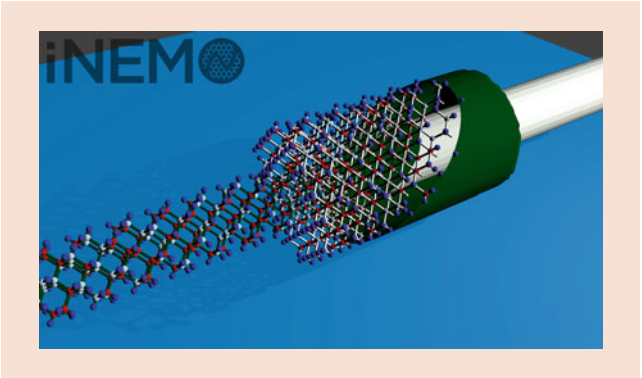

Fig. 45.8 Conceptualization of a finite sized nanowire. The difference between a typical continuum representation (**right end**) and an atomistic representation (**left end**) is eye opening. (Figure published online [147] created by Dr. Daniel Mejia in the NEMO5 development team)

effective masses one cannot provide real guidance to the design of nanometer-scaled transistors. These effective mass and bandgap accuracy requirements exemplify the concerns about DFT-TB discussed in Sect. 45.4.4 above.

Figure 45.4 above depicts unit cells of two different nanowires measuring 2.5 nm thick in the [100], [110], and [111] transport directions. If periodic boundary conditions are applied in the transport direction, then a dispersion in the transport direction can be computed with confinement in two dimensions. Band folding and band-to-band interactions result in complex new band structures owing to the confinement, as discussed extensively in the literature. For early tight-binding examples see Meija and Boykin et al. [148–151].

Visual inspection shows that the dispersions shown in Fig. 45.9 for [100], [110], and [111] Si nanowires vary dramatically. The [100] wire has four almost degenerate minimum band-edges at the Γ point with an effective mass of 0.31. The [110] wire has two almost degenerate bands of very light masses 0.14 and 0.18 at the Γ point. The [111] wire has three minimum band-edges off the Gamma point with an effective mass, two with masses $m^* = 0.48$, and one with $m^* = 0.68$. At the Γ point the [111] oriented wire has a negative effective mass of -0.26, effectively repelling carriers back into the source. Clearly, one can expect the [100] and [110] nanowires to conduct current much better than the [111] oriented wire.

The four lowest [100] wire bands are almost degenerate, with a mass of 0.31. In contrast, the two lowest bands of the [110] wire have effective masses of 0.14 and 0.18. Determining which one of the two nanowires has "better" electron transport requires more quantitative transport models.

At the macroscopic scale bandgap and effective mass are determined solely by bulk material properties. At the nanoscale, geometry, surfaces, and crystal orientation are equally important. Consequently, electron transport in nanowires varies significantly as a function of geometry.

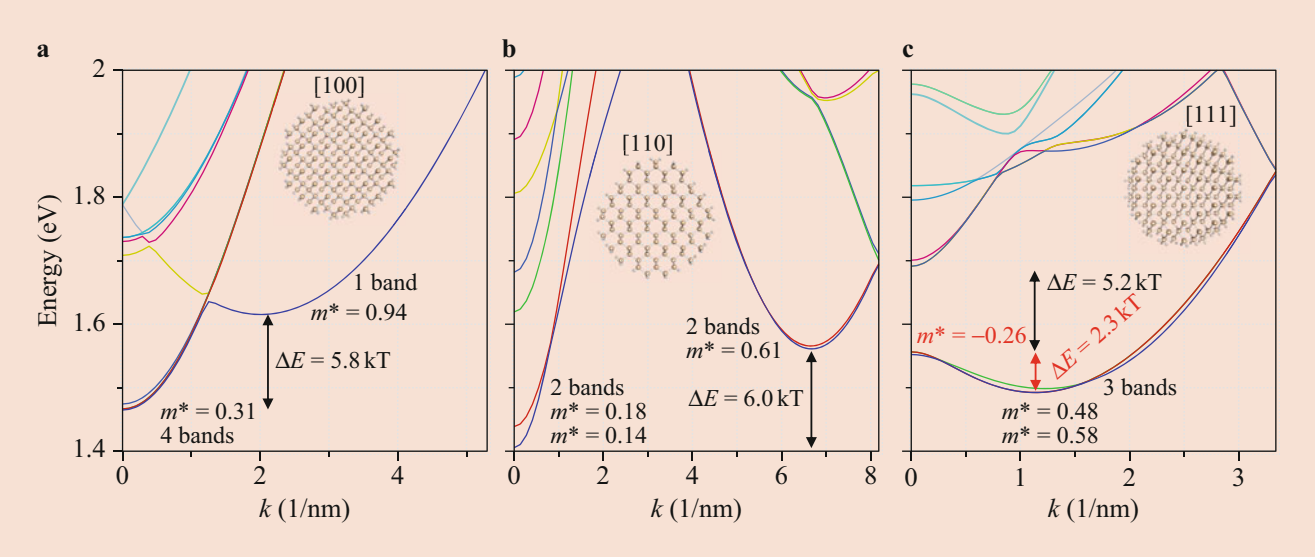

Fig. 45.9 Dispersion in the transport direction of infinitely long, ungated, and hydrogen passivated 2.1-nm Si nanowires in the (**a**) [100], (**b**) [110], and (**c**) [111] transport directions. (**a**) Four bands with $m^* = 0.31$ (units are the free-electron mass, m_0) at Γ are separated by an energy of about $5.8k_BT$ (at room temperature) from the next band with a heavier mass of $m^* = 0.94$. The heavy band with $m^* = 0.94$ is not occupied at the source injection of a transistor. (**b**) Two very light effective mass bands of $m^* = 0.14$ and $m^* = 0.18$ at Γ are separated by $6k_BT$ in energy from the next conduction band. (**c**) Three bands with the minimal conduction band of Γ, two with masses $m^* = 0.48$ and one with $m^* = 0.68$. These bands are close in energy of $2.3k_BT$ of hole-like masses of $m^* = -0.26$. Transport in the [111] direction experiences a significantly heavier mass and even carrier rejection due to the negative mass

This discussion demonstrates conclusively that *effective masses and bandgaps can be designed*!

45.7.3 Ballistic Transport from Nanowire Dispersions with the Top-of-the-Barrier Model

The beautifully simple top-of-the-barrier (TOB) model developed by Rahman et al. [152] can provide intuitive insight into the effects of material, geometry, and strain on the transport in nanoscaled transistors. Significant work has been published using the TOB model to examine and illustrate: atomistic versus effective mass models in Si nanowires [153]; injection velocity in ultra-thin-body Si [154] and III–V MOSFETs [155]; geometry effects on electrons [156] and holes [157, 158] in Si nanowires (as discussed above). The early application of the TOB model considered just the dispersion diagram without consideration of the effects of electrostatics. Later implementations, as are now available in NEMO5 or *Band Structure Lab* on nanoHUB [117] also consider the electrostatic effects in the device, which self-consistently relate band structure and local potential. Analytical extensions even help with estimating the effects of tunneling through the gated region with an "under-the-barrier model" [159].

The goal of this section is to demonstrate that very fast and "simple" tight-binding dispersion calculations for realistically sized nanowires can be mapped into simple methods that result in very fast estimates of nanowire I–V characteristics. The calculation of these I–V characteristics requires minutes versus hours in a full quantum transport model. We then compare these very fast calculations with full quantum transport calculations.

To estimate the transistor performance of the three nanowires considered here we utilize the TOB model implemented in the nanoHUB tool *FETtoy* [160]. *FETtoy* is configured with a small set of model parameters that are reminiscent of a compact model. The material parameters are entered as effective masses, band degeneracies, and dielectric constants. Multiple nondegenerate bands cannot be entered into the published version of *FETtoy*, but can, of course, be considered in the TOB model. For simplicity we choose the lowest lying bands to be degenerate and average out the masses. For the three wires considered we used [100]: $m^* = 0.31$ fourfold degenerate; [110]: $m^* = 0.16$ twofold degenerate; and [111]: $m^* = 0.51$ threefold degenerate. Shape and size of the nanowire are also entered. A gate dielectric measuring 1 nm thick is chosen, with dielectric constant 3.9. The TOB model can estimate effects of drain-induced barrier lowering (DIBL) and the degradation of the subthreshold swing with a gate control parameter α_G and a drain control parameter α_D. For clarity of the arguments we set $\alpha_G = 1$ and $\alpha_D = 0$, ignoring these gate issues and focus on the ideal, long wire performances.

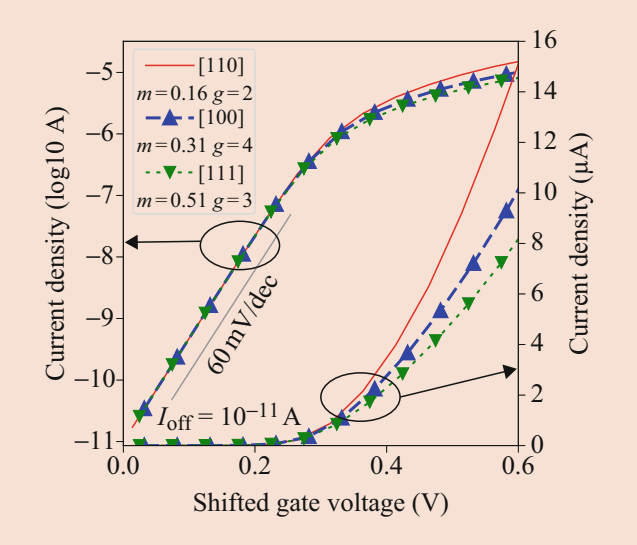

Fig. 45.10 Drain current versus gate voltage computed with the top-of-the barrier model implemented in the nanoHUB tool *FETtoy* [160]. Effective masses and band degeneracies taken from atomistic dispersions. The [110] wire delivers the highest ON current and the [111] wire delivers the lowest ON current

Figure 45.10 depicts the drain current versus gate voltage computed within the TOB as implemented in the nanoHUB tool *FETtoy* [160]. The left vertical axis is on a logarithmic scale and the right vertical axis on a linear scale for the drain current. The tool allows the user to set a threshold voltage that effectively adjusts the OFF current. We have taken the three current voltage characteristics for the three wires and shifted them to the same OFF current $I_{OFF} = 10^{-11}$A. As we consider ideal wires and neglect electrostatic effects along the channel all three transistors behave perfectly in the OFF region and deliver a subthreshold swing (SS) of 60 mV/dec. The three wires behave differently in their delivered ON current. As expected, the [111] wire delivers the lowest ON current. The low effective mass [110] with just two degenerate bands provides a higher ON current than the fourfold degenerate [100] nanowire with a mass that is roughly doubled compared with the [110] wire.

With these performance estimates for the three nanowires we emphasize here again that at the nanoscale geometry and crystal direction modify parameters such as bandgap and effective masses that in the past we considered material constants. *Bandgap and effective mass have become design choices.*

From the dispersion alone and the TOB significant insights can be gleaned about the transport properties of the nanowires. These calculations are computationally cheap as they principally involve the computation of a set of eigenvalues of a relatively small unit cell, as depicted in Fig. 45.4. Full quantum transport simulations are significantly more expensive and are discussed in the next section.

45.7.4 Full Quantum Transport in "Long" 15 nm Nanowires: 3D Representation

The TOB model is an excellent choice for screening for the fundamental effects of a variety of crystal directions and confinement effects. The TOB model has the ability to include some electrostatic effects to estimate DIBL and a subthreshold degradation. Analytical extensions might even help with estimating the effects of tunneling through the gated region with an "under-the-barrier model" [159]. A full TCAD-based 3D simulation of a wire, however, requires a full 3D representation of the carrier charges, gates, tunneling processes, and relaxation in the reservoirs. One of the first full 3D implementations of atomistic quantum transport was performed by Luisier et al. in the OMEN code [67, 75, 161]. Luisier continues to develop his OMEN code at ETH and Klimeck et al. continue to develop NEMO5 [113, 114] at Purdue. Within the scope of these modeling capabilities different cross-section shapes, materials, and stress conditions have been explored in a variety of materials systems such as Si, graphene, SiGe, III–V, and 2D materials.

OMENwire is a tool published in nanoHUB [161] powered by the OMEN simulation engine. *OMENwire* can easily be configured through a graphical user interface for different wire and UTB transistors. *OMENwire* runs on parallel machines typically for an hour or so to deliver the results in a fully graphical and interactive form. Different simulations for user choices such as geometries, crystal orientation, and material properties can be run and compared interactively. The results presented in this section have been generated with *OMENwire* code [161] and anyone can duplicate these results on nanoHUB.

We consider the same nanowire geometries as depicted in Fig. 45.4 above: 2.5 nm diameter Si in [100], [110], and [111] crystal direction. 10-nm source and drain at 2×10^{20} doping. 15 nm gate length with 1 nm EOT oxide. The drain voltage is set to 0.6 V and the gate voltage is ramped from 0 to 0.6 V. We use the default parameters of the dielectric constant of the Si channel (11.9), the channel material affinity (4.05 eV), dielectric function of the oxide (3.9), and the gate contact work function (4.1 eV). Figure 45.11 shows the drain current as a function of gate voltage on a logarithmic scale (left vertical axis) and a linear scale (right vertical axis).

Figure 45.11a depicts the direct numerical results as delivered by *OMENwire* given the specific geometries. Figure 45.11b shifts the three performance curves to the same OFF current $I_{OFF} = 10^{-11}$A. We note that the [111] wire simulations do not converge to meaningful results for gate voltages above 0.4 V, as further discussed below.

The threshold-shifted performance curves in Fig. 45.11b show that for the long gate length of 15 nm the three nanowires perform perfectly identically at 60 mV/dec in the subthreshold regime. With full 3D electrostatics the three

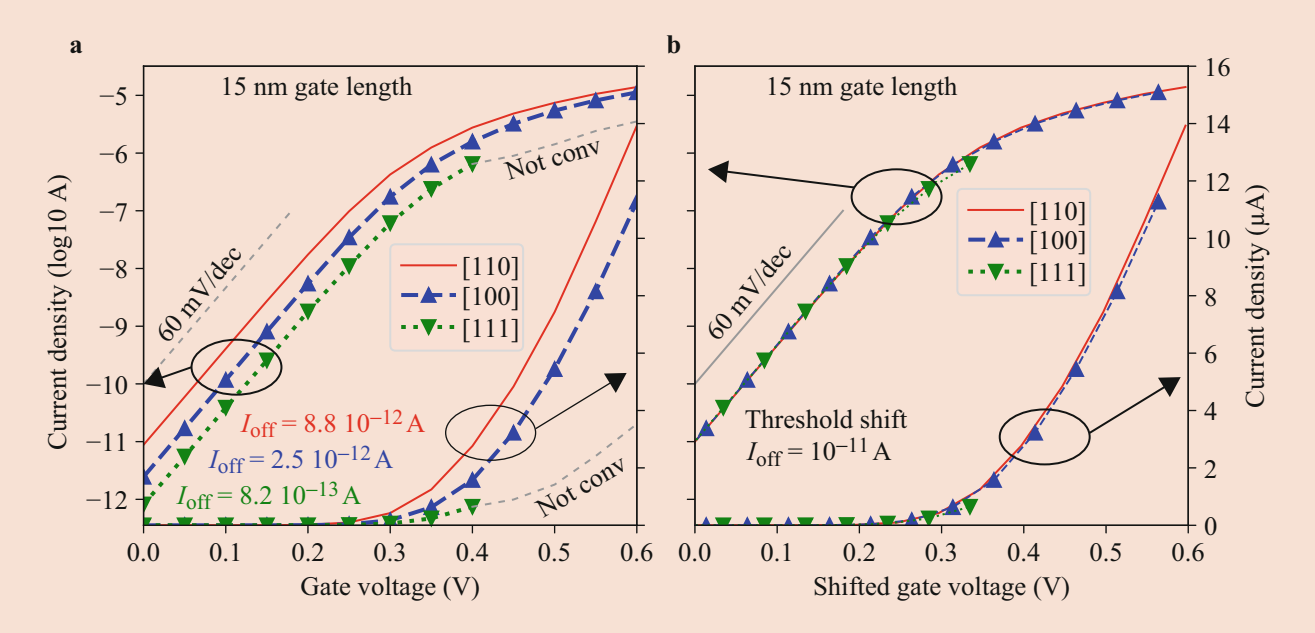

Fig. 45.11 (**a**) $I_d - V_g$ performance curves of the discussed [100], [110], and [111] nanowire transistors measuring 2.5 nm in diameter. Source-drain bias is 0.6 V. The gate length is long at 15 nm. (**a**) Simulation results with specific gate work function value of 4.05 eV. The [110] wire delivers the highest current and the [111] wire delivers the smallest current. (**b**) Performance curves of (**a**) shifted to a common OFF current 10^{-11} A. All transistor curves are virtually identical

wires also perform virtually the same in the ON region in this long channel device with ballistic transport. We note here that this result of virtually identical performance is different than the analytical TOB result depicted in Fig. 45.10.

Figure 45.11a shows the specific performance curves without adjustment of the threshold voltage. The [110] wire delivers the highest current and the [111] wire delivers the lowest current. Understanding the different performances requires a deeper understanding of the band structure, density of states and charge densities in the different wires.

Figure 45.12 shows a composite picture of localized band edge (black line), band structure in the source (green lines), band structure in the drain (orange lines), normalized current density (blue line), and transmission coefficient (brown line) for the three nanowires considered, with a source–drain voltage of 0.6 V and a gate voltage of 0.3 V. Each of these plots is available in *OMENwire* [161]. The rather different band structures discussed in Fig. 45.9 above are evident, resulting in rather dramatic transmission coefficients. The normalized current density under high bias is the product of the transmission and the Fermi function in the source. This composite picture Fig. 45.12 illustrates the relative energy scales and spatial positions in the nanowires. The different effective masses in the three wires combined with the same doping level results in three very different Fermi levels in the source and the drain, as indicated by the horizontal red lines. For the very heavy mass [111] wire the Fermi level is just under the conduction band by 5.4 meV, whereas the [100] and [110] Fermi levels are above the conduction band by 26.1 meV and 98.6 meV respectively. From a classical transport perspective, we can now look at the maximum barrier height in the channel measured against the Fermi level in the source. For the [111] wire that energy distance is 141 meV or about $5.5k_BT$. For the [100] and [110] wires this energy difference is much smaller, at 85 meV and 69 meV respectively, corresponding to about $3.3k_BT$ and $2.7k_BT$. With a barrier about $3k_BT$ higher in the [111] wire one can expect a factor of e^3, so about a $\times 20$ lower current in the [111] wire, regardless of transmission coefficient details. The simulated I_{OFF} difference in Fig. 45.11a is a factor of about $\times 10$, indicating that the Fermi level difference estimate is off by a factor of 2. The I_{OFF} difference in Fig. 45.11b between [110] and [100] is a factor of $8.8/2.5 \approx 3.5\times$. The Fermi level energy difference to the top of the barrier is just $0.6k_BT$, corresponding to a Fermi tail difference of $e^{0.6}$ or a factor of $\times 1.8$. Also, this Fermi level estimate difference is off by a factor of 2. The difference in current between the [100] and [110] requires some more detailed understanding.

The normalized current density and transmission coefficients shown in Fig. 45.12 are depicted for more clarity and ease of comparison in Fig. 45.13 again (taken directly from the *OMENwire* code) [161]. The figures are augmented by the band structure information in Fig. 45.9, which measures the number and effective mass of the lowest bands. For each available injection band one can see a close to step-like feature to a discrete value of transmission as expected. As

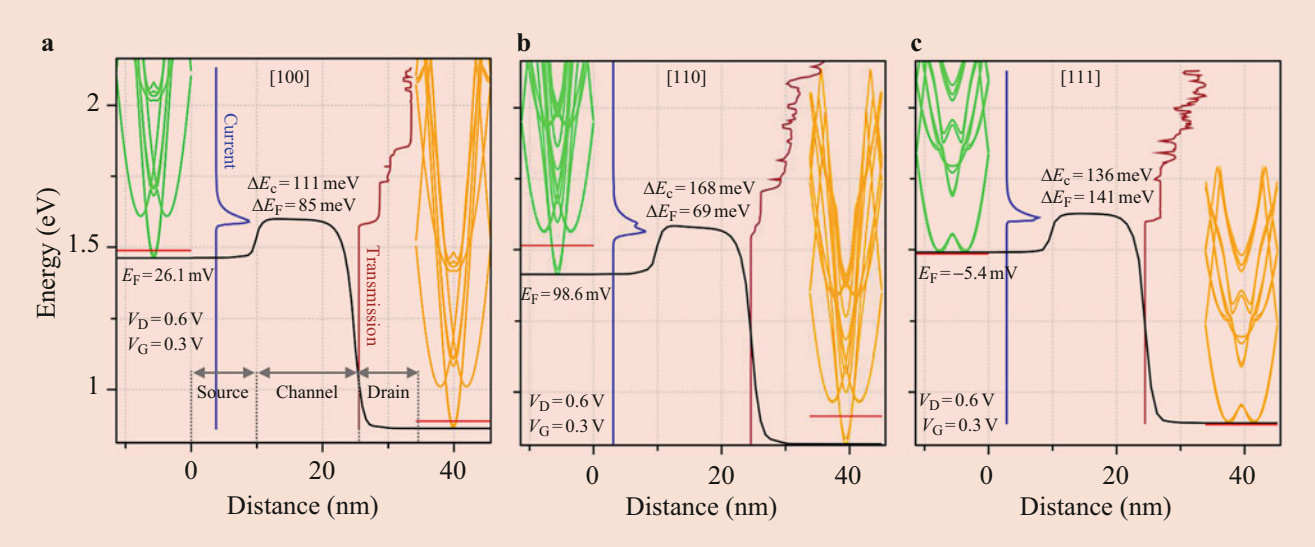

Fig. 45.12 Localized band edge (black line), band structure in the source (green lines), band structure in the drain (orange lines), normalized current density (blue line), and transmission coefficient (brown line) for the three nanowires considered, with a source–drain voltage of 0.6 V and a gate voltage of 0.3 V. (**a**) [100] wire, (**b**) [110] wire, and (**c**) [111] wire. The Fermi levels in the source are indicated as E_F, the maximum barrier height in the channel measured against the conduction band and Fermi level in the source as ΔE_C, ΔE_F respectively

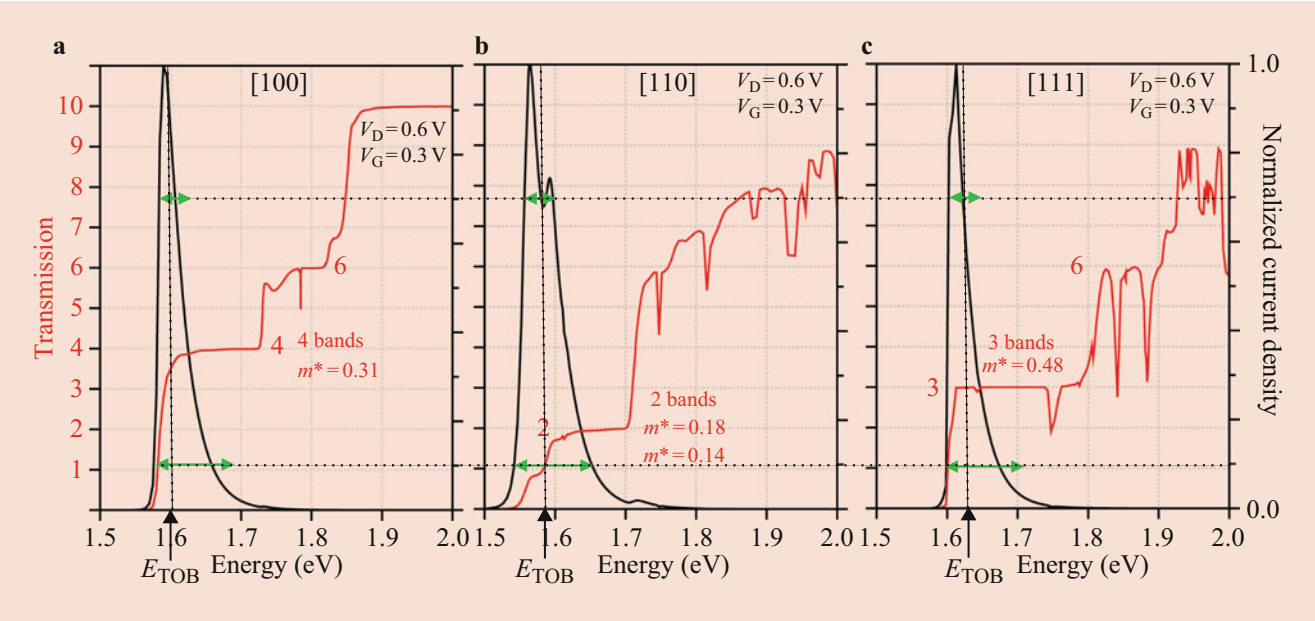

Fig. 45.13 Transmission (red lines) and normalized current density (black lines) for the three nanowires considered with a source–drain voltage of 0.6 V and a gate voltage of 0.3 V. The effective masses of the lowest bands correspond to the values in Fig. 45.9. The vertical dashed line labeled with E_{TOB} indicates the energy of the top of the barrier inside the channel. The green double arrows in (**b**) indicate the energetic width of the current flow at a normalized value of 10% and 70%. These two green vectors are also inserted in (**a**) and (**c**), indicating that the energetic width of current flow in the [100] and [111] wires is much narrower than in the [110] wire

discussed above in the context of effective masses of the three different wires, one can expect the [111] wire to conduct the current less well than the other two wires owing to its much larger effective masses. As also discussed above, the [100] wire has a nearly fourfold degenerate band set with effective mass of 0.31, whereas the [110] wire has two bands close to degenerate with masses 0.14 and 0.18.

The transmission coefficient of the [111] wire with its three lowest bands with effective mass 0.48 shows a rather steep rise at the band edge to a value of 3. The [100] wire,

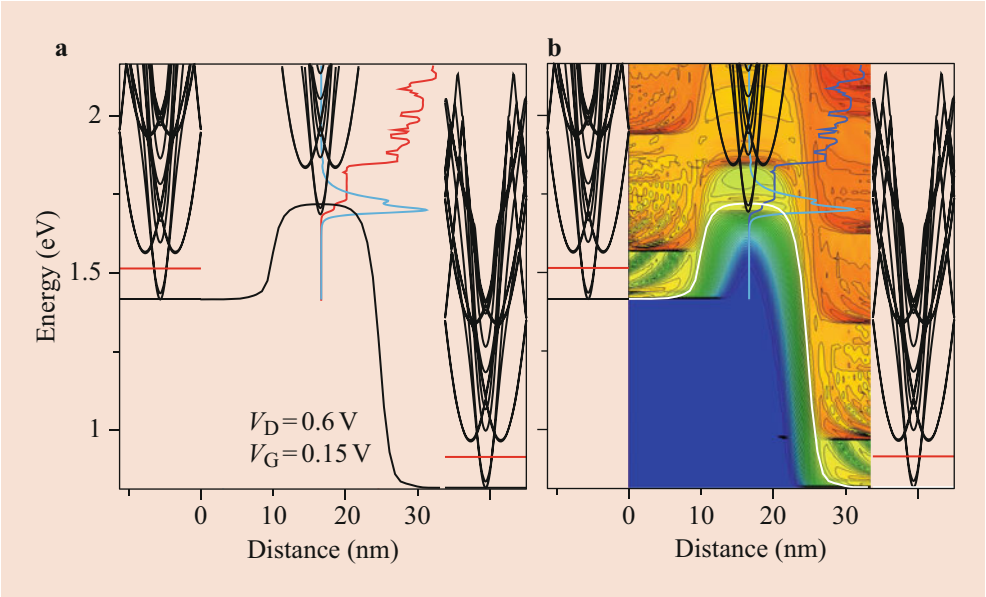

Fig. 45.14 (**a**) Localized band edge, band structure in the source and drain, normalized current density (blue line), and transmission coefficient (red line) for the [110] nanowire similar to Fig. 45.11b. The specific gate bias here is different – it is further in the OFF state at 0.15 V. The source/drain band structure is also superposed into the middle of the channel and aligned with the second set of bands. (**b**) Same as (**a**) but the local density of states is superposed in the quantum device simulation region

with its four lowest bands of effective mass 0.31, has a more gradual slope to a maximum transmission of 4 above the band-onset. The [110] wire has the broadest onset of the transmission and the two bands that are not quite degenerate result in a transmission step to values of 1 and 2. These different slopes of the transmission coefficients have a significant effect on the three different normalized current densities. Each of the three plots in Fig. 45.13 shows a dashed vertical line labeled E_{TOB}, corresponding to the TOB conduction band edge in the channel under 0.3 V gate bias. Even for this large gate length geometry of 15 nm *there is a significant tunneling current flow under the conduction band edge*. Just by visual inspection it appears that the [110] wire has the largest energy range in its tunneling current contribution. However, the tunneling current alone does not yet explain the differences in the current between the [100] and the [110] wire.

Two horizontal arrows in Fig. 45.13b "measure" the energetic width of the current density at a level of 10% and 70% of the peak value of the normalized current. These two arrows are transposed in the figures for the [100] and the [111] wire showing that the [110] wire transmits current over a significantly wider energy range.

Figure 45.14 examines in more detail why the [110] wire has a much wider energetic range in its current density. Figure 45.14a basically repeats Fig. 45.12b for a [110] wire, where, however, the gate bias is reduced to 0.15 V, further into the OFF region. Clearly, there is a lot of current flowing under the conduction band edge in the center of the device. Figure 45.14b superposes in addition the local density of states (DOS) in the simulation domain. It is rather evident that there is a significant DOS under the nominal conduction band edge. In the source and drain the DOS aligns with the band structure of an ideal wire. However, in the central device region the band structure really no longer aligns perfectly with the local DOS. There is a significant DOS in the bandgap and also the state spacing is (slightly) different to the additional OFF-state electrical confinement in the middle of the channel.

The conclusive reason why the [110] wire delivers a higher current than the [100] wire is the interplay of electrostatic potentials and tunneling through the gate-controlled potential.

45.7.5 Full Quantum Transport Versus an Analytical Model in "Long" 15-nm Nanowires

The full quantum transport simulations presented above provide significant insights into the device physics of the 2.5-nm-thin cross-section wires. Tunneling and modeling of the detailed potential are critical in the understanding of the device performance. It is, however, particularly interesting to see that the overall device characteristics for the long 15-nm gate length of the wires in the [100], [110], and [111] directions perform virtually the same when they are shifted

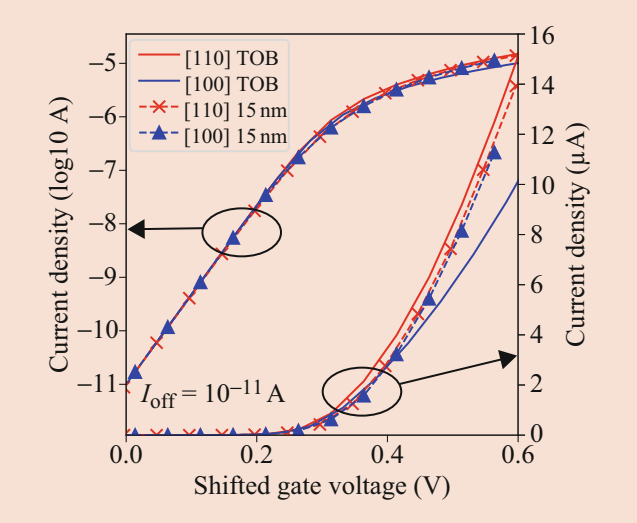

Fig. 45.15 Comparison of the TOB and full 3D quantum transport calculations. Solid lines are the results with the analytical top-of-the-barrier model shown in Fig. 45.10 for [110] and [100] wires. The dashed lines with labels correspond to the full 3D OMEN quantum transport results shown in Fig. 45.11b for a 15-nm gate length wire. All curves are threshold voltage shifted to the same off current at 10^{-11} A

to the same OFF current (see Fig. 45.11b). Not only are the subthreshold performance results the same at 60 mV/dec but the ON currents are also virtually the same. Figure 45.15 compares the full 3D quantum transport simulation results threshold-shifted from Fig. 45.11b and the analytical TOB results depicted in Fig. 45.10 for the [100] and [110] wires. The TOB model is configured in the *FETtoy* simulation on nanoHUB to ignore any assumptions of short channel effects. These simulations are agnostic of a channel length and the results are shown in solid lines. The full 3D *OMENwire* simulations are labeled in dashed lines with symbols. The subthreshold behavior of the cases considered is identical, performing at 60 mV/dec. Only the linear scale shows that the TOB model predicts slightly different ON currents for the two wires, whereas the full 3D model predicts virtually identical ON currents. If we were to consider the full 3D model as ground truth, then the TOB model underpredicts the [100] wire ON current by about 30%. There are plenty of uncertainties in the full 3D quantum transport model and one is compelled to ask: "are the hours of CPU time consumed in full quantum transport simulations worth it?" The next section will show the strength of a full 3D quantum transport model in a regime, where the analytical TOB model really breaks down – going from "long" 15-nm channel lengths to 5 nm.

45.7.6 Full Quantum Transport in Short 5-nm Nanowires: 3D Representation

The full quantum transport simulations presented above provide significant insights into the device physics of the 15-nm gate length nanowires with 2.5-nm cross sections. In this segment we consider a gate length of 5 nm and keep all other device parameters such as doping source/drain extension, gate oxide, etc., the same. Figure 45.16a depicts the drain current as a function of applied gate voltage for a source-drain voltage of 0.6 V. Just as before for the 15-nm gate length wire, here also for the 5-nm gate length the [100] wire delivers the highest current, followed by the [110] wire, and the [111] has the lowest current for the same work function specifications. However, Fig. 45.16a shows that the three different wire orientations show very different SS, far worse than the ideal 60 mV/dec. The high-current [110] wire shows the worst SS at 119 mV/dec. For zero gate voltage, its OFF current is 2 orders of magnitude higher than the [111] OFF current. The ON–OFF swing for the high-current [110] wire in the 0.6-V gate sweep is less than 3 orders of magnitude. For typical circuits the usual requirement is an ON–OFF swing of 4 or 5 orders of magnitude. *Although the [110] wire delivers the highest current, it fails to turn off effectively.*

Figure 45.16b depicts the same performance curves as (a) except for thresholds shifted to an OFF current of 5×10^{-10}A. The [110] wire is shifted out of range as it does not deliver such a low OFF current with the chosen work function in the simulation. Possibly, some work-function configuration could turn off the [110] wire enough to reach 5×10^{-10}A. The [100] and [111] wires roughly perform the same in the threshold region at an SS of 81 mV/dec and 79 mV/dec, respectively. The [100] wire delivers about twice as much ON current as the [111] wire.

Figure 45.17 explains the origin of the very different OFF current behaviors of the three different wires. Figure 45.17 depicts the local conduction band edge and density of states for the three different nanowires at zero gate voltage and source–drain voltage of 0.6 V. In each of the three wire source regions the Fermi level is indicated with a horizontal red line and an energy window of $5k_BT$ above the Fermi level is indicated with a gray box. The [110] has the highest Fermi level and the [111] wire has the lowest Fermi level owing to the very different effective masses, as discussed above. The normalized current density as a function of energy is indicated as a blue line and the red line indicates the transmission coefficient.

There is a significant density of states available under the nominal conduction band edge resulting in significant tunneling. The [110] wire (middle) with the very high Fermi level has virtually all of its normalized current flow within the $5k_BT$ energy range around the Fermi level. The central barrier height measured against the Fermi level in the source is $9.9k_BT$. The barrier is nominally high enough if this were a classical transport problem. Clearly, the OFF current in the [110] wire with its light effective mass is completely carried by tunneling.

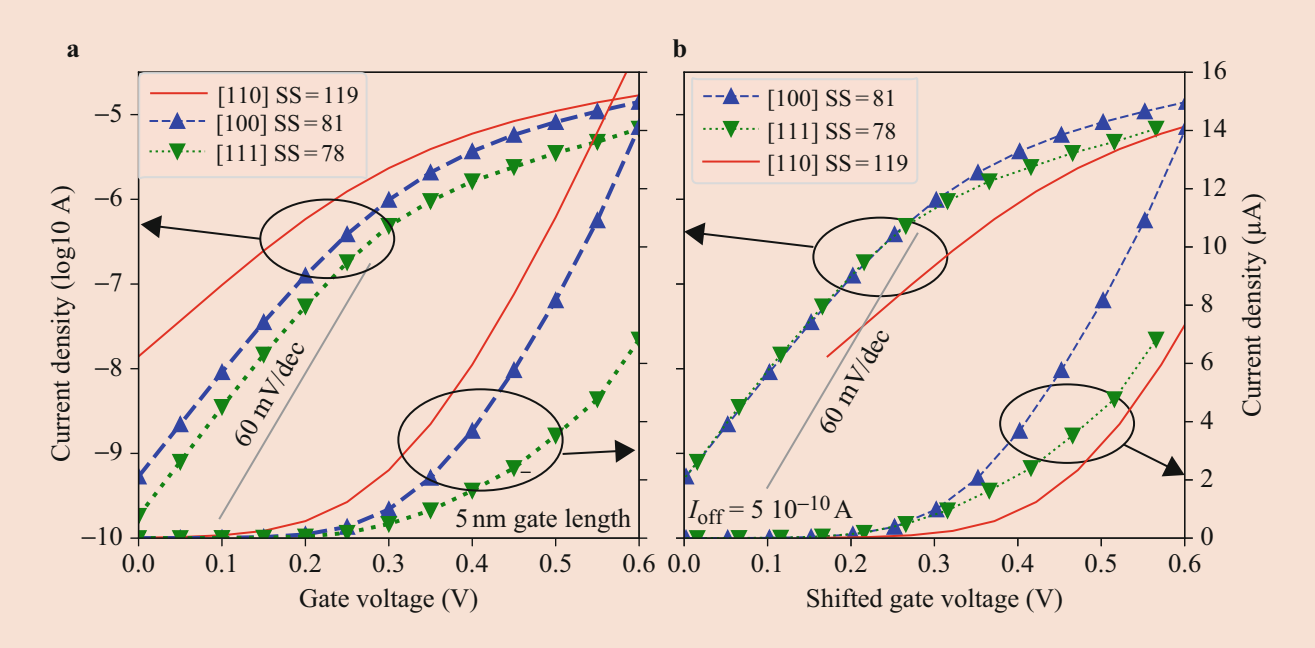

Fig. 45.16 $I_d - V_g$ performance curves of the [100], [110], and [111] nanowire transistors measuring 2.5 nm in diameter and with a gate length of 5 nm. Source–drain bias is 0.6 V. (**a**) Simulation results with specific gate work function value of 4.05 eV. The [110] wire delivers the highest current and the [111] wire delivers the lowest current. The [110] high-current wire fails to turn off effectively and has a subthreshold swing of 119 mV/dec. The ON/OFF current swing is less than 3 orders of magnitude. (**b**) Performance curves of (**a**) shifted to a common OFF current 5×10^{-10} A. The [100] wire delivers the best performance

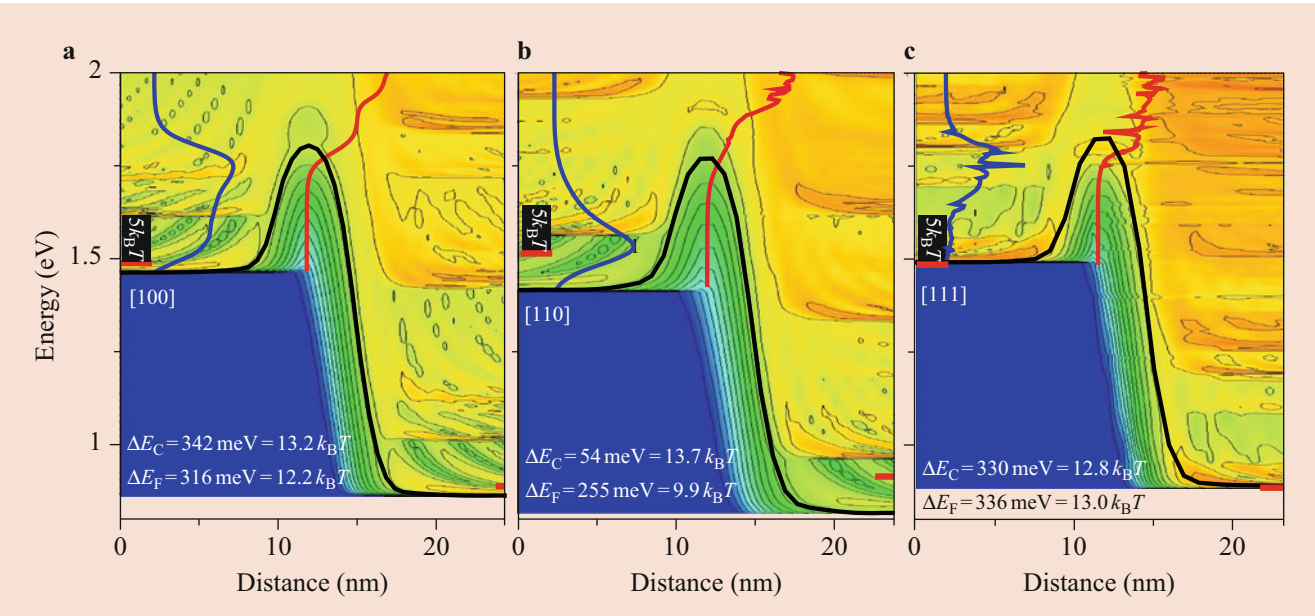

Fig. 45.17 Local conduction band edge and density of states for the three different nanowires a) [100], b) [110], and c) [111] at zero gate voltage and 0.6 V source–drain voltage. In each wire source region the Fermi level is indicated with a horizontal red line and an energy window of $5k_BT$ above the Fermi level is indicated with a black box. The blue line in the source region indicates the normalized current density as a function of energy and the red line in the central device indicates the transmission coefficient. ΔE_C and ΔE_F indicate in each figure the energy difference between the source conduction band and the Fermi level with respect to top of the barrier in the channel. There is a significant density of states available under the nominal conduction band edge resulting in significant tunneling. The [110] wire (**b**) has virtually all of its normalized current flow within the $5k_BT$ energy range around the Fermi level. The [100] wire (**a**) has some current flow within that $5k_BT$ energy range, but most of the current flows above. The [111] wire has virtually all its current flow above the $5k_BT$ window. Current flow above the 5kBT energy range implies that it is quite small in its absolute value. Therefore there is significant tunneling for the [110] (**b**) wire in terms of absolute current

The [100] wire shows some normalized current flow within that $5k_BT$ energy range, but most of the current flows above. As the availability of injected carriers above the $5k_BT$ window is exponentially lowered, one can clearly see why the [100] wire OFF current is much lower than the [110] wire OFF current. The [111] wire has virtually all its current flow above the $5k_BT$ window. In both [100] and [111] wires the exponential carrier fall-off above the Fermi function is compensated for by the exponential increase in the tunneling below the nominal barrier in the gate region, which results in some tunneling current flow. In these two wires, [100] and [111], the OFF current is dominated by tunneling, but because of the heavier transport effective masses the tunneling currents are significantly smaller.

45.7.7 Convergence Issues in High-Bias Coherent Transport Simulations

In Fig. 45.11 the dashed lines labeled "not conv" indicate that several high bias points calculations are not converged for the [111] wire. Such high bias convergence issues are not unusual for coherent quantum transport simulations and several authors have discussed the issues and suggested solution approaches [162–166]. At this time, we are not aware of a publicly available simulator that fundamentally addresses the non-equilibrium treatment of contacts. The *OMENwire* tool we use here does not have an implementation that can manage these fundamental contact issues. The tool can therefore be driven into nonconvergence and we would like to openly discuss the fundamental issues and limits of the simulation approach.

We focus on the drain current versus gate voltage characteristics of the [111] wire in a bias point range of 0.3 V to 0.6 V, as depicted in the insert of Fig. 45.18a. The main component of Fig. 45.18a depicts the electrostatic potential in the middle of the wire as referenced to the local band structure in the source similar to Fig. 45.12c, which depicted a single gate bias of 0.3 V. Here, we plot the band edge for gate biases ranging from 0.3 V to 0.6 V in steps of 0.05 V. The lowering of the barrier as a function of gate voltage is well visualized. At a gate bias of 0.5 V the local band edge develops an additional, step-like feature in the middle of the channel, which migrates closer to the source side for further increased gate voltages. The formation of the "unreasonable

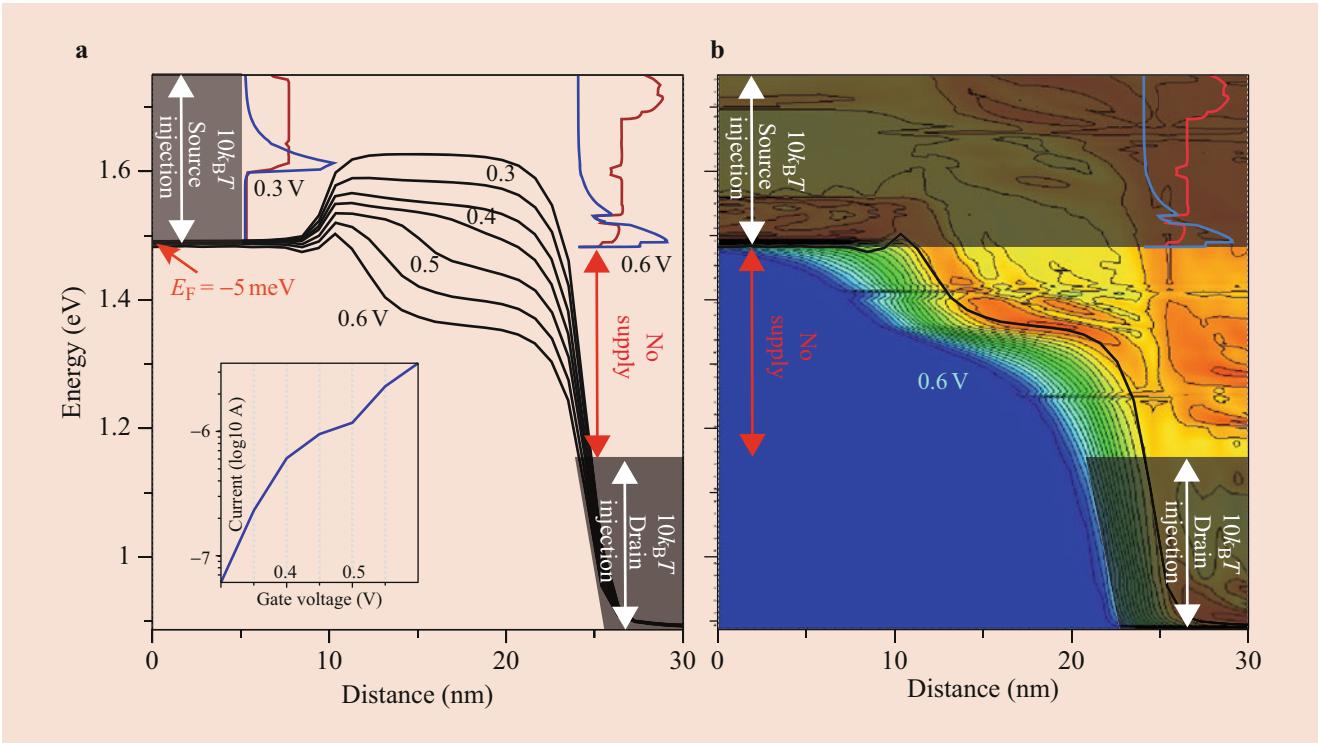

Fig. 45.18 (**a**) Insert: drain versus gate current voltage characteristic of the [111] 15-nm gate nanowire. A nonsmooth curve is visible, with a dip at 0.5 V. The main part shows the conduction band edge in the [111] nanowire for different gate biases ranging from 0.3 V to 0.6 V. Top left and bottom right shaded regions indicate the available Fermi sea of electrons to a height of $10k_BT$ above the Fermi level. Blue lines at the top right and left indicate the energy distribution of the current density for 0.3 V (**a**) and 0.6 V (**b**). (**b**) Similar to (**b**) for a gate voltage of 0.6 V with the local density of states superposed

looking" potential band edge in the middle of the channel is a symptom related to the sharp increase in dI/dV in the inset current-voltage characteristic.

The top left of Fig. 45.18 indicates the transmission coefficient (red) and current density injected from the source at a gate bias of 0.3 V. Next to it a gray box indicates a carrier distribution in the source that reaches as high as $10k_BT$. For the gate voltage of 0.3 V one can see that the barrier in the channel still limits the distribution of the current flow. That is, the current turns on about 0.1 eV or $4k_BT$ above the Fermi level in the source. At a gate bias of 0.6 V the barrier has virtually completely vanished and the current (as indicated in the top right of the figure) now flows above the source conduction band edge. As expected, there is no current flow under the conduction band edge. The bottom right of Fig. 45.18 indicates the supply function of carriers in the drain. Clearly, no electrons can reach from the drain into the channel at the applied source drain voltage of 0.6 V. All carriers in the channel must come from the source. The red vertical arrow between the label "No Supply" between the source and drain supply functions indicates that there are no carriers that can be injected within that energy range from either source or drain coherently.

The transport effective masses of the [111] wire are much larger than those of the [100] and [110] wires and therefore the injection of carriers from the source into the channel is not as intense in the [111] wire. The [111] wire cannot supply enough charge into the channel to "oppose" the electrostatic pull down from the gate and the drain.

Figure 45.18b considers the gate bias point 0.6 V in more detail with a superposition of the local density of states under the local band edge diagram of (a). The source and drain injection energy ranges are included, as well as the current density and transmission coefficient. The local density of states is numerically well resolved, and the channel broadened quasi bound states that were also visible in Fig. 45.14b. Again, there is no indication that the quantum mechanical components of this simulation have any issues of energy or spatial resolution.

One can now argue that the Poisson solution is not really stable and causes the step-like feature in the channel potential. Numerical experiments on this very device show that neither tightening the Poisson convergence criteria nor increasing the momentum or energy resolution in the quantum transport simulation neither changes the convergence of the potential nor adds more numerical detail. The Poisson solution "converges" to the same potential and overall current every time. Physical intuition tells us that the potential does not "look right." This electrostatic potential is not a result of bad numerical stability but is due to the incompleteness of the physical model. In a more realistic simulation one would need to include energy loss mechanisms in the channel and a more detailed model of the source contact.

The intuitive view to "fix" the issue of Fig. 45.18 is to include inelastic electron scattering mechanisms [101, 102, 167] such that the electrons can lose energy and populate the states in the channel, and then the potential will float up, restoring the expected smooth evolution of the electrostatic potential in the channel. In fact, OMEN has shown that scattering adds an additional potential drop into the channel and the source extension region. However, in light of the relatively short channel of 15 nm and an expected high degree of ballistic/coherent it is the authors' opinion that a more sophisticated treatment of the channel will not provide the real physical solutions.

The real issue is the treatment of the source contact [162–166]. The model assumption is that the Fermi level at the numerical start of the device is constant with regard to the equilibrium, zero bias condition. It is assumed that the contact can supply unlimited carriers, even at perfectly unit transmission in all available channels. A more realistic representation of that source injection would include the details of the electron reservoir and its ultimately connected metal contact. A comprehensive model would represent in more detail the ability of the "contact" to inject carriers into the device. A very nice depiction on how scattering self-consistently modifies the electrostatic potential in the gate region, as well as the highly doped spacer, has been given in Luisier and Klimeck [101, 102].

The failure of the coherent quantum transport model was relatively obvious for the 15-nm gate length [111] nanowire, as the current showed "unusual" behavior. The natural question now emerges, why was something similar not observed in the 5-nm gated [111] wire? The *OMENwire* simulator returns "converged" results and the current voltage characteristics do not reveal any trouble.

Intuitively, one can argue that the 5-nm gate region is already so short that the gate and drain voltage combined will pull very hard on the channel potential so that the drop should almost be linear. That intuition is actually about right, as depicted in Fig. 45.19a, where the expected electrostatic potential is shown throughout the nanowire for different gate potentials ranging from 0 to 0.6 V. Nicely visible is the increased asymmetry of the potential in the gate region, where the peak of the potential shifts from the middle of the channel more and more to the source. This effect is called drain-induced barrier lowering (DIBL).

The low gate voltage data sets from $V_G = 0$ V to $V_G = 0.4$ V are drawn in dotted lines. The last "reasonably looking" gate voltage data sets at $V_G = 0.5$ V are shown in a solid line and the data for $V_G = 0.6$ V are denoted with long dashed lines to draw the viewer's attention. All the potential profiles "look" reasonable except for the last bias point of 0.6 V, which we discuss below.

The charge filling of the channel as a function of gate voltage is depicted in Fig. 45.19b for different gate volt-

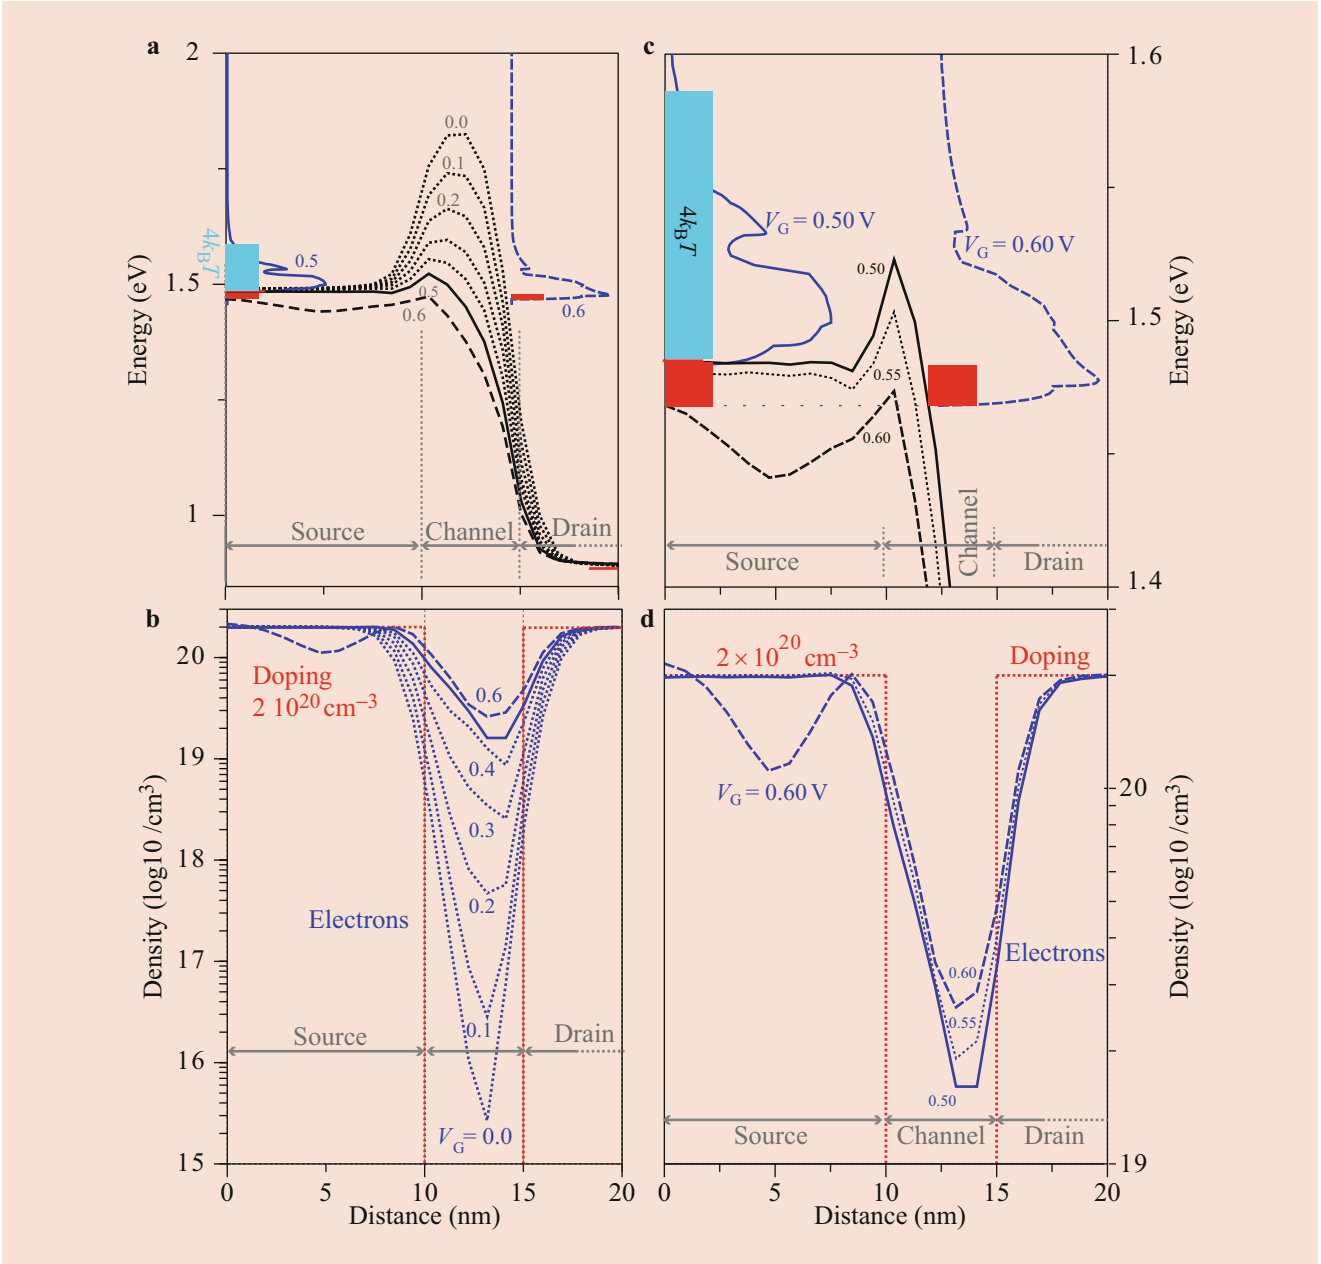

Fig. 45.19 (**a**) Conduction band edge (black lines) in the [111] nanowire for gate biases ranging from 0 to 0.6 V. Blue line indicates the energy distribution of the normalized current density (blue line). Fermi levels in source and drain are indicated by red lines. An energy range of $4k_BT$ above the Fermi level is indicated by a blue shaded region. Only a 5-nm section of the 10-nm drain region is shown. (**b**) Electron density (blue line) and doping density (red dashed line) in the wire for the same gate voltages as (**a**). (**c**) Zoomed in data of (**a**) for the gate bias $V_G = 0.5$ V and $V_G = 0.6$ V. A dotted line guiding the view of the potential evolution at $V_G = 0.55$ V is added as a dotted line. The conduction band edge shows a potential dip in the source at $V_G = 0.6$ V. There is a significantly increased energy range of injection from the source (red shaded area). (**d**) Zoomed in data of (**b**) for the gate bias $V_G = 0.5$ V and $V_G = 0.6$ V. A dotted line guiding the view of the potential evolution at $V_G = 0.55$ V is added as a dotted line

ages. At zero gate voltage the channel is virtually empty, with a smooth exponential decay at the abrupt doping profile change. Of course, this corresponds well to the high gate potential barrier in Fig. 45.19a for $V_G = 0$ V. As the gate voltage is increased, the charge in the channel increases linearly on a logarithmic scale, which corresponds to the linear subthreshold current increase on a logarithmic scale (Fig. 45.16). Everything looks reasonable about these charge profiles except the one for the gate voltage $V_G = 0.6$ V.

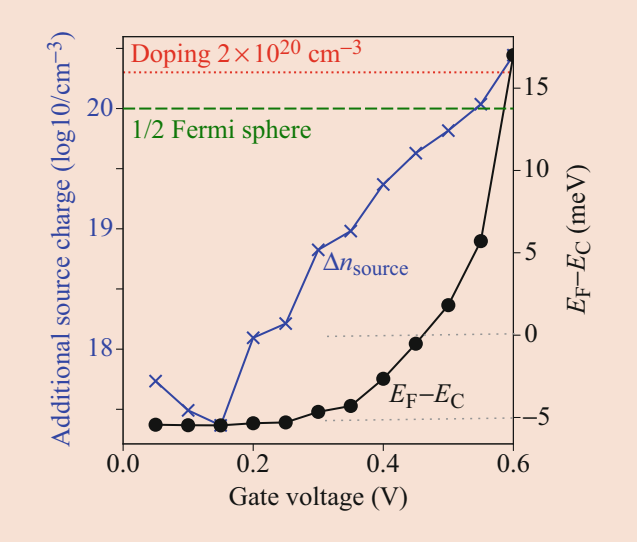

Fig. 45.20 Right scale: energy difference between the Fermi level and the conduction band edge at the coherent injection point at site 0 nm of the [111] 5-nm gate length nanowire. Left scale: additional charge needed at the coherent injection point to balance the charge throughout the device. At high gate biases that additional charge approaches and then exceeds that of half the forward-moving Fermi sphere. The source cannot possibly provide enough charge moving forward through the device

The right column of Fig. 45.19 shows the zoomed-in data sets of the left column for the gate voltages $V_G = 0.5$ V (solid line) and $V_G = 0.6$ V (long dashed line). A data set at $V_G = 0.55$ V is added as a dotted line to guide the eye in the evolution as a function of gate voltage. The data at $V_G = 0.5$ V all look very reasonable. At $V_G = 0.5$ V the source potential is still flat and pegged to the Fermi level (Fig. 45.19c). Current flow (blue line) sets in as expected above the conduction band edge, basically tunneling through the remaining tiny barrier. The electron density (Fig. 45.19d) for $V_G = 0.5$ V is converged to the doping profile level in the source region.

As the gate potential is increased above $V_G = 0.5$ V all the device internal quantities begin to show unusual behavior. At $V_G = 0.55$ V the electrostatic potential in the source region begins to drop slightly (on this scale) under the potential values that correspond to an equilibrium source. At $V_G = 0.6$ V the electrostatic potential at the injection point drops precipitously and the overall source potential develops a physically very unreasonable dip. The current continues to increase because now there is current flow within a potential range that previously had no injection (see the red energy range). The charge density in Fig. 45.19d shows a very unphysical dip in the source region. Clearly, something is starting to go "wrong" in the simulation that requires some careful attention.

Figure 45.20 depicts (black line with circles) the energy difference between the Fermi level and the conduction band edge at the coherent injection point of the source (at the 0-nm coordinate). As discussed above, the Fermi level is about 5 nm under the conduction band edge for $V_G = 0.0$ V. As the gate voltage is increased, the Fermi level remains roughly constant and then begins to increase. The Poisson solution in *OMENwire* requires more and more charge in the source to balance the doping level and the transport throughout the whole device. Let us look at a very trivial and incomplete model based on semiclassical charge, where

$$N_{\text{class}} = N_c \exp\left[-\left(E_C - E_F\right)/k_B T\right]. \tag{45.32}$$

At $(E_C - E_F) = -5.51$ meV for $V_G = 0.0$ V and a balanced doping of $N_D = 2 \times 10^{20}$ cm^{-3} we can take $N_C = 2.48 \times 10^{20}$ cm^{-3}. Now we define

$$\Delta n\left(V_G\right) = N_c \left\{\exp\left[-\left(E_C\left(V_G\right) - E_F\right)/k_B T\right] - 1\right\} \tag{45.33}$$

and plot $\Delta n(V_G)$ in Fig. 45.20 with a blue line. Although there is some numerical noise for gate voltages below $V_G = 0.2$ V we numerically observe that the extra charge in the source injection point grows exponentially over 3 orders of magnitude. At a bias of $V_G = 0.55$ V the additional charge reaches 1/2 of the Fermi sphere in the source and at $V_G = 0.6$ V the additional charge exceeds the doping in the source.

Figure 45.20 clearly demonstrates that the source injection is driven to a point where the assumption that it can provide "infinite" charge breaks down. As the charge needed to balance the Poisson equation approaches that of the doping level, the physical model breaks down completely and results in erroneous charge and potential profiles.

We argue the point here that the erroneous high gate bias results are not caused by a bad numerical implementation, but by the fundamental model assumption [162–166]. With prior research results, we conclude that a more comprehensive model of the contact regions of the highly doped semiconductor, as well as the connected metal, are needed in the limits of extreme bias operation, which would deplete the numerical contact regions.

We conclude this section by advising caution – look at the numerical data carefully even as you use sophisticated tools!

45.7.8 Short Channel Devices: A New Design Paradigm with New Requirements

Effective mass and bandgaps are design parameters: the discussions above have shown that at the nanometer scale effective masses and bandgaps *can be designed by geometry and crystal direction* [67, 168]. Strain alters the atomic arrangements and can be used to tune the band structure further [67, 156, 168–171]. The self-consistently calculated charge distribution in nanowires shows that the band structure is affected by charge filling [156]. Silicon nanowires can be designed to have effective masses that are competitive and

even lower than the traditional III–V materials. We note here that especially under scaling into the 5-nm regime, III–V materials show significantly increased masses owing to their nonparabolic band structure [20, 101, 102]. This typically reduces the perceived benefits of III–V materials even more [155, 171, 172].

III–V material versus *Silicon materials :* the discussions in the previous sections demonstrated that for a "long" 15-nm channel a light effective mass material can in principle deliver the highest current as derived from the TOB model. This seems to confirm the long-standing expectation that lighter effective masses as found typically in III–V materials will outperform typical silicon devices. However, with smart crystal orientation choice and strain engineering the effective masses in silicon can be tuned, as discussed above. The III–V material insertion into the silicon process flow is extremely expensive and silicon has been able to achieve competitive performance.

Fast materials with light effective masses are not desirable: for short channel devices such as the 5-nm gate length nanowire discussed here we can clearly demonstrate that low effective mass materials are not desirable at all. At such short gate lengths, the potential barrier becomes very small, electrons principally tunnel through it and a heavy mass is desired to suppress that tunneling [155, 169–174].

Tight-binding captures critical device physics: here, we have focused on the more intuitive electron transport physics. We note here that a nanowire electron dispersion begins to look just as complicated as a hole dispersion. All the methodologies presented here can be explored for hole transport and have been implemented in OMEN and NEMO5. Necessary physical details, such as spin-orbit coupling, strain dependence, geometry and crystal direction dependence can be captured efficiently with only a few model assumptions. Transport in hole nanowires and device design as a function of geometry and gating have been studied [158, 168, 173, 174].

Tight-binding combined with coherent and incoherent transport models: the combinations of tight-binding with QTBM and tight-binding with NEGF have now been established as the state-of-the-art device modeling basis sets and approaches. Software packages based on this baseline are built by industrial and by academic research groups and commercialization efforts are underway to release these methods in standard device TCAD packages. The methodology is stable and reliable enough that they can be released to the scientific community. The *OMENwire* and *Band Structure Lab* codes used here are available on nanoHUB as discussed below.

Roadmap modeling changed from analytical device models to full 3D quantum transport models: the 2013 International Technology Roadmap for Semiconductors (ITRS) roadmap [178] in its Process Integration, Device, and Structure chapter, relies for its device model performance projection on a compact model using the computer-aided design tool MASTAR [179]. The SS enters this model as a phenomenological parameter, rather than as a characteristic predicted by a physics-based model. Full 3D atomistic quantum transport modeling showed that such a compact model can lead to erroneous predictions [177] and physics-based model results were adopted to calibrate predictions in the subsequent ITRS release.

Physics-based contact models require further development: in the sections above we have also demonstrated and explained in detail how the state-of-the-art transport models break down, when driven to extreme conditions. We are not the first to explore these issues [162–166], but described this in detail so that users can be aware of the pitfalls of state-of-the-art simulation tools such as *OMENwire*. Under very high bias conditions the source may no longer supply enough charge to satisfy the channel transport ability. More sophisticated models are needed to model the heavy doping semiconductor source/reservoir, as well as the metal contact to that reservoir region. Several efforts to treat the occupation limitations of the injecting source regions in 1D geometries with an effective mass model have been reported [162, 166]. It is our opinion that the traditional NEGF perturbative scattering methods may provide some help when used in the semiconductor device region. However, we also believe that the source depletion and treatment of the contacts is a first-order effect that must be treated not as a perturbation but by a fundamental approach.

45.8 Beyond Device Physics Advancements: Reaching the World

Nanoelectronic devices such as QDs and nanowires that have been subject to intense research in the past 25 years are finding widespread adoption in today's technologies. As these devices are inserted into real products their design and optimization now require accurate physics-based models that can explore the design space through simulation. The approaches are literally used today, in the year 2022, to advance, develop, and integrate the 7-nm and 5-nm transistors that have been deployed for billions of users around the world in commercial products. This view and understanding of modeling transport at the nanometer scale truly enable products that impact the globe. However, transferring such modeling and simulation into the education and training of engineers who will shape the future requires more: (1) building upon, rather than rebuilding every time on the results of prior researchers, (2) duplicating the results of prior researchers, and (3) pushing the recent research knowledge into the education and training of future engineers.

nanoHUB.org offers the opportunity to researchers to share their simulation tools and results to the broader community. Anyone can contribute their own simulation tools and results into nanoHUB to enable duplication of research results and to infuse these results into further use. We utilize this capability extensively in this chapter with nanoHUB tools *Band Structure Lab* [117], *FETtoy* [160], and *OMENwire* [161] *where any reader can now duplicate the results shown here*.

nanoHUB analytics have shown that simulation tools will be adopted into the first classroom in a median time of 6 months [178]. This constitutes a rather rapid change in curricula compared with writing a new text book, which typically requires 4–6 years. As of January 2021 we have identified over 89,700 students at over 3840 classes at 185 institutions who have used nanoHUB for formal instruction in a classroom. *nanoHUB can support education!*

As of January 2021 [179], 2500+ citations of nanoHUB in the literature demonstrate that these tools are used in subsequent research. Over 30% of these papers include experimental data or an experimentalist as a co-author. nanoHUB does not just serve the computational folks, but also experimental work. The 2500 citations generated over 54,000 secondary citations, resulting in an h-index of 105. *nanoHUB can support research!*

The NEMO/OMEN team has deployed nine tools in nanoHUB over the years, which have been used by 30,700 users, as depicted in Fig. 45.21 (data as of summer 2019). These users have run over half a million simulations. The tools have been used in over 380 structured education settings or classrooms. The nine tools have been cited in the literature 112 times. All the data and figures involving the nanowire simulations in this chapter are directly generated using nanoHUB tools *Band Structure Lab* [117], *FETtoy* [160] and *OMENwire* [161].

The bottom-line message in this chapter on tight-binding is that through nanoHUB we can provide simple and rapid access to tight-binding-based physics descriptions for anyone in the world to use. We have reached a stage where users do not have to write their own tight-binding codes any more but can explore the physics and design devices. We provably reach users in education and in research with research-based, yet usable, software.

45.9 Conclusions

We have seen that the empirical tight-binding method is well-suited to modern nanodevice modeling. It is physics based, and naturally incorporates geometry at the atomic level (e.g., strain, disorder). It can successfully model both semiconductors and metals, and is efficient as it excludes core electrons; it handles varying geometries and materials easily. Its parameters represent interactions between orbitals centered on the same and neighboring atoms, and may be determined by either fitting to bulk band structures or by projection from ab initio Hamiltonians and wavefunctions. The method offers great flexibility in terms of basis orbitals and the extent of their interactions.

This flexibility in basis is responsible for one of the strengths of tight binding: its numerical efficiency. Choosing a somewhat larger atomic basis usually allows for a reduced range of interactions, often to first- or second-near neighbors. When the extent of interactions is limited in this way the Hamiltonian matrix becomes sparser, resulting in better time and memory efficiency. As a result, multi-million atom electronic structure calculations are possible on very small computer clusters, and realistic, extended nanowire and UTB transistor calculations are possible on moderately sized computer clusters.

Like all models, tight binding has challenges and limitations. Parameterization from experimental results or ab initio calculations can require significant effort. When projecting out of ab initio wavefunctions, the resulting tight-binding basis functions are not uniquely determined, so there remains some art in choosing their form. Likewise, for new materials (especially two-dimensional ones), determination of a basis that correctly reproduces the important band structure features is not easily automated; it still requires significant expertise. Finally, because the parameters depend on the interatomic potentials, parameters are generally not transferrable between dissimilar materials systems. Although these issues are different than those faced by other full-band methods, they are no worse.

Today, the method has been widely adopted in numerical simulation tools. QTBM and NEGF were established as state-of-the-art by 2004; somewhat later, the underlying materials models transitioned to tight-binding bases. The tight-binding approach coupled to QTBM or NEGF is now in wide use by academics, industrial researchers, and software vendors. Tight binding can be fed into compact-model-like approaches such as the TOB model and very rapidly deliver device trends. Many such tools are fully accessible to researchers, educators, and students on nanoHUB. The computational intensity for realistic nanodevice models is sufficiently low that NEMO/OMEN tools can be used on nanoHUB by anyone in the world.

Gerhard Klimeck is the Director of the Network for Computational Nanotechnology and Professor of Electrical and Computer Engineering at Purdue. His interests are the modeling of nanoelectronic devices and the understanding of user behavior in nanoHUB.org. He helped to create nanoHUB.org, the largest virtual nanotechnology user facility serving over 2.0 million global users, annually. Dr. Klimeck was elected to fellow of the Institute of Physics (IOP), the American Physical Society (APS), the Institute of Electrical and Electronics Engineers (IEEE), and the American Association for the Advancement of Science (AAAS), and was awarded the German Humboldt Research Prize for his work on nanoelectronic modeling and nanoHUB. He has published over 525 printed scientific articles; he has been recognized for his co-invention of a single-atom transistor, quantum mechanical modeling theory, and simulation tools. His team's NEMO5 software has been used since 2015 at Intel to design nano-scaled design transistors. In 2020 his nanoHUB team was awarded a top 100 by R&D award – Making simulation and data pervasive.

Timothy Boykin received the Ph.D. in Electrical Engineering from Stanford University in 1992. He has been a professor at UAH since 1992. His research concentrates on full band structure nanodevice modeling. He was advanced to Fellow of both the American Physical Society (2011) and IEEE (2018) in recognition of his work on atomistic nanostructure modeling.

Tight-binding Hamiltonian, 1588
Tight-binding models
  ballistic transport from nanowire dispersions, TOB model, 1622–1623
  complex bands, 1610–1611
  consequences of discreteness and incompleteness, 1608–1609
  DFT-TB and nanodevice modeling, 1614
  direct transmission methods, 1612–1614
  effective-mass formula, 1609
  electromagnetic coupling Hamiltonian, 1609–1610
  full quantum transport *vs*. analytical model in long 15nm nanowires, 1626–1627
  full quantum transport, in long 15nm nanowires, 1623–1626
  full quantum transport, in short 5nm nanowires, 1627–1628
  Green functions, transport with, 1614–1615
  Hamiltonian, 1605–1606
  Hamiltonian matrix structures and scaling for closed systems, 1615–1616
  high-bias coherent transport simulations, convergence issues in, 1629–1632
  interfaces and transport, 1610–1614
  large-scale numerical aspects, 1615–1620
  localized-orbital representations, 1609
  nanodevice characteristics, 1602–1604
  nanodevice modeling approaches, 1604–1605
  nanowire electronic structure, 1620–1621
  open boundary conditions, scaling issues with, 1616–1618
  parameter fitting, 1606–1607
  quantum dots, 1620–1621
  quantum transport, 1618–1619
  short channel devices, 1632–1633
  strain, 1607–1608
  surface passivation, 1618–1620
  transfer matrices, transmission calculations with, 1612
Tilted ion implant, 27
Time-dependence, 566
Time dependent dielectric breakdown (TDDB), 208, 227, 938
Time-independent Schrödinger equation, 1561
Time of flight (ToF), 645, 693
Time resolved electric response, 1464
Time-to-failure (TTF), 568
Time-voltage, 621
TiN metal hard mask, 172
TiO_x, 607
Titanium (Ti), 192
Titanium nitride (TiN), 192, 385
Titanium oxide, 1325
Titanium-tungsten, 379
TlBr, 757
TMR, 675
Top electrode (TE), 1044, 1181
Top port, 668
Top-down approach, 890
Top-of-the-barrier (TOB) model, 1622–1623, 1627
TopCon technology, 717
Topography, 195
Topological insulators (TIs), 1150
Topology optimization, 1319, 1320, 1322, 1323, 1325, 1326
  general considerations, 1319
  optimization method, 1322
  variational problem and regularization, 1320
  problem, 1313
Total current densities, 586
Total harmonic distortion (THD), 667
Trajectory split approach, 1270
Transadmittance efficiency, 411–412
Transconductance, 347, 433, 988
  efficiency, 405–407, 409, 412, 1002
  in MOSFETs, 347, 351, 354
Trans-impedance amplifier (TIA), 1013
Transducers, 636
Transfer characteristics, 347, 553, 897
  in MOSFETs, 347, 351
Transfer efficiency, 356
Transfer function, CCD, 359
Transfer inefficiency, CCD, 356, 363
Transfer length, 145
Transfer matrix, 1289, 1295, 1612
Transferred electron devices (TEDs), 810
Transient analysis, 985
Transient diffusion, 1280–1281
Transient electronics, 1027
Transistors, 1029
Transit-time mode Gunn oscillations, 810–811
Transition frequency f_T, 828–834, 836
Transition metal dichalcogenides (TMDs), 312, 372, 384, 790, 890, 1525, 1538, 1539, 1554
Transition rate, 1469
Transitions, inter-trap, 1472–1473
Transmission coefficient, 1473, 1475, 1625
Transmission electron microscope, 888
Transmission electron microscopy (TEM), 266, 1022, 1046, 1075
  definition, 118
  dislocations and stacking faults, 118
  image plane, 118
  material processes, 120
  methods, 118
  micrographs, 120, 121
  schematic illustration, 118
  sketch, 119
  thermionic or field effect, 118
  transmitted electrons, 118, 119
  Z contrast, 118
Transmission gate (TG), 949

Transmission line, 1238
Transmission line model (TLM)
alloyed contacts, 146
end-contact resistance, 146, 147
lateral current crowding, 148
literature data, 148
semiconductor sheet resistance, 145
specific contact resistance, 145
test structures, 145, 146
Transmission probability, 870, 1589, 1590
Transmission rates, 863
Transmon, 1211
Transport factor, 899
Transport model
ab initio quantum, for chalcogenides, 1473–1477
trap-limited, 1461–1463
trap-limited, in a random network, 1469
trap-limited, with dispersive band states, 1464
Transversal electric (TE) polarization, 858
Transversal magnetic (TM) polarization, 858
Transverse energy, 872
Trap level, 1340
Trap-assisted tunneling (TAT), 869, 875, 880, 881, 890
tunneling current, 882
Trap-limited conduction (TLC), 978, 1103, 1460
Trap-limited transport model, 1461–1463
in a random network, 1469
with dispersive band states, 1464
Trapezoidal rule, 1390
Traps (localized states), 1098, 1102
Tree, 1305
Trench CAVET, 549
Trench cell technology, 470
Trench etch process, 173
Trench FET, 111
Trench MOS barrier Schottky (TMBS), 486
Triangles
acute, 1443
obtuse, 1443
Trifluoromethanesulfonic acids, 305
Trimethyl silane, 208
Trimethylaluminium (TMA), 965
Triphenylsulfonium triflate (TPS-tf), 302
Triple patterning, 24
True random number generator (TRNG), 621
Tubes, cathode-ray, 354
Tumble, 665
Tungsten, 192
Tunnel device, 375
Tunnel diode, 376, 380
Tunnel field effect transistors (TFETs), 268, 371, 372, 375, 379, 381–384, 869, 896, 899, 932, 1492, 1498–1505, 1507, 1509, 1510, 1615
ambipolar conduction, 885
BTBT, 870–872
complementary technology platform, TFET inverters for, 1503–1507
complex gate dielectrics, 897
device structures, 1498–1499
GaSb/InAs-based TFET optimization, 1502–1503
heterojunction, 1500, 1501
homojunction, 1499
HTFET, 885–893
n-type TFET, 869
OFF current, 879
ON-current, 875–879
operation principles, 869–870
output characteristics, 883–885
Tunnel magnetoresistance (TMR), 1182
Tunnel-effect, 677
Tunneling, 1492, 1494, 1496, 1497, 1499, 1500, 1502, 1509, 1510
enhancement factor, 882
gap, 887
probability, 870, 872, 875, 882
width, 870
width modulation, 873
Tunneling field-effect transistors (tFETs), 1526, 1546
Tunneling magnetoresistance (TMR), 1145
Turn-off (GTO) thyristors, 448
Turn-off switching waveforms, 545, 547
Turn-on switching waveforms, 545, 547
Turn-on-voltage, 981
Two-dimensional (2D) materials, 372, 384, 1516, 1519, 1524, 1525, 1531–1534, 1538, 1544, 1552–1554
Two-dimensional CCD
frame-transfer, 360
line-transfer, 360
Two-dimensional charge coupling, 492
Two-dimensional electron gas (2DEG), 144, 149, 155
Two-dimensional manifold, 1320
2D Lebesgue measure, 1443
2D materials, 778, 790–795, 890
2D patterning, 177
2D version of secondary ions mass spectrometry (2D-SIMS), 152
Two-diode test method, 376
Two-phase CCD, 355

U

U-centers, 1459
UFSOI/UFPDB/UFDG, 1250
Ultra-dilute sulfuric peroxide (uDSP), 222
Ultrafast spectroscopy, 736
Ultra large scale integration (ULSI) circuits, 309
Ultra-low-k (ULK) materials, 172, 225
Ultrapure, 199
Ultras, 1247
Ultra-shallow p-n junction diode, 376
Ultrathin body (UTB), 371, 372, 376, 377, 379, 380, 383
Ultra-thin body and box (UTBB) fully depleted silicon-on-insulator MOSFET, 392–394
back-biased, 403–407
device cross-section, 395
first-cut analog sizing method, 416
Ultrathin cap, 211
Ultraviolet (UV) irradiation, 183, 279
UMOSFET, 427, 437–438
Uncertainty quantification, 1326
Unclamped inductive switching stress, 512
Uncollimated deposition, 195
Under-the-barrier model, 1623
Uniformity, 195, 197
Unipolar, 343
devices, 343
operation, 375
Schottky type operation, 373
Universal memory, 604–607
Universal screening potential, 1268
Urbach energy, 894, 896
Urbach tails, 159, 160, 893, 1098, 1456
USB power delivery systems, 83
USIM, 1247
UV cure, 183, 185

V
V_{60}, 875
Vacancies, 875, 1267, 1271, 1273, 1280
Vacuum depositions
  atomic layer deposition, 965
  CVD, 965
  sputtering, 964–965
  thermal evaporation, 964
Vacuum level, 332
Vacuum mainframe, 197
Valence-alternation pairs (VAP), 1102, 1456, 1458
Valence band, 373, 906
Valence band effective density of states, 373
Valence-band hole, 853
Valence force field (VFF), 1605
Value, tendential, 1465
