When GaN-based white LED's became the technology to beat for lighting applications after some major technological hurdles were overcome, such as the development of a workable epitaxy regime [1], scientific interest was aroused to use this material system also for purely electronic applications. By taking advantage of the strong polarization fields in the III-nitrides, which limit the performance of quantum well-based light emitters because of the quantum confined Stark effect [2], a unique structure for transistor channels was devised: the GaN/AlGaN high electron mobility transistor (HEMT) [3]. These lateral transistor devices can handle very large power densities due to the combination of the good transport properties on the one hand and of the excellent voltage handling capabilities on the other hand, courtesy of the material's high bandgap and critical electrical field. From epitaxy point of view, these two types of applications are characterized by a number of distinct differences.

For opto-electronics, the substrate of choice is sapphire, as it is optically transparent, relatively easy to perform hetero-epitaxy on and can be reused several times by taking advantage of the laser lift-off technique [4]. For electronic applications, sapphire has a major shortcoming in terms of its low thermal conductivity which causes trouble with thermal dissipation in high power density devices. Instead, the traditional choice for substrates for electronic applications is SiC, while in the recent years Si has become a very popular choice as well.

A second major difference between the two types of application is the range of alloys that is typically used. For the bulk of lighting applications, LEDs need to cover the visible range of the optical spectrum which is done by using InGaN alloys in combination with n- and p-doped GaN layers. Because of the volatility of Indium and the miscibility issues in InGaN alloys [5], epitaxy of such layers is performed at relatively low temperatures, roughly between 700 °C and 900 °C for MOCVD processes. For electronic applications, the critical electric field of the materials is an important parameter, which scales directly with the bandgap of the semiconductor materials. As a result, layers stacks for electronic applications typically consist of AlGaN alloys that require a rather different epitaxial regime, e.g., characterized by the higher growth temperatures (above 1000 °C when grown by MOCVD) to obtain the best material quality.

Obviously, the layer stack designs differ significantly as well: p-i-n diodes for LEDs as opposed to the undoped HEMT hetero-structures for lateral transistors.

15.1.1 Typical Layer Stacks for Lateral GaN Power Transistors

The lack of availability of native GaN substrates in large wafer diameters and at reasonable cost forces the GaN community to use hetero-epitaxy to grow III-nitride materials on foreign substrates, such as sapphire, silicon, or silicon carbide. The intrinsic mismatches between substrate and epitaxial materials, for instance, in terms of lattice constant or thermal expansion coefficient, prevent the direct growth of the active HEMT layers on top of the substrate. Instead, a relatively complex buffer stack needs to be inserted in between. Figure 15.1 shows the typical construction of the epitaxial layer stack, together with the most commonly used implementations. We will discuss the different variations below.

15.1.2 Substrates, Nucleation, and Strain Management

For electronic applications, typically two substrate types are used: silicon carbide (SiC) and silicon (see Table 15.1). Sapphire, which is the substrate of choice for the LED business, is not used because of its low thermal conductivity that becomes a reliability issue for transistors that operate at and dissipate high power densities.

15.1.3 Growth on SiC Substrates

For most RF applications, SiC is used as a substrate, first because of its relatively low lattice mismatch with GaN that allows a very simple nucleation and buffer structure and secondly because of its high thermal conductivity. In practice, the layer stack as depicted in Fig. 15.1 is simplified to consist of a thin AlN nucleation layer, a GaN-based confinement layer (typically unintentionally doped or Fe-doped) with a thickness of roughly 1 μm and the active channel/barrier layer combination.

Most SiC substrates are wafered from SiC bulk crystals that are grown using the Physical Vapor Transport (PVT) method [6]. The latter operates at temperatures exceeding 2000 °C, provides low growth velocities, and is thus very energy intensive. The typical crystals that can be obtained by PVT are typically only 20–30 cm long and yield only a limited number of wafers. As a result, SiC wafers are 20–50 times more expensive than their Silicon counterparts.

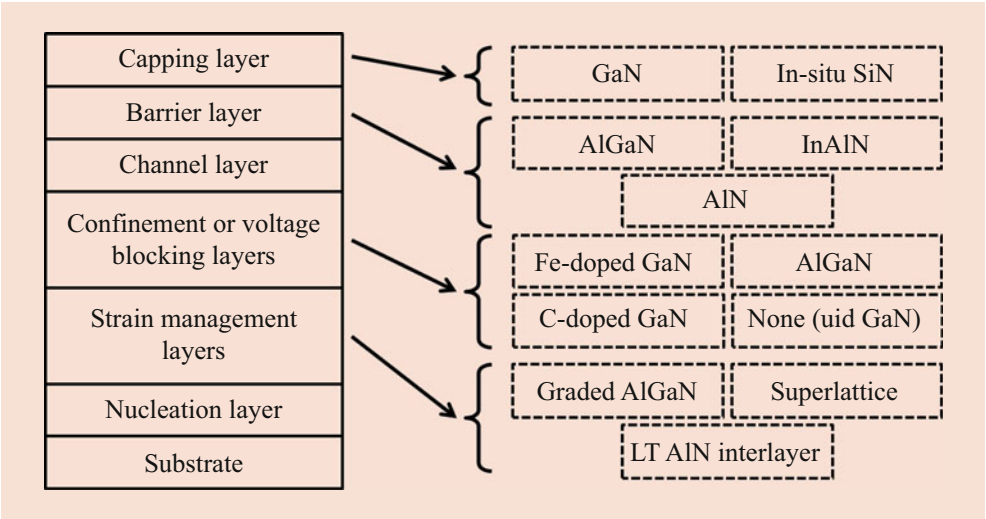

Fig. 15.1 Layer stack variations for GaN electronics

Table 15.1 Properties of commonly used substrate materials

Substrate materials	GaN	SiC	Sapphire	Si
Lattice constant (å)	3.19	3.08	4.76	5.43
Mismatch to GaN	*0*	*−3.6%*	*33.0%*	*41.3%*
Thermal expansion coefficient (10^{-6} K)	5.59	4.3	7.3	3.59
Mismatch to GaN	*0*	*30.0%*	*−23.4%*	*55.7%*
Thermal conductivity (W/cmK)	1.3	4.9	0.23	1.4

Moreover, scaling the diameter of the crystal boule has been proven difficult. Only recently has the industry made the step from 4″ to 6″ diameters, with however still some quality issues remaining to be solved for the outer ring of the 6″ substrates. 200 mm SiC has been demonstrated but is currently not commercially available in large quantities.

15.1.4 Growth on Si Substrates

Over the last 15 years, a lot of effort has been spent to develop an epitaxy process to grow GaN directly on Si substrates (Krost). Being able to work on Si is very appealing: it is obviously the material of choice on which the bulk of the semiconductor industry is built (e.g., for logic and memory applications). Si manufacturing technology is extremely mature (yields well above 95%), very cost effective and capable of mass production (hundreds of thousands of wafers per month). Besides the cost advantage compared to SiC, one of the main drivers to select Si substrates is that it allows for much more easy integration of GaN-based devices with circuitry manufactured in Silicon-based CMOS. This is due to ease of back-side processing (e.g., wafer thinning or through-Si-via processing using the Bosch process) as well as due to the fact that there is no mismatch in material properties (thermal expansion coefficient being a good example).

Unfortunately, the hetero-epitaxy of GaN on Si comes with a plethora of challenges. For starters, the electronically most suitable type of GaN comes in a hexagonal close packed crystal structure (also called Wurtzite), which doesn't match the crystal structure of Si: the face-centered cubic crystal structure. The typical technical work-around is to use the triangular symmetry of the <111> plane of the Si.

Although many epitaxial techniques exist such as molecular beam epitaxy (MBE), hydride vapor phase epitaxy (HVPE), or liquid phase epitaxy (LPE), almost all production of GaN epitaxial layers is performed by a technique called metal-organic chemical vapor deposition (MOCVD) or metal-organic vapor phase epitaxy (MOVPE). In this technique, the growth temperature for high-quality GaN or AlGaN layers is above 1000 °C. At these temperatures, Ga attacks the Si substrate because of the eutectic lowering of the melting point of the materials; a phenomenon called Ga melt-ba ck of Si [7]. As a result, one cannot directly grow GaN on Si, but one needs to insert a layer of a different material. As on SiC, the solution is to grow an AlN nucleation layer that not only constitutes a good starting crystal for consecutive epitaxial growth but that also protects the Si from Ga-containing molecules in the vapor phase. Different solutions with other intermediary layers exist such as the use of 3C-SiC or rare earth oxides, but these lack the elegance and simplicity of using an in situ grown layer.

The nucleation process is an important one, because the extended defects that originate in this layer tend to propagate as threading dislocations through the entire layer stack that is built on top. Because of the reactivity of both species and the strong bond strength between aluminum and nitrogen, the growing AlN has low surface mobility and as a result,

the growth occurs by the formation of many separate AlN islands that laterally expand and coalesce. The locations where the islands meet are a source for many kinds of 1D and 2D extended defects. For the same reasons as mentioned above, AlN easily reverts to a three-dimensional growth mode (Volmer-Weber or Stanski-Krastanov) thus forming pyramids, rather than the preferred two-dimensional layer-by-layer growth mode (Frank-van der Merwe). This easily leads to surface roughening.

It has been shown that the properties of the interface between the Si and the AlN is of major importance both for high-voltage power switching as well as for RF power applications. In the former case, lateral conductivity along this interface causes the premature breakdown of lateral devices (as will be explained in Sect. 15.2 of this chapter), whereas for the latter case, the conductive interface causes RF losses for propagating signals and efficiency degradation in amplifiers.

There are more issues with GaN-on-Si epitaxy. As indicated in Table 15.1, GaN and Si have rather different thermal expansion coefficients. Even when one manages to employ the nucleation techniques as described above to grow high-quality GaN material, the cool-down step of over 1000 °C after epitaxy induces a substantial amount of tensile stress in the GaN epilayers, proportional to the thickness thereof. This is especially critical for high-voltage applications where the vertical voltage rating scales linearly with the thickness of the epilayer stack, requiring for instance a more than 5 μm thick layer stack for a 650 V rated device. Without controlling this issue, GaN-on-Si wafers tend to have significant bow and warp and are prone to the formation of cracks or even wafer breakage [8].

Over the years, several solutions where proposed to compensate for this tensile strain formation. They are all based on the principle of designing a buffer that generates an equal amount of compressive stress. In this way, it is possible to manufacture GaN-on-Si wafers that are perfectly flat; yet it is important to understand that such flat wafers are never stress-free but merely well stress-compensated. There is a second implication as well: the total amount of compressive stress that may be generated by the buffer is limited by the onset of plastical deformation of the Silicon substrate. This means that, depending on the thickness of the Silicon substrate, there is an upper limit to the total thickness of the III-nitride epilayer that can be grown on top.

The first type of strain management buffer is based on graded AlGaN layers. On top of the AlN nucleation layer, AlGaN layers are deposited where the Al composition is reduced, either continuously or in discrete steps, from 100% (AlN) down to 0% (GaN). In this configuration, AlGaN layers with lower Al content have a larger lattice constant that the AlGaN material beneath, and the pseudomorphic growth of the former forces them to be compressed. Because of the finite composition range of the AlGaN and the presence of strain relaxation effects, the maximum layer thickness that can be deposited in this way is limited to 6–7 μm.

An alternative approach consists of the use of the so-called low-temperature AlN interlayers. Here the GaN layer growth is repeatedly interrupted to introduce a thin AlN layer that is grown at very low temperatures (e.g., 700 °C). In these conditions, the AlN will not build up strain internally because of the even further reduced surface mobility, and it very quickly relaxes to its native in-plane lattice constant (3.11 Å) which is lower than the one of the GaN (3.19 Å). Then, in a next step under "normal" growth conditions, the growth of the GaN is continued and generates compressive strain in a similar way as described above. This process can be repeated several times. The main drawback of this approach is the poor quality of the AlN interlayers themselves (due to the low growth temperature) which can impact the electrical behavior of the layer stack, for instance, in terms of leakage current or trapping effects.

The second alternative approach which is today widely employed for high voltage power switching applications is the use of strained superlattice (SSL) buffers. These consist of a large number of repetitions (e.g., 100–150 times) of a bilayer made up out of 5–20 nm thin AlN and (Al)GaN layers. By keeping the thicknesses of the individual layers below their critical thickness, the total strain of the superlattice can be controlled by varying the ratio between the thicknesses of the two constituent layers.

15.1.5 Back-Barrier Selection

Besides the chemical and mechanical considerations, the layers below the HEMT heterostructure also play an important electrical role. This is obviously the case in the devices' off-state, where the electric field extends into and causes a depletion of the buffer layers where it induces electrical stress that may lead to leakage and time-dependent breakdown effects. However, the presence of traps in the buffer layers can also lead to a degradation of the devices' on-state behavior: the so-called current collapse (see further, e.g., Figs. 15.8 and 15.9). The electrical requirements for the buffer layers directly under the GaN channel layer also depend on the application.

GaN-on-Si is attracting a lot of interest for power switching applications especially for devices rated at 600 V or 650 V. One of the requirements of the circuit designers is that there are no floating potential nodes, which implies that also the substrate is grounded. As a result the GaN-on-Si stack has to be capable of handling about twice the rated voltage to be able to cope with inductive voltage spikes and to guarantee a reasonable lifetime. The total voltage is split over the strain

management layers (that are typically designed with only the strain aspect in mind) and over the voltage blocking layers.

One attractive implementation for the voltage blocking layers is to use impurity-doped GaN. One can for instance increase the resistivity of GaN by incorporating deep acceptor levels in the form of Carbon-doping. In an MOCVD process, carbon is available from the source molecules for the group III elements (e.g., from methyl groups), so by modifying the thermodynamic growth conditions, the amount of Carbon that is incorporated in the epilayers can be tuned. Alternatively, one can opt for a dedicated dopant source gas for carbon, such as ethylene or methane, to allow a wider parameter space for the epitaxial conditions. Substantial amounts of work have been performed by various groups to understand and control the effect of such Carbon doping. Moens et al. showed that a layer stack as described above can be modelled as a leaky dielectric [9], with two regimes of current conduction below and above a certain critical voltage. One concern with deep acceptor levels is that they may serve as a trapping state causing current collapse. Also in this respect, different models have been proposed. Uren et al. showed the importance of charge redistribution between the 2DEG and the carbon-doped layer [10], while Verzellesi et al. [11] described the effect of how the carbon is incorporated into the crystal lattice on its trapping behavior.

For RF applications, one of the main device features is the use of short gate lengths which create very high electric field peaks at the drain edge of the gate that can cause punch-through [12]. When using a thick (i.e., more than 200–300 nm) unintentionally doped GaN channel layer with the gate pinched off, the 2DEG carriers may be pushed out of the quantum well and still travel from drain to source through the lower part of the GaN channel layer. This induces a bias-dependent off-state leakage current and a degradation of the sub-threshold slope. To prevent this effect, the carriers need to be better confined into the 2DEG quantum well by modifying the layer stack directly under the (thinned) GaN channel.

The most effective method, inspired by similar approaches in AlGaAs/GaAs HEMT technology, is the use of an AlGaN back-barrier just below the GaN channel layer. Even the use of AlGaN layers with Al content as low as 5% creates a very high-energy barrier for 2DEG electrons, based partly on the bandgap discontinuity but mostly on the polarization charge at the AlGaN/GaN back interface [13]. This makes the AlGaN back-barrier the most suitable configuration for very high frequency operation (e.g., W-band) where very short sub-100 nm gate lengths are used [14]. There is also a major drawback: the thermal conductivity of ternary AlGaN alloys is significantly lower than that of either GaN or AlN [15], so for a given power dissipation, the peak channel temperature will be significantly higher than in the case of using GaN-based confinement layers.

To limit the punch-through effect in thick GaN channel layers, one method is to use Fe-doping to compensate for the intrinsic n-type background of GaN material. Fe is a deep acceptor in GaN that makes the layer highly resistive. Fe-doped GaN buffers are the de facto standard for GaN on SiC epiwafers used for RF applications. However, iron is not allowed in Si CMOS processing foundries where Fe contamination levels should be below $5 \times 10^{10}/\text{cm}^2$, which severely limits its usefulness for GaN-on-Si wafers. Fe also has a long diffusion tail in GaN, making it impossible to make abrupt interfaces between the Fe-doped buffer and the UID GaN channel layer. Finally, there are some reports that link Fe-doping with a trap with activation energy of approximately 0.6 eV [16].

Triggered by the promising results and understanding obtained for power switching, the use of carbon-doped buffers is also being introduced for RF applications. On a device level, the impact of the buffer is evaluated mainly in terms of off-state leakage and subthreshold behavior, the absence of current collapse and the capability to dissipate large power densities. Carbon-doped GaN confinement layers have been compared directly to AlGaN back-barrier designs with favorable outcome [17].

15.1.6 HEMT Heterostructures

Even though the above explains the importance of the nucleation and buffer layers, it is obvious that in GaN epiwafers for electronics an important role is reserved for the channel and barrier layers of the HEMT heterostructure. The underlying physics behind the formation of the 2DEG in such structures are reviewed in Sect. 15.2 of this chapter and have also been described in an excellent way elsewhere [3].

The work-horse heterostructure both for power switching and RF applications is still the combination of a thin AlGaN barrier layer on top of a GaN channel layer. The thickness of the barrier layer typically ranges from 10 to 30 nm, with Aluminum content between 15% and 30%. This yields a two-dimensional electron gas with an electron density of between $6 \times 10^{12}/\text{cm}^2$ and $1.5 \times 10^{13}/\text{cm}^2$ and associated electron mobility above 1800 cm^2/Vs. The fine-tuning of the structural parameters depends on a wide range of criteria and applications such as maximized electron mobility, improved reliability [18], or reduced electron density to allow e-mode operation through the local depletion of the channel by a p-type (Al)GaN layer under the gate [19].

The AlGaN/GaN heterostructure benefits from a piezoelectric polarization component that adds up to the spontaneous polarization field of the AlGaN layer. As a result, adding more strain to the AlGaN layer by increasing the Aluminum content is beneficial for the number of carriers that are contained in the 2DEG. However during epitaxy,

a growing strained layer only remains pseudomorphic to the underlying lattice until a so-called critical thickness is reached [20, 21] after which the strained layer starts to relax, e.g., by the creation of misfit dislocations [22]. It was shown that for AlGaN/GaN heterostructures, strain relaxation can also occur by the formation of V-grooves in the AlGaN layer, caused by the preferential out-diffusion of Gallium from the ternary material [23]. By adding a thin layer of SiN during the epitaxy, this mechanism can be suppressed and the relaxation temporarily postponed [24] until another relaxation mechanism sets in. Thus, not only does in-situ SiN provide a rather effective surface passivation [25], it also allows for the epitaxial growth of aluminum-rich AlGaN barriers.

The most extreme case of this barrier configuration consists of a pure AlN barrier layer grown on top of the GaN channel layer, as AlN has the widest bandgap and the highest polarization coefficients of the InAlGaN alloys, making it theoretically the best choice for the HEMT heterostructure. As an example, an AlN barrier layer with a thickness of only 4 nm capped with 10 nm of in situ SiN yields a 2DEG density of $2.15 \times 10^{13}/\text{cm}^2$ with an associated electron mobility of about 1000 cm^2/Vs. These data points make this structure very interesting for RF purposes because it allows bringing the gate electrode very close to a densely populated 2DEG, which results in a much improved transconductance of the transistor [26].

One drawback of using AlGaN barrier layers is that the use of strained barrier layers may have a detrimental effect on device reliability [27]. Fortunately, it is also possible to create strain-free HEMT heterostructures, by combining the GaN channel with a lattice-matched InAlN barrier layer [28]. For an indium composition of about 17%, InAlN has the same lattice constant as GaN but a significantly higher bandgap energy of 4.4 eV. Because both InN and AlN have higher polarization fields than GaN, a 2DEG is still induced at the interface between InAlN barrier and GaN channel due to spontaneous polarization only. For example, for a lattice-matched InAlN barrier layer with a thickness of 6 nm with thin cap of SiN, the authors have obtained a 2DEG density of $1.65 \times 10^{13}/\text{cm}^2$, which is about 50% higher than for a standard 20 nm $Al_{25}Ga_{75}N$ barrier layer. One remarkable property is that the electron mobility in this InAlN/GaN heterostructure is as high with a value of 1800 cm^2/Vs, much higher than what can be obtained with the AlN barriers with values around 1000 cm^2/Vs. As a result, InAlN have the lowest sheet resistance of any HEMT configuration, in this case around 220 Ω/sq. compared to typical values of 350 Ω/sq. or above for AlGaN-based heterostructures. Values as low as 170 Ω/sq. have been reported for thicker InAlN barriers [29].

Recently, a new nitride alloy ScAlN was proposed as an alternative barrier material [30]. Even though results are still scarce, an 2DEG electron density of $3 \times 10^{13}/\text{cm}^2$ was reported for layer structures grown by MBE [31].

15.2 Lateral Devices Architectures

The first lateral gallium nitride device was reported for microwave applications in the late 1990s [32]. Subsequently, RF architectures expertize has been basically adapted for power and switching applications because of their high off-state breakdown strength combined with an excellent channel conductivity. These GaN-based switches would offer greater efficiency, power handling, and other performance attributes compared to the well-established, widely available silicon MOSFET power devices. The superior electron mobility means that a GaN transistor will have a smaller size for a given on-resistance and breakdown voltage than a silicon (Si) semiconductor. Thus, GaN also offers extremely fast switching speed and excellent reverse-recovery performance, critical for low-loss, high-efficiency performance. Furthermore, despite their large lattice mismatch (about 14%), high-quality GaN growth can be achieved on cost-effective Si substrate using advanced techniques to accommodate the strain issues. Although GaN on SiC substrates are generally advantageous for high power devices because of the high thermal conductivity and lower lattice mismatch, the growth on Si substrates is more promising for power applications because of the scalability of wafer diameters to 200 mm and more and due to the comparably low price level. The ability of power semiconductor devices to enhance the power electronics performance/cost figure of merit can be simplified by its own price/performance figure of merit, namely, dependent on the switching power loss, ohmic power loss, and the cost, where the switching power loss reflects the thermal limitation, most often achieved through increasing switching frequency and subsequent reduction in output filter components. Therefore, in addition to efficiency improvements, the use of GaN semiconductors instead of state of the art silicon-based devices for power electronic systems allows the reduction of size/weight of the conversion subsystems, due to significant reduction in cooling system requirements.

The structure of a common AlGaN/GaN high electron mobility transistor (HEMT) appears in Fig. 15.2 along with the band diagram. At the heterojunction between the AlGaN barrier and the GaN channel, the two materials discontinuity in polarization leads to carrier diffusion. The AlGaN free electrons are attracted to the GaN channel and create an accumulation of charges at the interface of both layers. At the thermodynamic equilibrium, a discontinuity of the conduction band at the AlGaN/GaN interface is observed. This discontinuity forms triangular potential well. Confine in a very small area, those electrons create a two-dimensional electron gas (2DEG) enabling a high charge density conduction between

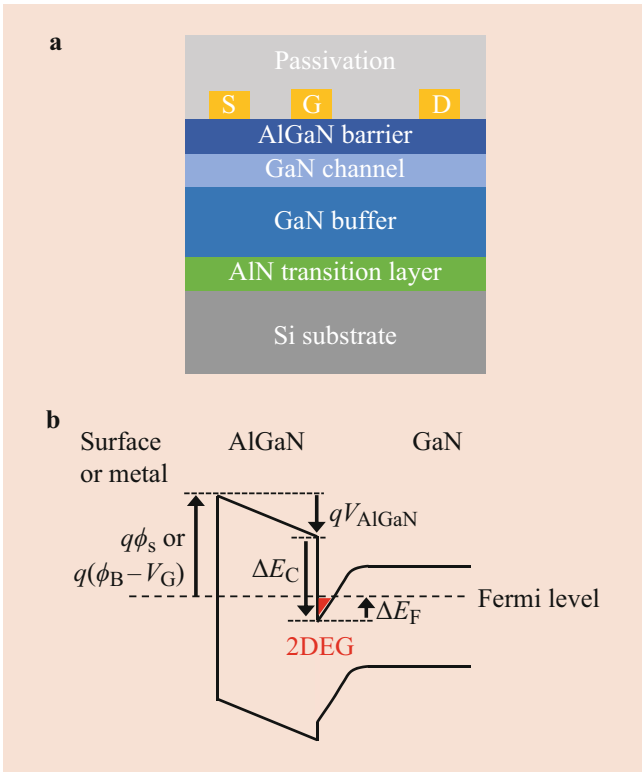

Fig. 15.2 (**a**) Cross section of an AlGaN/GaN HEMT associated with (**b**) his band diagram

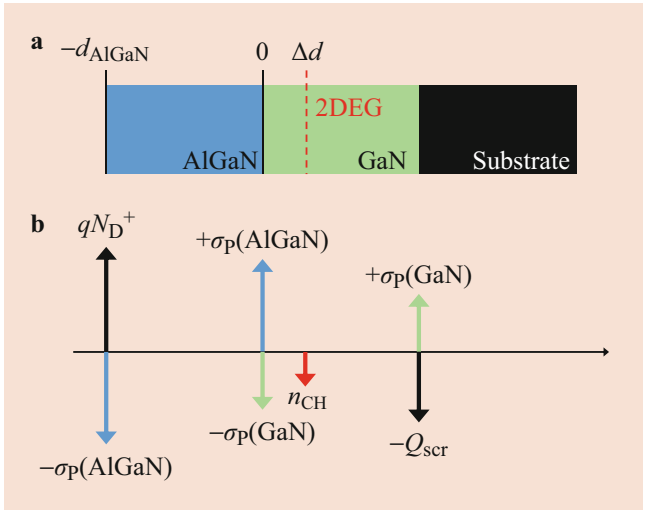

Fig. 15.3 (**a**) Schematic structure of a GaN HEMT for the calculation of the channel charge density and (**b**) charge distribution in the device. The AlN transition layer is not considered for easier understanding

the drain and the source. Unlike GaAs HEMTs, GaN HEMTs do not require any electron doping to create the 2DEG at the interface between the barrier and the channel. Indeed, the creation of the 2DEG is the result of the piezoelectric and spontaneous polarizations inherent of the AlGaN/GaN heterostructure. The electron density in the 2DEG is directly dependent on the nature and the thickness of the material used as barrier layer [33, 34]. The high electron confinement at the interface allows reducing the electron scattering, which leads to an electron mobility typically ranging from 900 and 2200 cm^2/Vs [35, 36].

In more detail, all the contributions leading to the formation of the channel can be computed as follows, referring to Fig. 15.3a for the device structure and dimensions, to Fig. 15.3b for the charge distribution and to Fig. 15.2b for the band diagram, and assuming Ga-face polarity. For thick AlGaN layers, the surface potential $q\phi_s$ is pinned by the surface donor levels located at the upper barrier surface and is almost equivalent to the donor energy depth E_D. Due to the lattice mismatch between AlGaN, and GaN, the thinner AlGaN barrier is submitted to tensile strain; therefore the total polarization charge $-\sigma_P$(AlGaN) at the AlGaN surface is the sum of the spontaneous polarization $-\sigma_{SP}$(AlGaN) and piezoelectric polarization $-\sigma_{PE}$(AlGaN) contribution

$$-\sigma_P\,(\text{AlGaN}) = -\sigma_{SP}\,(\text{AlGaN}) - \sigma_{PE}\,(\text{AlGaN}) \qquad (15.1)$$

An additional positive charge contribution N_D^+ is present at the surface, caused by the unscreened fixed positive charge left by the ionized donors. If the AlGaN layer is thick enough, the Fermi level will reach the donor state level, and the electrons will be stimulated into the conductive band and swiped toward the other side by the force of the polarization-induced electric field. Once contacting with a GaN layer, electrons will flow into the GaN side because of the drop of the Fermi level. The electrons will accumulate at the interface and contribute to the formation of the 2DEG. At the interface between the barrier and the channel region, the net polarization charge $-\sigma_{P,}$(net) is the sum of the contribution by the AlGaN and the GaN layers, σ_P(AlGaN) and $-\sigma_P$(GaN), respectively,

$$\sigma_P\,(\text{net}) = \sigma_P\,(\text{AlGaN}) - \sigma_P\,(\text{GaN}) \qquad (15.2)$$

Given the stronger spontaneous polarization field in AlGaN with respect to GaN, the net charge is a positive number. This positive net charge leads to the presence of an electron distribution in the channel region close to the hetero-interface. We assume that this charge density qn_{CH} is distributed as a two-dimensional charge layer at a distance Δd from the AlGaN/GaN interface, where Δd is the center of the charge distribution. Starting from the AlGaN surface, we can follow the profile of the lower edge of the conduction band from the Fermi level in the metal to the Fermi level in the GaN buffer and write

$$\phi_s - V_{AlGaN} - \frac{\Delta E_C}{q} + \frac{\Delta E_F}{q} = 0 \tag{15.3}$$

where ΔE_C is the conduction band energy discontinuity at the hetero-interface, ΔE_F the distance between the Fermi level and the lower edge of the conduction band at the interface, and V_{AlGaN} the potential across the AlGaN region

$$V_{AlGaN} = \frac{\left|\sigma_P\,(\text{net}) - qn_{CH}\right| \cdot d_{AlGaN}}{\varepsilon} \tag{15.4}$$

ΔE_F can be expressed as

$$\Delta E_F = \frac{qn_{CH}}{\varepsilon} \cdot \Delta d \tag{15.5}$$

The electron channel density n_{CH} is then

$$n_{CH} = \frac{\sigma_P\,(\text{net}) \cdot d_{AlGaN} - \varepsilon(\phi_s - \Delta E_C/q)}{qD} \tag{15.6}$$

where

$$D = d_{AlGaN} + \Delta d \tag{15.7}$$

is the distance between the AlGaN surface and the channel location. In a complete HEMT structure, a gate metal is deposed on top of the AlGaN barrier, which can be used to vary the AlGaN surface potential. When a bias V_G is applied to the gate contact, the surface potential ϕ_s equals $\phi_B - V_G$, where ϕ_B is the barrier height of the metal-semiconductor junction, and therefore we obtain

$$n_{CH}\,(V_G) = \frac{\sigma_P\,(\text{net}) \cdot d_{AlGaN} - \varepsilon\,(\phi_B - V_G - \Delta E_C/q)}{qD} \tag{15.8}$$

Concluding, at the interface between the gallium nitride buffer and the substrate, we have the positive polarization charge of the gallium nitride $+\sigma_P$(GaN) and an additional screening charge $-Q_{scr}$ to ensure charge neutrality in the full structure.

The high electron mobility combined to the high density of charges in the 2DEG enable very low on-state resistances (R_{ON}). Up to 650 V voltage range, GaN devices can thus be foreseen as the best choice as compared its counterparts considering a proven high level of reliability. At higher-voltage operation, this technology is basically limited by the Si substrate. This limitation will be detailed later in this chapter. However, increasing the blocking voltage of GaN lateral devices would pave the way for more efficient devices beyond 1 kV applications [37, 38].

15.2.1 Applications

Silicon-based devices such as MOSFETs (Metal-Oxide-Semiconductor Field Effect Transistor) or IGBTs (Insulated-Gate Bipolar Transistor) have been extremely successful and represent the present standard for power switches in power applications – AC/DC supplies, DC/DC supplies, and motor controls – ranging from just tens of watts up to hundreds and even thousands of watts. They have seen continual improvements in key parameters such as on-resistance $R_{DS(ON)}$, voltage ratings, switching speed, packaging, and other attributes. However, the rate of improvements in these MOSFETs has leveled off, as their performance is now close to the theoretical limit as determined by the underlying fundamental physics of these materials and processes. In this frame, GaN lateral devices have a growing impact on the current power market. Indeed, due to its impressive intrinsic characteristics (shown Fig. 15.4), GaN material has a truly predisposition for high-voltage and high-speed switching applications as confirmed by many market reports for low and mid-voltage range (<600 V) in a short term.

GaN could impact a wide range of applications using various operating voltage. For instance, GaN presents a unique palette of viable solutions for both high power and medium power applications that can power the next generation cars efficiently and economically. Hybrid vehicles represent today a growing market where companies are significantly investing. The emergence of wireless power is another key application enabled by GaN. Eventually, the entire home can be equipped with transmitters and repeaters that will power the lights, TV, and other household appliances wirelessly. GaN transistors will support this rapidly emerging application. Another good example is the use of GaN components in an extremely small x-ray machine that fits in the size of a pill. In this case, GaN's superior performance to obtain 10–100 times higher resolution so diseases can be detected earlier, more accurately and less expensively. Also, in addition to its ability to survive in a harsh environment, the small size, and high efficiency of GaN device make them very attractive for use in space application. GaN is inherently radiation tolerant. Unlike silicon, where special fabrication techniques and special packaging is needed to shield semiconductors from the effects of radiation, GaN's natural properties make it relatively immune to these harmful rays.

15.2.2 State-of-the-Art

The specific on-state resistance of any semiconductor devices used for power electronic applications is one of the key performance parameters. An ideal power switching device should have a high breakdown voltage to cope for the off-state condition with a sufficient margin while its on-state

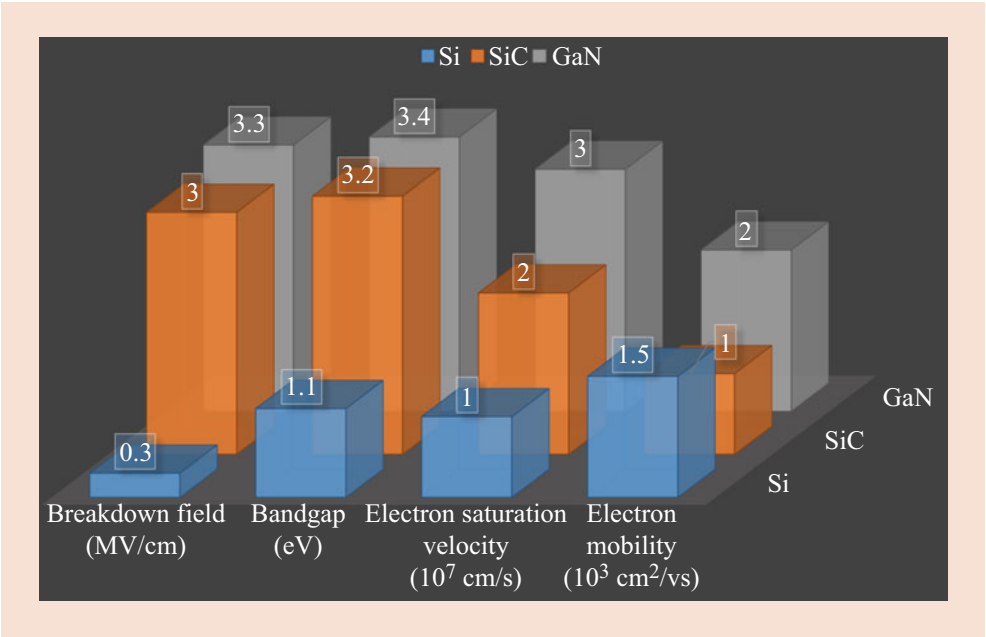

Fig. 15.4 Comparison of intrinsic characteristics of GaN, Si, and SiC material

resistance should be as small as possible. This request translates into the trade-off situation depicted in Fig. 15.4. High breakdown devices require extended drift regions, e.g., the distance between gate and drain needs to be sufficiently large. This means that the increase of the breakdown voltage induces resistive elements that are added to the device thus increasing the on-state resistance. As shown in Fig. 15.5, the optimum on-state resistance for each types of devices follows specific theoretical limits, which have been calculated for unipolar devices. In fact, as power switching devices are operated in the linear (mobility controlled) region at on-state, the on-state resistance increases with breakdown voltage practically in a quadratic dependency. Accordingly, GaN devices have an advantage over Si devices by theoretically at least three orders of magnitude. They even outperform SiC devices.

It can be noticed that many large companies are devoted to the development of GaN power devices. A wide range of commercial GaN power devices are already commercialized. This reflects the potential short-term market penetration of these emerging devices. Nevertheless, several hurdles still need to be overcome such as the cost that needs to be reduced in order to be competitive with Si-based devices while delivering superior performance; the reliability of normally-off GaN devices and in particular the control of the dynamic on-resistance up to high temperature; the integration and associated packaging that needs to be implemented without sacrificing the performances; and the sourcing that needs to be increased to allow high acceptance of this technology from the industry. Furthermore, higher voltage range (>1.2 kV), limited currently to below 1 kV would extend the impact of GaN lateral devices for power applications.

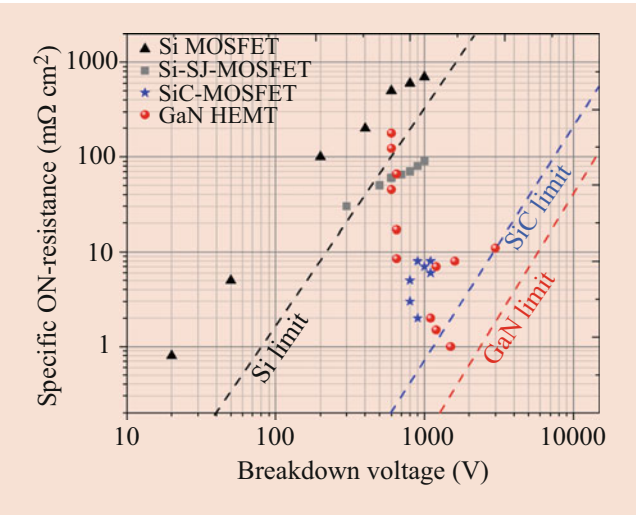

Fig. 15.5 Specific on-resistance as a function of the breakdown voltage of various materials

15.2.3 Limitations of GaN Lateral Devices

As discussed previously, GaN lateral devices are already showing attractive performances as compared to silicon technology [39–41]. However, the operating voltage of GaN devices is limited to below 1 kV, which is significantly lower

than the full potential of this technology. One of the main technological bottlenecks include:

- The parasitic conduction at the buffer/Si substrate interface under high voltage
- The dynamic R_{ON} issues
- The normally-on behavior

Parasitic Conduction Under High Voltage

Many different physical effects are limiting the high voltage performance of GaN devices. They all have to be taken into account when developing high voltage GaN devices. The breakdown voltage is often defined as the voltage level at which the drain current of the pinched-off transistors is exceeding a normalized value of 1 μA per mm device width. The main sources of leakage for an AlGaN/GaN HEMT device are represented in Fig. 15.6. Device breakdown mainly depends on the specific epitaxial design of the buffer layer, its material quality, the lateral geometrical design of the devices, and their passivation technique. The latter issues are mainly dependent on processing technology, whereas the former parameters are due to the GaN/AlGaN epitaxial design, the material properties and the interfacing between GaN/AlGaN material technologies and processing. Some mechanisms, for example, surface arcing between adjacent conductive structures with a large potential difference are known from standard power electronic device technologies.

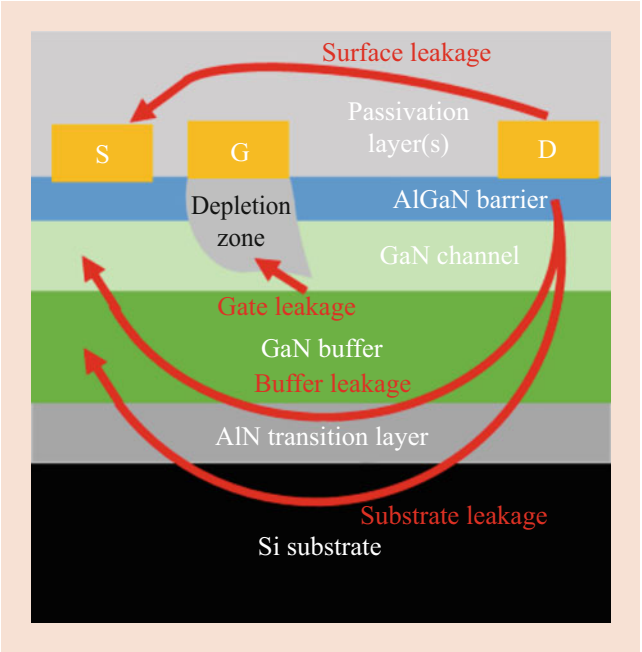

Fig. 15.6 Representation of the main sources of leakage for a HEMT AlGaN/GaN device on Si substrate

These mechanisms can be harnessed by applying adapted passivation and encapsulation schemes.

Buffer leakage current is due to the injection of charge carriers into the buffer under high bias. This phenomenon is commonly called punch-through effects [42]. In this case, if the channel is closed by a sufficiently negative gate bias, electrons are bypassing the gate control region via the buffer. Several solutions have been developed to overcome this issue by the use for instance of carbon or Fe-doped buffer [44–45] or an AlGaN back barrier [46].

In off-state condition, the gate polarization creates a large depletion region, and the electrons can flow from the gate to the drain, most probably due to electron injection across the gate barrier. As these effects are triggered by high electric field strength, particularly at the drain side edge of the gate or close to the drain electrode, field plates can suppress this effect and thus shift the breakdown voltage to higher values.

A strong limitation of GaN lateral devices grown on silicon substrate is the parasitic conduction at the buffer/Si substrate interface under high voltage. Figure 15.7 shows the breakdown voltage (BV) defined for a leakage current of 1 μA/mm, for various epitaxial thicknesses as a function of the gate-drain voltage distance (L_{GD}). If the leakage currents are suppressed by suitable technological means, GaN HEMTs BV scales with increasing L_{GD}. Thus, L_{GD} determines the maximum allowable operation voltage. For small L_{GD} (typically <15 μm), the breakdown voltage monotonically increases, generally indicating a breakdown mechanism that is triggered by properties directly influenced by L_{GD} scaling. In this case, breakdown occurs between the drain side edge of the gate and the channel region with a simultaneous increase of gate and drain current. On the other hand, for higher L_{GD}, BV saturates with respect to the epitaxial total thickness. Detailed investigations have shown that the dominating current flow at breakdown condition is now originating from the source, flowing vertically through the buffer to the conductive substrate and back to the drain terminal.

Therefore, increasing the epitaxial thickness allows improving BV. However, buffer thickness typically above 6–7 μm with low bow is extremely difficult to achieve on large wafer diameters and often leads to higher defect density and eventually cracks. Another way to reduce the parasitic conduction at the buffer/Si substrate interface [48–50] is to locally remove the substrate and subsequently replace by a wider bandgap material. This approach will be described later in this chapter.

Dynamic R_{ON} Issues

GaN-based power transistors can only gain market acceptance if they demonstrate switching properties superior to

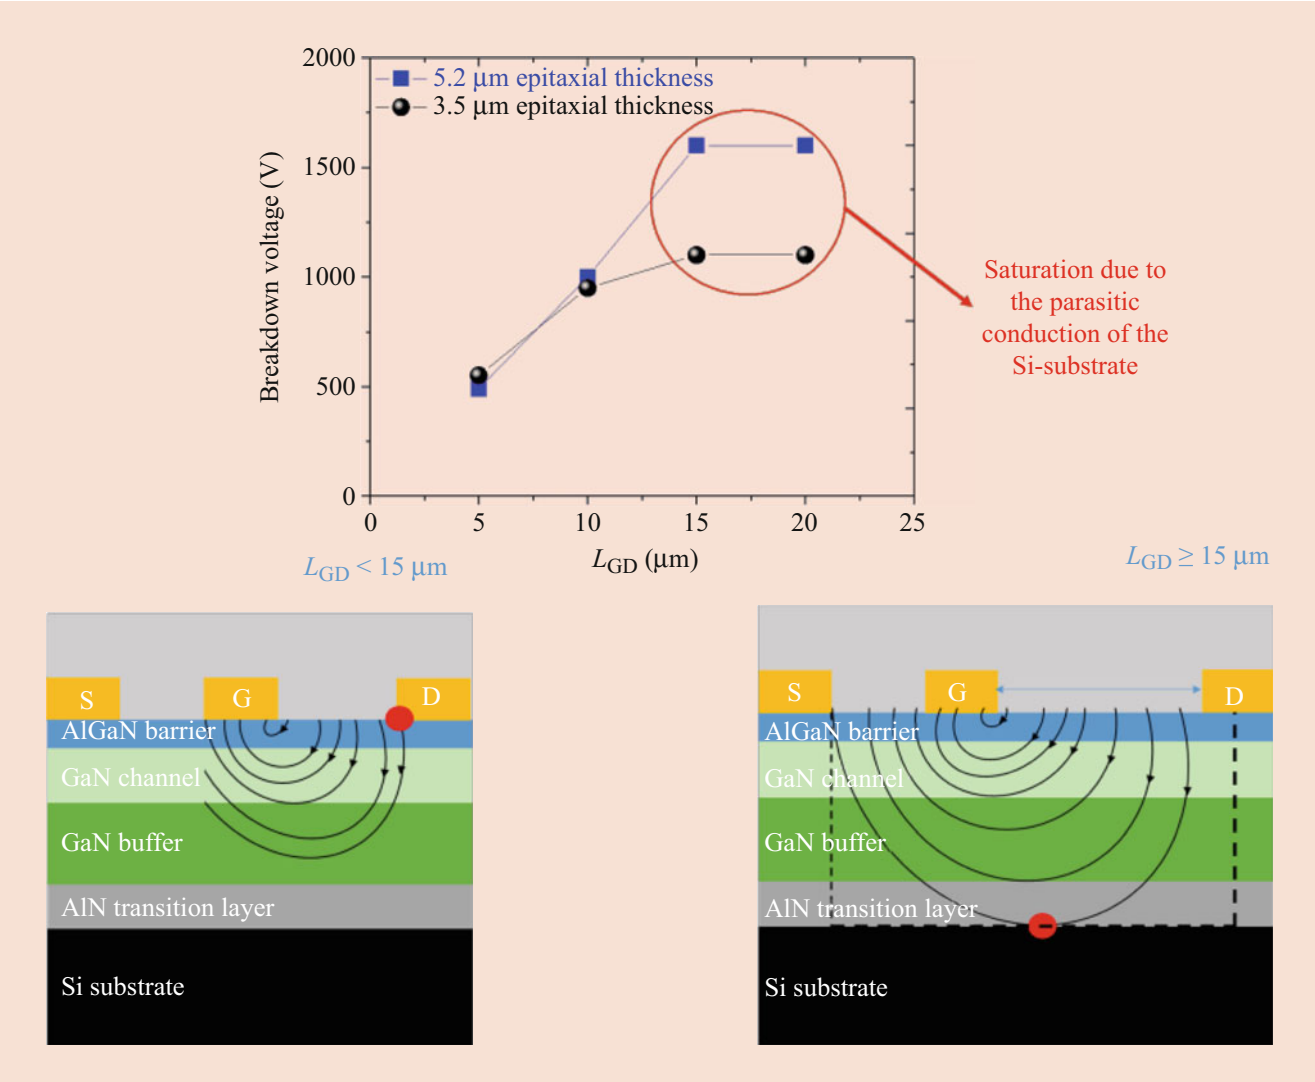

Fig. 15.7 Breakdown voltage comparison of AlGaN/GaN HEMTs with various epitaxial thicknesses as a function of the gate-drain distance [47]

competing technologies. Due to trapping effects the static on-state resistance R_{on_stat} may increase upon dynamic switching of the device leading to a degraded dynamic on-state resistance (R_{on_dyn}). This effect is also known from GaN microwave transistors. As power switching devices are never driven into saturation for most of the switching sequence (only dynamically during a switching event), the dynamic change of the on-state resistance is taken as a criterion to quantify the dynamic trapping effects. As shown in Fig. 15.8, this parasitic effect can cause a strong degradation of the dynamic on-state resistance, which often scales with device switching voltage and thus significantly challenges high voltage GaN switching applications.

The trapping effects in the device structure responsible of the degradation of the dynamic R_{ON} are commonly represented by negative electric charges located in different areas: near the surface (usually process induced) and into the buffer layers (poor interface quality, doping compensation, etc.) [52–53]. Figure 15.9 depicts the mechanism of the traps and the degradation of the dynamic R_{ON} during switching. Trapping can take place at various places, in the epitaxial layers, at passivation semiconductor interfaces or even at interfaces between different passivation layers. In consequence, electron transport in the channel region immediately after switching from one condition to another is impeded by negatively charged traps until they are emptied. This leads to increased switching losses, reduced system efficiency, and explains time dependence of R_{on_dyn}. An optimized buffer design avoiding deep trapping with a proper surface passivation and the use of field plates to spread the peak electric field are some essential countermeasures towards optimized power switching.

15.2.4 Pushing the Limits of Lateral GaN Devices: Enhancement of the Blocking Voltage

One of the main challenges with GaN-on-Si lateral devices is the enhancement of the blocking voltage. Several parameters still limit today the device operation for higher voltage (silicon substrate, epitaxial structure thickness). One way to increase the breakdown is the use of thicker buffer layers. Advanced architectures based on AlN/GaN superlattices or thick (up to 7 μm) quasi-carbon-free buffer combined with strain-management interlayers have been developed successfully. A key point is that regardless of the chosen approach, buffer trapping should be avoided.

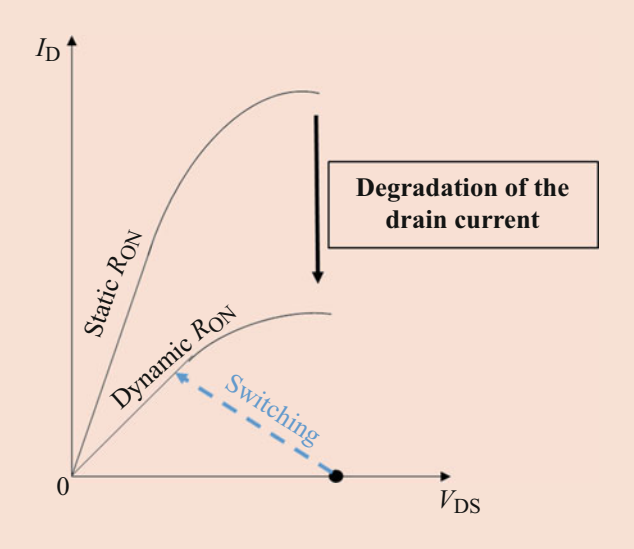

Fig. 15.8 Degradation of the dynamic R_{ON} during switching of a GaN HEMT

An example of electrical characteristics from a thick and excellent buffer crystal quality showing low leakage current and state-of-the-art vertical breakdown voltage above 1400 V (~2 MV/cm) appears in Fig. 15.10 [54]. Furthermore, substrate ramp measurements reveal very low trapping effects up to 1.2 kV (Fig. 15.10b. It has been indeed shown that ramping the substrate to a high (negative) potential allows to reproduce the off-state operation under the drain contact in a transistor. In this case, any buffer charge trapping or storage will be visible in the substrate ramp characteristics.

Another promising solution to increase the blocking voltage of GaN-on-Si lateral devices is the local substrate removal (LSR). This method consists in a selective silicon substrate removal around the device and subsequent replacement by an ultra-wide bandgap followed by a backside metallization [49] as described in Fig. 15.11.

Aluminum nitride (AlN) deposited by PVD is a promising dielectric in this frame since it has a low mismatch with the nucleation layers, a significant breakdown field above 4 MV/cm and offers a cost effective manufacturing technology scalable to large wafer diameter [55]. The LSR

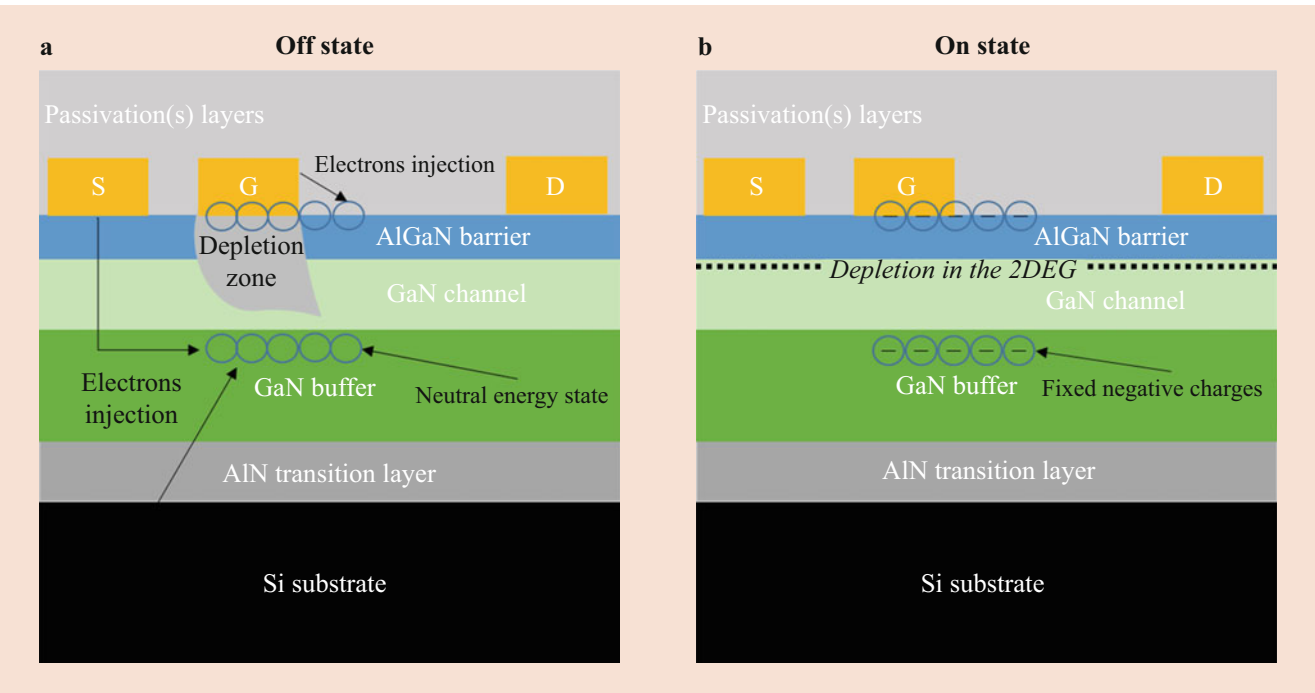

Fig. 15.9 Illustration of the influence of the trapping effect on the R_{ON} of a GaN HEMT during switching (**a**) off state (**b**) on state

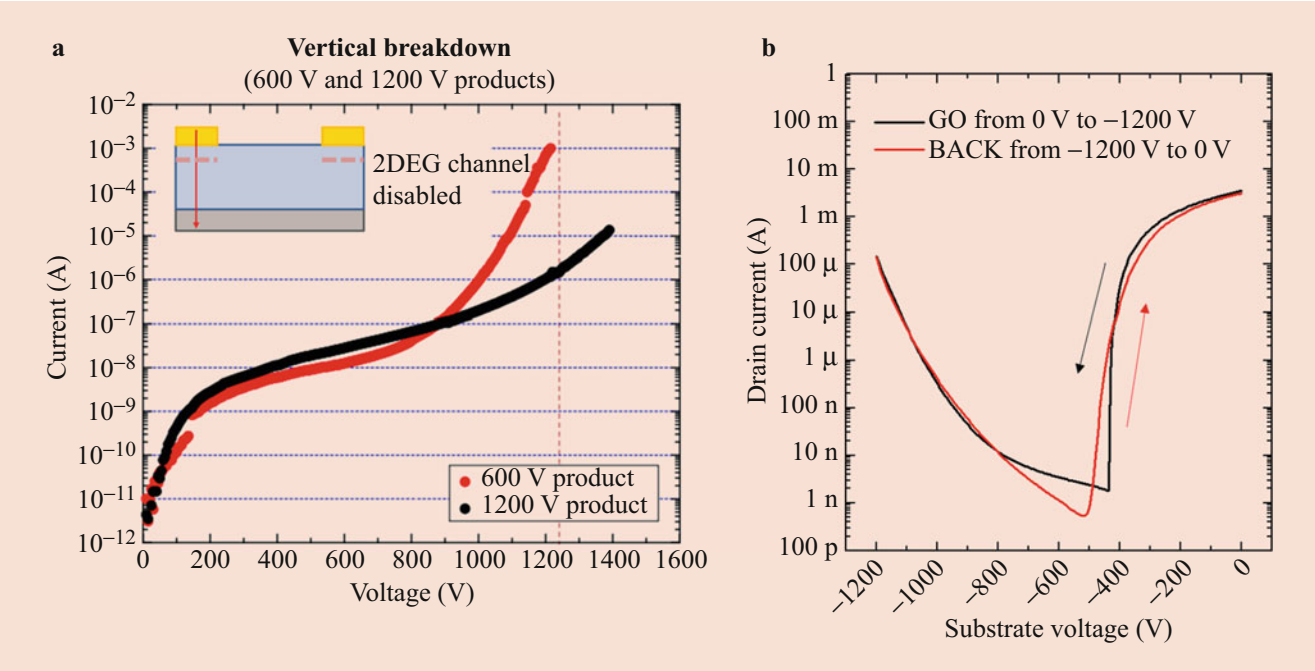

Fig. 15.10 (**a**) Vertical breakdown voltage and (**b**) substrate ramp measurement up to 1.2 kV of GaN-based heterostructure

technique combined with 15 µm thick AlN layer resulted in state-of-the-art GaN-based HEMTs with remarkably low off-state leakage current (<1 µA/mm) beyond 3 kV while maintaining a low specific on-resistance about 10 mΩ.cm^2 (Fig. 15.12). The comparison of these devices without LSR confirms that the drain leakage current flows essentially at the AlN nucleation layer/Si substrate interface. Furthermore, significant recovery of the maximum current density after the backside metallization enabled to reduce the self-heating. It can also be pointed out that this approach do not induce additional charge trapping. The integrity of a trap-free buffer is thus not affected by the substrate removal while extending significantly the bias operation capability.

15.2.5 Normally-Off GaN Lateral Devices

Normally-off configuration is an essential prerequisite for power applications in order to reduce the power consumption and keep a simple gate drive configuration. Many approaches have been demonstrated toward normally-off GaN lateral transistors. The general approach is to shift the conduction band of the channel region controlled by the gate above the Fermi level at zero gate bias and thus to obtain a positive threshold voltage. For power applications threshold voltage (V_{TH}) ranges above +1 V are desirable to ensure safe operation conditions, while the on-state resistance should be kept as low as possible.

MISHEMTs

The main advantage of the MISHEMT (*Metal Insulator Semiconductor HEMT*) structure is that a high threshold voltage levels can be obtained. A gate recessing is combined with gate dielectric isolator techniques to avoid gate leakage increase (Fig. 15.13). However, interface charges subsequent to the gate recess etching and dielectric deposition still plague this type of devices. The choice of the insulator has a strong impact on the interface traps. For instance, some studies showed that the use Al_2O_3 induces negative charges, while HfO_2 gives rise to positive charges [56].

F$^-$ Ion Implant under the Gate

Another possibility to achieve normally-off operation on a GaN HEMT is the use of ion implantation by plasma Fig. 15.14. This method was first demonstrated in 2006 [57] showing positive V_{TH}. The fluorine F$^-$ ion implantation into the AlGaN barrier layer localized under the gate makes use of the natural strong electronegativity of the F$^-$ ion to deplete the DEG as charge neutrality is ensured. A trade-off between the mobility/R_{ON} degradation and higher V_{TH} positive shift exists depending on the plasma condition such as time and power used. Furthermore, the device reliability under high voltage still needs to be demonstrated for this approach. For instance, several groups have shown a strong dependence of the amount of fluorine ion implantation on the increase of the current collapse and the annealing temperature [58] leading to a threshold voltage instability.

Fig. 15.11 Cross section describing the fabrication of the local substrate removal approach

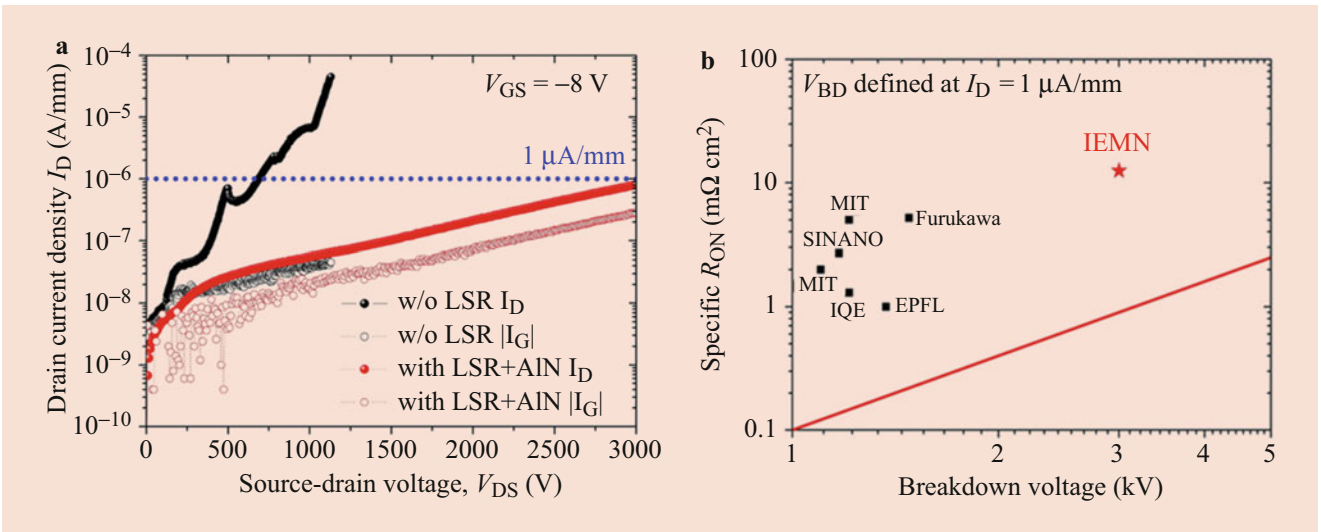

Fig. 15.12 (**a**) Off-state leakage current characteristics of AlGaN/GaN MISHEMTs with and without LSR/thick AlN deposition. [55] under the terms of the Creative Commons Attribution 4.0 license (CC-BY) http://creativecommons.org/licenses/by/4.0/)

The Cascode Circuit

Normally-off behavior can also be obtained by connecting a standard normally-off Si MOSFET optimized for low-voltage operation and a high-voltage GaN normally-on transistor in cascode configuration (Fig. 15.15). In this hybrid configuration, the Si MOSFET is used to control the GaN HEMT gate with only positive gate voltage through the Si MOSFET resulting in a normally-off overall behavior. On-state and off-state properties should be determined by the GaN device, whereas the normally-off property is due to the Si device. The packaged cascode configuration looks like a high-voltage normally-off transistor. It combines the advantages of a large gate threshold voltage and gate voltage swing (feature of the Si normally-off transistor), a high breakdown voltage and a comparably low on-state resistance related to the normally-on GaN HEMT. Combining these two devices brings several drawbacks: the input capacitance is determined by the Si-MOSFET and therefore comparably high slowing down the switching speed [59]. Furthermore, the Si MOSFET limits strongly the overall temperature operation offered by the GaN technology. Nevertheless, several manufacturers are pursuing the commercialization of the cascode design.

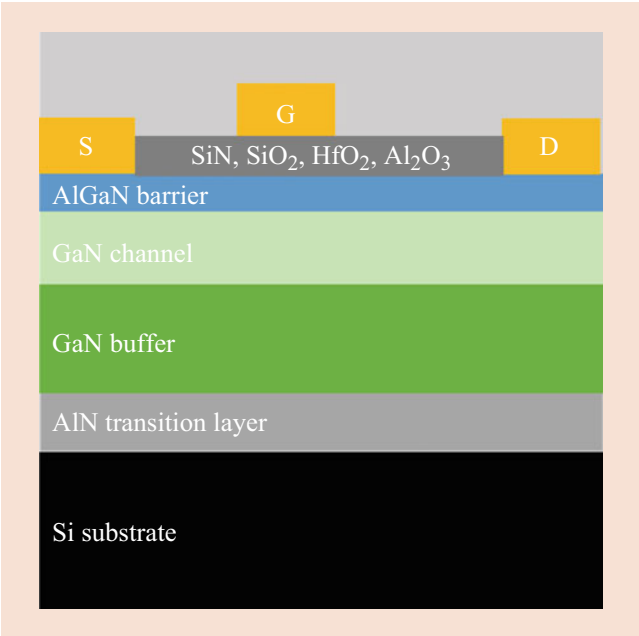

Fig. 15.13 Cross-session of a MISHEMT

P-GaN

The first demonstration of p-AlGaN or p-GaN under the gate in order to achieve normally-off operation has been realized by Panasonic in 2007 [60] despite the challenge of p-doping (Magnesium) of GaN material. Figure 15.16 describes the band diagrams with and without a p-GaN cap layer. At zero gate bias, the p-GaN layer is depleted leaving back a fixed negative charge which in turn depletes the channel. When the positive gate bias increases further, holes are injected into the pn heterojunction, which results in a higher drain current of the device.

In practice, a careful epilayer design needs to be used in order to achieve a positive threshold voltage. One of the key parameter is the concentration of Mg in the p-GaN layer. Some studies have shown that a concentration in the range of 2×10^{19} cm^{-3} is necessary [62] with a trade-off with defect density increase in the case of higher Mg concentration. A second important parameter to be considered is the Al content into the $Al_xGa_{1-x}N$ barrier layer. A lower electron density into the 2DEG resulting from a reduced Al content favors a stronger depletion and thus higher pinch-off voltage.

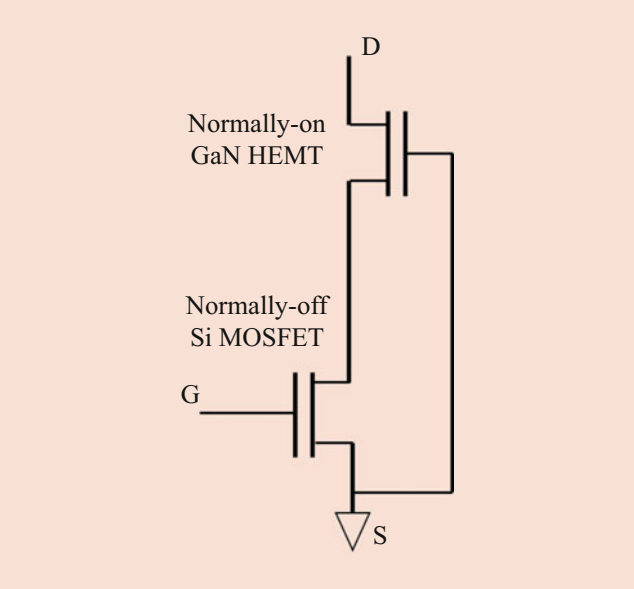

Fig. 15.15 Cascode type hybrid integration of GaN normally-on and Si normally-off device

Processing of GaN Lateral Devices

A conventional Schottky gate D-mode and p-GaN E-mode GaN HEMT device structures are schematically shown in Fig. 15.17. The process modules for the GaN HEMT device fabrication include the ohmic contact formation for source and drain, device isolation, p-GaN gate contact or MIS gate, surface passivation, and interconnects. The source and drain metal stacks facilitate the ohmic contacts. In order to avoid cross-contamination with Si processes in production lines, Au-free metallizations have to be used. The gate contact is deposited on top of a high-quality dielectric for the D-mode GaN HEMTs. In the case of E-mode, the p-GaN layer should be removed except under the gate area. The dry etching is widely used for this step. One of the key factors to achieve high performance device and high yield is the etching selectivity of GaN over AlGaN. The commonly used Cl_2/BCl_3 plasma results in a poor selectivity. Fluorine-based chemistry etching technique has been reported to provide better selectivity. The etching of compound semiconductor films containing Al can be optimized in Cl-based plasmas by adding F-containing gases. For instance, the BCl_3/SF_6 selective dry etching on AlGaN/GaN allows decreasing the AlGaN etching rate resulting from the formation of non-volatile AlF_3 residues on AlGaN surface. Actually, the AlF_3 reduces the etching efficiency of chlorine enabling a selective etching of GaN over AlGaN. To further enhance the etching selectivity, a thin AlN etch stop layer can be inserted between the p-GaN and AlGaN layers improving the V_{TH} uniformity. Finally, the surface passivation (especially of the sidewalls) plays a crucial role for proper device operation in order to prevent the current collapse and related large dynamic on-resistances.

Future Prospects

GaN power switching devices will play an important role in future power electronic applications due to their outstanding properties. With the continuous progress of manufacture technology, GaN power devices with high breakdown voltage, high temperature resistance, low conduction losses, and high output power should penetrate large markets soon. In particular, the increasing need of higher efficiency will make GaN devices extremely attractive. The collection of data shows that the newest generations of the emerging GaN power switching definitely outperform their Si competitors. It is now the time to convert prototype devices to highly mature industrial devices. Nevertheless, the better performance/cost ratio than available devices needs to be realized by proving their reliability to a large extend. Furthermore, higher switching frequency and higher operating temperatures translate indeed in smaller passive components and cooling systems, which would benefit any power applications. However, the main challenge will be the lack of passive components, advanced packaging technologies, and circuit designs for handling such small dies with their fast-switching characteristics at the converter level. This may postpone the introduction of GaN devices for some applications in a short term. On the other hand, in several applications (e.g., mobile applications in transportation systems, power supplies for notebooks, and communication units), there is a high pressure to reduce the power converter's size and weight while increasing the efficiency.

15.3 Vertical Devices Architectures

Power electronics is a highly discussed topic of our century. As we prepare ourselves to address the next-generation power requirements, we make a note of the changing landscape of power generation and delivery. With the rollout of renewables as sources for electricity, more and more electronics are getting connected to the source side and load side of our grid. The trend will only continue upwards. This suggests higher power device integration to the grid which to a device engineer translates to finding solutions that are power dense. Besides grid, there are several applications, extending from automotive to robotics and touching our daily lives, which require a more efficient power conversion unit. Every power conversion unit requires a solid-state switch to perform their job.

Silicon-based power electronics have served us well. However, it is time for wide bandgap semiconductors to address the issues of high-power electronics, where higher power density is a key driver. Vertical GaN technology is one of the pillars that would prove its worth in the coming years in delivering the appropriate performance over cost benefit that the market is looking for. In this chapter,

we go over vertical devices in GaN like Current aperture vertical electron transistor (CAVET), vertical Metal Oxide Field Effect transistor (v-MOSFET), and Static Induction transistor (SIT) [63]. But before we go over the devices, we will discuss about TCAD models that we found extremely valuable to predict device performance during our research.

15.3.1 Device/Circuit Hybrid Modeling

For power semiconductor devices, technology computer-aided design (TCAD) simulation is a vital tool to accurately predict the behavior and optimize the design of devices. For the well-proven practice of Si-based devices, there are reliable simulation platforms that include process, device, and circuit (system) models. However, due to the maturing nature of the GaN technology, there are very few available device simulation tools. Due to the expensive manufacturing of GaN devices, it becomes even more important to develop an accurate and reliable TCAD modeling for GaN devices to predict device behaviors.

A flowchart of the device/circuit hybrid modeling approach is shown in Fig. 15.18 [64]. Before the development of the model, a 700 V AlGaN/GaN HEMT was fabricated. Based on the extracted data from the fabricated HEMT, we developed a physics-based device model for it, and then integrated it with a circuit model to study the dynamic characteristics and power losses of the HEMT. Using this device-circuit-integrated model, we can start with 2D drift-diffusion modeling of the device and build all the way up to its circuit implementation to evaluate its switching performance. The method of using a hybrid model should give us an inexpensive and accurate way to project and benchmark the performance that can be extended to any GaN-based power transistors.

15.3.2 Physics Models for GaN

Drift-Diffusion Model

The TCAD device simulation uses the drift-diffusion model, which solves the Poisson and current continuity equations. The equations are shown as

$$\nabla^2 \varphi = \frac{q\,(n - p + N_{\mathrm{A}} - N_{\mathrm{D}})}{\varepsilon_{\mathrm{s}}}, \tag{15.9}$$

$$\frac{\partial n}{\partial t} = G_{\mathrm{n}} - U_{\mathrm{n}} + \frac{1}{q}\nabla \cdot \vec{J}_{\mathrm{n}}, \tag{15.10}$$

where φ is the electrostatic potential, q is the electron charge, n is the free electron density, p is the free hole density, N_{A} is the ionized acceptor density, N_{D} is the ionized donor density, G_{n} is the regeneration rate for electron, U_{n} is the recombination rate of electron, and $\boldsymbol{J}_{\mathrm{n}}$ is the electron current density.

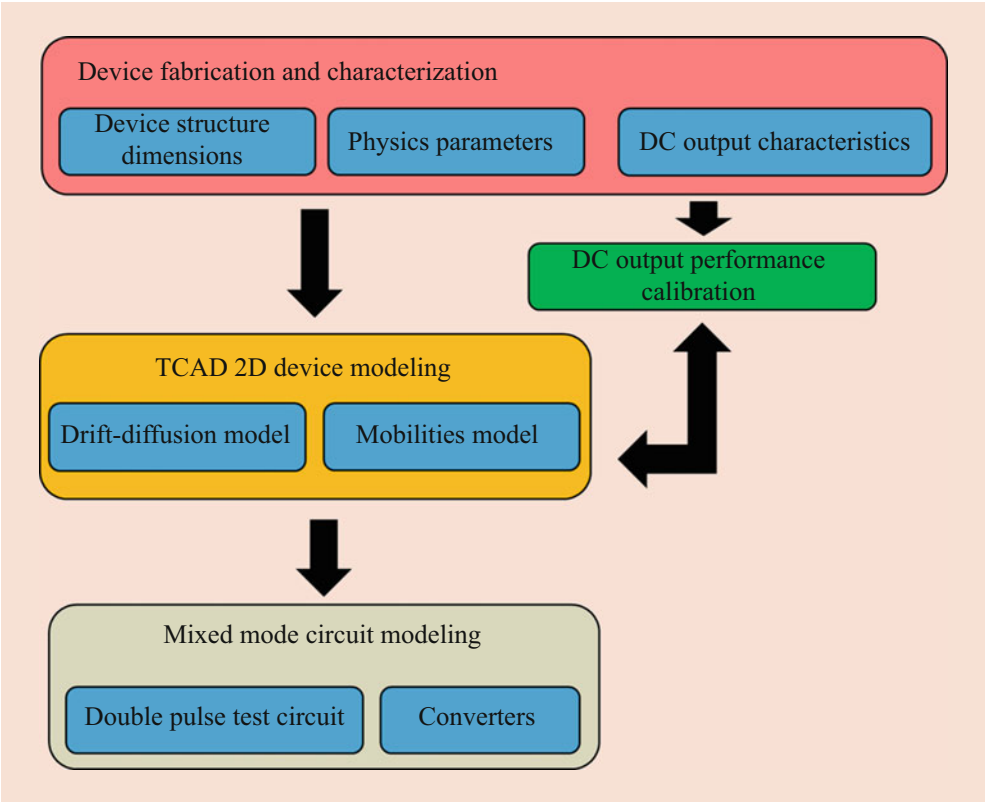

Fig. 15.18 The flowchart of simulation methodology

B. Polarization

The non-centrosymmetric compound crystals exhibit polarity along the axes of (0001) of GaN. Two types of polarization existence in the AlGaN/GaN heterostructure: the strain-induced piezoelectric polarization P_{PE} and the spontaneous polarization P_{SP}. The amount of the polarization induced sheet charge density can be written as [65]

$$|\sigma(x)| = \left|2\frac{a(0)-a(x)}{a(x)}\left\{e_{31}(x) - e_{33}(x)\frac{C_{13}(x)}{C_{33}(x)}\right\} + P_{SP}(x) - P_{SP}(0)\right|, \tag{15.11}$$

where the x is Al mole fraction in AlGaN, the lattice constant $a(x)$ is given by $a(x) = (-0.0077x + 0.3189)$ nm; a$(t) = (-0.0077t + 0.3189)$nm elastic constants $c_{13}(x)$ and $c_{33}(x)$ can be written as $c_{13}(x) = (5x + 103)$ GPa and $c_{33}(x) = (-32x + 405)$ GPa, respectively; piezoelectric constants $e_{33}(x)$ and $e_{31}(x)$ can be expressed as $e_{33}(x) = (0.73x + 0.73)$ C/m^2 and $e_{31}(x) = (-0.11x - 0.49)$ C/m^2, respectively; and the spontaneous polarization $P_{sp}(x)$ is given by $P_{sp}(x) = (-0.052x - 0.029)$ C/m^2.

Electron Mobility

Electron mobility is a key parameter to determine the conductivity of a given semiconductor. A number of theoretical and experimental studies have been performed to understand the electron mobility in GaN. In a recent report, a dual model, one for low-field and the other for high field, was observed to well fit to the reported theoretical and experimental data [66]. The low field electron mobility is given according to the doping and temperature-dependent Arora model [66]:

$$\mu_0(T,N) = \mu_{min}\left(\frac{T}{300}\right)^{\beta_1} + \frac{(\mu_{max}-\mu_{min})\left(\frac{T}{300}\right)^{\beta_2}}{1+\left[\frac{N}{N_{ref}\left(\frac{T}{300}\right)^{\beta_3}}\right]^{\alpha(T/300)^{\beta_4}}}, \tag{15.12}$$

T is temperature, μ_{min}, μ_{max}, β_1, β_2, β_3, β_4, and α are parameters that can be determined by experiment.

Due to the unique energy band diagram, GaN shows a negative differential region in the field-velocity curve for electrons at very high fields. This is caused by the movement of high-energy electrons from lower Γ valley to the higher M and L valleys, where electrons have higher effective mass, reducing the velocity. The transferred electron effect model was found to have a reasonable fit to the tendencies observed for the experimental and theoretical data [66].

Table 15.2 Mobility model parameters used in GaN device simulation [66–68]

Parameters	Values
μ_{min}	115 cm^2/Vs
μ_{max}	1800 cm^2/Vs
β_1	−1.5
β_2	−1.5
β_3	3.02
β_4	0.81
A	0.8
N_{ref}	7×10^{16} cm^{-3}
$v_{n,sat}$	1.9064×10^7 cm/s
E_C	1.7×10^5 V/cm
n_1	4.19
n_2	0.885
A	5.64

$$\mu(T,N) = \frac{\mu_{n0}(T,N) + v_{n,sat}\frac{E^{n1-1}}{E_C{}^{n1}}}{1 + a\left[\frac{E}{E_C}\right]^{n_2} + \left[\frac{E}{E_C}\right]^{n_1}}, \tag{15.13}$$

The parameters used in GaN simulation are listed in Table 15.2.

Device Modeling Calibration

The TCAD simulated device was identical in design with the fabricated device, the structure of which is shown in Fig. 15.19. An excellent agreement between the experimental and the simulated data was obtained by optimizing the physical parameters to replicate GaN's physical parameters. We repeated the optimization until a satisfactory fit of the experimental and simulated data was obtained as illustrated in Fig. 15.20.

Figure 15.21 shows the capacitances in a single E-mode device, the output capacitance (C_{oss}), input capacitance (C_{iss}), and reverse capacitance (C_{rss}) can be written as

$$C_{oss} = C_{GD} + C_{DS} \tag{15.14}$$

$$C_{iss} = C_{GS} + C_{DS} \tag{15.15}$$

$$C_{rss} = C_{GD} \tag{15.16}$$

In a cascoded configuration, the D-mode GaN device is cascoded with an E-mode Si MOSFET to render the combination into a normally-off device. The capacitance distribution is shown in Fig. 15.22. Capacitances labeled

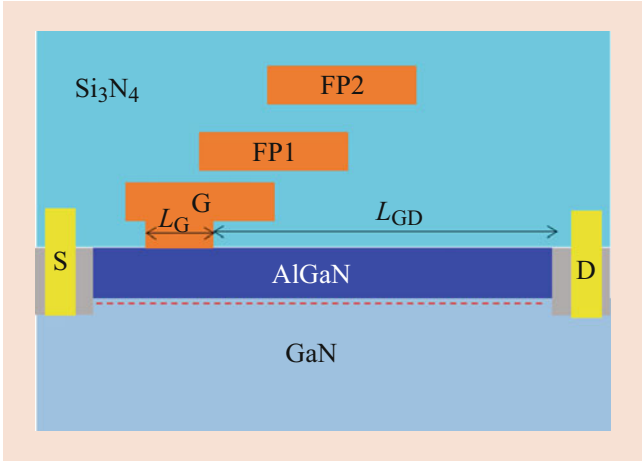

Fig. 15.19 HEMT structure used in the simulation. The HEMT has three field plates (FP) with a gate to drain distance $L_{GD} = 10\ \mu m$, gate length $L_G = 2\ \mu m$. (© 2016 IEEE. Reprinted, with permission, from D. Ji et al. [64])

with a subscript "1" and "2" represent for Si MOSFET and AlGaN/GaN HEMT, respectively.

In this cascoded configuration, the output capacitance (C_{oss}), input capacitance (C_{iss}), and reverse capacitance (C_{rss}) can be written as [64]

$$C_{iss} = C_{GS1} + \frac{C_{GD1}\,(C_{GS2} + C_{DS1} + C_{DS2})}{C_{GD1} + C_{GS2} + C_{DS1} + C_{DS2}}, \qquad (15.17)$$

$$C_{oss} = C_{GD2} + \frac{C_{DS2}\,(C_{GD1} + C_{DS1} + C_{GS2})}{C_{GD1} + C_{DS1} + C_{GS2} + C_{DS2}}, \qquad (15.18)$$

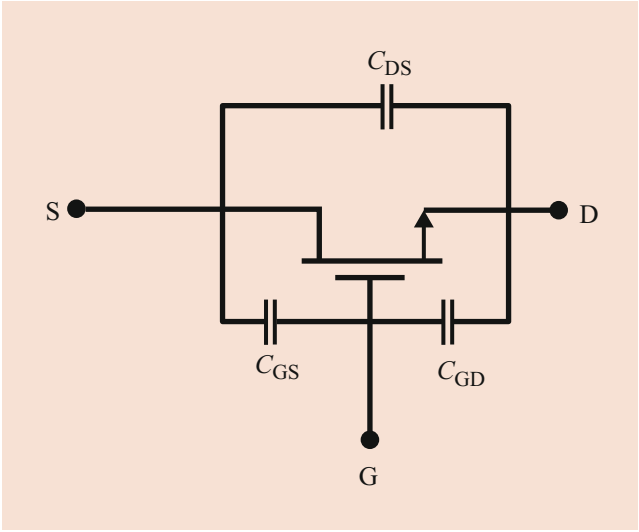

Fig. 15.21 Capacitance distribution in a single power MOSFET

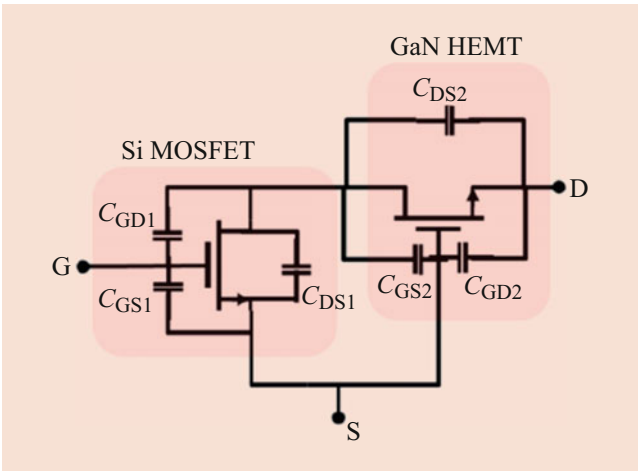

Fig. 15.22 Capacitance distribution in a cascoded HEMT. (© 2016 IEEE. Reprinted, with permission, from D. Ji et al. [64])

$$C_{rss} = \frac{C_{DS2}C_{GD1}}{C_{GD1} + C_{DS2}}, \qquad (15.19)$$

The *C-V* characteristics, which determine the switching performance of a power transistor, was obtained from the simulation and is shown in Fig. 15.23.

Figure 15.24 shows a double pulse test circuit with an inductive load that is widely used in the evaluation of power devices. The free-wheeling diode was assumed to be ideal, and a current source was adopted instead of the inductor to simplify the simulation. The Si MOSFET has a voltage rating of 30 V and R_{ON} of 20 mΩ. One of the highlights of this work is the successful incorporation of the parasitic inductance in the cascoded device. The parasitic inductances in our model were $L_G = 2$ nH, $L_S = 10$ nH, and $L_D = 1.9$ nH [64].

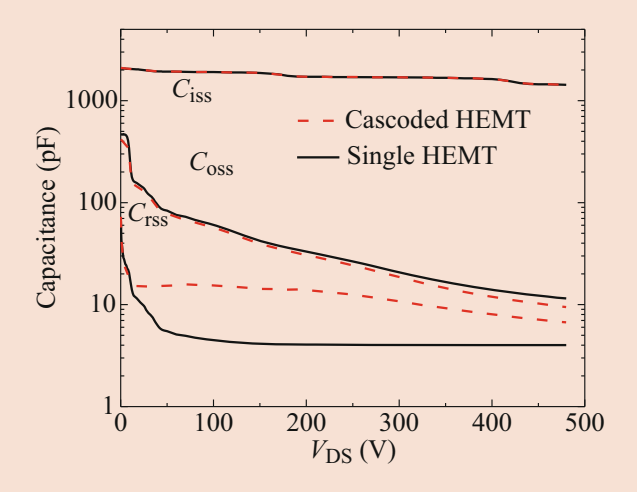

Fig. 15.23 *C-V* characteristics in the cascoded HEMT and single E-mode HEMT

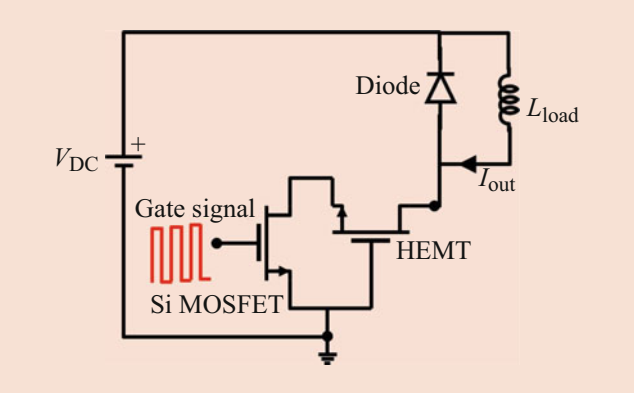

Fig. 15.24 Test circuit used in the simulation. (© 2016 IEEE. Reprinted, with permission, from D. Ji et al. [64])

Figure 15.25a shows the turn-on switching characteristics of a 600 V cascoded HEMT, with a total on-state resistance R_{ON} of 290 mΩ. The resistance and the capacitance characteristics discussed in the previous section applies to the particular device discussed in this section. A V_{DS} of 480 V, I_D of 5.5 A and external gate resistance R_G of 2 Ω were used in this simulation.

From the waveforms shown in Fig. 15.8a, the turn-on delay time $t_{d(on)}$ is 5 ns, and rise time t_r is 3 ns, showing a turn-on $\Delta v/\Delta t$ of ~120 kV/μs. Figure 15.25b shows the power loss during the turn-on transient, the total energy loss is 37 μJ.

From the waveforms of Fig. 15.26a, the turn-off delay time $t_{d(off)}$ is 12.5 ns, and fall time t_f is 4 ns, giving a turn-off $\Delta v/\Delta t = \sim 95$ kV/μs. The power loss shown in Fig. 15.26b indicates a turn-off switching loss of 3 μJ.

For the validation of the device-circuit integrated model, we chose a commercially available HEMT (Transphorm TPH3002LD) to perform the simulation. We first simulated

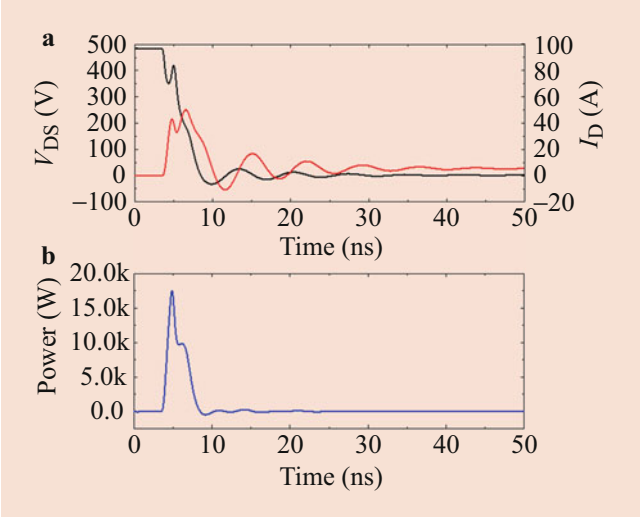

Fig. 15.25 (**a**) Simulated turn-on switching waveforms of the cascoded HEMT; (**b**) power loss during the turn-on switching

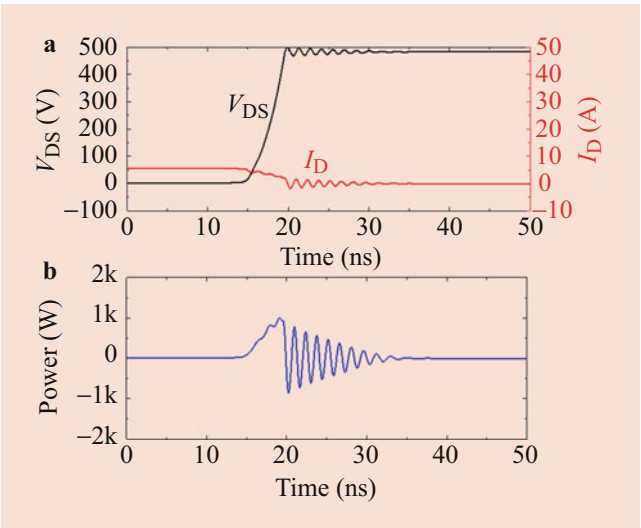

Fig. 15.26 (**a**) Simulated turn-off switching waveforms of the cascoded HEMT; (**b**) power loss during the turn-off switching

the HEMT and then tested it in a cascode configuration to replicate TPH3002LD, using the same circuit as shown in Fig. 15.24. A comparison between TPH3002LD and our simulated device is shown in Table 15.3. A reasonable agreement was obtained as evident from Table 15.3, now confirming both drift-diffusion and circuit model, and hence our hybrid modeling technique. The reasonable agreement of the TPH3002LD with our simulated data built and reassured a reliable platform to now apply for any GaN power device and project its switching performance.

Modeling of Vertical GaN Devices

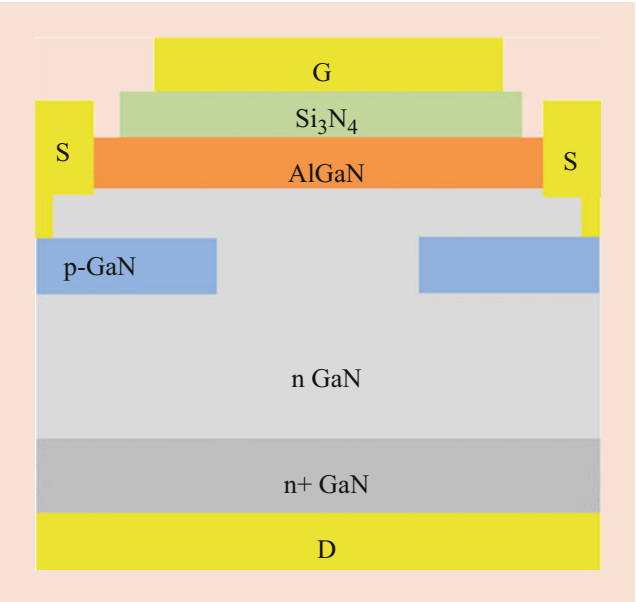

Fig. 15.27 Schematic of a normally-on CAVET

HEMTs [64], the switching performance of the vertical GaN transistor was analyzed. In this section, a current aperture vertical electron transistor (CAVET) was used, since this device was one of the most developed vertical GaN devices. The structure of the CAVET is shown in Fig. 15.27.

Figure 15.27 shows the schematic of a normally-on CAVET. A thick n-GaN with 10^{16} cm^{-3} doping was designed to form the drift region on a conductive GaN (10^{18} cm^{-3}) substrate. 0.4 μm-thick p-type current blocking layers (CBLs) were implemented with a doping density of 3×10^{17} cm^{-3} to block current from flowing through any other path other than the designed aperture ($N_D = 3 \times 10^{17}$ cm^{-3}). AlGaN/GaN channel was defined on top of the CBL and the aperture to conduct electrons from the source through a high mobility 2D channel obtained at the hetero-interface. Sources contacting the 2D electron gas were designed on either side of the gate at a distance of 2 μm. The p-GaN CBLs were connected to the source to provide a discharge path for any electrons trapped in the p-type layer.

CAVETs are normally-on devices similar to GaN HEMTs. Techniques that are typically applied to HEMTs can be applied to CAVETs to render it normally-off. We adopted a cascoded CAVET approach in this work to achieve normally-off operation, where the cascode was designed with a low-voltage Si MOSFET. The cascoded CAVET was subjected to switching operation, and detailed performance matrix was generated.

Figure 15.28 shows the cascode configuration designed with a low-voltage normally-off Si MOSFET as the input and a high-voltage normally-on CAVET as the output. The current paths of the forward conduction are labeled with the arrows in Fig. 15.28a. In the forward conduction, the total on-state resistance (R_{on}) is the sum of the MOSFET R_{on} and the CAVET R_{on}. In the reverse conduction cycle (shown in Fig. 15.28b), the current flows through the body diode of the Si MOSFET and the CAVET channel. It is important to note that the body diode of the CAVET does not conduct current at any time of the operation.

Figure 15.29 shows the turn-on switching characteristics of a 1.2 kV cascoded CAVET, with a total on-state resistance R_{ON} of 80 mΩ. A V_{DS} of 800 V, I_D of 20 A and external gate resistance R_G of 2.5 Ω were used in this simulation. Before we discuss the results a close-up look at the turn-on event in a switching cycle will be befitting. The turn-on event can be divided into three stages [64].

In the first stage, when a V_{GS} is applied to the gate electrode, the gate current I_G starts charging the Si MOSFET gate to source capacitor C_{GS_MOS}. As a result, Si MOSFET gate to source voltage V_{GS_MOS} increases.

Once the V_{GS_MOS} reaches the threshold voltage of Si MOSFET, in the second stage, the MOSFET channel is turned on, and channel current increases. The Si MOSFET channel current discharges three capacitors: Si MOSFET gate to drain capacitor C_{GD_MOS}, Si MOSFET drain to source capacitor C_{DS_MOS}, and GaN CAVET gate to source capacitor C_{GS_CAVET}, as a result of which, MOSFET drain to source voltage V_{DS_MOS} decreases, and the CAVET source to gate voltage V_{SG_CAVET} decreases as well.

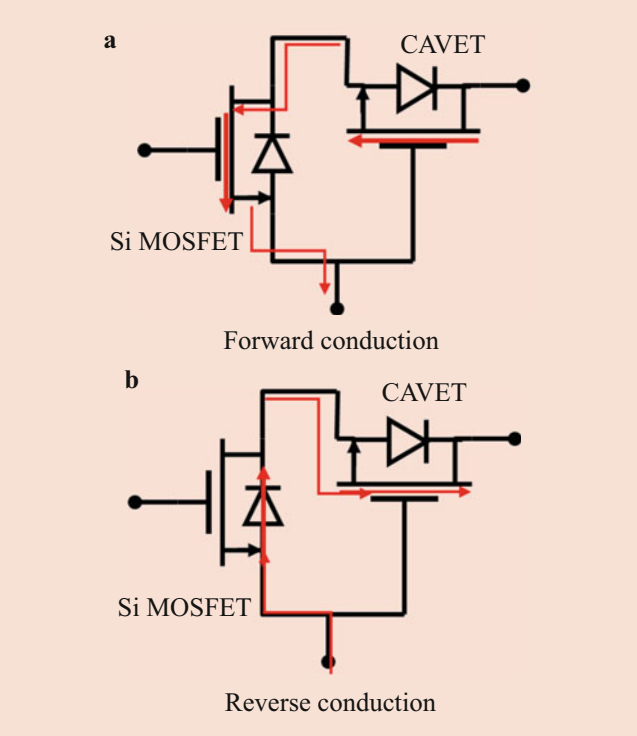

Fig. 15.28 (**a**) Forward conduction of the cascoded CAVET; (**b**) reverse conduction of the cascoded CAVET

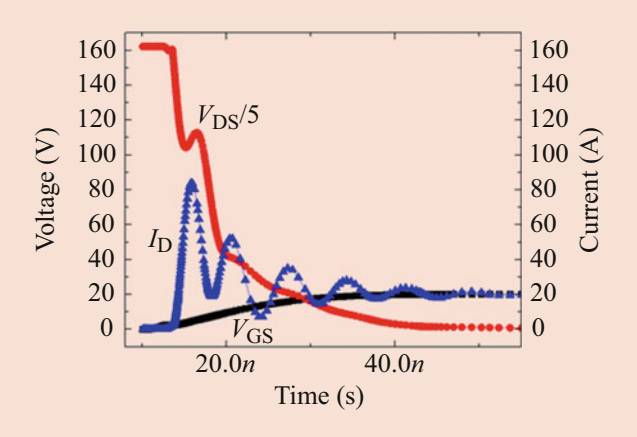

Fig. 15.29 Simulated turn-on switching waveforms of the cascoded CAVET. (© 2016 IEEE. Reprinted, with permission, from D. Ji et al. [64])

Third, when V_{SG_CAVET} reaches the threshold voltage of GaN CAVET, CAVET channel current increases, and this current start discharging the GaN CAVET drain to source capacitor C_{DS_CAVET} and GaN CAVET gate to drain capacitor C_{GD_CAVET}, reducing V_{DS_CAVET} further.

From the waveforms shown in Fig. 15.29, the turn-on delay time $T_{on\text{-}delay}$ is 2 ns, and rise time T_r is 16 ns, showing

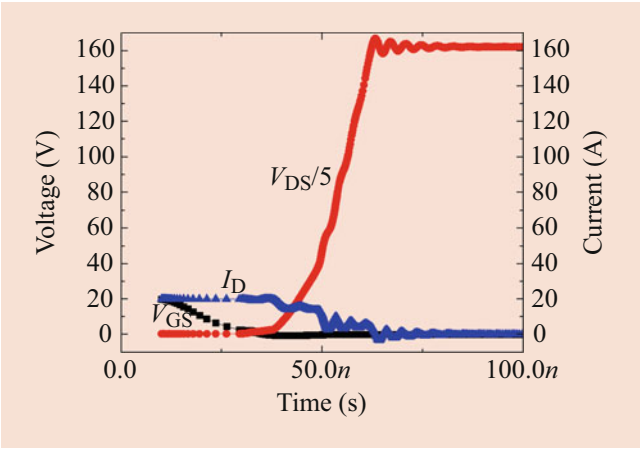

Fig. 15.30 Simulated turn-off switching waveforms of the cascoded CAVET. (© 2016 IEEE. Reprinted, with permission, from D. Ji et al. [64])

a turn-on $\Delta v/\Delta t$ of 40 kV/μs. The total gate charge of the CAVET is 88 nC.

The turn-off switching waveforms are shown in Fig. 15.30. Similar to the turn-on transient, the turn-off phenomenon can be subdivided into three stages.

First, when the applied MOSFET V_{GS} changes from on to off state (from 10 V to 0 V), the Si MOSFET gate to source capacitor C_{GS_MOS} is discharged and as a consequence, Si MOSFET channel current decreases, which is smaller than the operation current (output current in current source), and the excess current charges the MOSFET drain to source capacitor C_{DS_MOS}, increasing V_{DS_MOS}. Since the GaN CAVET source to gate capacitor C_{SG_CAVET} is in parallel with C_{DS_MOS}, the voltage V_{SG_CAVET} also increases.

Next, when V_{SG_CAVET} increases, the channel current in CAVET decreases, as a result, the channel current is smaller than the output current. The excess current starts charging CAVET drain to source capacitor C_{DS_CAVET} and gate to drain capacitor C_{GD_CAVET}, as a result, V_{DS_CAVET} increases.

When V_{SG_CAVET} reaches a value smaller than the threshold voltage of CAVET, the channel is completely pinched off, and the remaining gate current continues to charge the capacitors: C_{GD_MOS}, C_{DS_MOS}, C_{GD_CAVET}, and C_{DS_CAVET}, further raising the V_{DS_MOS} and V_{DS_CAVET}.

From the waveforms of Fig. 15.30, the turn-off delay time $T_{off\text{-}delay}$ is 29.5 ns, and fall time T_f is 18 ns, giving a turn-off $\Delta v/\Delta t = 35.6$ kV/μs.

Table 15.4 shows the comparison of CREE SiC MOSFET (CREE Inc.), simulated SiC MOSFET, and simulated cascoded CAVET with the same voltage and current rating. The switching performance agreement between CREE and simulated SiC MOSFETs provides the competency of the model. When compared to standard SiC MOSFET, cascoded CAVET has faster switching time, and lower switching loss, hence enabling higher frequency operation.

Table 15.4 Switching performance comparison of SiC MOSFET and GaN CAVET

15.3.3 A Review of CAVET

CAVETs are vertical GaN vertical devices that take full advantage of the polarization-based two-dimensional electron gas (2DEG) in its design. Comprised of a 2DEG induced channel to carry the current, a CAVET needs a thick homoepitaxially grown drift region to hold the blocking voltage. There have been two types of approach in fabricating CAVETs: (1) planar CAVET and (2) trench CAVET. The planar CAVET has an AlGaN/GaN 2DEG channel in the c-plane, which has high electron density and high mobility. The trench CAVET adopts the semi-polar plane as the channel, the density of the electrons depends on the slope of trench sidewalls.

The first GaN CAVET based on a sapphire substrate was developed in 2004 [69]. The device structure began with a p-GaN/n-GaN/*n*+GaN epilayers. An aperture region was etched and an AlGaN/GaN HEMT structure was regrown by MOCVD to refill the aperture region and served as the channel as well. The design of the first GaN CAVET was for radio frequency (RF) applications. Several years later in 2008, the first power GaN CAVET based on bulk GaN substrate was reported with the CBL formed by Mg-ion implantation [70]. The device process began with the MOCVD grown *n*-GaN on conductive bulk GaN substrate; then, the selective area Mg-ion-implantation was implemented to form the CBL to block current from the aperture region other than any other paths. The top AlGaN/GaN structure was regrown by MBE. The first high-voltage CAVET with switching characteristics was demonstrated by Chowdhury et al. with a 300 V breakdown voltage and a $R_{on,sp}$ of 2.2 mΩ•cm^2 [71]. A significant progress in the device development was realized with the demonstration of 1.5 kV JFET (a variant of CAVET) on bulk substrate by H. Nie et al. in 2014 from Avogy Inc. [72].

15.3.4 Operation Principle of the CAVET

A CAVET is a unique design where the best properties that GaN offers are best utilized. Polarization doping is one of these properties which is leveraged in a CAVET design. Due to the positive polarization charge locates at the AlGaN/GaN interface, a triangular quantum well is formed, and electrons are attracted (shown in Fig. 15.31). The high-density electrons are confined in the triangular quantum well, forming the 2DEG. Under a zero-gate bias, the channel is conductive due to the 2DEG, the device is in the on-state. During on-state of the CAVET, the electrons from the source go through the 2DEG channel, the aperture and the drift region and are finally collected by the drain electrode. The overlap between the gate electrode and the CBL is the effective gate length that offers channel modulation.

Like in a HEMT, in order to pinch off the 2DEG channel in a CAVET, a negative gate bias is required. At the off-state, the electrons in the channel are depleted by the gate potential. The p-n junction formed by p-type (or Mg-implanted) CBL and drift region blocks the off-state voltages. Figure 15.29 shows the schematic of a planar CAVET where the CBL (shown as p-GaN) is formed using an ion implantation process of GaN with Mg ions. During the on-state, the voltage applied between the source and the drain drops across the channel. The design must ensure that the aperture is more conductive than the channel. Under the off-state, the depletion region is extended into the drift layer to sustain the drain to source voltage. Besides forcing the current flow through the aperture and blocking any parasitic current flow from drain to source, the CBL also needs to be conductive enough to prevent charge trapping which may lead to current collapse. From our experiments [73, 74], we found that CAVETs with Al-implanted CBL was dispersive, whereas CAVETs with Mg-implanted CBL were dispersionless. CAVETs with ion-implanted CBL require regrowth of AlGaN/GaN channel. The regrown channel and the aperture

are grown on the planar surface where CBL is formed by ion implantation. One significant challenge in the ion-implanted process was the out-diffusion of Mg from the CBL to the regrown layers causing the channel to get totally wiped off. Although several tactics were employed, one of those being using a thin AlN diffusion-stopper layer [73, 74], the most successful technique was achieved through the regrowth of the channel through a lower temperature MBE regrowth that led to the successful CAVETs. In an alternative approach MOCVD grown p-type layers were used to form the CBL. This is the basic building block for a Trench CAVET which is discussed next.

15.3.5 Trench CAVET

The conventional GaN CAVET typically uses Mg-implanted p-GaN for the CBL. A major fabrication challenge is posed by Mg out-diffusion during the regrowth process. First, the channel resistance can go very high due to the diffusion of Mg species into the channel, thereby depleting 2DEG. To prevent the diffusion of Mg into the regrown channel the regrowth temperature of the channel in a CAVET is restricted, making it rely on low-temperature growth processes. Low-temperature MOCVD regrowth process does not typically result into a high-quality material. MBE regrowth although has proven to be successful in arresting Mg diffusion, there are concerns on the formation of vertical highly conductive paths under metal-rich growth conduction, causing shorts in the device. An MBE-regrown channel requires exposure of the sample to the atmosphere for prolonged interval, and process limitations make it challenging to remove environmental contaminants from the regrowth interface. Low-temperature flow modulation epitaxy by MOCVD may be considered an alternative, but it is not yet understood whether the material quality produced in such a fashion that can support high-current and high-voltage devices.

A solution to the aforementioned problem was proposed by introducing a trench gate structure into the conventional CAVET, as shown in Fig. 15.32 [75, 76]. Instead of using Mg-implanted p-GaN for the CBL, the trench CAVET adopts MOCVD-grown Mg-doped p-GaN as the CBL material. The trench CAVET utilizes the regrown AlGaN/GaN on the trench sidewall as the channel. The trench sidewall angle determines the polarization scale of the channel: a 90-degree angle indicates a non-polar plane, and a 45-degree angle indicates a semi-polar plane. The threshold voltage in a trench CAVET can be adjusted by the trench sidewall angle. The functioning of a trench CAVET is similar to a trench MOSFET, except for the AlGaN/GaN channel. In a conventional trench MOSFET, the channel is formed by inversion layer between the oxide and the p-type semiconductor. The electron mobility in the inversion layer is typically below

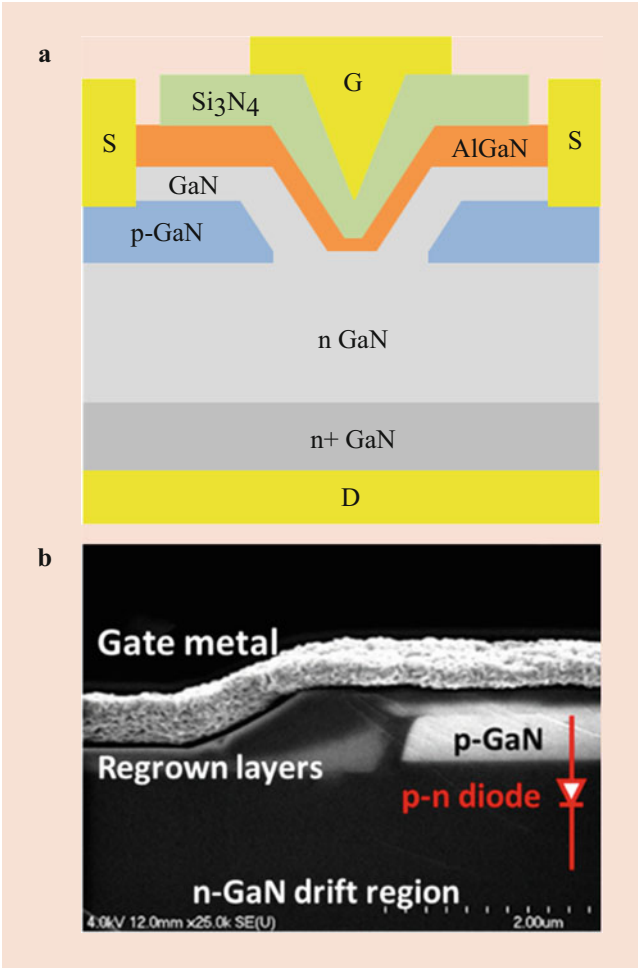

Fig. 15.32 (**a**) Schematic illustrations of the trench CAVET. (**b**) SEM image showing a buried p-n junction which blocking voltage in the off-state. (© 2017 IEEE. Reprinted, with permission, from D. Ji et al. [75])

50 cm^2/Vs, limited by the interface roughness scattering. However, in a trench CAVET, the channel is formed by the 2DEG, which takes the advantage of the high mobility in the HEMT structure. Ideally, the channel mobility in a trench CAVET can be as high as 1690 cm^2/Vs [77].

In GaN, a robust oxide technology is not available yet. However, thanks to the development of GaN HEMT in the last decade, the in situ grown Si_3N_4 on AlGaN/GaN structure has low interface traps, which is essential to the device reliability. A trench CAVET takes the advantage of the matured HEMT gate dielectric technology to suppress gate leakage.

The first metal-insulator-semiconductor (MIS) gate trench CAVET was reported by Ji et al. in 2016 on bulk GaN substrates [75]. The device had a breakdown voltage of 225 V limited by the gate-to-drain breakdown. By using a thicker gate dielectric layer and a low damage RIE trench etch, a high breakdown voltage of 880 V was obtained in 2018 [76]. A low hysteresis of ~0.1 V was achieved by using high-quality in situ Si_3N_4 gate dielectric (Figs. 15.33, 15.34, and 15.35).

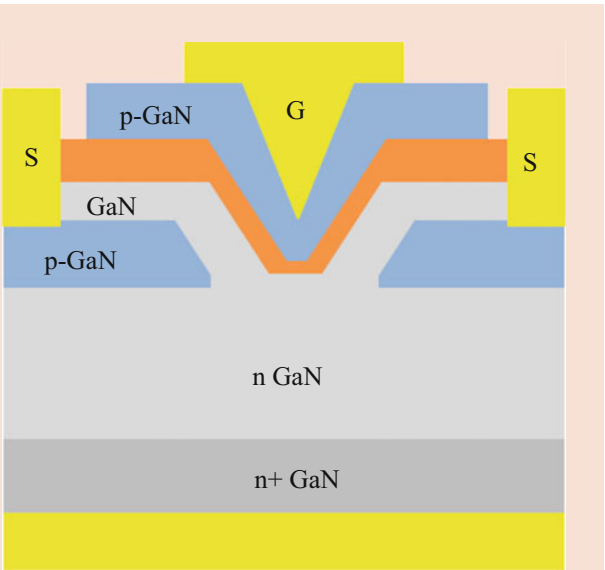

Fig. 15.36 Trench CAVET with a p-GaN gate layer [77]

The p-GaN gate structure is widely used in normally-off lateral GaN HEMTs. Due to the high electron density of 2DEG induced by the polarization charge, the threshold voltage of p-GaN gated HEMT is typically less than 2 V. However, a more positive threshold voltage can be realized in a p-GaN gated trench CAVET with the channel formed at the semi-polar plane. This was first demonstrated by Shibata et al. in 2016 [77]. Based on a p-n epitaxial structure on bulk GaN substrate, a "V"-shaped trench was formed using inductively coupled plasma (ICP) etching, the p-GaN/AlGaN/GaN triple layers were regrown over the trench by MOCVD. Because the channel locates at the semi-polar plane instead of the c-plane, the threshold voltage shifted toward the positive side by 1.5 V. A high positive threshold voltage of 2.5 V was demonstrated with 1700 V blocking capability on a 13 μm-thick drift region offering a low specific on-resistance of 1 mΩ·cm^2 (Fig. 15.36).

15.3.6 Vertical MOSFETs

Vertical GaN MOSFETs are the other branch of devices, showing a promising performance by offering a normally-off solution, thereby overcoming a significant drawback of any GaN HEMT-based design.

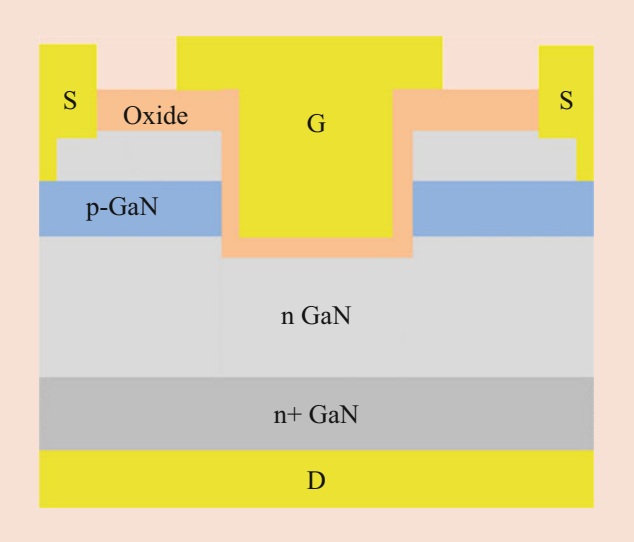

Fig. 15.37 Structure of GaN MOSFET

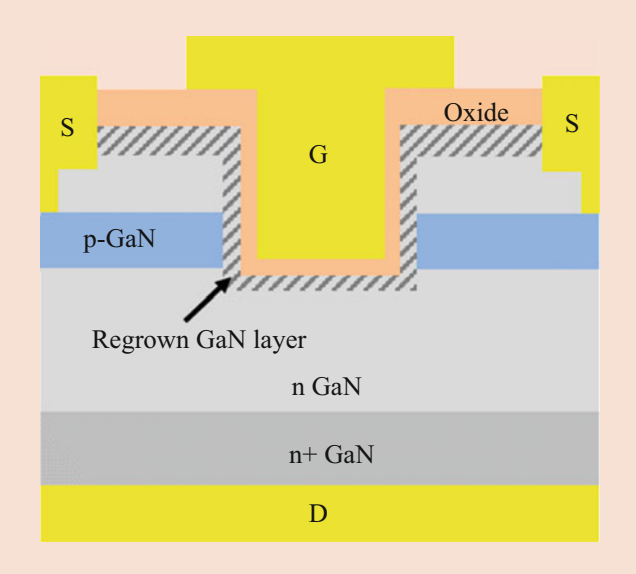

Fig. 15.38 Structure of GaN OGFET. (© 2018 IEEE. Reprinted, with permission, from D. Ji et al. [168])

There are two types of MOSFET reported so far (1) non-regrowth-based MOSFET and (2) regrowth-based MOSFET (OGFET). In this section, both devices will be introduced.

Since the development of dry etch technology in the early 1990s, the trench MOSFET has been a dominant device structure for power electronics. To date, both Si- and SiC-based trench MOSFET have been commercialized and shown excellent performance. However, because of the absence of bulk GaN substrate, the GaN-based trench MOSFET was not available until 2004–2005. In 2007, the first GaN MOSFET was reported by Otake et al. [78], the device has a high threshold voltage of 5.1 V. After 7 years of intense research, a 1.6 kV device was developed by Oka et al. in 2014 [79].

Figure 15.37 shows the structure of a vertical GaN MOSFET. A key feature of these devices, the p-n junction between source and drain is formed by p-base and n-drift regions. The device breakdown voltage is determined by the reverse characteristics of the main p-n junction. A n+ source region is created partially on top of the p-base region, while the junction between the n+ source region and the p-base region is connected to the source contact to improve the breakdown voltage by eliminating the n-p-n open base effect. The channel located at the etched sidewall is formed by the inversion layer of the MOS structure.

Compared to the CAVET structure, there are two basic advantages of the MOSFET: (1) the MOSFET is a reliable normally-off device with a high threshold voltage over 2 V; (2) regrowth can be avoided which makes the process less challenging, reducing the cost and turnaround time. Such advantages of the MOSFET make it an attractive design for vertical GaN transistors. However, for GaN MOSFET, the biggest challenge lies in the channel electron mobility of the device. During on-state, the electrons flow through the inversion layer of the sidewall MOS structure, the channel electron mobility is limited by the surface roughness and impurity scattering. Another issue along with the poor channel property is the device reliability. The GaN MOSFET cannot be widely recognized without a strong reliability.

15.3.7 Regrowth-Based Vertical MOSFET (OGFET)

GaN OGFET is a modified structure based on the conventional trench MOSFET. Compared to the conventional trench MOSFET, the OGFET has two features: (1) an unintentional doped (UID) GaN interlayer is used as the channel region, which enhances the channel electron mobility to reduce the Coulomb scattering by the dopants; (2) the oxide is in situ grown by MOCVD, which reduces the interface states and improves the gate oxide reliability. The novelty of the OGFET is enhancing the channel electron mobility without scarifying the normally-off behavior.

The working principle of the OGFET is similar to the MOSFET. Under a zero V_{GS}, the electrons in the GaN interlayer (shaded region in Fig. 15.38) are depleted by the p-GaN base region making the OGFET go to its off-state. The energy band diagram and the simulated electron contour are shown in Fig. 15.39. The p-n diode formed by the p-GaN base region and the n-GaN drift region is used to hold the high off-state blocking voltage. The electric field distribution along the p-GaN base region and the n-GaN drift region is shown in Fig. 15.40.

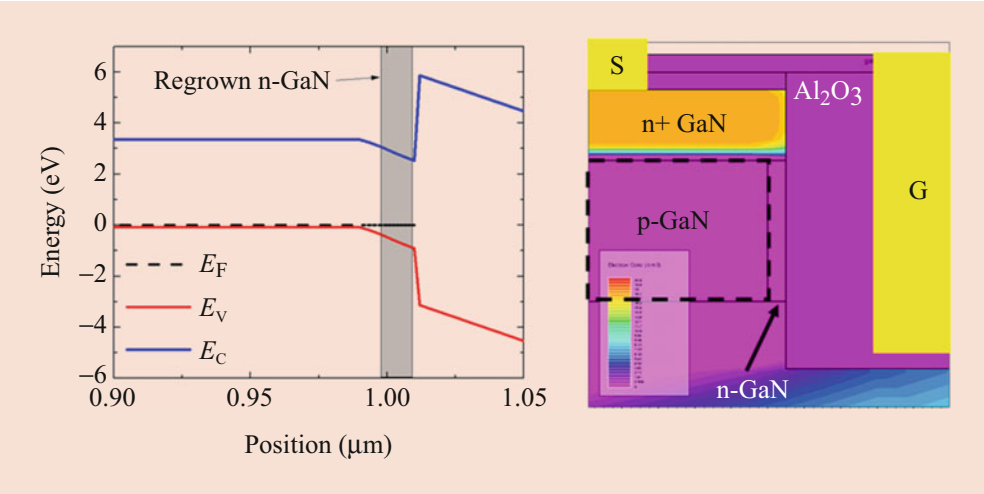

Fig. 15.39 Energy band diagram and the electron distribution of the OGFET in off-state

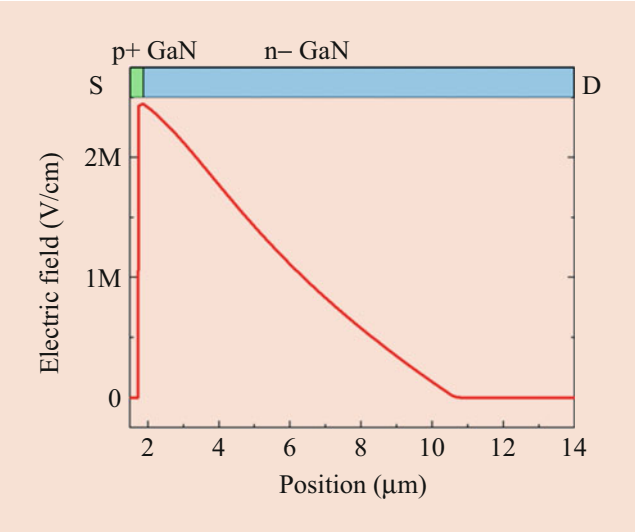

Fig. 15.40 Electric field distribution along the drift region

Under a positive V_{GS} > threshold, electrons are accumulated in the UID GaN insert layer, and the transistor is in its on-state. The energy band diagram and the electron concentration is shown in Fig. 15.41. Because of the enhanced channel electron mobility, the OGFET has smaller $R_{on,sp}$ compared to the conventional trench MOSFET.

In 2016, Gupta et al. reported the first OGFET results based on the sapphire substrates, the device showed a 60% $R_{on,sp}$ reduction while maintaining the threshold voltage >2 V [80]. In 2017, Gupta et al. demonstrated an OGFET on bulk GaN substrates with a breakdown voltage of 990 V and a low $R_{on,sp}$ of 2.6 mΩ·cm^2 [81]. In the same year, *Ji* et al. demonstrated a high-performance OGFET with a breakdown voltage over 1.43 kV with a low $R_{on,sp}$ of 2.2 mΩ·cm^2 [82]. The *I-V* characteristics of the fabricated OGFET are shown in Fig. 15.26. Figure 15.27 shows the transfer I_D-V_{GS} characteristics and the gate leakage. The threshold voltage, V_{TH}, defined at a current level of 10^{-4} A/cm^2 ($I_{on}/I_{off} = 10^6$), obtained was 4.7 V (when V_{GS} sweeps up). A clockwise hysteresis of ΔV_{TH} of 0.3 V was observed. Low sub-threshold slope of 283 mV/decade was measured from $I_D = 10^{-5}$ A/cm^2 to 10^{-2} A/cm^2. The off-state characteristics of the fabricated devices are shown in Fig. 15.42 (Figs. 15.43 and 15.44).

15.3.8 Static Induction Transistor

Static induction transistor is another form of vertical devices, in which current flows vertically through a short channel as shown in Fig. 15.45 [83, 84]. From the equivalent circuit, the overall transconductance, G'_m, is described by intrinsic transconductance, G_m, and series channel resistance, r_s, to be $G'_m = G_m/(1 + r_s \cdot G_m)$. The small distance between gate and source induces $r_s \rightarrow 0$, so that $G'_m \rightarrow G_m$. Consequently, SIT shows a triode-like non-saturating output property, not following square-law behavior shown in the pentode-like FET, which has $r_s \cdot G_m \gg 1$, leading to $G'_m \rightarrow 1/r_s$. The drain current is controlled by electrostatically induced potential energy barrier, that is why the transistor is named, depending on the gate and drain bias. With no gate bias, the drain current is simply defined by the effective cross-sessional area of the channel (A_{eff}), which is related to the depletion width formed at the junctions, so that $I_d = qA_{eff}\, v_d\, N_d$, where q is electron charge, v_d is electron velocity, and N_d is electron density. As applying more negative gate bias, the depletion width increases further and merges at pinch-off, developing the electrostatic barrier in the channel. The minimum barrier height (Φ_0), saddle point, now depends on the drain bias through the drain induced barrier lowering (DIBL) as shown

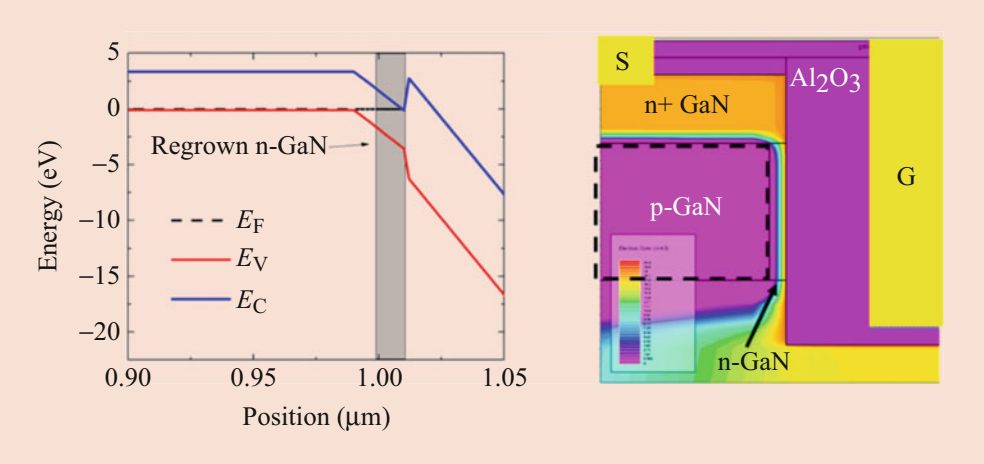

Fig. 15.41 Energy band diagram and the electron distribution of the OGFET in on-state

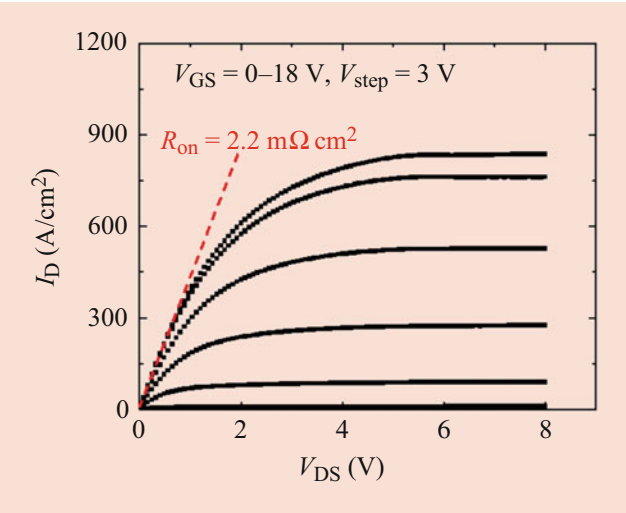

Fig. 15.42 I-V characteristics of fabricated OGFET with saturation current density of 850 A/cm^2 and $R_{on,sp}$ of 2.2 mΩ·cm^2. (© 2017 IEEE. Reprinted, with permission, from D. Ji et al. [82])

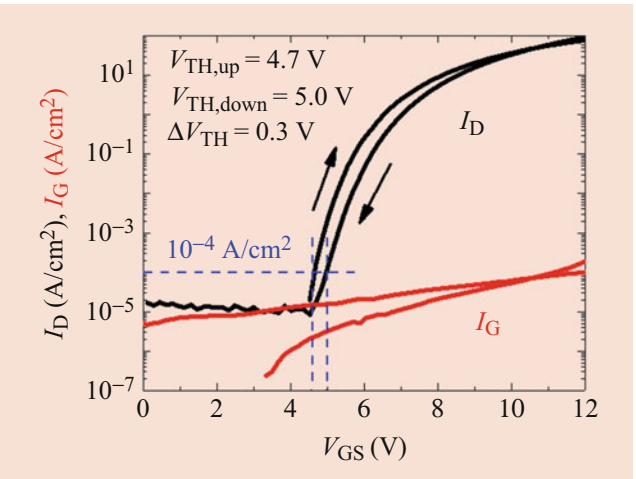

Fig. 15.43 Transfer characteristics of the fabricated OGFET (black curves) and gate leakage (red curves). The threshold voltages of sweep up and down were 4.7 V and 5 V (defined at a current level of 10^{-4} A/cm^2). The sub-threshold slope was 283 mV/decade measured from 10^{-5} A/cm^2 to 10^{-2} A/cm^2. (© 2017 IEEE. Reprinted, with permission, from D. Ji et al. [82])

in Fig. 15.46, governing the electron flow in a manner of thermionic emission, so I_d can be described as,

$$I_d = I_0 \exp\left\{\frac{q}{kT}(\Phi_0 - \alpha V_d)\right\}, \tag{15.20}$$

where α is DIBL coefficient. As increasing drain bias, space charge limited conduction is dominant in the current flow, and the electron velocity becomes saturated. Under high gate and drain bias, the current can be modified as

$$I_d = 2A_{eff}\varepsilon_s v_{sat}\frac{V_d}{L^2}, \tag{15.21}$$

where ε_s is permittivity, v_{sat} is saturation velocity, and L is channel length. This linear relationship between I_d and V_d together with small channel resistance provide benefits to power devices.

The SIT design has been developed from buried-gate to recessed-gate structures using various materials such as SiC and GaN [85–88]. Figure 15.47 presents the output and transfer characteristic of the GaN SIT. By using a Schottky junction, the SIT was fabricated without any p-type GaN or gate dielectrics, which involve difficulty in the activation and reliability. The current density and on-resistance are estimated to be 0.65 kA cm^{-2} and 1.48 mΩcm^2. It is also shown the off current increase as applying larger V_d because

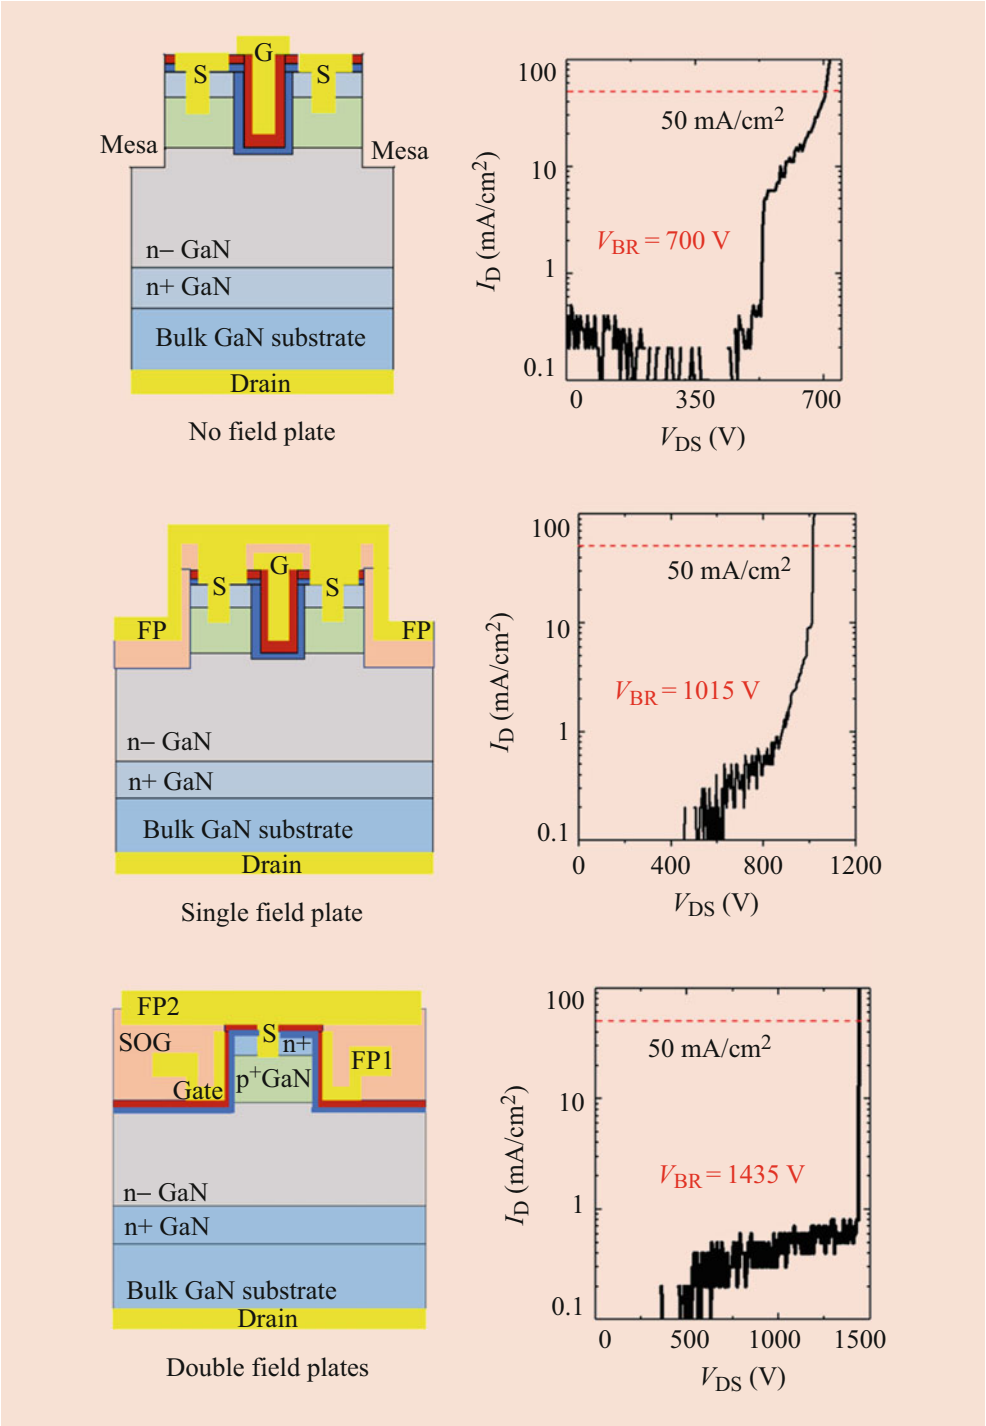

Fig. 15.44 Off-state characteristics of the fabricated OGFETs with no field plate (mesa etch only), single field plate, and double field plates. With the help of the double-field-plate structure, a 1.4 kV breakdown voltage was achieved [82]. (© 2017 IEEE. Reprinted, with permission, from D. Ji et al. [82])

the potential barrier height becomes lower, allowing the thermionic electrons to pass through the barrier.

SITs in GaN form a useful set of devices where without any p-type layers or any gate oxide, one can realize a transistor.

15.3.9 Conclusions on GaN Vertical Transistors

In this chapter, we have discussed the importance of TCAD models in GaN. We went through the details of setting up a model that gives us a scope to study devices inside a

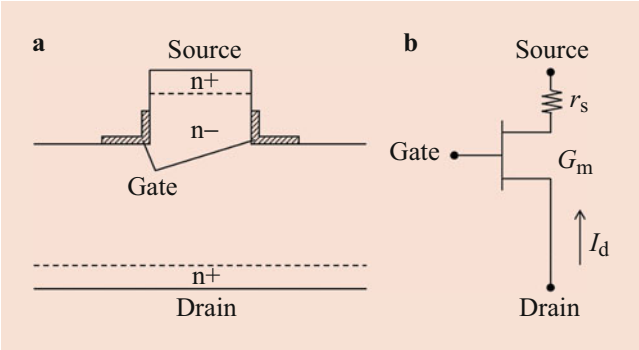

Fig. 15.45 (**a**) Schematic cross-section of static induction transistor and (**b**) its equivalent circuit

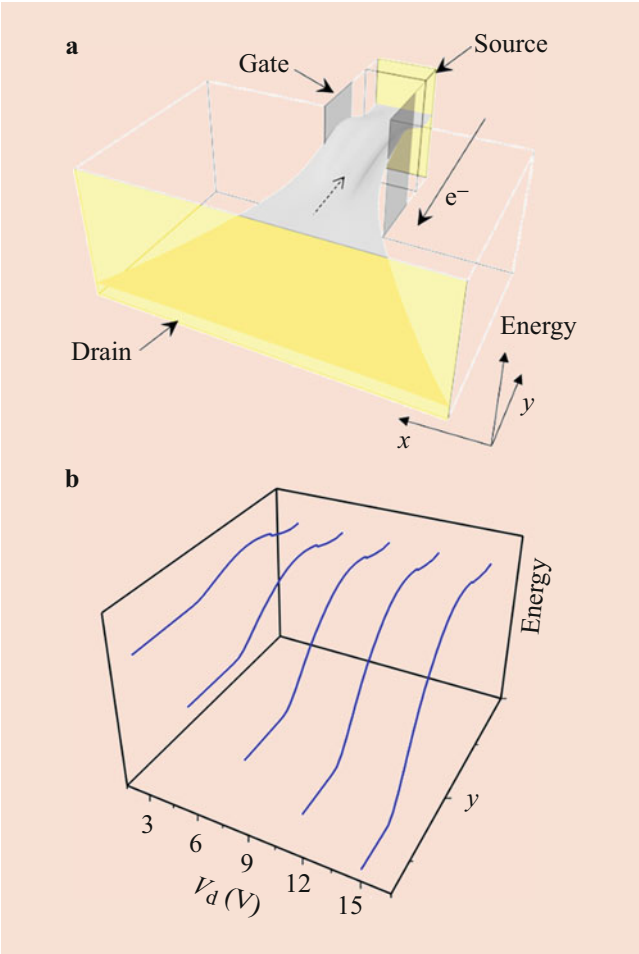

Fig. 15.46 (**a**) Schematic diagram of potential distribution in SIT. (**b**) Dependence of the minimum barrier height, which is pointed by a dashed arrow in (**a**), on the drain bias

power converter application. We went through the operation principles of three important variations of vertical devices possible in GaN. CAVET, MOSFET, and SITs, discussed in this chapter, come with their unique advantages and limitations. In terms of their applications, all three flavors of vertical device would play a significant role. In our view, a SIT is suited for 200–600 V application, a CAVET is best suited for operations up to 900 V and above 900 V, v-MOSFETs are the best candidates. Besides playing a role as a potential power electronic switch, SITs can be used for RF amplification application, making it quite versatile.

15.4 Parasitics and Reliability

In this section, we discuss the main parasitic mechanisms that limit the performance of GaN-based devices, with a specific focus on charge trapping. In addition, we describe the most relevant degradation processes and their impact on device characteristics and lifetime.

15.4.1 Charge-Trapping in GaN-Based Power HEMTs

GaN power devices have unique properties compared to conventional silicon transistors. Specifically, GaN transistors take advantage of the high mobility of the 2-dimensional electron gas and have a very low on-resistance. As an example, commercially available devices can have an on-resistance of 25 mΩ for a 60 A transistors, see [89]. In addition, the breakdown field of GaN (3.3 MV/cm) is more than 10 times higher than that of silicon, and this enables high voltage operation [90]; kV-range devices have already been demonstrated, thus clearing the way for 1200 V GaN-based technology [91]. Finally, GaN is a wide-bandgap semiconductor ($E_g = 3.4$ eV), and for this reason devices based on GaN can be operated at high temperatures (functional operation was demonstrated up to 900 °C, see [92] for details). The fact that GaN can operate at such high temperatures and electric fields may pose significant limitations in terms of trapping and reliability. In this section, we will focus mostly on charge trapping processes, which may limit the dynamic performance of the devices.

In absence of defects, the two-dimensional electron gas of a HEMT should always have a high mobility; unfortunately, when GaN devices are fabricated, point and extended defects are inevitably incorporated in the material.

Defects in GaN may be intrinsic or extrinsic: intrinsic defects include vacancies, self-interstitials and antisites, and their presence is strongly influenced by the growth conditions. Extrinsic defects originate from impurities introduced by growth (such as carbon, hydrogen, oxygen), dopants (such as magnesium, silicon, carbon), or external contaminants. Surface defects can also play a role, especially at interfaces, in presence of a non-optimized passivation.

Several papers have been published on defects in GaN: a comprehensive list of relevant references in this field can be

found in [93]. Here we list the most common defects, along with some key publications on the topic.

- Nitrogen vacancies have been identified and studied in several GaN-based devices, with relatively shallow activation energy, in the upper half of the bandgap (E_C – 0.09 eV/E_C – 0.27 eV) [94–97].
- Mg-related acceptors are typically located 0.16–0.20 eV above the valence band and may be present both in GaN-based optoelectronic devices and in normally-off transistors with p-GaN gate [98].
- Nitrogen antisite defects have been detected in GaN samples and devices in the energy range between E_C – 0.5 eV and E_C – 0.62 eV [96, 99–103].
- Iron and iron-related defects have been investigated by Silvestri et al. and detected at E_C – 0.72 eV [104, 105].
- Gallium vacancies (that have been correlated to the presence of yellow luminescence in GaN, see [106] and references therein) typically have activation energies in the range E_V + 0.85/E_V + 0.94 eV (see [107, 108]).
- Substitutional carbon (or carbon at nitrogen site, C_N) has been also indicated as a source for yellow luminescence in GaN [109]. C_N is typically located at E_V + 0.9 eV and plays an important role in determining the electrical properties of GaN-based transistors [110].

Dislocations have been found to significantly impact on the density and concentration of deep levels in GaN-based materials and devices; recent papers have described the activation energy of defects whose concentration increases with dislocation density (see for instance [95, 111, 112]).

In a GaN power HEMT, traps may be present at several locations within the device structure and several mechanisms may lead to charge trapping. With reference to Fig. 15.48, we discuss briefly the following processes:

1. The trapping of charge in the gate stack (mechanism 1 in Fig. 15.48); this process results in a shift of threshold voltage, whose sign depends on the type of trapped carrier. Trapping of electrons induces a positive threshold voltage shift and may be particularly severe for metal-insulator-semiconductor (MIS) structures, as discussed in several recent reports (see, for instance, [113–117]). In the case of MIS structures, electrons can be trapped at high positive gate bias, being injected at the dielectric/semiconductor interface, or in the dielectric itself [116]. GaN power transistors with a p-GaN gate may also suffer from hole trapping, that leads to a negative threshold voltage shift when the devices are submitted to positive gate stress [90, 118].
2. The trapping of hot-electrons within the AlGaN barrier or in the GaN channel/buffer layers (mechanism 2 in Fig. 15.48). This process can impact the on-resistance of the devices and worsens the performance of the transistors [119, 120].
3. The ionization of buffer traps; this process is prevalent when the devices are in the off-state, and the buffer is significantly depleted (mechanism 3 in Fig. 15.48). Ionization of buffer traps can be promoted by the injection from the silicon-substrate [10, 110, 121].
4. The injection of electrons at surface states located in the access regions (mechanism 4 in Fig. 15.48), with consequent increase in the resistivity of the access regions [122]. This effect can be mitigated through the optimization of the surface treatments and passivation.

15.4.2 Methods to Investigate Charge-Trapping Phenomena

In power devices, the gate-drain spacing is much longer than the gate length and the gate-source spacing. Trapping in the gate-drain access region can significantly lower the on-resistance of the devices, leading to the so-called dynamic-R_{on} issue. Trapping under the gate may lead to positive- or negative-threshold bias instabilities (PBTI or NBTI). The de-trapping time-constants of known traps in GaN are in the range between 1 μs and 100–1000 s, depending on the temperature and activation energy [93]. As a consequence, a careful optimization of the material and interface properties is needed in order to ensure than power GaN HEMTs can reach operating frequencies in the range 100 kHz–10 MHz, needed for the applications [123, 124].

Several techniques have been proposed for the investigation of trap properties in GaN-based transistors. We discuss here one of the most commonly adopted, the drain-current transient (DCT) spectroscopy, which is quite similar to current deep-level transient spectroscopy (I-DLTS). A typical schematic of the measurement setup is reported in Fig. 15.49, as presented by Bisi et al. in [125]. The gate and the drain are driven by two independent pulse generators, whose output is amplified by two power amplifiers. The devices are biased through a resistive load (R_{sense} in Fig. 15.49); the drain-source voltage (V_{DS}) is measured through a voltage probe, while the drain current (I_{DS}) is measured through a high voltage differential probe. Both probes are connected to an oscilloscope, controlled by a computer. Such systems can be used both on device and on wafer level, for the dynamic characterization of the transistors up to 600–1200 V. Typically, transient measurements are carried out after a double-pulsed measurement has been performed, to evaluate the total increase in dynamic R_{on} induced by trapping. The measurement sequence for DCT is as follows: the devices are first kept in a trapping bias point (e.g., in the off-state, point

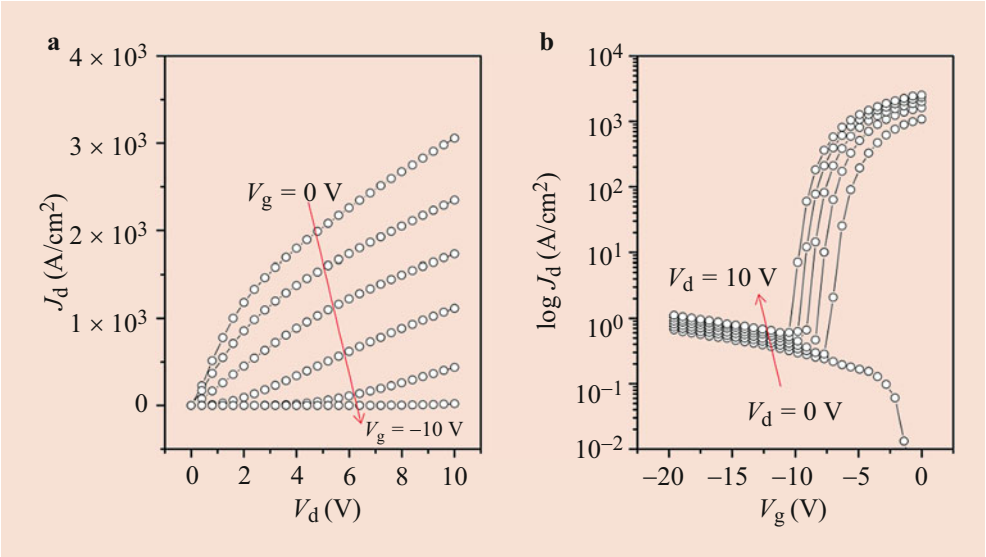

Fig. 15.47 (**a**) Output characteristic of the GaN SIT. The V_g was applied from 0 to −10 V in a step of −2 V. (**b**) Corresponding semilog transfer curve. The V_d biased from 0 to 10 V in 2 V steps

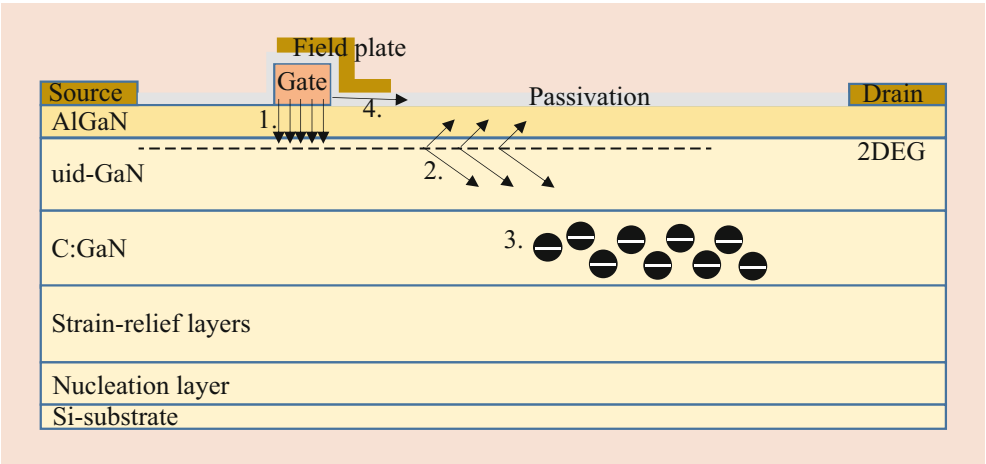

Fig. 15.48 Schematic representation of a GaN-based power HEMT, showing different possible locations for traps and trapping processes. (1) Trapping in the gate stack; (2) injection of hot-electrons in the barrier or in the buffer; (3) ionization of acceptors in the buffer; (4) injection of carriers at surface states

F in Fig. 15.49b), for a relatively long time (10–100 s). This ensures filling of all traps. Then, devices are turned-on, with the aim of reaching a bias point in the linear regime (point M in Fig. 15.49b). The evolution of the current transient during the turn-on phase is measured, and the changes in dynamic on-resistance are probed.

Figure 15.50 reports the results of double-pulsed measurements carried out on a GaN transistor; trapping was induced by exposing this device to off-state conditions. As can be noticed (Fig. 15.50a), increasing stress bias induced a significant increase in on-resistance. The physical properties of the traps responsible for the increase in dynamic-R_{on} were extrapolated by means of R_{on}-transient measurements (Fig. 15.50b). As can be noticed, right after turn-on the value of on-resistance is significantly higher than the reference value (at 100 s), and a gradual recovery transient is observed with increasing times from 1 μs to 100 s. Figure 15.50c reports the derivatives of the drain-current transients with respect to logarithmic time ($dR_{ON}/\log(t)$, DCT spectral plot). The position of the peaks of these curves are related to the time constant of the traps, while the peak height is related to trap density.

Plots like Fig. 15.50c give only a qualitative idea of the trapping and de-trapping processes and provide a visual representation of the mechanisms. A more quantitative investigation can be done by stretched- or multi-exponential

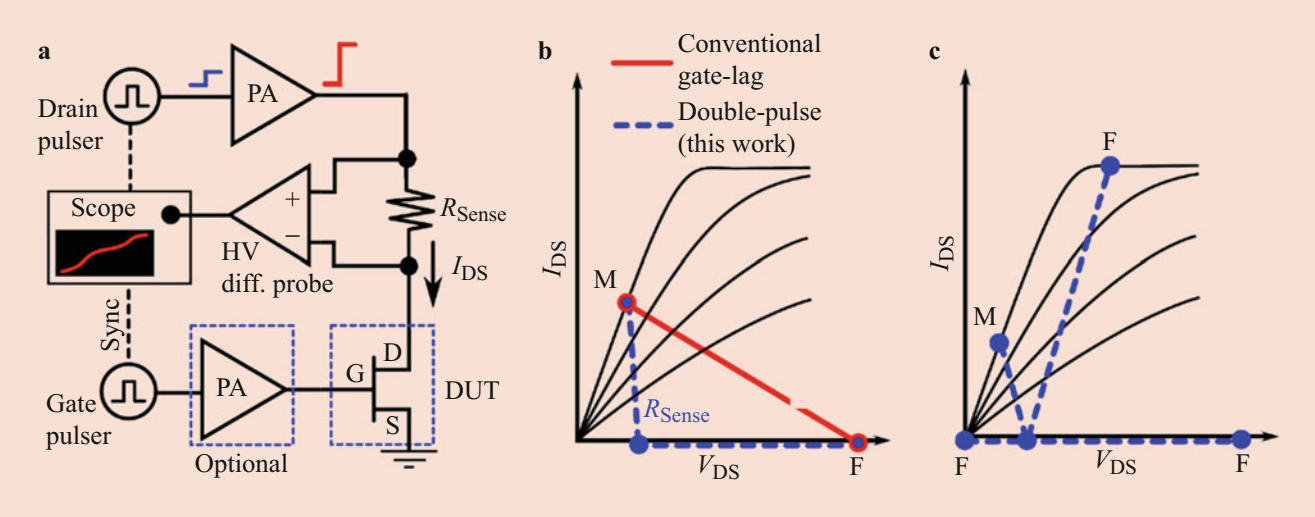

Fig. 15.49 (**a**) Conceptual schematic diagram of the proposed high-voltage double-pulsed system, including the low-voltage pulse generators, the high-speed power amplifiers, the high-voltage differential probe devoted to the current probing, and the oscilloscope. (**b**) Comparison between the conventional fixed-V_{DD} gate-lag technique and the proposed double-pulsed technique. The latter allows the releasing of the load-line constrains and the de-coupling of Filling/Measuring (F/M) bias-pairs. Reprinted, with permission, from [125])

fitting of the de-trapping transients, that permit to extrapolate the time-constants of the de-trapping processes [120]. In a recent paper [93], Bisi et al. presented a comprehensive comparison of three different methods for the extrapolation of time-constants from drain-current transients: (i) fitting of transients by polynomial function and subsequent extrapolation of τ from the peaks of the derivative curves $dR_{ON}/\log(t)$; (ii) the fitting of the current transients as the sum of 100 exponentials with fixed time constants and variable amplitudes; and (iii) the fitting by means of a stretched multi-exponential function

$$I_{DS}(t) = I_{DS,final} - \sum_{i}^{N} A_i e^{-\left(\frac{t}{\tau_i}\right)^{\beta_i}} \tag{15.22}$$

where the fitting parameters represent the amplitude of the individual exponentials (A_i) and the related time constant (τ) and stretching factors (β_i) [126]. The stretching factor is introduced to take into account the non-ideality of the de-trapping processes, that can deviate from pure exponential due to (a) the presence of multiple deep levels; (b) a high density of defect states, that leads to the creation of mini-bands [127, 128]; (c) the fact that transients originate from the presence of defect states in alloys, such as AlGaN, which lead to multiple defect signatures [129]; and (d) de-trapping can be governed by non-purely thermal processes, such as hopping or tunneling [130, 131]. All the three techniques described above can provide an estimate of the time constants and be used for the extrapolation of the Arrhenius plot of the traps. However, a recent paper [93] indicated that the time constants extrapolated by polynomial fitting and fixed-time constant exponential can be significantly different from those extrapolated by stretched exponential fitting, since several traps feature a non-purely exponential behavior. Care must be taken to identify, case by case, the most suitable technique for the study of the de-trapping transients and for the identification of the related time constants.

For GaN power devices, the de-trapping kinetics are investigated in the linear regime, i.e., with a low V_{DS} (e.g., 0.5–1 V). For this reason, the activation energy is not strongly influenced by Poole-Frenkel effects, i.e., by a field-assisted change in the de-trapping barrier. However, if de-trapping transients are measured in the saturation region, a higher field may be present, that can modify the de-trapping kinetics. For more information on the role of Poole-Frenkel phenomena one can refer to [132], that shows that in presence of electric field, the de-trapping barrier decreases by an amount $\Delta\phi_{PF}$, proportional to the square root of the electric field F according to

$$\Delta\phi_{PF} = \left(\frac{q^3}{\pi\varepsilon}\right)^{\frac{1}{2}}\sqrt{F} = \beta\sqrt{F} \tag{15.23}$$

As a consequence, the ionization energy (E_i) of a trap is modified with respect to the zero-field value $E_i(0)$ according to

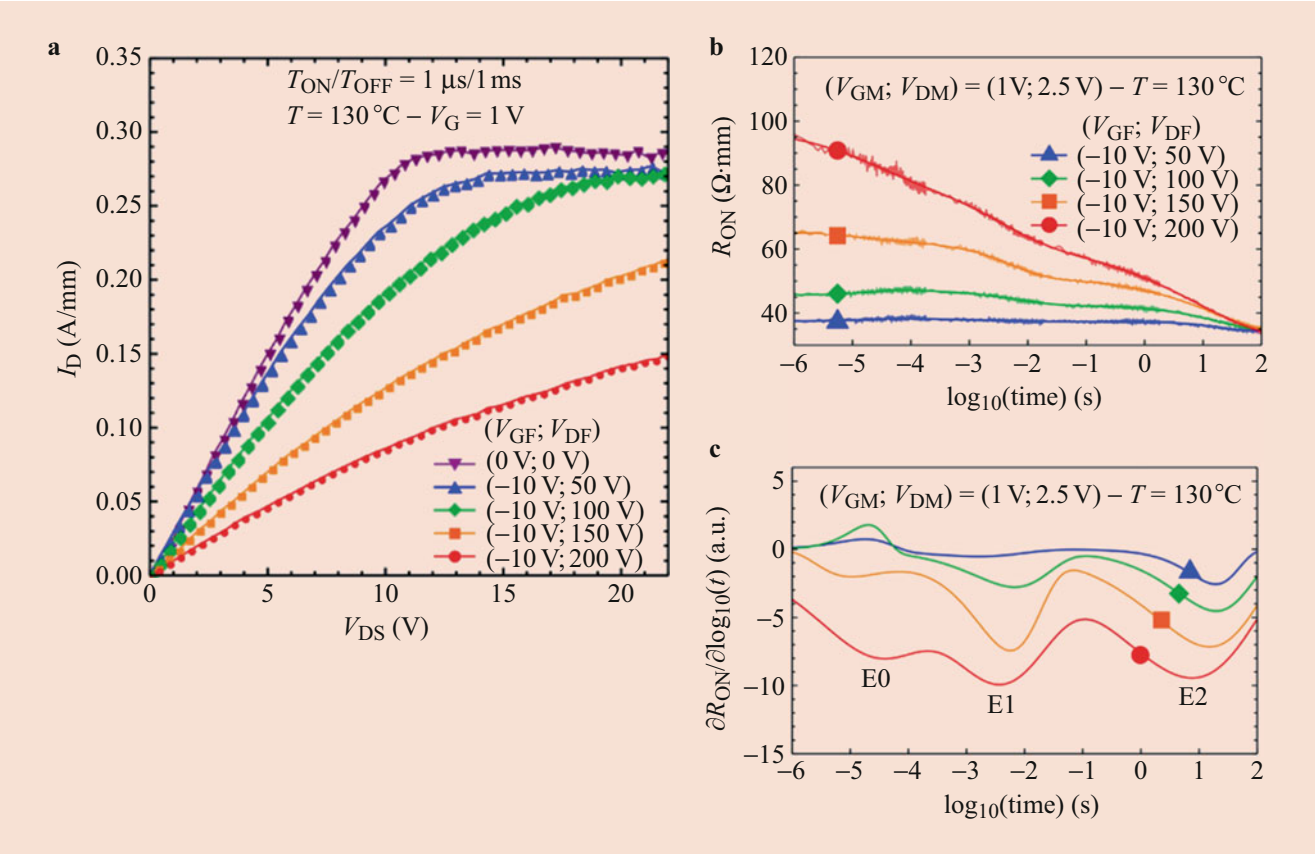

Fig. 15.50 (**a**) Double-pulsed I_D–V_D characterization with high-voltage off-state (V_{GF}; V_{DF}) quiescent-bias-points. As the quiescent drain-voltage is increased from 50 to 200 V, the device experiences a dramatic increase of the dynamic R_{ON}. (**b**) Time-resolved dynamic R_{ON} recovery transients, and (**c**) derivative of the stretched-exponential fit-functions, employed to extrapolate the three distinct deep-levels signatures. Three dominant charge (de)trapping process can be identified. As the filling drain-voltage is increased from 50 to 200 V, the increase of peak-amplitudes, ascribed to charge-trapping magnitude, can be observed. (© 2014 IEEE. Reprinted, with permission, from [125])

$$E_i(F) = E_i(0) - \beta\sqrt{F} \tag{15.24}$$

It is worth noticing that traps located in a 10^6 V/cm field region can have an activation energy 0.2–0.25 eV smaller than the zero-field energy (see [132] for details).

When analyzing the de-trapping transients, one should also consider the impact of self-heating effects on the extracted activation energy: Chini et al. [133] demonstrated that if devices have a significant self-heating during the de-trapping phase, this can lead to a wrong estimation of the activation energy. By calibrating the temperature data taking into account device self-heating, one can correct the Arrhenius plots and obtain a reliable estimation of the activation energy of the traps. This requires a careful estimation of the thermal resistance of the devices, which must be done on the very same wafer prober used for the DCT analysis. A reliable on-wafer technique for such estimation was proposed by Joh et al. in [134].

15.4.3 Performance and Characteristics of GaN Devices and Challenges

So far we have discussed about the typical traps present in AlGaN/GaN power devices, and about the methods to investigate these traps. Now we will focus on the performance and characteristics of GaN devices.

Figure 15.51 reports the dependence of on-resistance on the trapping voltage and temperature for a GaN (lateral) power HEMT. The used measurement conditions range between 0 V and 600 V (voltage) and between 30 °C and 150 °C (temperature), which are consistent with real-life operation. Dynamic R_{on} has a non-monotonic trend with off-state voltage, in the whole measurement range. An explanation for this behavior can be given based on previous papers [10, 126] and on Fig. 15.51b: at low trapping voltages (<200 V), the buffer (carbon-doped) is partly depleted, thus resulting in the accumulation of negative charge. This increases dynamic-

R_{on} with respect to the de-trapped conditions. In the buffer, the carbon acceptors have energy equal to $E_V + 0.9$ eV. At higher voltages, the increase in vertical (drain-substrate) leakage leads to a re-distribution of charge within the stack. Also, band-to-band conduction may lead to the storage of positive charges at the interface with the strain-relief layer (Fig. 15.51b). As a consequence, for voltages higher than 300 V a decrease in dynamic-R_{on} is observed (Fig. 15.51a). Remarkably, the value of dynamic-R_{on} after stress at 600 V is almost equal to the value under rest-condition, indicating that current technologies have a negligible dynamic-R_{on} increase at high voltage. The interplay between the increase and decrease in dynamic R_{on} can be affected by temperature, as shown in Fig. 15.51a.

From the discussion above, it is clear that there are two strategies to reduce the dynamic-R_{on} in high-voltage GaN transistors. A first approach is to minimize the influence of carbon doping on 2DEG concentration; this can be achieved through optimization of the level of C-doping and of the thickness of the undoped GaN. A second approach is the optimization of the leakage through the unintentionally doped GaN layer; this can favor the redistribution of charge through the structure, without increasing the vertical leakage current too much. Thanks to the continuous optimization of the growth and processing parameters, it is now possible to fabricate devices with zero dynamic-R_{on} both at room temperature and high temperature (see an example in Fig. 15.52, up to 600 V, 150 °C). In [126], drain current transient measurements were carried out to identify the properties of the traps responsible for dynamic-R_{on}. The authors commented that activation energies in the range 0.6–0.9 eV are typically ascribed to acceptors in GaN [135, 136]. It is worth noticing that lateral and vertical charge redistribution can take place during R_{on} measurements, thus slightly changing the activation energy of defects with respect to what expected from theoretical calculations (see details in [137]).

So far, we only discussed charge trapping mechanisms induced by the off-state field. During real-life operation, GaN transistor cross also another regime which is relevant in terms of trapping, the semi-on state. Typically, semi-on conditions are reached during the switching transient, e.g., when in a boost power converter the transistor is switched from off- to on-state. During this transition, there is a short interval during which a high drain voltage and a high drain current are simultaneously present. This leads to the presence of hot-electrons, which can favor charge trapping within the structure of the devices. One strategy for investigating the impact of hot-electrons in a hard switching event is to artificially create hard switching conditions by tuning the overlap between the drain and gate waveform. In [138], Rossetto et al. investigated the impact of soft- and hard-switching conditions on the dynamic-R_{on} of AlGaN/GaN power HEMTs. They used a custom setup that permits to modify the overlapping between drain and gate waveforms

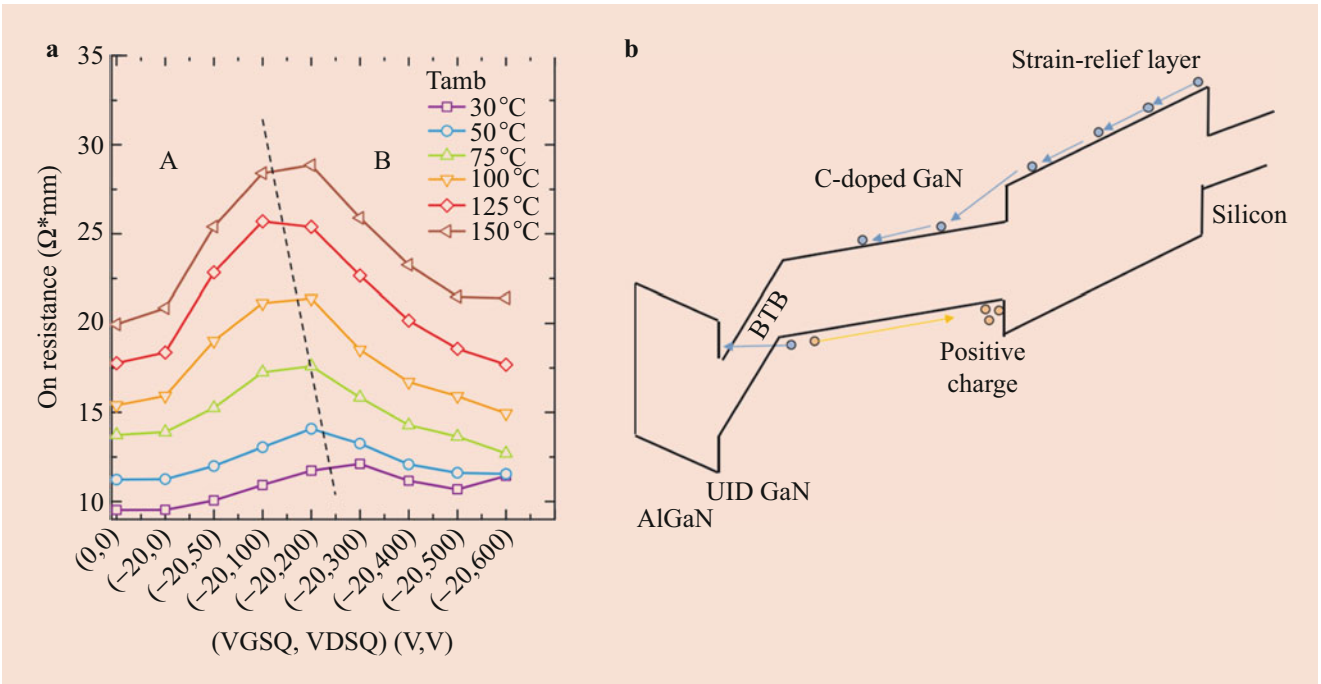

Fig. 15.51 (**a**) Dependence of dynamic-R_{on} (as measured from pulsed I-V measurements) on trapping voltage and temperature. (**b**) Schematic representation of the mechanisms responsible for non-monotonic dynamic-R_{on} as a function of trapping voltage. Fig. 15.53 (**a**) Dependence of dynamic-R_{on} on the trapping voltage V_{DSQ} and on the overlapping between the gate and drain waveforms. (**b**) EL patterns measured during soft and hard switching transitions. (Reused from [126], doi: https://doi.org/10.1016/j.mssp.2017.10.009, Creative Commons Attribution License (CC BY) http://creativecommons.org/licenses/by/4.0/)

used to induce charge trapping. The results of their study demonstrated that the investigated samples have a small dynamic-R_{on} up to V_{DS} = 600 V in soft switching. On the other hand, a significant increase in dynamic-R_{on} was observed in hard switching. A representation of this phenomenon is reported in Fig. 15.53a, which shows that the dynamic-R_{on} vs off-state voltage curves change as a function of the parameter DGD (drain-gate delay). This parameter represents the time interval between a drain voltage equal to V_{DSQ}/2 and a gate level equal to the threshold voltage V_{TH}. Therefore DGD is positive for soft-switching transitions and negative for hard-switching transitions. As can be noticed, for DGD < 0 (hard switching) the dynamic-R_{on} is significantly enhanced compared to soft-switching (DGD > 0). The hard switching intervals reached in Fig. 15.53a (µs range) are significantly longer than in real-life operation (where a slew rate of 10–100 V/ns is more realistic), thus corresponding to an extremely stressful scenario.

The increased dynamic-R_{on} measured in hard switching conditions is ascribed to the trapping of hot-electrons within the devices. A confirmation of the presence of hot-electrons was obtained by means of electroluminescence measurements (Fig. 15.53b). No EL signal was measured in soft switching, since no current flows through the devices during the switching transition. On the contrary, under hard switching conditions, EL signal was detected on the whole channel width, with a peak on the drain-side gate edge.

A further mechanism of charge trapping is related to the gate stack; in several cases, V_{th} instabilities have been reported for GaN-based power transistors, causing negative- or positive-threshold bias instability (NBTI or PBTI). The physical origin of such V_{th} shifts are strongly dependent on the gate architectures (e.g., metal-insulator semiconductor, Schottky-gate, p-type gate, etc.).

In MIS-transistors [113–117], threshold voltage instabilities are due to the trapping of electrons at the interface between dielectric and semiconductor or to the injection of charge inside the dielectric [116].

More recent papers indicated that also normally-off GaN power transistors can suffer from threshold voltage instabilities [90, 118, 139, 140]; different mechanisms have been indicated as responsible for the positive and negative threshold voltage instabilities in GaN-based transistors with p-type gate. In [140], the authors suggested that a positive threshold voltage shift may be detected after stressing the devices at $V_{GS} = 1$ V (see Fig. 15.54a, b). This V_{th} variation was ascribed to the injection of electrons from the 2DEG to the AlGaN barrier, which may occur once the 2DEG has been formed (see Fig. 15.54c). For higher voltages, the accumulation of positive charges (holes) in the AlGaN barrier and/or at the passivation/AlGaN interface can induce a negative shift in threshold voltage (Fig. 15.54). Another paper [139] investigated the role of hole accumulation in the p-GaN (causing a negative threshold voltage shift) and hole depletion in the p-GaN (causing a positive threshold voltage shift). This chapter indicated that an unbalance between the hole tunneling current through the Schottky barrier and the thermionic emission on the AlGaN barrier can significantly change the total charge in the p-GaN, thus resulting in V_{th} shift.

Finally, one of the latest trends in GaN technology is the development of vertical transistors. In several cases, an MOS approach is used, in order to ensure a high robustness and a good threshold current. Recently, only few papers on the stability and reliability of GaN-on-GaN vertical devices have been published [141–144]. As an example, we refer here to the results presented in [144]. In this paper, the authors investigated the stability of the threshold voltage of GaN-on-GaN vertical fin field-effect transistors (VFETs). The results of threshold voltage transients indicated the existence of two different trapping processes (Fig. 15.55a). At low voltages, a negative shift in threshold voltage was observed; this effect was ascribed to the de-trapping of electrons from the Al_2O_3 insulator, induced by a low positive bias. At high voltages

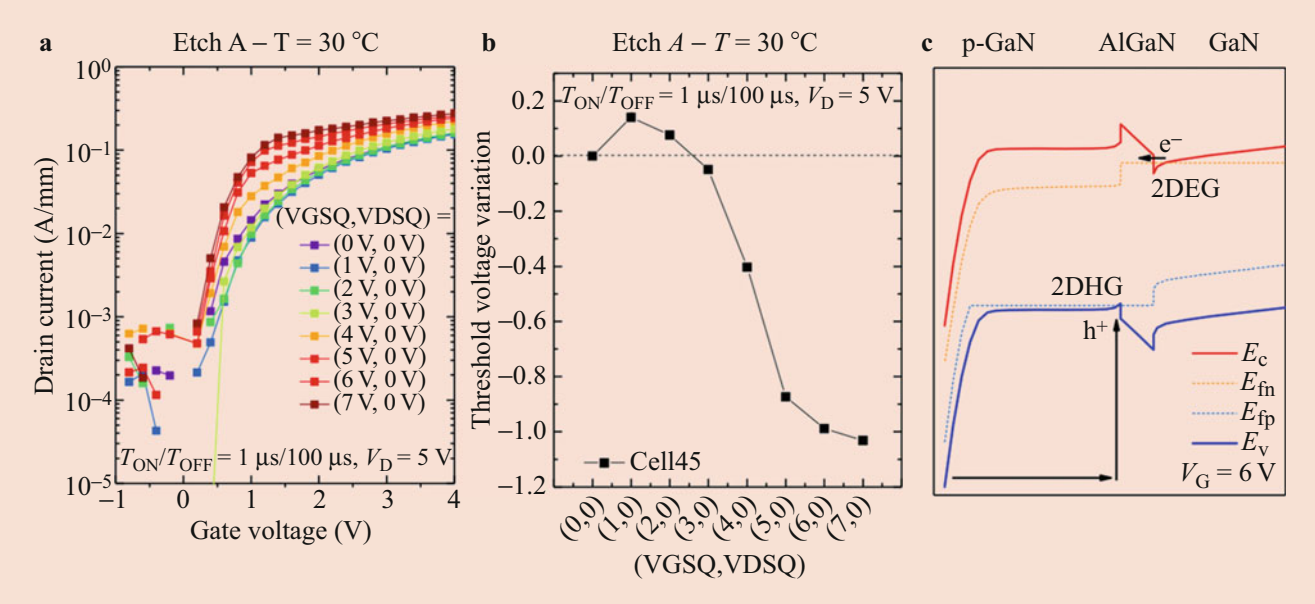

Fig. 15.54 (**a**) drain current versus gate voltage after different forward gate voltage stress; (**b**) pinch-off voltage variation versus forward gate voltage stress; (**c**) band diagram under the region at $V_G = 6$ V (simulated with Sentaurus provided by Synopsis). Two mechanisms are reported: (1) injection of electrons from the 2DEG towards the AlGaN barrier; (2) accumulation of positive charges (holes), injected from the gate. Fig. 15.55 (**a**, **b**) On-resistance and (**c**, **d**) threshold voltage variation during 100 s of (**a**), (**c**) stress at different $V_{Gstress}$ and 1000 s of (**b**), (**d**) recovery (all terminals at zero voltage) at $T_{amb} = 25$ °C. The R_{ON} decrease is a recoverable process. At low stress voltages ($V_{GS} < 2$ V) a negative recoverable ΔV_{TH} is observed; for high stress voltages ($V_{Gstress} > 2$ V) a positive ΔV_{TH} is induced, not recoverable in 1000 s. (**e**) Schematic representation of the two mechanisms responsible for (1) negative and (2) positive threshold voltage shift. The two mechanisms take place at low and high stress voltage, respectively. (© 2017 IEEE. Reprinted, with permission, from [144])

(≥5 V), a substantial positive threshold voltage shift was observed. This process is due to the injection of electrons from the channel to the insulator. The recovery of this second process was found to be slow. A schematic representation of the two processes is given in Fig. 15.55b; see [144] for details.

15.4.4 Reliability Issues of GaN-Based Power HEMTs

Thanks to the unique material properties of GaN, AlGaN/-GaN transistors may be subject to extremely high stress conditions during operation. GaN devices are currently targeting the 600–650 V market segment [89], but research is ongoing to extend to 1200 V and beyond. Current levels can be higher than 50 A on a single component, while – at least for the moment – specifications are quite relaxed for the maximum junction temperature (see, for instance, [89, 145] showing a maximum $T_j = 150$ °C). For E-mode devices, also the maximum gate voltage/current are critical in terms of reliability. In some cases, the maximum gate-to-source voltage is specified in the datasheet (see, for instance, [89], indicating a limit of +7 V), while in some other cases the maximum gate leakage current is defined (see for instance [145], indicating a maximum gate current of 50 mA). Finally, during a switching event GaN power transistors can reach high levels of instantaneous power dissipation; for a representative example, the reader may refer to the results reported by Bahl et al. in [146], showing that in a boost converter, a significant current/voltage overlap is observed during the turn-on phase; peak currents around 15 A were observed when switching from 400 V, resulting in high power densities and hot carrier effects.

Studying the reliability of GaN transistors is a necessary step for the development of this technology. In this section, we describe the most common failure mechanisms that limit

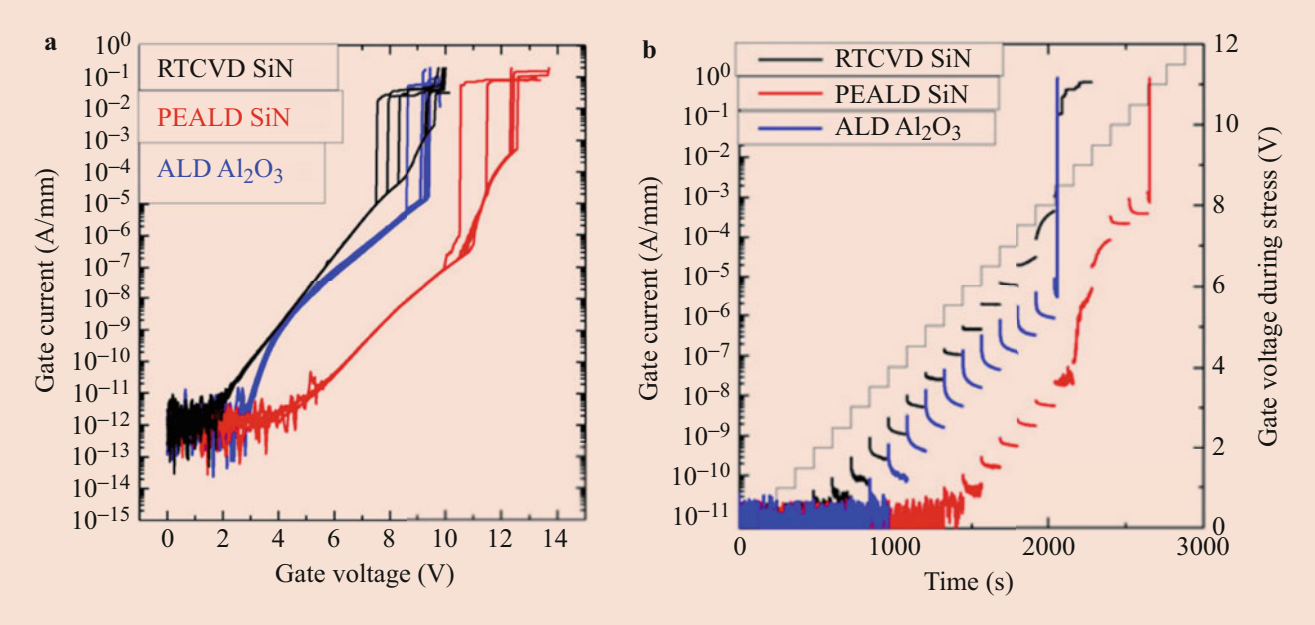

Fig. 15.56 (**a**) Current-voltage breakdown measurements on devices with different gate insulators: RTCVD SiN (black line); PEALD SiN (red line); and ALD Al_2O_3 (blue line). (**b**) Gate current monitored during step stress with drain and source terminals grounded ($V_D = V_S = 0$ V) and increasing V_G in devices with different gate insulators: RTCVD SiN (black solid line), PEALD SiN (red solid line), and ALD Al_2O_3 (blue solid line). Corresponding gate voltage applied during the step stress is reported with a staircase curve. (Reprinted from [147], Copyright 2015, with permission from Elsevier)

the reliability of GaN power devices, along with a description of the related root causes.

15.4.5 Gate-Stack Reliability

As discussed above, the two most studied technologies for the fabrication of the gate are metal-insulator-semiconductor (MIS) and p-GaN gate. The threshold voltages of commercial GaN HEMTs are around 1.1–1.3 V [89, 145], and a certain overdrive is required. For instance, the datasheet of [89] indicates a gate drive range from 0 V to 6 V. For this reason, it is important to evaluate the stability and reliability of GaN transistors at high positive gate voltage and to define proper ways to extrapolate acceleration factors and lifetime.

For insulated-gate devices, the time-dependent failure of the gate dielectric is one of the most relevant degradation process. This mechanism is similar to what has been detected and studied in silicon devices and leads to a catastrophic failure of the gate when a prolonged high-voltage stress is applied to the samples.

As a representative example, we refer here to the case of partially recessed GaN HEMTs with insulated gate. In [147], Meneghesso et al. studied the breakdown voltage of three different wafers of transistors with a residual AlGaN thickness of 3.7 nm, having three different gate insulators: a 15 nm SiN layer deposited by rapid thermal chemical vapor deposition (RTCVD); a 15 nm SiN layer deposited by plasma-enhanced atomic layer deposition (PEALD); and a 15 nm Al_2O_3 layer, deposited by atomic layer deposition (ALD). The results of this study indicated that devices with PEALD-SiN insulator have a leakage more than three orders of magnitude lower than the two other wafers (Fig. 15.56a). In addition, devices with PEALD-deposited SiN were found to have a higher robustness at positive gate voltage (average failure voltage = 11.9 V), compared to RTCVD-SiN and Al_2O_3 (8.65 V and 9.25 V, respectively).

The breakdown voltage evaluated by a simple dc sweep is not fully representative of the real device robustness under long-term stress; typically, step-stress experiments and constant-voltage stress tests are carried out with the aim of analyzing the failure distributions and the related statistics. Figure 15.56b reports the results of a step-stress experiment carried out on one device per wafer; gate voltage was increased by 0.5 V every 120 s, while monitoring the electrical parameters. For positive stress voltages (and above threshold), the 2DEG is fully formed, and a high electric field builds across the residual AlGaN layer and the gate insulator. Such field is rather uniform, since the metal and the 2DEG act as the two plates of a capacitor. As can be noticed, the properties and quality of the dielectric strongly influence the overall reliability of the devices. In addition, the samples with

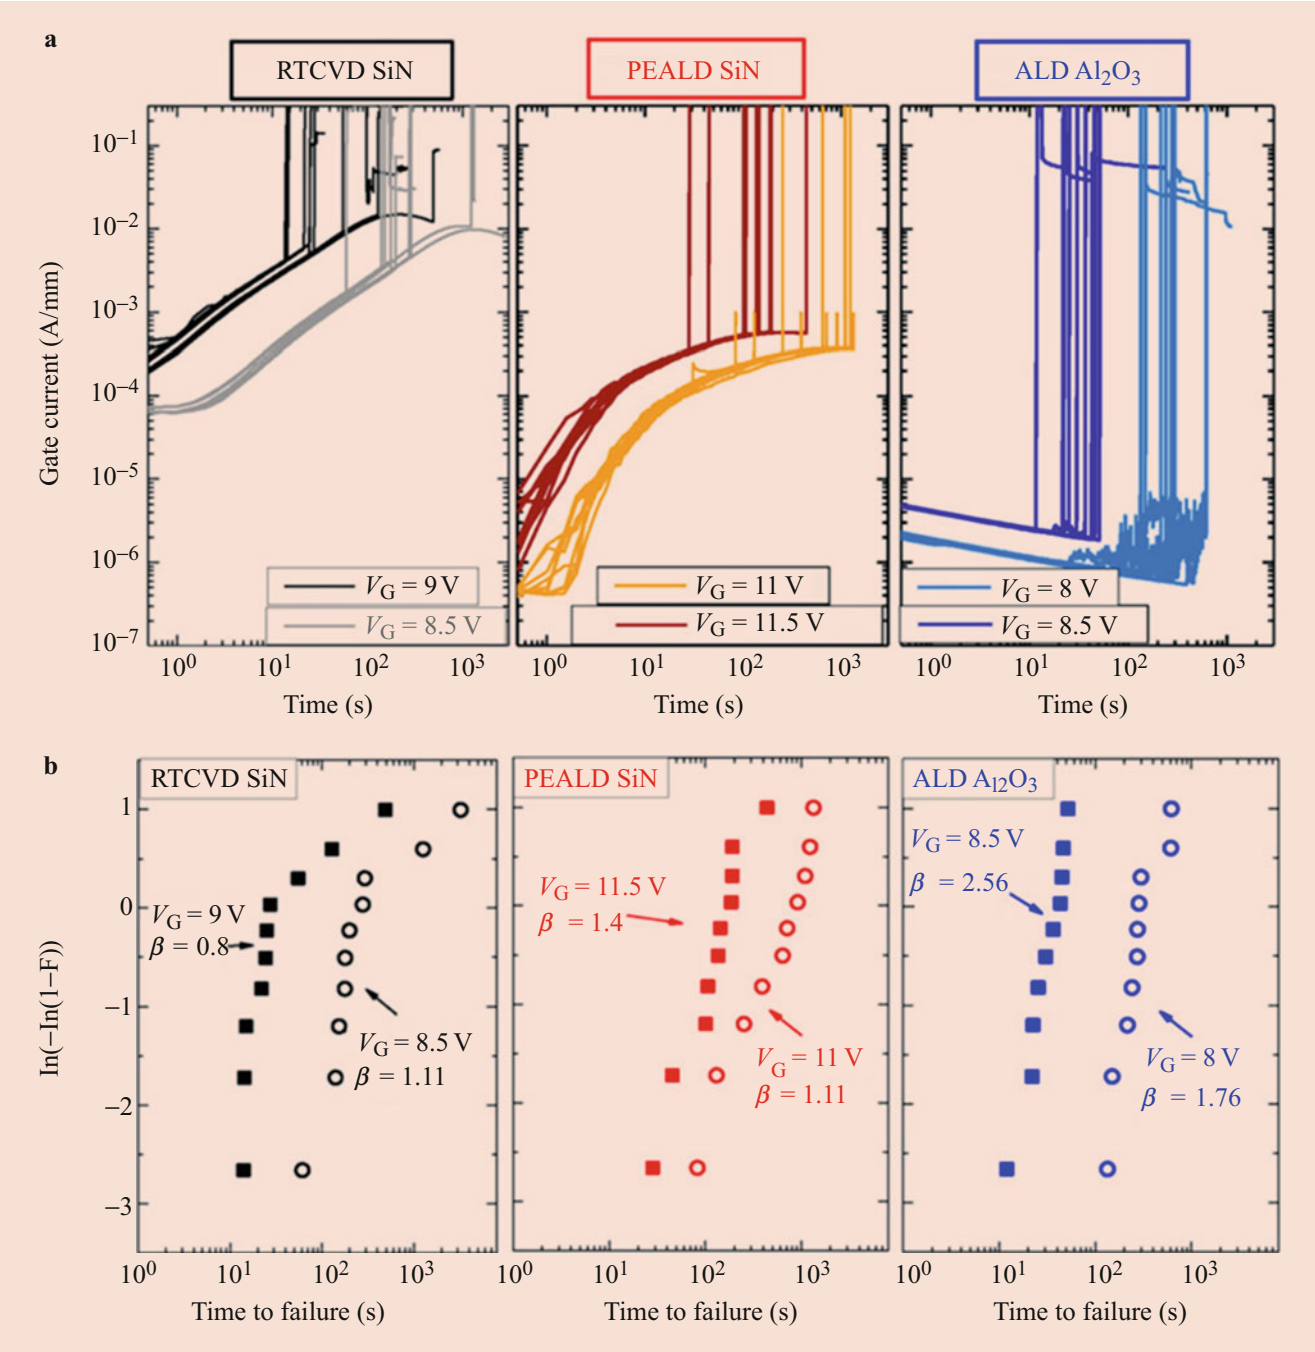

Fig. 15.57 (**a**) TDDB measurements performed on devices with different insulating layers: RTCVD SiN (black line), PEALD SiN (red line), and ALD Al_2O_3 (blue line). (**b**) Weibull plot on devices with different insulating layers: RTCVD SiN (black line), PEALD SiN (red line), and ALD Al_2O_3 (blue line). (Reprinted from [147], Copyright 2015, with permission from Elsevier)

PEALD SiN and RTCVD SiN show a sudden increase in gate leakage at the end of the stress experiment.

Representative results on the effect of constant-voltage stress on the gate leakage of insulated-gate HEMTs are shown in Fig. 15.57. In Fig. 15.57a, we report the variation of gate leakage during a constant voltage stress (ten devices per stress condition, two voltages per insulating material). As expected, by increasing stress voltage a decrease in time-to-failure is observed. Time-to-failure is generally Weibull-distributed (see the Weibull plots in Fig. 15.57). In the example reported in Fig. 15.57b, the shape parameter β does not strongly depend on stress voltage and is around 1.1–1.5, i.e.,

indicative of intrinsic failure. A more detailed analysis of the failure of MIS-HEMTs and related TDDB was given by Wu et al. in [148]. The authors of this chapter demonstrated that the Weibull distribution scales with gate width, confirming the hypothesis on intrinsic failure. In addition, they extrapolated the lifetime to 0.01% of failures at 150 °C, 20 years ($W_g = 36$ mm), giving voltages of 4.9 V (power law) or 7.2 V (exponential law).

In a recent paper [149], Warnock and del Alamo discussed the physical origin of progressive breakdown (PBD) in high-voltage GaN-based MIS-HEMTs. They observed PBD, characterized by a rapid increase in gate leakage noise, taking place before hard breakdown. They indicated that the degradation does not take place at the AlGaN/GaN interface. Their results were found to be consistent with those obtained on silicon MOSFETs [150], supporting the percolation model to explain PBD and hard breakdown.

The time-dependent breakdown of dielectrics can be critical also for vertical GaN devices. Several vertical transistor structures have been recently proposed: the current aperture vertical electron transistor (CAVET) [71], which is based on the use of a current-blocking layer, used to stop vertical current flow through any path other than the aperture to the drain; the V-MOSFET or trench-MOSFET (also modified in the recent OG-FET layout) [81], where a buried p-type GaN layer is used to increase the threshold voltage of the devices; and the vertical fin power-FET [151] and vertical nanowire-FET [152], where current flow is accurately controlled through the use of nanometer-size channels. In most cases, a dielectric is placed under the gate; this dielectric layer can be exposed to high electric fields, especially when the devices are in on-state.

An example of this has been presented by Ruzzarin et al. in [143]. The authors of this paper studied the stability and degradation of vertical fin power-FETs submitted to positive gate stress. The analyzed devices have a vertical metal/insulator/semiconductor layout, where the semiconductor is *n*-type. When submitted to positive gate stress, an accumulation layer is formed in the semiconductor, at the interface with the dielectric. At high gate bias (>7 V), the field in the 15 nm dielectric becomes high and can favor a time-dependent breakdown of the oxide. Specifically, a soft failure was observed at a stress voltage equal to $V_{Gstress} = 7.25$ V (corresponding to an abrupt increase in gate leakage, Fig. 15.58). A catastrophic failure was detected at $V_{Gstress} = 8.75$ V (~6 MV/cm in the gate insulator, Al_2O_3).

Results of simulations (Fig. 15.59) indicated that in vertical fin power-FET at high drain voltage the electric field peaks at the corner of the dielectric. This is supposed to be the region where failure takes place at high drain bias, in the off-state. Strategies for reducing the field in the material

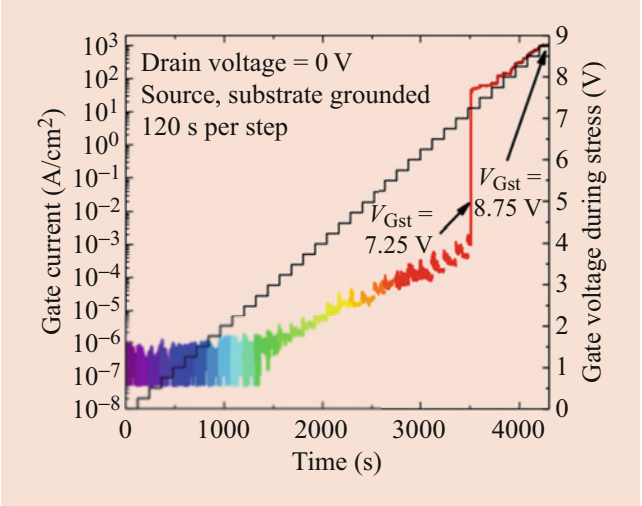

Fig. 15.58 Step stress performed with $V_{Dstress} = 0$ V and by increasing the $V_{Gstress}$ by 0.25 V each 120 s of stress. A positive gate stress induces a permanent increase in gate current, for stress voltages higher than 7.25 V, due to the breakdown of the gate dielectric. The catastrophic failure occurs at $V_{Gstress} = 8.75$ V. (© 2018 IEEE. Reprinted, with permission, from [143])

can be adopted to significantly improve the robustness of the transistors at high drain bias.

For devices with p-GaN gate, different degradation mechanisms have been proposed over the past years. The metal/p-GaN interface can be either Ohmic or Schottky [153]. The second approach allows to substantially reduce the leakage at the gate. When a Schottky junction is created on p-GaN, the resulting stack can be modeled as the back-to-back combination of two diodes. The first results from the metal/p-GaN Schottky junction, and the second is represented by the p-GaN/i-AlGaN interface [154]. Wu et al. [155] analyzed the forward-bias breakdown mechanisms in Schottky metal/p-GaN gate HEMTs. They demonstrated a positive temperature dependency of the gate breakdown voltage, with a coefficient equal to 5×10^{-3} C/V. They demonstrated that – on average – the breakdown voltage at 200 C is 1 V higher than at 25 C. They explained this positive temperature dependence by considering the avalanche multiplication in the space charge region that is present at the metal/p-GaN junction. The electrons can transfer to the p-GaN and be accelerated by the high field in the depleted region. Further, they were able to observe the presence of avalanche luminescence, suggesting that high gate voltages may lead to the generation of electron-hole pairs.

Tapajna et al. [156] analyzed the effect of forward stress on normally-off p-GaN/AlGaN/GaN HEMTs. They indicated that the time-dependence of the gate current increase is consistent with percolation process. By using the Weibull statistics, they estimated the maximum gate voltage

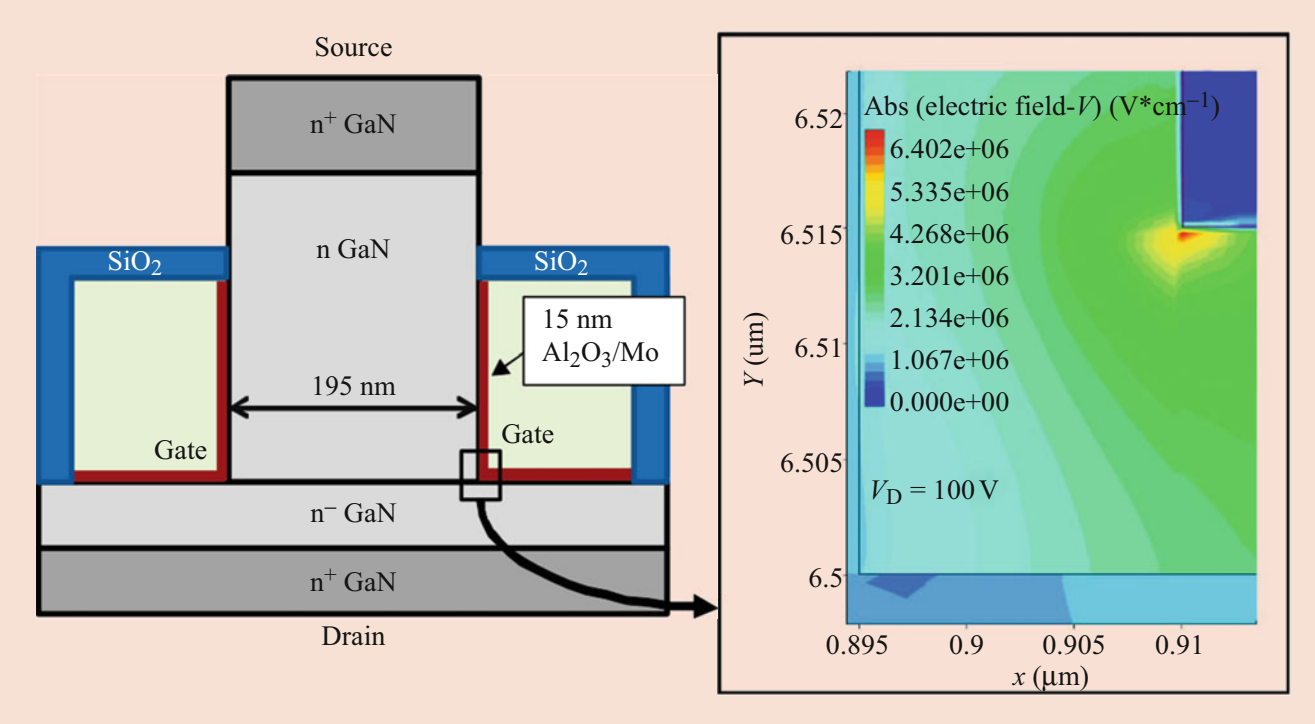

Fig. 15.59 Simulation of the electric field at the dielectric/GaN channel interface at higher drain voltages (in the real device the fin corners are not exactly 90° corners). (© 2018 IEEE. Reprinted, with permission, from [143])

for long-term operation. In addition, they demonstrated that the observed degradation process has a low activation energy.

Tallarico et al. [154] demonstrated that the time-to-failure of GaN-on-Si power HEMTs with p-type gate follows a Weibull distribution. Also, they suggested that the time-to-failure is a function of the initial gate leakage, with higher gate leakage corresponding to a shorter lifetime. They suggested that breakdown is related to the creation of a percolation path in the p-GaN layer.

Rossetto et al. [153] analyzed the influence of the Mg doping concentration on the robustness of AlGaN/GaN HEMTs at positive gate overstress. They proposed a method to separately investigate two different processes, namely, (a) a field-driven breakdown of the metal/p-GaN Schottky junction, induced by TLP test with short pulses. High Mg doping correspond to higher junction fields, thus resulting in lower failure voltages. (b) A current-driven process detected during long-term stress, ascribed to the accumulation of charge at the p-GaN/AlGaN interface [157]. For this process, an increase in Mg doping was found to improve the stability.

In a more recent paper, Masin et al. [158] demonstrated that GaN-HEMTs with p-GaN gate can show a time-to-failure with positive temperature coefficient, when submitted to positive gate stress. They ascribed degradation to the accumulation of holes at the p-GaN/AlGaN interface. This is supposed to increase the injection of electrons from 2DEG to p-GaN, which are then accelerated by the electric field. This eventually leads to defect generation and breakdown.

15.4.6 Off-State Reliability

Another relevant regime where GaN transistors can undergo significant stress is off-state bias, i.e., (for e-mode devices) a null gate voltage and a high (up to 600–650 V) drain voltage. Recent papers have investigated the impact of high off-state bias on the electrical characteristics of GaN transistors (see, e.g., [159–165]). Under off-state conditions, two main factors can promote the degradation of the devices. First, the high lateral field, between gate and drain, can promote a failure of the devices in proximity of the top epitaxial and/or passivation layers. In this case, we refer to "lateral breakdown," since the mechanism originates from the lateral field. Second, in off-state conditions a high bias is present also between drain and substrate. This creates a significant vertical field, which may lead to the "vertical breakdown" of the epitaxial stack.

An example of lateral breakdown was reported in [161–163]. Here the authors demonstrated the existence of time-dependent dielectric breakdown in GaN-based high electron mobility transistors (HEMTs) submitted to stress in off-state bias. Specifically, they demonstrated that under off-state

stress at 600–700 V the devices can show a time-dependent failure, which was ascribed to the failure of the SiN dielectric at the edge of the gate overhang, on the drain side. A representative example of this failure process is shown in Fig. 15.60a: the variation of drain current during stress in off-state with $V_{DS} = 600$ V is reported on ten identical samples. All the analyzed devices reached a catastrophic failure, i.e., a sudden increase in drain current. Time-to-failure (TTF) was found to have an exponential dependence on stress bias. This was explained by considering the existence of a field-dependent degradation process. In addition, TTF was found to be Weibull-distributed (see, for instance, Fig. 15.60b), with a β around 0.5. Such a value is indicative of an extrinsic failure mechanism. Degradation was then ascribed to the time-dependent breakdown of the dielectric under the gate overhang. Numerical simulations were carried out to support this hypothesis. As shown in Fig. 15.61, the electric field in the nitride peaks at the edge of the gate overhang

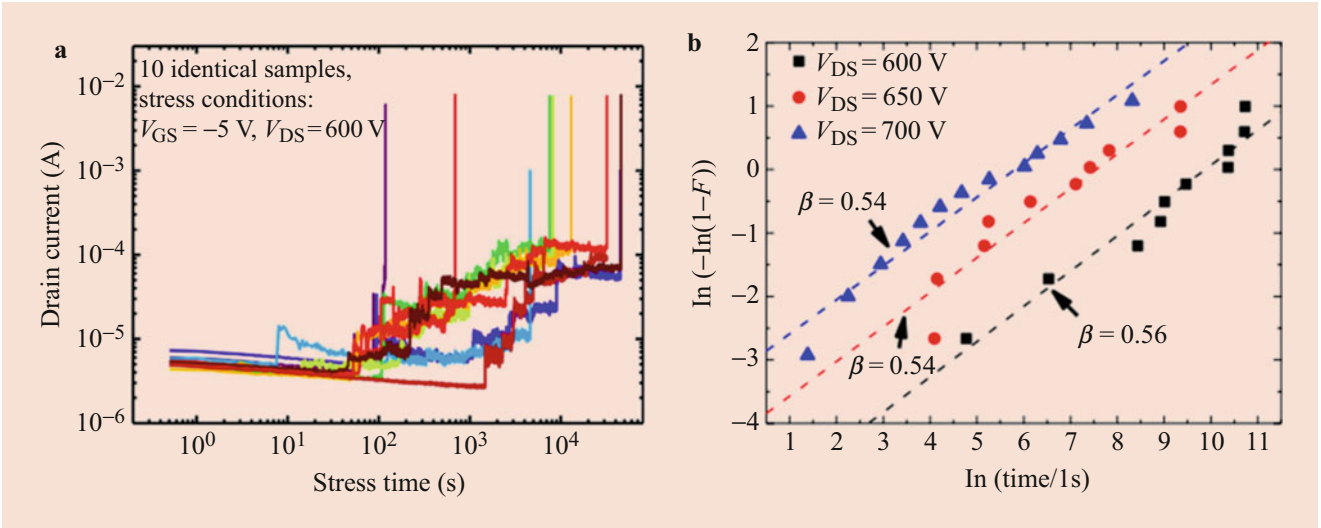

Fig. 15.60 (**a**) Results of constant voltage stress experiments carried out on a set of ten identical devices; the stress conditions are $V_{GS} = -5$ V, $V_{DS} = 600$ V. Only drain current is reported for clarity. (**b**) Weibull-distribution for three sets of devices stressed with VGS = −5 V, and increasing V_{DS} (600, 650, and 700 V). (© 2015 IEEE. Fig. 15.62 (**a**) Emission microscopy evaluated during stress with $V_{GS} = -5$ V and $V_{DS} = 600$ V. The three frames are referred to increasing stress times. The portion cut for the TEM evaluation in is highlighted in yellow. (**b**) TEM performed on a cross section corresponding to the hot spot indicated in (a), after the constant voltage test, showing a severe degradation in the gate side/edge. (**c**) Enlargement of the damaged portion of the device. (© 2017 IEEE. Reprinted, with permission, from [161])

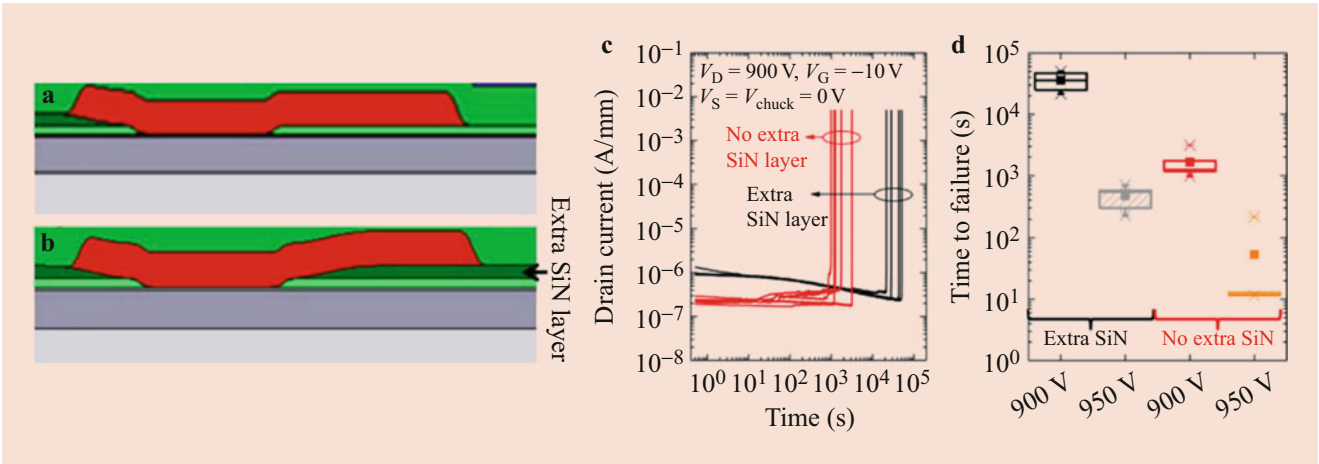

Fig. 15.63 Schematic of the variation in the device geometry, showing a structure (**a**) without and (**b**) with an extra SiN layer. An additional SiN layer is introduced in order to reduce the electric field at the edge of the gate. (**c**) Constant voltage test at $V_D = 900$ V, demonstrating that the extra nitride layer increases time to failure by one order of magnitude. (**d**) Box chart showing the measured time to failure in devices with and without extra SiN layer stressed at $V_D = 900$ V and $V_D = 950$ V. (© 2017 IEEE. Reprinted, with permission, from [161])

and can reach values around 6 MV/cm at $V_{DS} = 600$ V. A physical evidence of this hypothesis was obtained by TEM evaluation [161]. First, emission microscopy was performed in off-state conditions, to identify the presence of hot spots (Fig. 15.62). Then, cross sections were prepared by Focused Ion Beam (FIB) and then observed by Transmission Electron Microscopy (TEM, Fig. 15.62). The results demonstrated that degradation is effectively located at the drain-side gate edge. Stress induced the generation of a shunt-path between the gate head and the 2DEG, across the SiN/AlGaN stack. Such a degradation process is extrinsic (in the sense that it involves a material other than GaN, i.e., SiN). In [161], the authors proposed to add a graded layer of silicon nitride under the head of the gate to improve device reliability (Fig. 15.63). Figure 15.63 reports the results of a constant voltage stress experiment: the presence of the extra SiN layer can increase the TTF by one order of magnitude.

After discussing the extrinsic breakdown mechanisms induced by off-state stress (see above), we discuss here the intrinsic breakdown mechanisms related to the GaN material itself. Recent papers (see, for instance, [160, 165]) studied the robustness of the buffer stack submitted to high off-state conditions. To separately evaluate lateral and vertical breakdown, two-terminal stress experiments are typically carried out. The devices are stressed from drain to substrate, and this results in a significant vertical field. At industrial level,

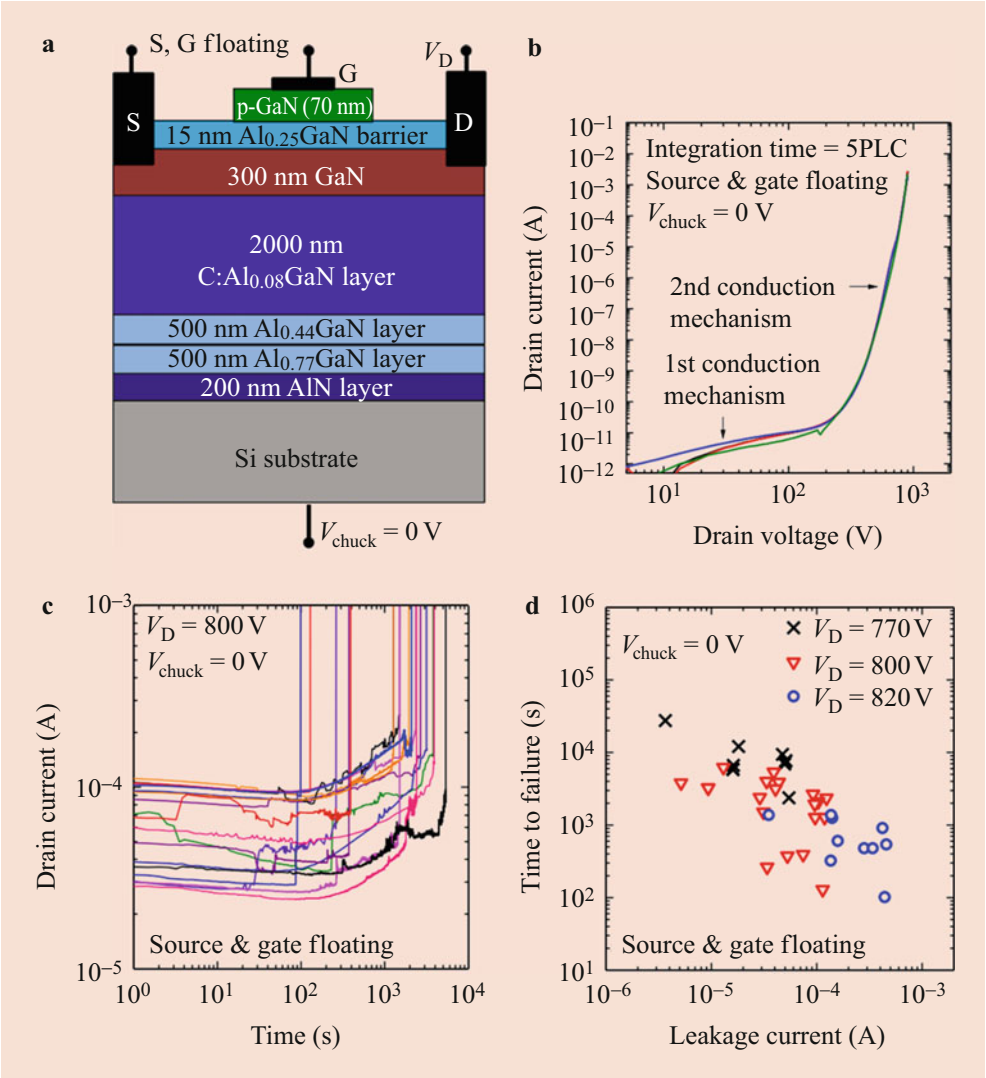

Fig. 15.64 (**a**) Schematic representation of the device under test. (**b**) Drain- controlled vertical leakage current measurement. The measurements were stopped at breakdown. (**c**) Drain current monitored during a constant voltage stress ($V_D = 800$ V). (**d**) TTF dependence on the initial leakage for three drain bias levels applied during the constant voltage stress. results on buffer reliability can be obtained also by means of high-oltage off-state stress (HVOS) [165], a condition where a high voltage is applied to the drain, with substrate and source grounded and gate in pinch-off.

Recently, Borga et al. demonstrated that GaN can show a time-dependent vertical breakdown that can result in a sudden increase in vertical leakage current [160]. The study was carried out on devices having the schematic structure reported in Fig. 15.64a, that are designed for 200 V operation. Before the execution of the stress tests experiments, the vertical (2-terminal) leakage current was characterized (see Fig. 15.64b): two conduction mechanisms were identified, with a change in slope around $V_D = 300$ V. Such behavior was explained by considering that for low vertical bias (<200 V) conduction is nearly ohmic and possibly assisted by dislocations. For higher voltages (>300 V) the depletion of the buffer results in the ionization of defects. Poole-Frenkel effects are favored, and an increase in vertical leakage is observed at high bias.

Figure 15.64c reports the results of a constant voltage stress test carried out on 18 identical devices with a vertical voltage of 800 V. After an initial stage where the leakage is stable, devices show first an increase in the noise superimposed to leakage current and then a sudden increase in vertical leakage. This is similar to the behavior of dielectrics under time-dependent breakdown testing, typically explained by the defect-percolation model. Figure 15.64d shows the time-to-failure (TTF) and leakage current measured on three

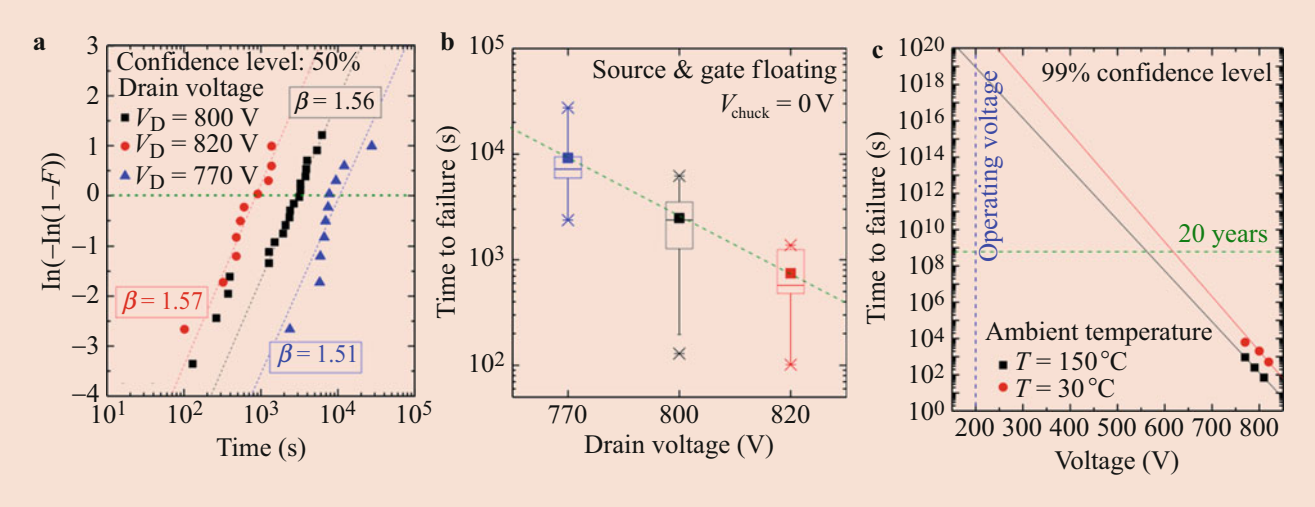

Fig. 15.65 (**a**) Weibull plot of the constant voltage stress. (**b**) TTF dependence on the applied drain voltage (box chart). (**c**) TTF dependence on the drain voltage applied at ambient temperature of 30 °C and 150 °C. Each point represents the Weibull scale factor with a confidence level of 99%. (© 2017 IEEE. Reprinted, with permission, from [160])

sets of samples stressed at different voltages. As expected, by increasing stress bias a decrease in TTF and an increase in leakage current are detected.

A further similarity with dielectric breakdown comes from the fact that TTF is Weibull-distributed. For reference, one can look at Fig. 15.65a, which reports the Weibull plots obtained by stress at three different voltage levels. Figure 15.65b indicates that TTF has an exponential dependence on stress voltage and supports the hypothesis that the degradation mechanism is field-dependent. In addition, a low thermal activation (0.25 eV) was measured.

The time-dependent breakdown of GaN does not represent a major limitation for this material. For the 200 V technology analyzed in [160], the maximum voltage for 20 years lifetime with 1% failure rate is around 560 V.

15.4.7 Stability in Semi-on Conditions

In several real-life application scenarios, GaN-based transistors can be operated under hard switching conditions. A basic example is the case of a boost power converter, where the simultaneous presence of high current and high voltage can take place during the turn-on phase of the devices. It is therefore important to evaluate the stability of the devices not only under soft switching, but also under the more dangerous hard switching regime.

Recently, the interest toward the hard switching behavior of GaN HEMTs has significantly increased. As an example, we mention here three recent papers on the topic, that significantly contributed to the understanding of the trapping/degradation processes under hard switching, i.e., [138, 166, 167].

In [167], Joh et al. investigated the current collapse in GaN-based HEMTs by a novel setup, capable of controlling independently the gate and drain pulses. They suggested that the current collapse can improve under hard switching, due to the generation of holes through impact ionization. The hypothesis in [167] is that in hard switching, if there is a substantial overlap between voltage and current waveforms, hot carriers are produced (in density proportional to $I_D \bullet \exp(-a/V_{DG})$) and can generate holes via impact ionization. Such holes can compensate the electrons trapped at the surface of the devices.

A similar setup was used by Rossetto et al. in [138], see a representative schematic in Fig. 15.66. Here the drain-gate-delay (the time interval between $V_D = V_{DSQ}/2$ and $V_G = V_{TH}$) is changed to generate hard switching events. In this paper, the authors showed that hard switching conditions may lead to an increase in dynamic-on resistance. They ascribed this effect to the fact that during the switching events, channel electrons are accelerated and consequently trapped within the devices.

A comprehensive description of the reliability of GaN-based transistors under hard switching tests was presented by Tanaka et al. in [166]. In this chapter, the authors presented the results of dynamic high-temperature operation life (D-HTOL) tests, carried out on transistors used in half-bridge configuration. They used a frequency of 6.6 kHz, an input voltage of 480 V and a switching current of 10 A. In addition, they compared two different kinds of transistors, the GITs and the HD-GITs, during the D-HTOL test. Here the HD-GIT is the hybrid-drain-embedded gate injection transistor, namely, a GIT where a pdrain is formed over a thick AlGaN barrier to suppress current collapse. The authors of this paper

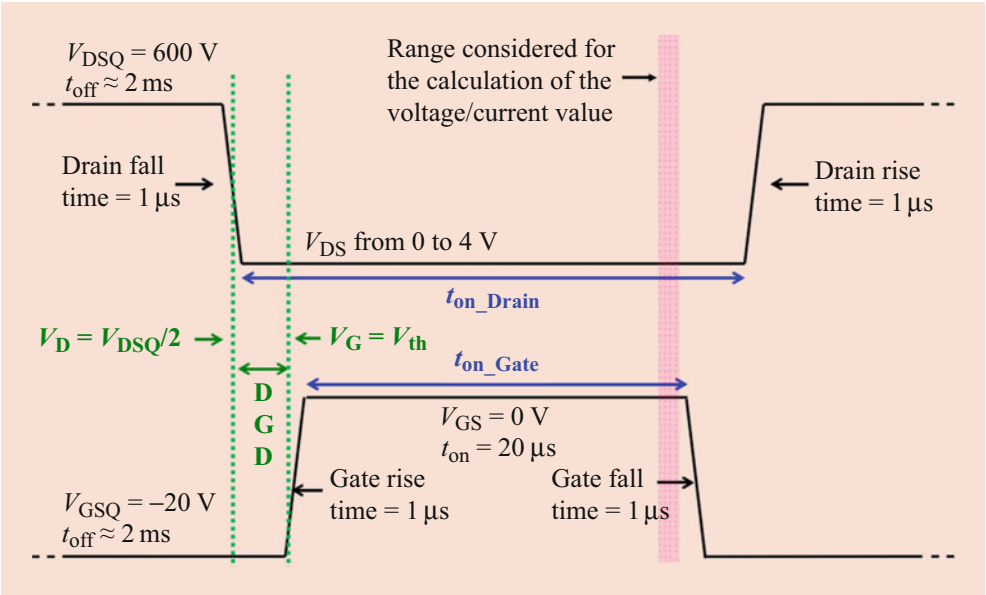

Fig. 15.66 Representative schematic of the drain and gate pulses applied during the analysis of the dynamic ON-resistance. The DGD is defined as the time range between $V_D = V_{DSQ}/2$ and $V_G = V_{TH}$. The range of the pulse considered for the calculation of the current–voltage curve is highlighted in shaded pink. (© 2017 IEEE. Reprinted, with permission, from [138])

demonstrated that in the GIT the maximum switching voltage decreases as the switching current increases; eventually, for high switching currents, the maximum switching voltage becomes lower than the rated voltage. On the other hand, HD-GITs do not fail even under the most severe hard switching conditions (V_{DS} = 640 V, I = 27 A). Thermal runaway is not the primary reason for GIT breakdown. On the contrary, the better reliability of HD-GITs is explained by the injection of holes from pdrain. Such holes can compensate the hole emission from the GaN epilayer under high off-state stress and the capture of hot electrons under semi-on state. Tanaka et al. [166] suggested that the hot electron trapping at the surface of the GIT can trigger the destructive breakdown; a positive-feedback loop is created, that may lead to the sudden shift of the EL position from the gate edge to the drain edge.

15.5 Conclusions

The continuous progress of GaN technology makes gallium nitride an ideal candidate for the development of advanced power semiconductor devices. Exciting challenges in growth and fabrication have already been faced, and GaN transistors are ready to start playing a major role in power conversion.

Within this chapter, we have discussed the main properties of GaN and of GaN-based devices, with focus on four aspects: epitaxial growth, lateral device technology, GaN vertical devices, charge trapping, and reliability issues.

This chapter is a useful reference for the readers willing to approach GaN technology and for experts in the field desiring an up-to-date discussion of the most relevant technological challenges and issues.

Matteo Meneghini received his PhD in Electronic and Telecommunication Engineering (University of Padova), working on the optimization of GaN-based LED and laser structures. He is now associate professor at the Department of Information Engineering at the University of Padova. His main interest is the characterization, reliability, and simulation of compound semiconductor devices (LEDs, Laser diodes, HEMTs). Within these activities, he has published more than 300 journal and conference proceedings papers.

Farid Medjdoub received his Ph.D. degree in Electrical engineering from the University of Lille in 2004. He then worked as a research associate at the University of Ulm and as a senior scientist at IMEC on GaN-based devices.He is currently a CNRS scientist leading a team at IEMN in France. His current research focuses on wide bandgap semiconductor device development for power and RF applications including simulation, design, fabrication, and advanced characterization.

Srabanti Chowdhury (George and Ida Mary Hoover faculty fellow'19, Gabilan fellow'19) is an associate professor of Electrical Engineering (EE) at Stanford. Her research focuses on wideband gap (WBG) materials and device engineering for energy efficient and compact system architecture for power electronics and RF applications. Besides gallium nitride, her group is exploring diamond for various electronic applications.

Dong Ji received his Ph.D. in Electrical and Computer Engineering from the University of California Davis in 2017. He worked as a postdoctoral scholar at Stanford University. His research focus on III-V compound semiconductors for power electronics and optoelectronics applications.

Joff Derluyn received his PhD from the University of Gent in 2003. Afterwards, he worked at imec in Leuven Belgium, on the fabrication of GaN electronic devices. In 2010, he co-founded the start-up company EpiGaN, where he still works as CTO. There, he focuses on the epitaxial growth of GaN for electronic applications.

Jaeyi Chun received his Ph.D. degree in Nanobio Materials and Electronics in 2016 from Gwangju Institute of Science and Technology, South Korea. He worked at the University of California, Davis, as a postdoctoral researcher from 2016 to 2019. He is currently a post-doctoral researcher, working on GaN vertical transistors at Stanford University.

Riad Kabouche received his Ph.D. degree in Electrical engineering from the University of Lille in 2017. He has been working on circuit design and characterization of devices based on the emerging AlN/GaN heterostructure for millimeter wave power applications.Since 2018, he works as a Postdoctoral researcher in the Institute of Electronic, Microelectronic and Nanotechnology (IEMN).His current research interests include the characterization and simulation of RF and Power GaN devices.

Carlo De Santi was born in Verona, Italy, in 1985 and obtained his Ph.D. in 2014. He holds a post-doc position in the microelectronics group at the university of Padova. His main research activities are characterization, physical modeling, and reliability of various GaN-, Ga2O3-, SiC, GaAs-, InP-, diamond, and CdTe- and Si-based electronic and optoelectronic devices.

Enrico Zanoni is full professor at the University of Padova, Department of Information engineering. His research interests involve electrical characterization, modeling, and reliability of semiconductors devices.

Gaudenzio Meneghesso graduated in Electronics Engineering at the University of Padova in 1992 working on the failure mechanism induced by hot electrons in MESFETs and HEMTs. In 1997 he received the Ph.D. degree in Electrical and Telecommunication Engineering. He is now full professor at the University of Padova. His research interests involve the Electrical characterization, modeling, and reliability of semiconductors devices.

Abstract

This chapter addresses the principle of operation of PN junction diodes, bipolar transistors and Schottky diodes. Basics characteristics of diodes are derived by merging electrostatics with semiconductor physics, leading to well know exponential relationships between the current and the applied voltage. Concerning bipolar transistors, they are discussed in a circuit application framework, leaving behind the details of the physics and putting more focus on biasing and the common modes of operation.

16.1 The PN Junction

16.1.1 Introduction

Despite its quite simple architecture, the pn junction is one of the most fundamental semiconductor devices entering in micro- and nano-electronics technology. In addition to be used as a diode, the pn junction is at the root of the bipolar transistor and still plays an essential role in field effect transistors as it defines the source and drain contacts.

In this context, this section aims at recalling the basics in modeling the pn junction in forward and reverse bias under steady-state operation. Initially, the theory was developed by Shockley [3]. To get a simple while predictive analytical model, this section will consider a one-dimensional pn junction and will make use of simplifying assumptions that are common to many textbooks on the topic [1, 2].

In the following, we start analyzing the case of the pn junction in reverse bias. The situation where the pn junction is forward biased will be detailed later.

16.1.2 The PN Junction at Equilibrium and in Reverse Bias

We recall the basics of electrostatics of the pn junction in reverse bias adopting the full depletion approximation viewpoint. This kind of analysis ends with simple relationships that still accurately predict the charge distribution in pn junctions with uniform doping concentrations.

Potentials and Charges: Electrostatics Analysis at Equilibrium

Considering a one dimensional system, the analysis of the pn junction at equilibrium is based on the solution of the Poisson equation:

$$\frac{\mathrm{d}^2V(x)}{\mathrm{d}x^2} = \frac{-\rho(x)}{\varepsilon_{sc}} \tag{16.1}$$

where $V(x)$ and $\rho(x)$ are, respectively, the electrostatic potential and the charge density at abscissa x; see Fig. 16.1.

Assuming full ionization of donors and acceptors, which holds true at working temperatures and for the doping densities of interest, i.e., 10^{14} cm^{-3} – 10^{17} cm^{-3} (note that for higher densities, full ionization and action mass law assumptions may become invalid), the charge density in the semiconductor is

$$\rho(x) = q\left(N_D(x) + p(x)\right) - q\left(N_A(x) + n(x)\right) \tag{16.2}$$

and relation (16.1) becomes

$$\frac{\mathrm{d}^2V(x)}{\mathrm{d}x^2} = \frac{-q\left(N_D(x) + p(x)\right) - q\left(N_A(x) + n(x)\right)}{\varepsilon_{sc}} \tag{16.3}$$

Charge in Neutral Regions

In the neutral regions, i.e., for $x < x_p$ and $x > x_n$ (see Fig. 16.1), we assume that all the dopant atoms are fully ionized, i.e., each dopant releases an electron, meaning that the approximation $n = N_D$ holds true (again, this holds only partly for high doping densities, typically above 10^{18} cm^{-3}). Conversely, in the neutral p-doped region ($x < x_p$), every acceptor will release a hole and we can write $p = N_A$.

In addition, the action mass law $\left(np = n_i^2\right)$ implies that the minority-carrier concentrations in the neutral n-type and p-type doped semiconductors satisfy $p = n_i^2/N_D$ and $n = n_i^2/N_A$, respectively.

Creation of Space Charge Regions

In the vicinity of the interface between the n- and p-type doped layers, free electrons from the n-type semiconductor will diffuse into the opposite p-type region, whereas free holes in the p-type semiconductor will diffuse into the n-type one.

A common and quite justified assumption presumes that there is a deficiency of mobile carriers within some "depletion regions," whose extensions are $W_n = x_n$ and $W_p = -x_p$, while the semiconductor remains neutral otherwise; see Fig. 16.1.

Relation (16.3) must then be solved for these three distinct domains, which writes:

For $0 < x < x_n$, $\rho(x) = qN_D$
For $x_p < x < 0$, $\rho(x) = -qN_A$
Otherwise $\rho(x) = 0$

Note that the continuity of the potential and electric field at $=x_n$, $x = x_p$, and $x = 0$ is also required. Solving relation (16.3) between $x = x_p$ and $x = 0$ and imposing the electric field null at x_p (neutral semiconductor) gives

$$\frac{\mathrm{d}V(x)}{\mathrm{d}x} = -E(x) = \frac{qN_A}{\varepsilon_{sc}}(x - x_P) \tag{16.4}$$

which after integration leads to

$$V(x) = \frac{qN_A}{2\varepsilon_{sc}}(x - x_P)^2 + V_p \tag{16.5}$$

Similarly, imposing the electric field null at x_n, the electrostatic potential in the depleted region between $x = x_n$ and $x = 0$ satisfies

$$\frac{\mathrm{d}V(x)}{\mathrm{d}x} = -E(x) = \frac{-qN_D}{\varepsilon_{sc}}(x - x_n) \tag{16.6}$$

and after integration

$$V(x) = \frac{-qN_D}{2\varepsilon_{sc}}(x - x_N)^2 + V_n \tag{16.7}$$

According to relations (16.5) and (16.7), it comes out that the general solution for the potential distribution in the non-neutral regions follows a quadratic law.

In addition, relations (16.5) and (16.7) still involve unknowns such as the potential in the neutral regions, i.e., V_n and V_p, as well as the extension of the depletion regions, x_n and x_p. Lastly, what is needed is to impose the charge neutrality for the structure as a whole, as well as the limit conditions in terms of potential drop across the pn junction

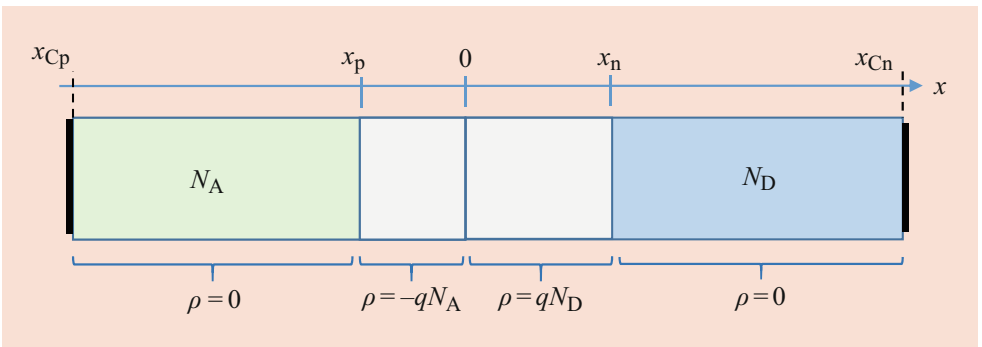

Fig. 16.1 Doping profile and depletion regions in a pn junction at equilibrium

(note that the device is expected to be in reverse bias, a condition that will be made clear later).

The charge neutrality of the diode imposes that the depletion regions are linked to each other:

$$qN_A x_P + qN_D x_N = 0 \tag{16.8}$$

Note that this condition also means that the electric fields at $x = 0$ given by relations (16.4) and (16.6) are equal (in fact, we should say that the displacement vectors $D = \varepsilon_{sc} E$ are equal at the junction interface, i.e., $x = 0$). This condition links the depletion regions (whose extension will then vary inversely with the doping concentration).

Finally, the potential must be continuous at $x = 0$. This last condition links the depletion width to the potential drop $V_n - V_p$:

$$\frac{qN_A}{2\varepsilon_{sc}} {x_P}^2 + V_p = \frac{-qN_D}{2\varepsilon_{sc}} {x_N}^2 + V_n \tag{16.9}$$

$$\begin{aligned} V_n n - V_p &= \frac{qN_A}{2\varepsilon_{sc}} {x_P}^2 + \frac{qN_D}{2\varepsilon_{sc}} {x_N}^2 \\ &= \frac{qN_A\,(-x_P)}{2\varepsilon_{sc}}\,(-x_P) + \frac{qN_D x_N}{2\varepsilon_{sc}} x_N \end{aligned} \tag{16.10}$$

Defining the width of the depleted regions as $W_p = -x_P$ and $W_n = x_n$, and making use of the neutrality condition (relation 16.8), we obtain

$$V_n - V_p = \frac{qN_D W_n}{2\varepsilon_{sc}} \left(W_p + W_n\right) = \frac{qN_D {W_n}^2}{2\varepsilon_{sc}} \left(\frac{W_p}{W_n} + 1\right) \tag{16.11}$$

Or, equivalently,

$$V_n - V_p = \frac{qN_D {W_n}^2}{2\varepsilon_{sc}} \left(\frac{N_D}{N_A} + 1\right) = \frac{qN_D {W_p}^2}{2\varepsilon_{sc}} \left(\frac{N_A}{N_D} + 1\right) \tag{16.12}$$

At this point of the derivation, note that even though the depletion regions are linked to one another, their extension is still not known. Depending on the depletion widths, the electric field will build up a potential that varies quadratically with x according to relations (16.5) and (16.7). However, the potential difference between the p-type neutral and n-type neutral regions *cannot be arbitrary*. This potential should also be consistent with the band bending experienced across the device. Here is the second condition that will fix the depletion width.

The Built-In Potential

The profiles of the charge, electric field and potential satisfying the full depletion approximation are summarized in Fig. 16.2a–d.

Semiconductor statistics link the free-carrier densities to the difference between the Fermi energy and the conduction/-valence bands as follows:

$$n = N_C\, e^{\frac{-(E_C - E_F)}{kT}} \tag{16.13}$$

$$p = N_V\, e^{\frac{(E_V - E_F)}{kT}} \tag{16.14}$$

where N_C and N_V are the effective density of states for the conduction and valence bands

$$N_{C,V} = 2\left(\frac{2\,\pi\, m_{e,h}\, k\, T}{h^2}\right) \tag{16.15}$$

Symbols have their usual meaning (note that $m_{e,h}$ is the *density-of-states effective mass*). Relations (16.13) and (16.14) are valid as far as $n < N_C$ and $p < N_V$ for n- and p-type doped semiconductors, respectively, i.e., they are valid for non-degenerate semiconductors. For instance, in silicon at room temperature, these effective density of states represent quite high concentrations of free carriers, i.e., around 2.8 10^{19} cm^{-3} for electrons and 1.8 10^{19} cm^{-3} for holes. For silicon, when considering regular doping densities used to create p- and n-doped regions, these levels are usually not met, and doping densities are lower than $N_{C,V}$. Only for very high doping levels, like those required for source and drain implants in MOSFETs, relations (16.13) and (16.14) should be revised. Another exception would be small band gap semiconductors, where the density of states is quite low, for instance InAs where $N_C \cong 9\ 10^{16}$ at 300 K.

To calculate the potential difference between the n- and p-type neutral regions, relation (16.13) must be satisfied in each domain.

$$n_n = N_C\, e^{\frac{-\left(E_C^n - E_F\right)}{kT}} \tag{16.16}$$

$$n_p = N_C\, e^{\frac{-\left(E_C^p - E_F\right)}{kT}} \tag{16.17}$$

In addition, we still consider that the free carrier and doping densities are equal (here we use electrons, but the same results would be obtained when considering holes):

$$n_n = N_D \tag{16.18}$$

which implies that minority carriers are known as well:

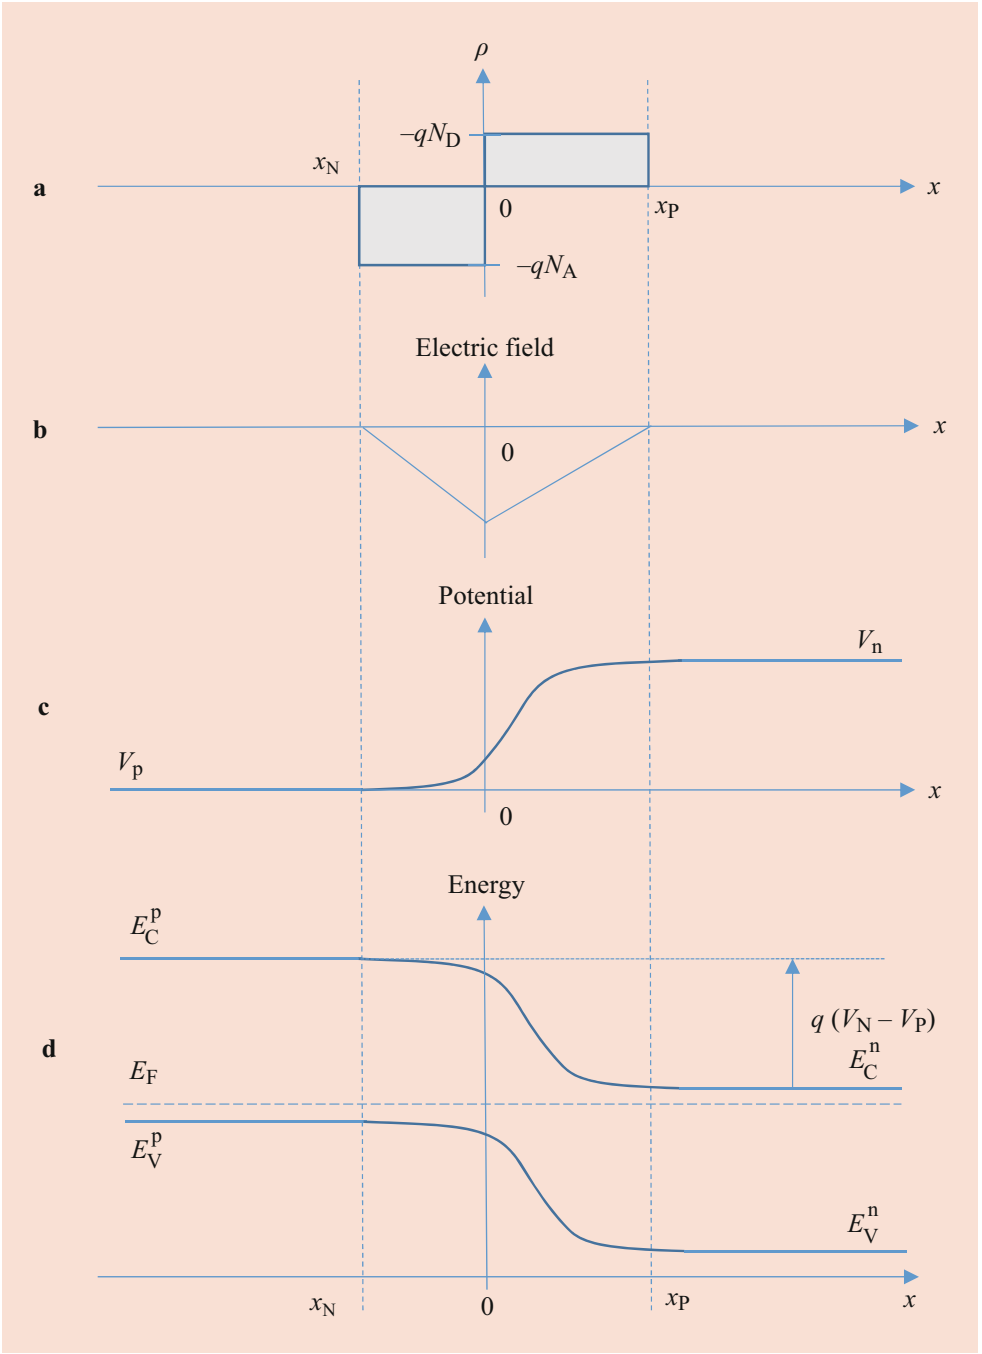

Fig. 16.2 Representation of the charge density (**a**), electric field (**b**), electrostatic potential (**c**) and energy bands bending (**d**) in a pn junction at zero bias

$$n_{\mathrm{p}} = \frac{n_i^2}{N_{\mathrm{A}}} \tag{16.19}$$

Dividing relations (16.16) by (16.17) gives the difference in the conduction (or valence) band energy between the neutral regions of the pn junction:

$$E_{\mathrm{C}}^{\mathrm{p}} - E_{\mathrm{C}}^{\mathrm{n}} = kT\,\mathrm{Ln}\left(\frac{N_{\mathrm{D}}N_{\mathrm{A}}}{n_i^2}\right) \tag{16.20}$$

which in terms of potentials reads

$$V_{\mathrm{n}} - V_{\mathrm{p}} = \frac{kT}{q}\mathrm{Ln}\left(\frac{N_{\mathrm{D}}N_{\mathrm{A}}}{n_i^2}\right) \tag{16.21}$$

This quantity is known as the *built-in potential* of the pn junction, namely, $V_{\mathrm{bi.}}$.

Its value is about 0.7 volt in silicon for doping densities of 10^{16} cm^{-3} (for N_{A} and N_{D}) at 25 °C.

The Depletion Width

So far, we obtained the potential drop in each region depleted from mobile carriers under the full-depletion approxima-

tion; see relation (16.12). Imposing now the condition given by relation (16.21), which is specific to the semiconductor (whereas so far we considered electrostatics only), gives

$$\begin{aligned}\frac{kT}{q}\mathrm{Ln}\left(\frac{N_\mathrm{D}N_\mathrm{A}}{n_i^2}\right) &= \frac{qN_\mathrm{D}{W_n}^2}{2\varepsilon_\mathrm{sc}}\left(\frac{N_\mathrm{D}}{N_\mathrm{A}}+1\right)\\ &= \frac{qN_\mathrm{D}{W_\mathrm{p}}^2}{2\varepsilon_\mathrm{sc}}\left(\frac{N_\mathrm{A}}{N_\mathrm{D}}+1\right)\end{aligned} \tag{16.22}$$

The depletion regions for each doped semiconductor layer are then readily obtained:

$$\begin{aligned}\mathrm{W_n} &= \sqrt{\frac{2\varepsilon_\mathrm{sc}kT}{q^2N_\mathrm{D}}}\sqrt{\frac{N_\mathrm{A}}{N_\mathrm{A}+N_\mathrm{D}}\mathrm{Ln}\left(\frac{N_\mathrm{D}N_\mathrm{A}}{n_i^2}\right)}\\ &= L_{\mathrm{D-n}}\sqrt{\frac{N_\mathrm{A}}{N_\mathrm{A}+N_\mathrm{D}}\mathrm{Ln}\left(\frac{N_\mathrm{D}N_\mathrm{A}}{n_i^2}\right)}\end{aligned} \tag{16.23}$$

Similarly,

$$W_\mathrm{p} = L_{\mathrm{D-p}}\sqrt{\frac{N_\mathrm{D}}{N_\mathrm{A}+N_\mathrm{D}}\mathrm{Ln}\left(\frac{N_\mathrm{D}N_\mathrm{A}}{n_i^2}\right)} \tag{16.24}$$

where $L_{\mathrm{D-n}}$ and $L_{\mathrm{D-p}}$ are the Debye lengths defined as $L_{\mathrm{D-n}} = \sqrt{\frac{2\varepsilon_\mathrm{sc}kT}{q^2N_\mathrm{D}}}$ and $L_{\mathrm{D-p}} = \sqrt{\frac{2\varepsilon_\mathrm{sc}kT}{q^2N_\mathrm{A}}}$.

Finally, the total depletion with W of the pn junction is $W = W_\mathrm{n} + W_\mathrm{p}$.

Note that relation (16.8) indicates that the ratio between the depletion widths scales with the counter ratio of the doping concentrations. Therefore, when a concentration dominates (a quite common situation in real devices), the depletion width of the pn junction can fairly be approximated by the depletion width of the lesser-doped domain:

$$W \cong W_\mathrm{p} = L_{\mathrm{D-p}}\sqrt{\mathrm{Ln}\left(\frac{N_\mathrm{D}N_\mathrm{A}}{n_i^2}\right)} \text{ when } N_\mathrm{D} \gg N_\mathrm{A} \tag{16.25}$$

Analysis of the pn Junction in Reverse Bias

The depletion region can be modulated by applying an external potential V between the n- and p-type doped regions. Here, we consider that we apply a negative voltage to the n side with respect to the p side and define $V = V_\mathrm{N} - V_\mathrm{P}$. This voltage V splits the energy between the Fermi levels on each side of the junction by qV, and therefore it will shift the bands in the neutral regions by the same amount (since the free carrier density is not changed in the neutral regions).

Again, supposing $N_\mathrm{D} \gg N_\mathrm{A}$, relation (16.22) writes

$$V + \frac{kT}{q}\mathrm{Ln}\left(\frac{N_\mathrm{D}N_\mathrm{A}}{n_i^2}\right) \cong \frac{qN_\mathrm{A}{W_\mathrm{p}}^2}{2\varepsilon_\mathrm{sc}} \tag{16.26}$$

and the depletion in the p-type semiconductor is now voltage-dependent

$$W_\mathrm{p}(V) \cong \sqrt{\frac{2\varepsilon_\mathrm{sc}}{qN_\mathrm{A}}}\sqrt{V+V_\mathrm{bi}} \tag{16.27}$$

(the p side is taken as the reference for the potentials).

Depending on the sign of V, the depletion region will either increase ($V > 0$) or decrease ($V < 0$).

Since the charge density can be modulated, the depletion capacitance follows. The charge stored per unit surface in each depletion region (in absolute value) is given by

$$Q_\mathrm{Dep}(V) = q\,N_\mathrm{A}\,W_\mathrm{p}(V) = \sqrt{2\varepsilon_\mathrm{sc}q\,N_\mathrm{A}}\sqrt{V+V_\mathrm{bi}} \tag{16.28}$$

Therefore, the depletion capacitance per unit surface $C_\mathrm{Dep}(V)$ is given by ($N_\mathrm{D} \gg N_\mathrm{A}$):

$$C_\mathrm{Dep}(V) = \frac{\mathrm{d}Q_\mathrm{Dep}(V)}{\mathrm{d}V} = \sqrt{\frac{\varepsilon_\mathrm{sc}q\,N_\mathrm{A}}{2}}\frac{1}{\sqrt{V+V_\mathrm{bi}}} \tag{16.29}$$

This depletion capacitance varies with the applied potential. This characteristic is commonly used to modulate a resonance frequency of a resonant circuit with a DC bias and is known as the junction varactor device [7].

16.1.3 The pn Junction in Forward Bias

When the potential barrier across the pn junction is lowered, the balance between diffusion and drift currents is no longer satisfied and generates a net current flowing across the junction. The common way to model a pn junction in forward bias is to evaluate the excess in minority-carrier concentrations at the limit of each space-charge region. These excess carriers will tend to diffuse inside the neutral region, where a fraction will recombine with the majority carriers introduced by the doping. *Note that this process takes place outside of the depletion region.*

This kind of analysis is formulated with the basics of semiconductor physics (in non-degenerate conditions), ensuring the current continuity condition. Here, we adopt the convention $V = V_\mathrm{P} - V_\mathrm{N}$, where V_P and V_N are the potentials applied to the p- and n-type doped semiconductors, respectively (note that the convention adopted here is different from the reverse bias case in order to consider positive voltages).

Estimation of the Minority Carrier Concentrations

The minority carrier concentration in the neutral regions is known from the intrinsic carrier concentration and the doping densities; see Fig. 16.3.

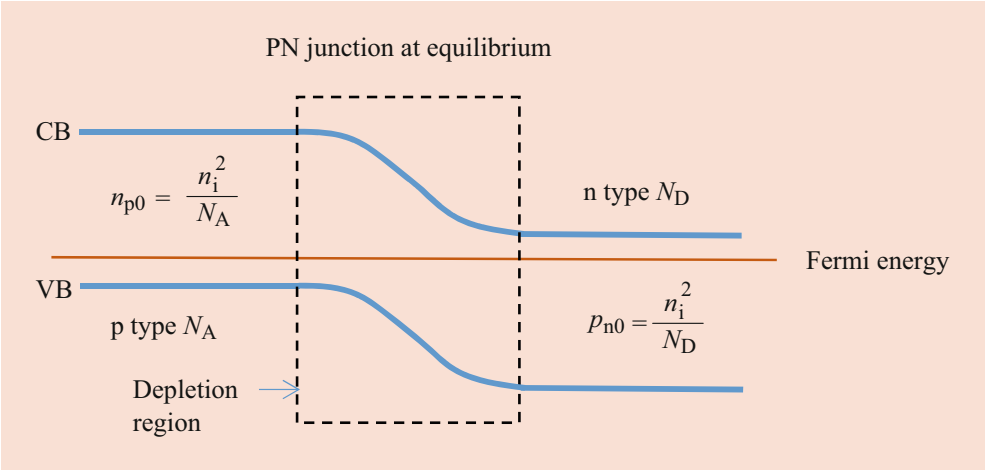

Fig. 16.3 Conduction and valence extrema energies across the pn junction at equilibrium. Minority carrier concentrations are indicated, as well as the limit of the depletion regions

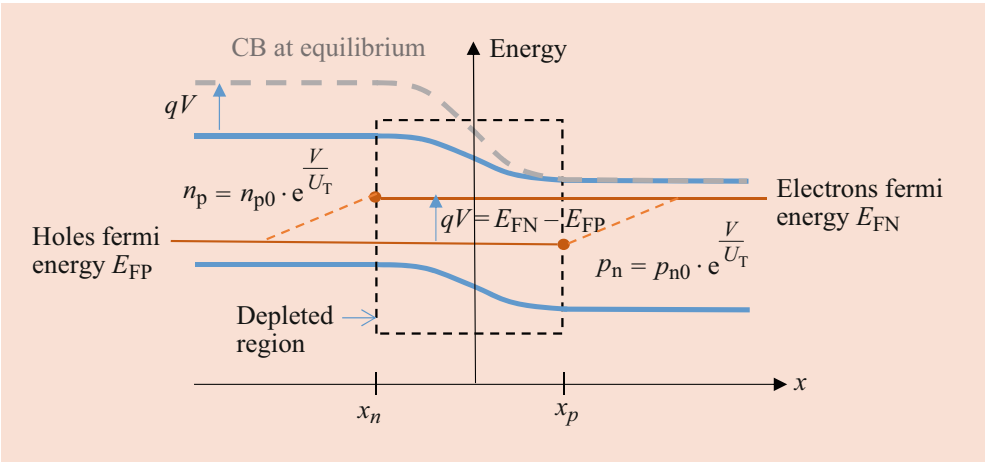

Fig. 16.4 Conduction and valence bands extrema energies across the pn junction under forward bias. Minority-carrier concentrations at the limit of the depletion regions are enhanced with respect to the concentration they have at equilibrium

$$n_{p0} = \frac{n_i^2}{N_A} \tag{16.30}$$

$$p_{n0} = \frac{n_i^2}{N_D} \tag{16.31}$$

As already mentioned, applying a potential V across the pn junction splits the electron and hole Fermi energies by qV and shifts the conduction and valence bands as sketched in Fig. 16.4.

Provided the quasi-Fermi levels for electrons and holes do not vary across the depletion region (but merge in a common Fermi level in the neutral regions at equilibrium, see dotted lines in Fig. 16.4), we obtain the concentrations of minority carriers at the limit of the depletion regions:

$$n_p\left(x_p\right) = n_{p0}\, e^{\frac{qV}{kT}} = \frac{n_i^2}{N_A}\, e^{\frac{V}{U_T}} \tag{16.32}$$

$$p_n\left(x_n\right) = p_{n0}\, e^{\frac{qV}{kT}} = p_{n0}\, e^{\frac{V}{U_T}} = \frac{n_i^2}{N_D}\, e^{\frac{V}{U_T}} \tag{16.33}$$

where $U_T = \frac{kT}{q}$ is the thermal voltage.

When V is positive, the minority carrier concentrations are enhanced at the limit of the depletion regions. The next step is to calculate how these carriers will generate a current.

The Current-Continuity Equation

Assuming that there is no electric field in the neutral regions, under steady state, the continuity equation reverts to a simple second order differential equation:

$$D_p \frac{d^2 p_n}{dx^2} - \frac{p_n - p_{n0}}{\tau_p} = 0 \tag{16.34}$$

where D_p is the diffusion coefficient of holes in the n-type doped semiconductor and τ_p their lifetime.

The same relation can be derived for electrons in the p-type doped layer

$$D_{\mathrm{n}}\frac{\mathrm{d}^2 n_{\mathrm{p}}}{\mathrm{d}x^2}-\frac{n_{\mathrm{p}}-n_{\mathrm{p0}}}{\tau_{\mathrm{n}}}=0 \tag{16.35}$$

Introducing the diffusion length of electrons in the p-type semiconductor, $L_{\mathrm{n}}=\sqrt{D_{\mathrm{n}}\tau_{\mathrm{n}}}$, and for holes in the n-type semiconductor, $L_{\mathrm{p}}=\sqrt{D_{\mathrm{p}}\tau_{\mathrm{p}}}$, we obtain

$$\frac{\mathrm{d}^2 n_{\mathrm{p}}}{\mathrm{d}x^2}-\frac{n_{\mathrm{p}}-n_{\mathrm{p0}}}{{L_{\mathrm{n}}}^2}=0 \tag{16.36}$$

$$\frac{\mathrm{d}^2 p_{\mathrm{n}}}{\mathrm{d}x^2}-\frac{p_{\mathrm{n}}-p_{\mathrm{n0}}}{{L_{\mathrm{p}}}^2}=0 \tag{16.37}$$

Solving these differential equations gives the profile of the minority carrier concentrations in both neutral regions. The last step is to set the limit conditions.

One condition happens at the limit of the space charge region and is rebuilt from relations (16.32) and (16.33). The other one is at the contact itself, i.e., $x=x_{\mathrm{Cn}}$ and $x=x_{\mathrm{Cp}}$, where full recombination in excess minority carriers is imposed:

$$p_{\mathrm{n}}\left(x_{\mathrm{Cn}}\right)=p_{\mathrm{n0}}=\frac{{n_i}^2}{N_{\mathrm{D}}} \tag{16.38}$$

$$n_{\mathrm{p}}\left(x_{\mathrm{Cp}}\right)=n_{\mathrm{p0}}=\frac{n_i^2}{N_{\mathrm{A}}} \tag{16.39}$$

Then, the general solution is

$$p_{\mathrm{n}}(x)-p_{\mathrm{n0}}=p_{\mathrm{n0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\frac{\sinh\left(\left(x_{\mathrm{Cn}}-x\right)/L_{\mathrm{p}}\right)}{\sinh\left(T_{\mathrm{n}}/L_{\mathrm{p}}\right)} \tag{16.40}$$

$$n_{\mathrm{p}}(x)-n_{\mathrm{p0}}=n_{\mathrm{p0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\frac{\sinh\left(\left(x-x_{\mathrm{Cp}}\right)/L_{\mathrm{n}}\right)}{\sinh\left(T_{\mathrm{p}}/L_{\mathrm{n}}\right)} \tag{16.41}$$

where $T_{\mathrm{p}}=W_{\mathrm{p}}-x_{\mathrm{Cp}}$ and $T_{\mathrm{n}}=x_{\mathrm{Cn}}-W_{\mathrm{n}}$ are the extensions of the p- and n-doped neutral regions.

Minority-Carrier Current

The excess of minority carriers in the neutral regions is responsible for diffusion currents:

$$J_{\mathrm{p}}(x)=-qD_{\mathrm{p}}\frac{\mathrm{d}p_{\mathrm{n}}(x)}{\mathrm{d}x} \tag{16.42}$$

$$J_{\mathrm{n}}(x)=qD_{\mathrm{n}}\frac{\mathrm{d}n_{\mathrm{p}}(x)}{\mathrm{d}x} \tag{16.43}$$

Making use of relations (16.40) and (16.41), these currents become explicit functions of the potential and coordinate.

$$\begin{aligned}J_{\mathrm{p}}(x)&=-qD_{\mathrm{p}}\frac{\mathrm{d}p_{\mathrm{n}}(x)}{\mathrm{d}x}\\&=\frac{qD_{\mathrm{p}}n_i^2}{L_{\mathrm{p}}N_{\mathrm{D}}\sinh\left(T_{\mathrm{n}}/L_{\mathrm{p}}\right)}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\operatorname{csh}\left(\left(x_{\mathrm{Cn}}-x\right)/L_{\mathrm{p}}\right)\end{aligned} \tag{16.44}$$

$$\begin{aligned}J_{\mathrm{n}}(x)&=qD_{\mathrm{n}}\frac{\mathrm{d}n_{\mathrm{p}}(x)}{\mathrm{d}x}\\&=\frac{qD_{\mathrm{n}}n_i^2}{L_{\mathrm{n}}N_{\mathrm{A}}\sinh\left(T_{\mathrm{p}}/L_{\mathrm{n}}\right)}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\operatorname{csh}\left(\left(x-x_{\mathrm{Cp}}\right)/L_{\mathrm{n}}\right)\end{aligned} \tag{16.45}$$

From relations (16.44) and (16.45), the minority carrier diffusion currents are not constant as they vary with x. However, this does not mean that the *total current* is not constant. Indeed, this condition was already enforced by introducing the current-continuity equation in the steady-state analysis (note that very high-frequency operation requires another approach). In fact, at any coordinate, there is a recombination current that is compensated by a current of majority carriers. This majority carrier current "brings" the majority carriers that will be "used" to enable recombination.

Simplifying Assumptions

Two situations are of practical interest.

The first case is when the neutral regions are wider than the diffusion lengths, i.e., $T_{\mathrm{p}}\gg L_{\mathrm{n}}$ and $T_{\mathrm{n}}\gg L_{\mathrm{p}}$. This case corresponds to "long diodes."

The second case refers to short diodes, i.e., when $T_{\mathrm{p}}\ll L_{\mathrm{n}}$ and $T_{\mathrm{n}}\ll L_{\mathrm{p}}$.

Long Diodes

In a long diode, relations (16.40) and (16.41) can be simplified and excess in minority carrier concentrations are given by

$$\begin{aligned}p_{\mathrm{n}}(x)-p_{\mathrm{n0}}&=p_{\mathrm{n0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\frac{\mathrm{e}^{\left(x_{\mathrm{Cn}}-x\right)/L_{\mathrm{P}}}}{\mathrm{e}^{T_{\mathrm{n}}/L_{\mathrm{p}}}}\\&=p_{\mathrm{n0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\mathrm{e}^{\left(x_{\mathrm{n}}-x\right)/L_{\mathrm{p}}}\end{aligned} \tag{16.46}$$

$$\begin{aligned}n_{\mathrm{p}}(x)-n_{\mathrm{p0}}&=n_{\mathrm{p0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\frac{\mathrm{e}^{\left(x-x_{\mathrm{Cp}}\right)/L_{\mathrm{n}}}}{\mathrm{e}^{T_{\mathrm{p}}/L_{\mathrm{n}}}}\\&=n_{\mathrm{p0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}}-1\right)\mathrm{e}^{\left(x-x_{\mathrm{p}}\right)/L_{\mathrm{n}}}\end{aligned} \tag{16.47}$$

Applying relations (16.42) and (16.43), the current density for each type of carrier is (the long diode approximation can also be directly obtained from relations (16.44) and (16.45)):

$$J_{\mathrm{p}}(x) = \frac{qD_{\mathrm{p}}n_i^2}{L_{\mathrm{p}}N_{\mathrm{D}}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right)\mathrm{e}^{(x_{\mathrm{Cn}}-x)/L_{\mathrm{p}}} \tag{16.48}$$

$$J_{\mathrm{n}}(x) = \frac{qD_{\mathrm{n}}n_i^2}{L_{\mathrm{n}}N_{\mathrm{A}}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right)\mathrm{e}^{(x-x_{\mathrm{Cp}})/L_{\mathrm{n}}} \tag{16.49}$$

In long diodes, minority carrier currents are not constant along the neutral regions (see comment above).

Short Diodes

In short diodes the hyperbolic sine and cosine function can be replaced by the first order term of a Taylor series, $\sinh(T_{\mathrm{n}}/L_{\mathrm{p}}) \cong T_{\mathrm{n}}/L_{\mathrm{p}}$ ($\sinh(T_{\mathrm{p}}/L_{\mathrm{n}}) \cong T_{\mathrm{p}}/L_{\mathrm{n}}$) and $\mathrm{csh}((x_{\mathrm{Cn}} - x)/L_{\mathrm{p}}) \cong 1$, ($\mathrm{csh}((x - x_{\mathrm{Cp}})/L_{\mathrm{n}}) \cong 1$) leading to

$$p_{\mathrm{n}}(x) - p_{\mathrm{n0}} = p_{\mathrm{n0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right)\frac{(x_{\mathrm{Cn}} - x)}{T_{\mathrm{n}}} \tag{16.50}$$

$$n_{\mathrm{p}}(x) - n_{\mathrm{p0}} = n_{\mathrm{p0}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right)\frac{(x - x_{\mathrm{Cp}})}{T_p} \tag{16.51}$$

These expressions lead to current densities that are now independent of the coordinate:

$$J_{\mathrm{p}} = \frac{qD_{\mathrm{p}}n_i^2}{T_{\mathrm{n}}N_{\mathrm{D}}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right) \tag{16.52}$$

$$J_{\mathrm{n}} = \frac{qD_{\mathrm{n}}n_i^2}{T_{\mathrm{p}}N_{\mathrm{A}}}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right) \tag{16.53}$$

Where we assumed for simplicity $p_{\mathrm{n0}}N_{\mathrm{D}} = n_i^2$ and $n_{\mathrm{p0}}N_{\mathrm{A}} = n_i^2$.

The limit conditions are represented in Figs. 16.5 and 16.6 for the minority carrier concentrations and minority-carrier currents, respectively.

In short diodes, the diffusion current is constant in the neutral regions.

Total Current Densities

In each domain, the sum of the currents generated by the diffusion of minority carriers and the current originating by majority carriers enabling recombination is constant. This condition holds in particular at the edge of the depletion regions, i.e., at x_{p} and x_{n}. At these coordinates, the recombination current is null since recombination did not operate yet (this is where minority carriers are 'freshly' injected). Therefore, only the diffusion current exists, meaning that the current density arising from the transfer of electrons from the n-type into the p-type doped semiconductor layers is given by

$$J_{\mathrm{n}} = J_{\mathrm{n}}\left(x_{\mathrm{Cp}}\right) = qD_{\mathrm{n}}\frac{\mathrm{d}n_{\mathrm{p}}(x)}{\mathrm{d}x} = \frac{qD_{\mathrm{n}}n_i^2}{L_{\mathrm{n}}N_{\mathrm{A}}\tanh\left(T_{\mathrm{p}}/L_{\mathrm{n}}\right)}\left(\mathrm{e}^{\frac{V}{U_{\mathrm{T}}}} - 1\right) \tag{16.54}$$

The same reasoning applies for the current generated by injection of holes in the n-type region:

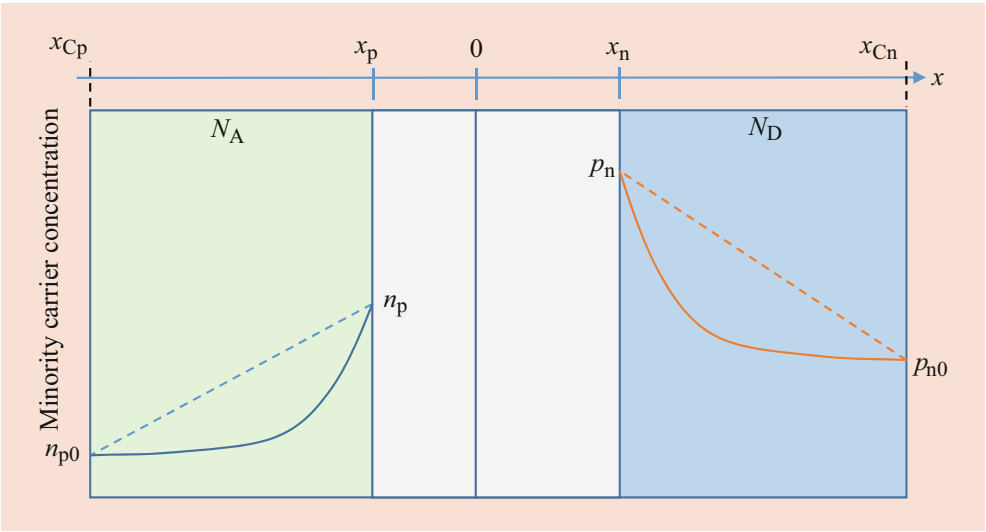

Fig. 16.5 Sketch of the minority-carrier concentration profiles in the neutral regions. Dotted lines are for short diodes. Continuous lines for long diodes. Note that the limit conditions are identical in both cases

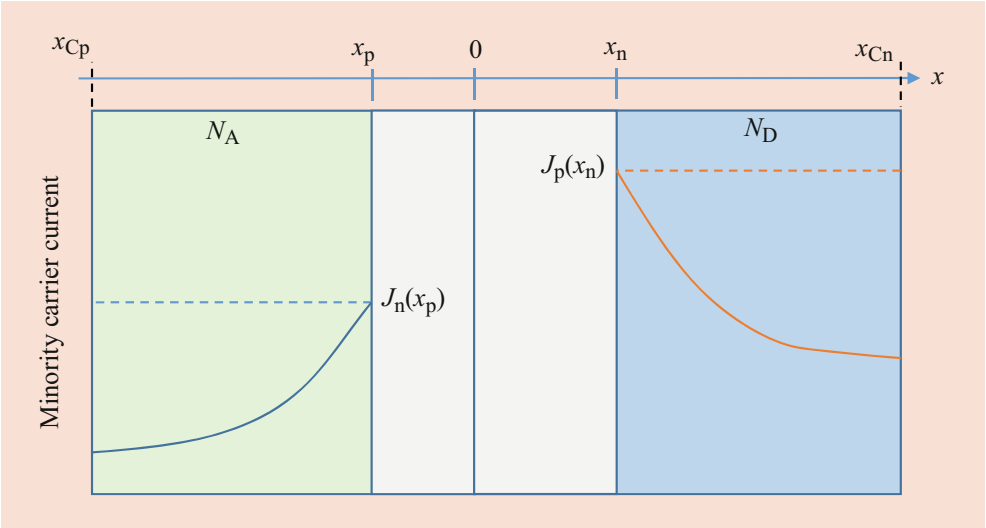

Fig. 16.6 Sketch of the minority-carrier current (diffusion current) profiles in the neutral regions. Dotted lines are for short diodes. Continuous lines for long diodes. Note that only for short diodes the diffusion current is constant in the neutral regions

$$J_p = J_p\,(x_{Cn}) = -qD_p \frac{dp_n(x)}{dx} = \frac{qD_p n_i^2}{L_p N_D \tanh\left(T_n/L_p\right)} \left(e^{\frac{V}{U_T}} - 1\right) \tag{16.55}$$

Finally, the total current flowing in the diode is the sum of electron and hole currents:

$$J_T = J_n + J_p = qn_i^2 \left(e^{\frac{V}{U_T}} - 1\right) \left(\frac{D_n}{L_n N_A \tanh\left(T_p/L_n\right)} + \frac{D_p}{L_p N_D \tanh\left(T_n/L_p\right)}\right) \tag{16.56}$$

Defining the saturation current density J_s as

$$J_s = qn_i^2 \left(\frac{D_n}{L_n N_A \tanh\left(T_p/L_n\right)} + \frac{D_p}{L_p N_D \tanh\left(T_n/L_p\right)}\right) \tag{16.57}$$

The total current in the diode becomes

$$J_T = J_s \left(e^{\frac{V}{U_T}} - 1\right) \tag{16.58}$$

Additional Generation and Recombination Currents from the Space-Charge Region

Depending on the polarization of the pn junction, kinetics of capture and release of mobile carriers by traps in the depletion region are responsible for what is called generation and recombination currents; see [4, 5].

The cases of forward and reverse polarizations are discussed briefly.

Forward Polarization: Recombination-Current Contribution

When the forward bias V exceeds a few U_T, it can be shown that the recombination rate in the space charge region greatly simplifies and can be approximated with [1]:

$$r = \frac{n_i}{2\,\tau}\, e^{\frac{V}{2U_T}} \tag{16.59}$$

This approximation is valid for a limited extension of the depletion region, W_{rec}. This value, as well as the recombination rate, is only meant to give the overall voltage dependence of those additional currents, but is not an exact expression.

Adopting relation (16.59) for the recombination rate, the space charge recombination current is

$$J_{rec} = q\,r\,W_{rec} = W_{rec}\,\frac{q\,n_i}{2\,\tau}\, e^{\frac{V}{2U_T}} \tag{16.60}$$

This current adds to the diffusion currents of the diode in forward bias, and therefore it is dominant only at low forward voltage biases. In practical cases, the recombination current is a parameter which is extracted from measurements.

Reverse Polarization: Generation-Current Contribution

When the diode is reverse biased, traps in the depletion region will be responsible for enhanced thermal emission of carriers. The induced generation current can be approximated by

$$J_{\text{gen}} = -\frac{q\, n_i}{2\, \tau}\, W \tag{16.61}$$

This current adds to the reverse current of the diode; see Fig. 16.7. Note that since the depletion width slightly varies with the reverse bias, this generation current may have some weak dependence on bias too.

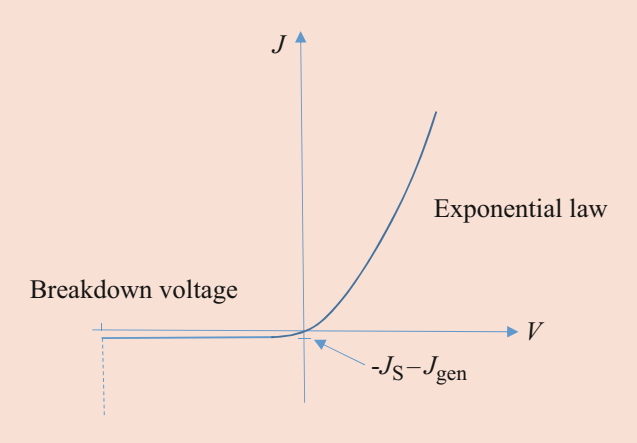

Fig. 16.7 Typical characteristics of a pn junction in forward and reverse bias. Note that the reverse bias cannot exceed a breakdown voltage beyond which the device will be damaged

16.2 Bipolar Transistors

16.2.1 Introduction

In 1947, the first bipolar junction transistor (BJT) was invented by a research team at Bell Laboratories using a germanium substrate. The bipolar junction transistor is one of the most important semiconductor devices. In this chapter we will learn about the bipolar junction transistors. The invention of the transistor led to the invention of many other semiconductor devices, including the integrated circuits, and enabled modern computers and complex electronic systems [6].

The bipolar junction transistor (BJT) is a three-terminal semiconductor device (see Fig. 16.8) which can act as a conductor or insulator based on the applied input signal; due to this property, the transistor can be used as a switch in the digital electronics or can be used as an amplifier in the analog electronics. Nowadays, the bipolar junction transistors are widely used in the electronic industry, and, therefore, anyone who is interested in electronics should have some basic knowledge of BJT [6].

A bipolar junction transistor (BJT) is a solid-state device used for high-speed circuits, analog circuits and power applications. It uses two types of carriers, electrons and holes, whence its name. In this chapter, we focus on the static

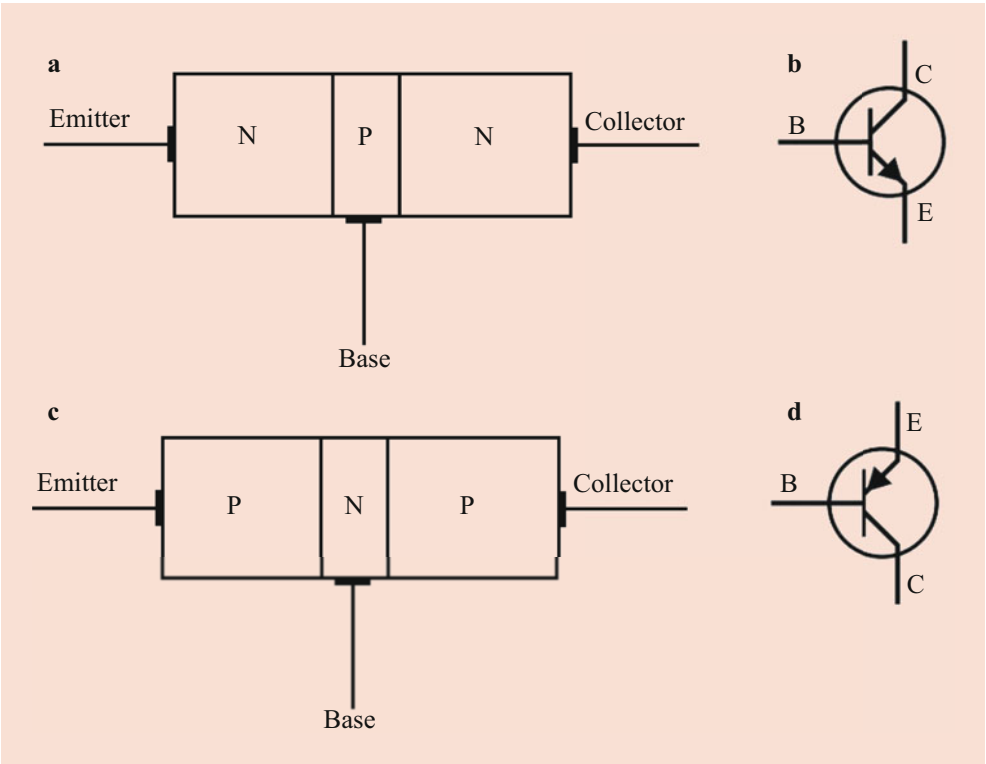

Fig. 16.8 The bipolar junction transistor (BJT) is a three terminal semiconductor device consisting of two semiconductor types, i.e., n-type and p-type. It involves two types of carrier, electrons and holes

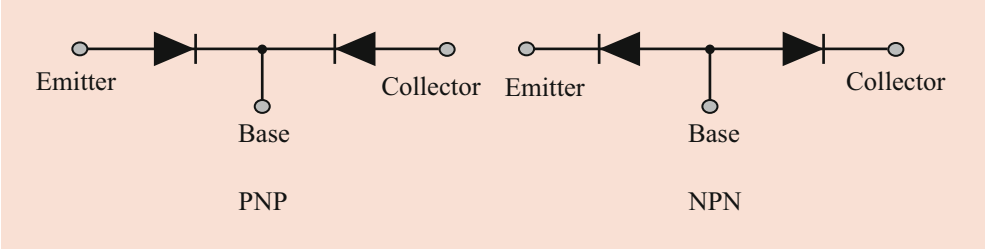

Fig. 16.9 Bipolar junction transistor (BJT) appears as if two back-to-back diodes were connected in series

characteristics obtained from the minority-carrier distributions in coupled p-n junctions. In the final section, we will end up with current gain and modes of operation of bipolar transistors.

16.2.2 Structure

As shown in Fig. 16.8, two types of bipolar transistor are available for BJTs, known as n-p-n (a, b) and p-n-p (c, d) [6]. The n-p-n bipolar transistor is the complementary structure to the p-n-p bipolar transistor. An n-p-n transistor shares a thin p-doped region sandwiched between two n-doped layers, while a p-n-p transistor shares a thin n-doped region sandwiched between two p-type layers. A BJT is a three-terminal device with base (B), emitter (E), and collector (C) contacting to three-doped semiconductor regions called emitter, base, and collector regions. The emitter region is heavily doped compared to the other two layers, and the collector dopant concentration is much smaller than the base one.

16.2.3 Principle of Operation

A BJT is made of two p-n junctions: one holds for the emitter-base junction, while the other defines the base-collector junction. These junctions appear as two back-to-back diodes connected in series (see Fig. 16.9). Actually, without additional analysis, such a device would not behave like a bipolar transistor because when connecting two back-to-back diodes, there is no interaction between them, which means that the two diodes are operating independently [6]. The main difference is that n- and p-type diffusions share the same crystal, i.e., there is no "contact" linking the diodes internally at the base level.

A careful analysis demonstrates that there is a strong interaction between the emitter and the collector by means of the intermediate base region. The emitter is heavily doped and its function is to supply the majority carriers, whereas the collector is lightly doped. The doping concentration of

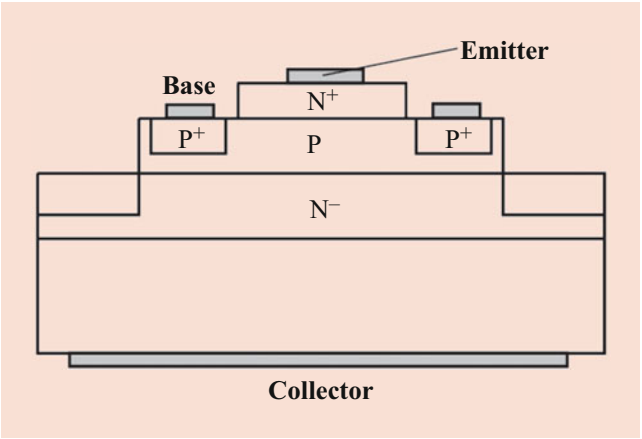

Fig. 16.10 Cross-sectional view of an n-p-n bipolar transistor

the base is between that of the emitter and the collector. In addition, the thickness of the base region is very narrow compared to the others, in order to avoid recombination of minority carriers which should travel across it before being be collected by the collector [6]. A typical cross-section is shown in Fig. 16.10.

From the point of view of applications, bipolar transistors operation is split in three distinct regions:

I. The **Active Region** where the transistor acts as an amplifier and where the base and collector currents are proportional (β is the current transistor gain): $I_C = \beta\, I_B$
II. The **Saturation Region** when the device is "fully-ON" and operates as a switch, $I_C = I_{C\,(Sat)}$
III. The **Cutoff Region** where the transistor is in "OFF-state" and operates as an open switch, $I_C = 0$.

These various modes depend on the biasing of each terminal.

In the active region of operation, the emitter-base junction is forward biased, and the base-collector junction is reverse biased. The voltage at the emitter is V_E, V_B at the base, and V_C at the collector. Considering by way of example the n-p-n transistors, in the active region the base voltage should be larger than that of the emitter, and the collector

voltage should be larger than that of the base (reverse biased collector-base junction).

In the cutoff region, both base-emitter and base-collector junctions are reverse biased. So, to operate the BJT in the cutoff region, both the emitter and collector voltages must be larger than the base voltage.

Lastly, when the BJT operates in saturation, both the base-emitter and base-collector junctions are forward biased, which means that the base voltage V_B must be larger than the emitter and collector voltages. In summary, these are the three regions of operation of the BJT (apart from a fourth one, known as "reverse active region of operation," where the role of the collector and emitter are interchanged [6], but which is not used).

Similarly, when the p-n-p transistor is considered, in the active region of operation the base-emitter junction is still forward biased and the collector-base junction is still reverse biased, but the emitter voltage is larger than the base voltage, and, similarly, the base voltage is larger than the collector voltage.

16.2.4 DC Operation of the n-p-n BJT Under Forward Active Mode

The principle of operation of a bipolar transistor relies on the fact that the base region of the transistor is very thin. The p-n junction between base and emitter is forward biased so that a current made of electrons flows from the emitter into the base, and a hole current flows from the base into the emitter. However, since these forward currents scale with the doping density, (see relations 16.48 and 16.49 for instance), the current injected by the base is negligible with respect to the emitter current (there are about two orders of magnitude between the doping of the base and that of the emitter). On the other hand, the base-collector junction is reverse biased. Most of emitter-injected electrons are swept straight through the very thin base. Once they reach the base-collector depletion layer, they are accelerated by the electric field in the depletion region and are swept across the depletion layer before being collected by the collector. The operating principle of bipolar devices is different from that of unipolar devices, e.g., field-effect transistors (FETs), where the current is controlled either by electrons or holes. BJTs are classified as minority-carrier devices [6].

16.2.5 Bipolar-Transistor Configurations

There are three possible ways to connect the bipolar transistor within a circuit:

- **Common-base configuration** with voltage gain but no current gain
- **Common-emitter configuration** with both current and voltage gain
- **Common-collector configuration** with current gain but no voltage gain
  - Whenever a BJT is used for ***amplification***, it is set in the active region adopting different configurations, i.e., common emitter, common base, common collector.
  - Whenever a BJT is used as a ***switch***, it works either in the saturation or in the cutoff region.

In this section, we discuss in detail these different regions of operation [6].

16.2.6 Common-Emitter Configuration

To use the BJT as an amplifier, the base-emitter junction is forward biased, while the collector-base junction is reverse biased (see Fig. 16.11 [6]).

In case of a common-emitter configuration, the emitter terminal is common to the input and the output ports (see Fig. 16.12). In this configuration, the input signal is applied between the base and the emitter, and the output signal is measured between the collector and the emitter.

More precisely, the base current is the input current while the collector current is the output current (see Fig. 16.13). Voltage V_{BE} is the voltage on the input side, and voltage V_{CE} is the voltage on the output side.

Supposing that DC biasing voltages are already applied, then superimposing a sinusoidal voltage between the base and emitter terminals will modulate the output voltage between the collector and emitter terminals, which can give rise to an amplification. In this configuration, to understand the behavior of the device, we need to understand two types of characteristics, namely, the input and output characteristics.

The input characteristic defines the relationship between the base current I_B and the base-to-emitter voltage V_{BE}.

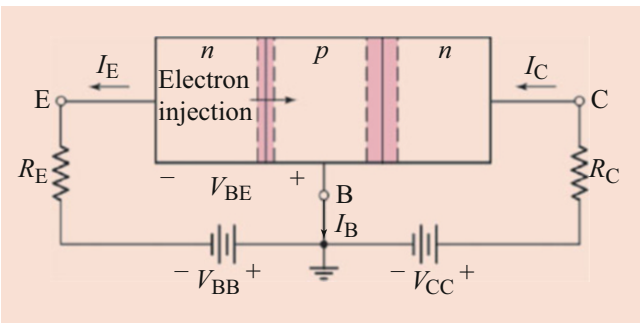

Fig. 16.11 n-p-n transistor biased in forward-active mode. Colored regions sketch the depletion regions of the pn junctions

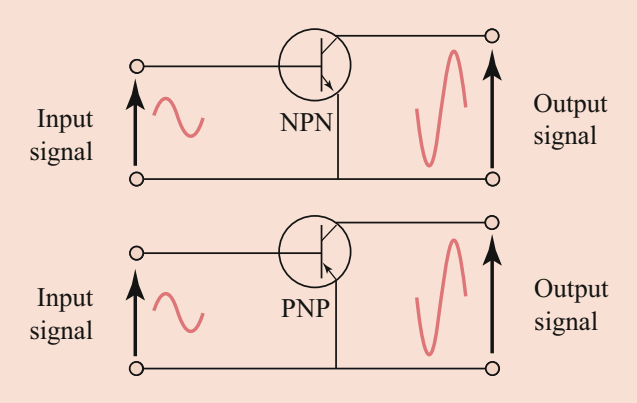

Fig. 16.12 The mostly used amplifier configuration of the bipolar transistor: the common-emitter configuration. Both n-p-n and p-n-p transistors are represented

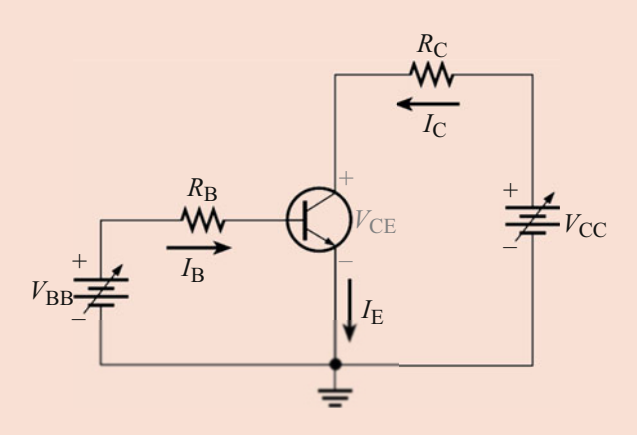

Fig. 16.13 Common-emitter biasing for the n-p-n transistor

Similarly, the output characteristic defines the relationship between the collector current I_C and the collector-to-emitter voltage V_{CE}. Figure 16.14 shows the input characteristics where I_B is plotted versus V_{BE} for different values of V_{CE}.

These curves look very similar to the forward characteristics of a pn junction diode, which is expected since the base-emitter junction on the input side is forward biased. However, note that as the V_{CE} increases, the base current decreases.

The V_{CE} voltage can be written as

$$V_{CE} = V_{CB} + V_{BE} \tag{16.62}$$

Note that for a fixed value of V_{BE}, if V_{CE} is increased, then V_{CB} will also increase, meaning that the reverse bias applied between the collector and the base terminal will increase. This means that the depletion region created at the collector-base junction will get wider (see, for instance, relation (16.27) for the case of a p-type doped semiconductor). Therefore, the effective base width will shrink, and so the probability of recombination for the minority carriers

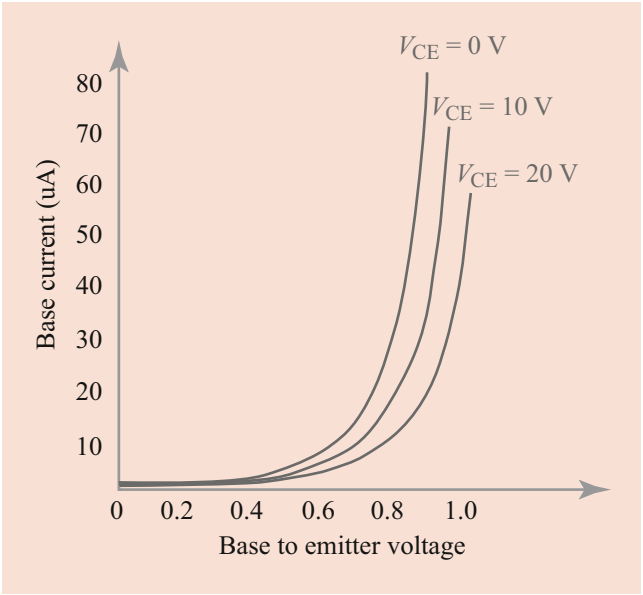

Fig. 16.14 Input characteristics of a BJT in the common-emitter configuration

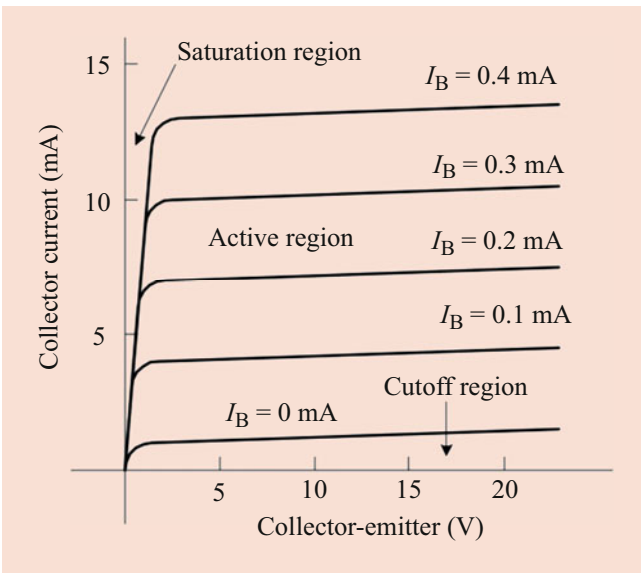

Fig. 16.15 Output characteristics of a BJT in the common-emitter configuration

injected by the emitter into the base will decrease, which will lower the base recombination current I_B. This quite empirical analysis explains the shift in the input characteristics plotted in Fig. 16.14.

In Fig. 16.15, the output characteristics show the relationship between the collector current I_C and V_{CE} for different base currents. Each curve can be divided into the three regions discussed before: one corresponds to the active region, the second to the saturation, and the third to the cutoff region.

In the case of active-region operation, since the base current I_B increases, the collector current increases as well. Here, unlike the common-base configuration, as V_{CE} increases and pushes the transistor in the active region, the collector current I_C also increases, meaning that the collector current characteristics are not strictly "horizontal."

Such a current increase with V_{CE} is attributed to a widening of the depletion region of the collector-emitter, reverse-biased pn junction, resulting in a shorter neutral region for the n-type base. As the effective base width reduces, the probability of recombination in this region will also decrease, and more electrons will be able to cross the base without recombining, meaning that the collector current will increase. Whenever the BJT is used as an amplifier, it is used in the active region. In this region, the base current gets amplified by a factor β, meaning that if I_B is the base input current and I_C is the collector current, then

$$I_C = \beta\, I_B \tag{16.63}$$

Note that under AC operation, this relation still holds, $\Delta I_C = \beta_{AC}\, \Delta I_B$.

Here, β_{AC} is the ratio of the collector- to base-current variations [6]. Usually the values of β_{AC} and β are not the same, but as they are very close to each other, they are often used without discrimination.

In case of operation in the saturation region, the collector-to-base junction and the base-to-emitter junctions are forward biased. This happens when the value of V_{CE} reduces so that the base-collector junction is no longer set in reverse bias. Indeed, as V_{CE} gets close to zero, the collector-to-base junction becomes forward biased. Note that when $V_{CE} = 0$, we obtain $V_{BC} = V_{BE}$, i.e., the base-to-collector junction is also forward biased.

The third region of operation corresponds to the so-called cutoff region.

In the cutoff region, the base current is set to zero, while the collector current is non-zero and can be relatively large. Its expression reads

$$I_C = \alpha\, I_E + I_{CBO} \tag{16.64}$$

where I_{CBO} is the reverse saturation current.

Also, remembering that $I_C = I_E + I_B$, the collector current is equal to

$$I_C = \alpha\ (I_E + I_B) + I_{CBO}. \tag{16.65}$$

Rearranging the above equation, we can write

$$(1-\alpha)\ I_C = \alpha\, I_B + I_{CBO} \text{ or, equivalently}$$

$$\begin{aligned} I_C &= \alpha/(1-\alpha)\ I_B + 1/(1-\alpha)\ I_{CBO} \\ &= \beta\, I_B + 1/(1-\alpha)\ I_{CBO} \end{aligned} \tag{16.66}$$

Whenever the base current I_B is zero, the collector current reduces to $1/(1-\alpha)\, I_{CBO}$.

Typically, the value of α varies from 0.95 to 0.99., meaning that $1/(1-\alpha)$ can be quite large.

On the other hand, the current gain satisfies $1/(1–\alpha) = (\beta + 1)$. Therefore, whenever the base current is set to zero, the "leakage" collector current I_{CEO} is $I_{CEO} = (\beta + 1)\, I_{CBO}$.

It represents the leakage current that flows from the collector to the emitter whenever the base terminal is open.

By way of example, if β is equal to 99 and the value of I_{CBO} is equal to 1 uA, the current I_{CEO} will be equal to 100 uA, which is a quite large leakage current.

As we mentioned already, in the active region of operation the input current gets amplified by the β factor, which is known as the current gain of this configuration. Whenever a load is inserted at the collector or emitter terminals, then we can also obtain a gain in terms of voltage.

So this common-emitter configuration provides the moderate current gain as well as the moderate voltage gain, but it provides very high power gain. This is why this configuration is frequently used for the signal amplification. However, the input and output impedances are in the moderate range. In this configuration, typically the output impedance lies in the range of 50–100 kΩ, which is high, but lower than that of the common-base configuration. Similarly, the input impedance is in range of kΩ, which can be found from the slope of the input characteristics. Here, the input impedance is given by

$$R_{in} = \Delta V_{BE}/\Delta I_B \tag{16.67}$$

16.2.7 Common-Collector Configuration

Similarly, in case of the common-collector configuration, the collector terminal is common between the input and output side (Fig. 16.16).

In this configuration, the input is applied between the base and the collector terminal, and the output is measured between the emitter and the collector terminal (see Fig. 16.16). To use this configuration as an amplifier, it necessary to bias it in a such a way that the base-emitter junction gets forward biased and the collector-base junction gets reverse biased. In fact, in terms of DC biasing, it resembles the common emitter configuration.

From the DC perspective, Fig. 16.17 shows how typical biasing voltages are applied [6].

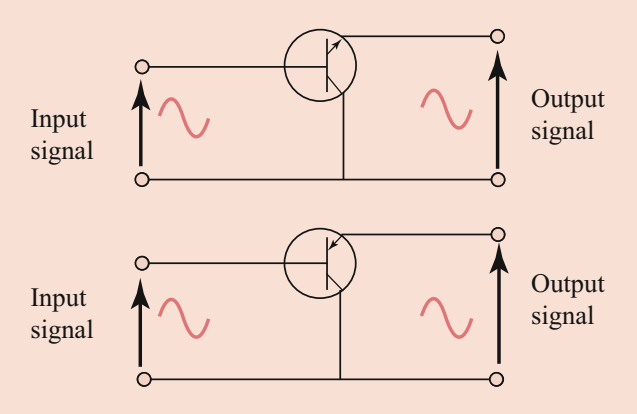

Fig. 16.16 Common-collector configuration

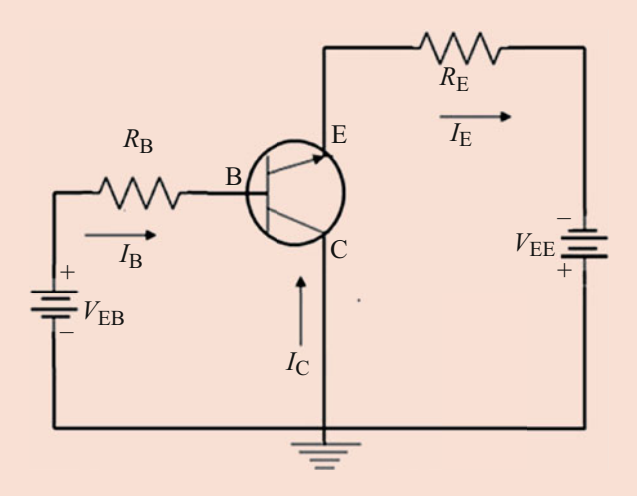

Fig. 16.17 Common-collector configuration

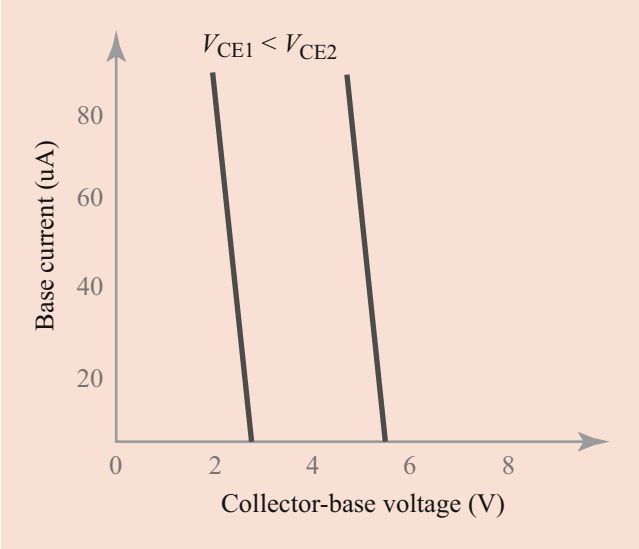

Fig. 16.18 Input characteristic of a common-collector configuration

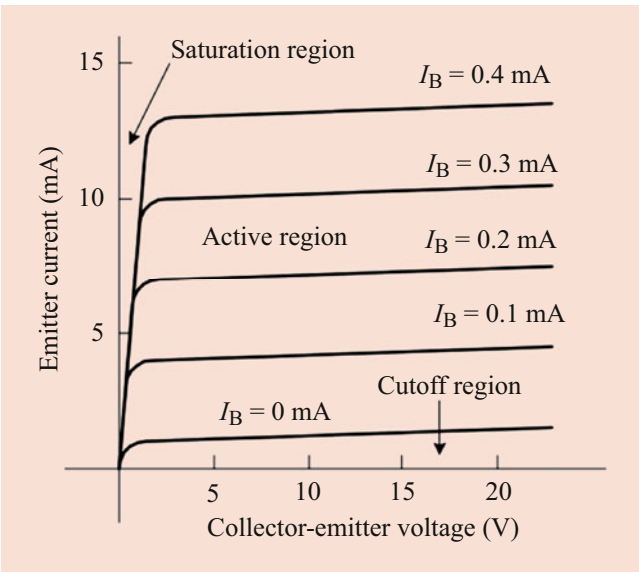

Fig. 16.19 Output characteristics of a BJT in the common-collector configuration

The base current is the current on the input side, while the emitter current is the current on the output side. The emitter current can be expressed as [6, 7]

$$I_E = \alpha\, I_C \tag{16.68}$$

As the value of α is very close to unity, the emitter current is approximately equal to the collector current and that's why the output characteristic in this configuration is very similar to that of the common-emitter configuration.

Similar to other configurations, the behavior of the device can be described by two characteristics, i.e., the input and the output characteristics.

The output characteristics define the relationship between emitter current I_E and V_{CE}, which is very similar to the common-emitter configuration.

The input characteristics show the relationship between the base current I_B and V_{CB}. As shown in Fig. 16.18, for a fixed value of V_{CE}, the base current decreases as the reverse collector-base junction bias V_{CB} increases.

In addition, as seen in the output characteristics (Fig. 16.19), for a fixed value of V_{CB}, the base current I_B increases as V_{CE} increases. This is expected since the base-emitter forward bias V_{BE} will increase ($V_{BE} = V_{BC} + V_{CE}$).

As mentioned already, in the common-collector configuration, the emitter current is the current on the output side, while the base current is the current on the input side; the ratio between this emitter current to the base current is known as the current gain and is denoted by symbol γ:

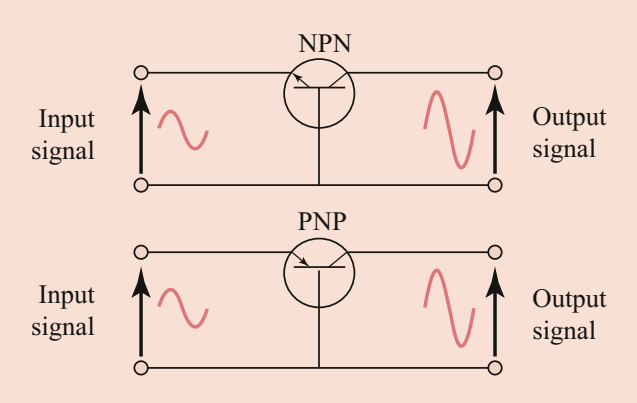

Fig. 16.20 Common-base configuration

$$\gamma = I_E/I_B \tag{16.69}$$

An interesting feature of the common-collector configuration is a very high input impedance and very low output impedance; therefore, it is often used for the impedance matching in circuit amplifiers. Moreover, it provides a very high current gain and a very low voltage gain. In this configuration, the current gain is equal to $\beta + 1$ while the voltage gain is close to unity.

Common-base configuration: Likewise, in the common-base configuration, the base terminal is common between the input and the output side (Fig. 16.20).

Here, the input is applied between the base and the emitter terminal, and the output is measured between the collector and the base terminal. When this configuration is used as an amplifier, the BJT must work in the active region of operation. This means that the base-emitter junction is forward biased and the collector-base junction is reverse biased. For the n-p-n transistor, the applied bias should be set up as shown in Fig. 16.21 [7].

The base-emitter junction is forward biased and the collector base junction is reverse biased. The emitter current will exit the transistor, while the base current and the collector current will enter into the transistor. In case of a p-n-p transistor, the direction of the currents reverses. In all cases, the emitter current is the sum of the base current and the collector current [6].

In this common-base configuration, the behavior of the device can be described by two characteristics, the input and output characteristics. These characteristics are similar to the I-V characteristics which we have seen for the diode. These characteristics show the behavior of the device when the voltage and the current are interchanged. In this case, the emitter current is the input current, and the voltage between the base and the emitter terminal, V_{BE}, is the input voltage.

Therefore, the input characteristics define the relationship between the base-emitter voltage and the emitter current for

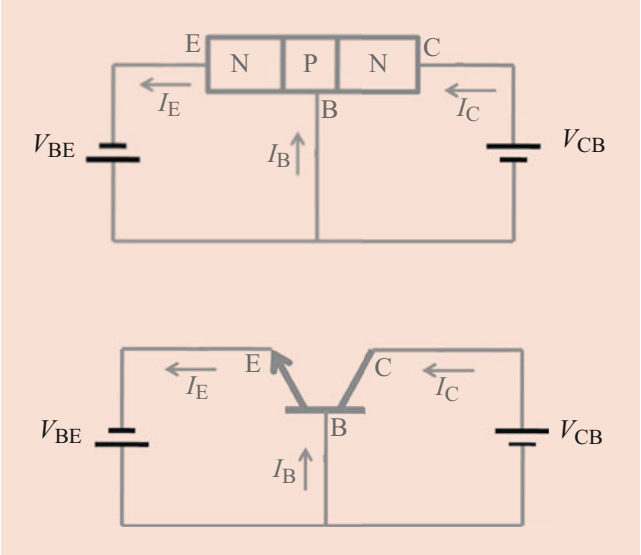

Fig. 16.21 Common-base configuration

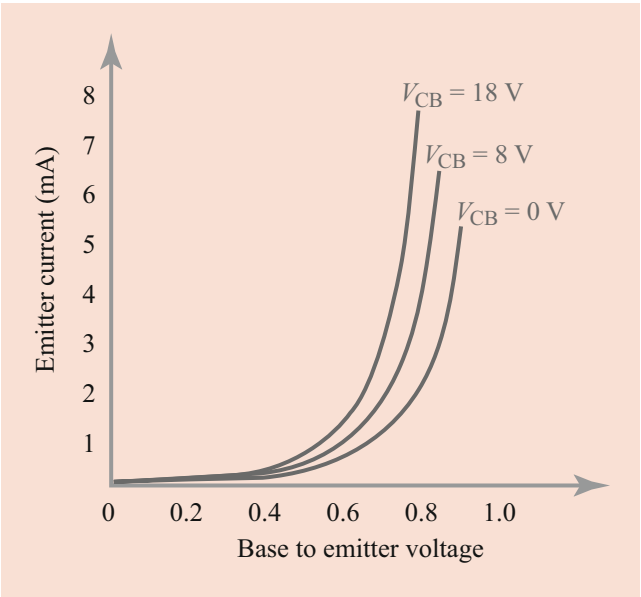

Fig. 16.22 Input characteristics of a BJT in the common-base configuration

a fixed value of V_{CB}. Throughout this discussion, the n-p-n transistor will be considered, whose input characteristics in the common base configuration have the form shown in Fig. 16.22 [6, 7].

As illustrated in Fig. 16.22, there are three curves for the different values of V_{CB}. These curves look similar to the forward characteristics of the pn junction, since the input side corresponds to the forward biasing of the base-emitter diode. As V_{CB} increases, the curve slightly shifts toward the left-hand side and, at the same time, the emitter current also increases. The reason is that when the collector-base junction gets more and more reverse biased, the width of

the depletion region increases. Due to that, the base region will get narrower, and therefore a smaller voltage is sufficient to forward bias the emitter-base junction. From the input characteristic, the input impedance of the device is obtained by considering the slope of the curve. The input resistance is equal to

$$R_i = \Delta V_{BE}/\Delta I_E \tag{16.70}$$

One notes that a small change in V_{BE} produces a large change in the emitter current. This means that in this configuration, the input impedance of the device is very low. This is expected because in the forward-bias conditions, the resistance of the pn junction diode is very small and is typically in the range of ohms, thus a quite low value.

Output characteristics: the collector current is the output current, and the voltage between the collector and the base terminal is the output voltage. The output characteristic defines the relationship between this collector current and the collector-base voltage when the input parameters (among which is the emitter current) are kept constant. If the collector-to-base voltage is changed, then the collector current will change as in Fig. 16.23, where the curves are shown for different values of the emitter current. As the emitter current increases, the collector current increases linearly.

In each curve there are three regions: the active region, the cutoff region, and the saturation region.

In the active region, the relationship between the collector current and the emitter current can be fairly well described by $I_C = \alpha\ I_E$. Here the emitter current is the input current, and the collector current is the output current. The ratio of this collector current to the emitter current gives the current gain α of the BJT in the common-base configuration. In this configuration, even if the reverse collector-base voltage is increased, the increase in the collector current remains marginal [6–8].

Here, the collector behaves like a constant current source, and, for a fixed value of emitter current, it is almost independent of the collector-to-base voltage. Hence, since the collector current only changes proportionally to the input current, this region is used for amplification.

The saturation region. In this region, as V_{CB} is lowered and becomes negative, the collector current starts to decrease. Indeed, without a reverse bias across the collector-base junction, electrons injected from the emitter will hardly be collected by the electric field at the collector junction, thus decreasing the collector current. Therefore, whenever the emitter-base and collector-base junctions are simultaneously forward biased, the BJT operates in the saturation region.

The cutoff region. Whenever the emitter current is zero, the collector current will remain close to zero even if the collector-to-base voltage is increased, since this junction is still reverse biased. To be more precise, the collector current will be very small and will consist in the reverse saturation current of the reverse-biased, collector-base pn junction, which originates from thermal generation of minority carriers. The total collector current I_{CT} is then given by

$$I_{CT} = I_C + I_{CO} \tag{16.71}$$

where I_{CO} is the reverse saturation current.

In the case of a common-base configuration, the emitter terminal is kept open; the reverse saturation current flows between the collector and base terminals and is termed I_{CBO}. This current is similar to the reverse saturation current which was discussed for the diode (note that, as for the diode,

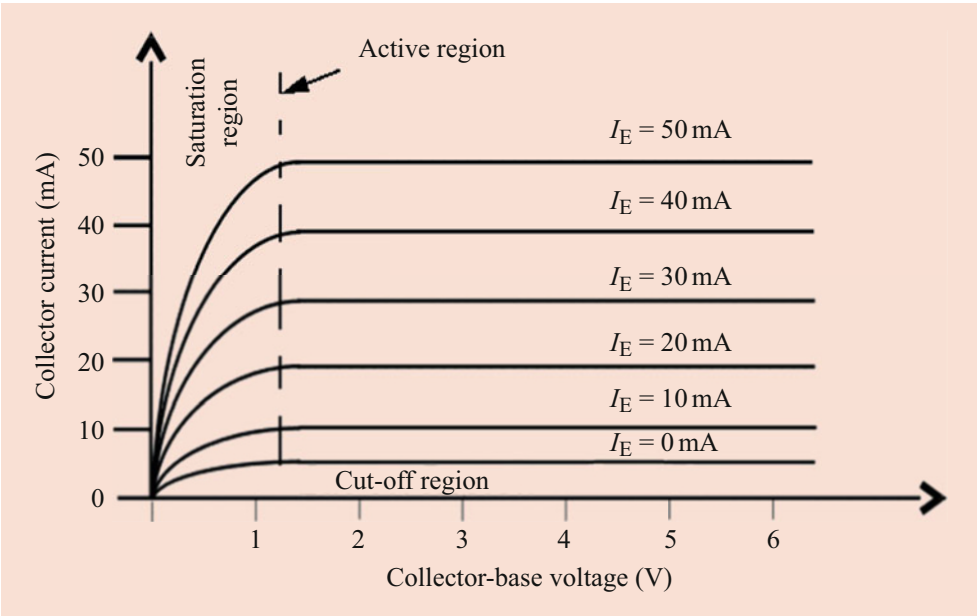

Fig. 16.23 Output characteristics of a BJT in the common-base configuration. The vertical, dashed line indicates the limit of the active region

the reverse saturation current is sensitive to temperature: when temperature increases, the reverse saturation current increases). Due to the improvement in technology, the reverse saturation current is typically in the nA range, meaning that in the cutoff region the collector current is practically negligible (note that for high-power transistors, this current is in the μA range).

In conclusion, the total collector current I_{CT} can be expressed as $I_{CT} = I_C + I_{CBO}$, or in terms of the emitter current

$$I_{CT} = \alpha\, I_E + I_{CBO} \tag{16.72}$$

As already mentioned, in this configuration, the input impedance is very low, typically in the range of ohms. In order to carry on an estimate, assume that the input impedance or the input resistance is equal to 10 Ω and that the input voltage is equal to 5 mV, so that the input current is 0.5 mA. If one assumes that α is equal to 1, then the output current is the same as the input current (since the collector current I_C equals $\alpha\, I_E$). This means that the same current will also flow in the output circuitry. For the common-base configuration, the output impedance R_0 is very high [8].

This is also evident from the output characteristics of Fig. 16.23. In fact, in the active region of operation, when the collector-base voltage increases, the collector current remains almost constant, meaning that the output resistance $\Delta V_{CB}/\Delta I_C$ is very high, typically in the range of hundreds of kΩ. In the example considered here, if the output impedance R_0 is 100 kΩ and R_L is 1 kΩ, V_0 is given by

$$V_0 = I_0 \times R_L = 0.5\,\text{mA} \times 1\,\text{k}\Omega = 500\,\text{mV} \tag{16.73}$$

In this example, the input voltage is 5 mV while the output voltage is 500 mV, namely, the input signal gets amplified by the factor of 100, or, equivalently, the voltage gain is equal to 100.

In conclusion, in the common-base configuration the voltage signal is amplified, whereas the ratio of the collector current to the emitter current is less than unity. This means that whereas the current gain in the common-base configuration is less than 1, it still provides a substantial voltage gain: typically, the voltage gain in this configuration varies from 50 to 300.

It should be noted that the same current is transferred from the input side toward the output side: this means that there is a transfer of current from the low-resistance to the high-resistance circuit; this is why the BJT was named as "transistor" (*transfer resistor*) [6–9].

16.2.8 Common-Emitter Amplifier

With reference to Fig. 16.13, for the base and the collector supplies a double subscription is used, namely, V_{BB} is the source voltage for the base and V_{CC} is the source voltage connected to the collector terminal. The V_{BE} voltage defines the difference between the voltage at the base and emitter terminals, namely, $V_{BE} = V_B - V_E$ and, similarly, $V_{CE} = V_C - V_E$.

Therefore, the base and collector voltages are applied in such a way that the base-emitter junction will be forward biased and the base-collector junction will be reversed bias; in other terms, V_B and V_C are both positive. In addition, whenever the base-emitter pn junction is forward biased, the typical voltage drop across this junction is in range of 0.6 to 0.7 V.

Once the electrons injected from the emitter enter the base region, they become minority carriers; as the base-collector junction is reverse biased, these electrons will be pushed by the electric field toward the collector terminal. It follows that most of the electrons which are injected by the emitter will be collected by the collector region, while a very small amount of electrons will flow into the base terminal. The relations among the currents are established by applying, first, the Kirchhoff law [6, 7, 9],

$$I_B + I_C = I_E \tag{16.74}$$

where the emitter current is the sum of the base and collector currents. As already mentioned, only a fraction of the injected electrons enters the base terminal; thus, the base current will be very small, and, therefore, the collector current is approximately equal to the emitter current:

$$I_C \approx I_E \text{ or } I_C = \alpha\, I_E \tag{16.75}$$

where α defines what fraction of the emitter current is flowing through the collector. Replacing (16.75) in (16.74) yields

$$I_B + \alpha\, I_E = I_E \text{ or } I_B = (1-\alpha)\; I_E = (1-\alpha)\; I_C/\alpha \text{ or } I_C = \alpha/(1-\alpha)\; I_B = \beta\, I_B \tag{16.76}$$

where β is given by [8].

$$\beta = \alpha/(1-\alpha) \tag{16.77}$$

Parameter β is known as the "current gain" of the BJT; its typical values vary from 50 to 400. From these expressions, we can write

$$I_B + I_C = I_E => I_B + \beta\, I_B = I_E => I_E = (\beta + 1)\ I_B. \tag{16.78}$$

Note that the base current is the current on the input side while the collector current is the current on the output side, these two currents being related by (16.76) [7].

That means that controlling the base current on the input side controls the collector current, which is the reason why the bipolar junction transistors are known as the "current-control devices." In contrast, the other type of transistor known as the field-effect transistor is a voltage-controlled device where controlling the input voltage controls the output current. In the configuration of the BJT described above, the output collector current is amplified by the factor β, and, by connecting a resistor between the collector and the emitter terminal, it is also possible to amplify the input signal: in other terms, when the BJT is used in this common emitter configuration, an input AC signal will be amplified.

So far we have not considered the minority carriers in the collector region when the base-collector junction is reverse biased. If the emitter is left open, the current which flows through the collector is only due to minority carriers, and equals I_{CO}. Therefore, this current is similar to the reverse saturation current of the pn junction diode.

In conclusion, the total collector current is given by [6]

$$I_{CT} = I_C + I_{CO}, \tag{16.79}$$

where I_{CO} is the current due to the minority carriers; its typical values are in the range of μA, while those of the collector current I_C are in the range of mA [7, 8].

16.3 The Metal-Semiconductor Schottky Diode

16.3.1 Introduction

In addition to the pn junction, when properly designed, a metal-semiconductor contact may exhibit an asymmetric electrical characteristic that can be used to rectify currents [10]. Initially, the metal-semiconductor rectifier was simply made of a sharp metal pressed on the bare surface of a piece of semiconductor. This kind of device was known well before the physics of semiconductors was understood as was widely used in the early age of radio receivers, the so-called galena-rectifier crystal detector, a metal lead sulfide point-contact device. Later on, Schottky explained this "anomalous" rectifying behavior in terms of space charge in a lightly doped semiconductor, giving its name to this device, i.e., the Schottky diode. The main feature of the Schottky diode with respect to the "usual" pn junction diode is the quite low forward voltage which is about 0.3 volt, compared to 0.7 volt for silicon based pn junctions. Another advantage if the fast recovery time when used in switching applications since only majority carriers are involved, avoiding the recombination time delay inherent to the injection of minority carriers in pn junctions. In addition, Mead [11] proposed to use the property of the Schottky contact as the gate electrode for GaAs field effect transistors, namely, the metal-semiconductor field effect transistor (MESFETs), since, unlike silicon, a reliable oxide is missing in these alloys. The device structure was further refined by Hooper [12]. Today, this Schottky contact is widely used in high-electron mobility transistors (HEMTS) made of III-V semiconductors [13] (see [14] for an overview of applications).

Energy Analysis of Isolated Metal-Semiconductor Systems

The way charges are transferred between a metal and a semiconductor when these come in contact is a fundamental question since it governs the electrical properties of the metal-semiconductor interface [15]. The physics of this hybrid contact can be understood by examining the relative energies of the conduction and valence bands in each material near the interface, in particular the band bending inside the semiconductor. A primary analysis is to consider the amount of energy required to extract an electron, either from the metal or from the semiconductor into vacuum.

From a didactic point of view, it is instructive to consider first the semiconductor and the metal isolated from one another to neglect any interaction between them (see Fig. 16.24). Without loss of generality, we assume an n-type low-doped semiconductor. The Fermi energy as well as the conduction and valence band extrema are drawn, as for the vacuum level.

For each material, a minimum energy is required to extract an electron out of the body into vacuum, i.e., away from the surface. In semiconductors and insulators, this energy is the affinity $q\chi$ which holds for the energy separation between the bottom of the conduction band and the vacuum level.

The electron affinity is an intrinsic energy that depends on the chemical composition and crystalline structure of the material, but not on the doping density of the semiconductor (at least as far as the amount of impurities does not affect the composition, which is assumed).

Concerning metals, since the density of states at the Fermi level is very high (and the Fermi energy is "fixed" due the large amount of electrons), it is the energy separation between the Fermi level and the vacuum level that will be considered as the minimum energy required to extract an electron, that is, the work function. Note that, in semiconductors, the work function will then depend on the doping density (in semiconductors, the Fermi level depends strongly on doping), whereas this quantity can be considered constant in metals.

Energy Distribution Across a Metal-Semiconductor Contact

The relative position of energies in Fig. 16.24 is modified when the metal and the semiconductor come into contact. The energy difference between their electronic states is responsible for a transfer of electrons between the metal and the semiconductor until an equilibrium is reached. The new energy profile of the metal-semiconductor system is sketched in Fig. 16.25.

When no external voltage is applied between the metal and the semiconductor, the Fermi levels in each solid should be equal. Given that the electron affinity and work function are "invariant" quantities for the semiconductor and the metal, respectively, an intrinsic potential drop V_{bi} will build up in the semiconductor (see Fig. 16.25).

For instance, when the work function of the metal is higher than the affinity of the semiconductor, some electrons in the semiconductor are transferred into the metal, leaving ionized donors in a depletion region close to the interface. Since the free-carrier concentration in the metal is very high, the potential drop will mainly take place in the semiconductor.

As for the pn junction, the depletion region generates a built-in voltage V_{bi}. This built-in voltage is the difference between the work function of the metal and the semiconductor

$$V_{bi} = \varnothing_M - \varnothing_{SC} \tag{16.80}$$

On the other hand, the difference between the metal work function and the semiconductor electron affinity is responsible for the energy barrier seen by electrons in the metal at the Fermi level:

$$\varnothing_B = \varnothing_M - \chi_{SC} \tag{16.81}$$

The built-in voltage V_{bi} can also be written in terms of the Fermi energy with respect to the conduction band minima:

$$V_{bi} = \varnothing_B - \varnothing_F \tag{16.82}$$

Whereas $\varnothing_B$ is fixed for a metal-semiconductor system (relation 16.81), relation (16.82) highlights that the built-in voltage depends on the doping density in the semiconductor through the Fermi energy $q\varnothing_F$.

These barrier energies are those that will control the flux of electrons across the interface.

In addition, as for the pn junction, the potential drop inside the semiconductor creates a depletion width W. Under the full depletion approximation, W is given by

$$W = \sqrt{\frac{2\varepsilon_{sc} V_{bi}}{qN_D}} \tag{16.83}$$

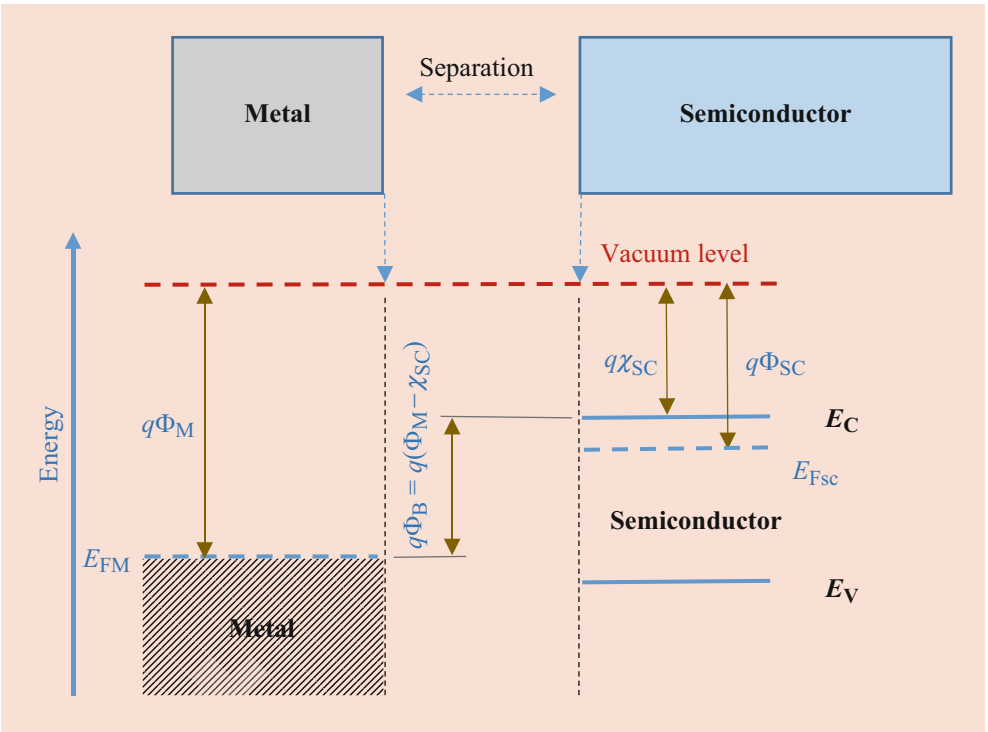

Fig. 16.24 Energy diagram for a metal and a semiconductor when these are separated with negligible interaction. Each material is then characterized by the energy needed to extract an electron into vacuum, i.e., the electron affinity $q\chi$ for semiconductors and the work function $q\Phi_M$ for metals

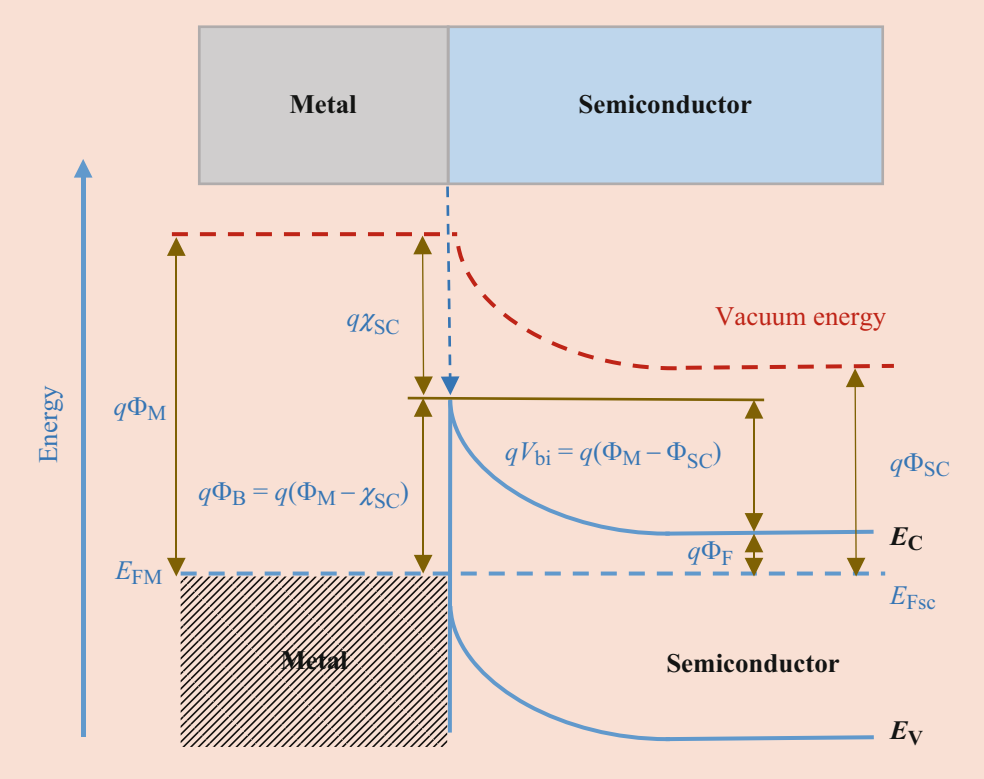

Fig. 16.25 Energy diagram across a metal semiconductor interface at equilibrium. The transfer of electrons from the low n-doped semiconductor into the metal creates a depletion region and an energy barrier qV_{bi} that drops essentially in the semiconductor

The built-in voltage and the depletion depth will then depend on the metal work function, the semiconductor affinity, and the doping.

The Schottky Diode Under Non-equilibrium

When applying a voltage V across the metal-semiconductor junction, the Fermi energies between the metal and the semiconductor split by qV, thus modifying the energy profile at the interface.

There are mainly two approaches to model the voltage-current characteristics of the Schottky diode. Whereas it is quite common to assume that the current is generated by thermionic emission of majority carriers over the barrier energies, another description of charge transport across the interface relies on drift and diffusion currents taking place in the depletion region of the semiconductor, while ensuring the current-continuity condition. Here, we will adopt the thermionic emission viewpoint without necessarily detailing all the steps, which would go beyond the aim of the section. It can be shown that for semiconductors with relatively large mobility and moderate doping densities, the thermionic emission theory is justified.

The thermionic emission at the metal-semiconductor interface is understood in terms of injected fluxes of electrons originating from the metal and the semiconductor at the interface and therefore depends on the electrons concentration at the barrier (see Fig. 16.26).

The current density arising from the transfer of electrons from the semiconductor into the metal (J_{sc-m}) scales linearly with the electron density n_B in the conduction band of the semiconductor evaluated at the barrier peak

$$|J_{sc-m}| = K\, n_B \tag{16.84}$$

where K is a multiplying factor that will not be detailed here.

In the semiconductor, at the barrier interface, the electron density n_B follows the Boltzmann statistics (non-degenerate semiconductor):

$$n_B = N_C e^{-\varnothing_B/U_T} \tag{16.85}$$

where N_c is the effective density of states of the semiconductor and $q\varnothing_B$ is the Fermi level with respect to the conduction band evaluated at the interface.

Then, the current density originating from the transfer of electrons from the semiconductor into the metal can be written as

$$|J_{sc-m}| = K\, N_C e^{-\varnothing_B/U_T} \tag{16.86}$$

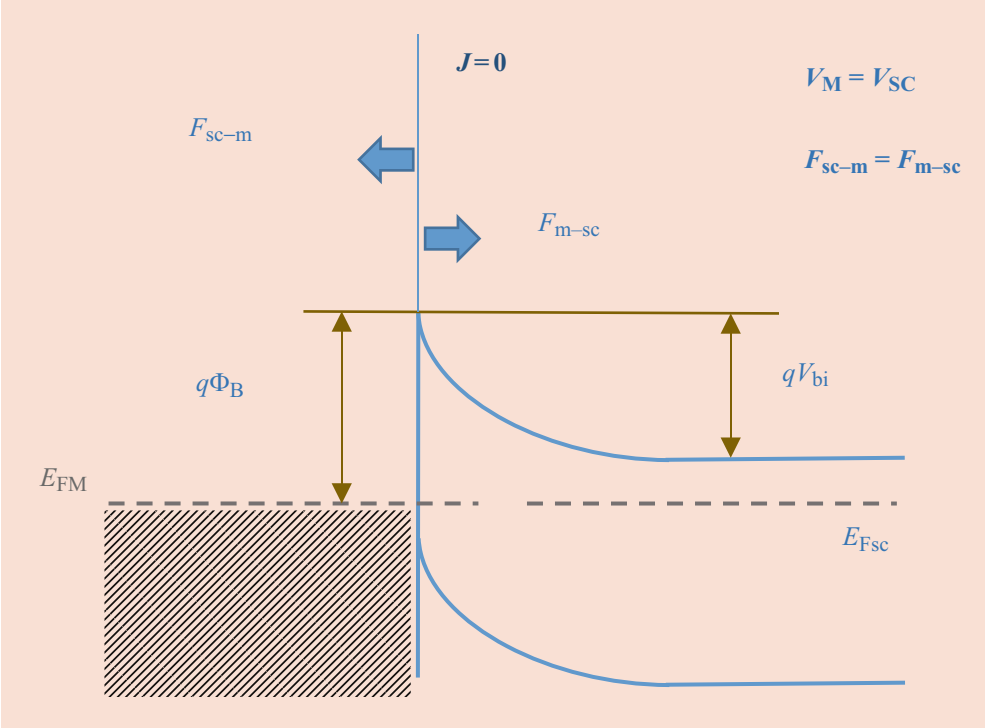

Fig. 16.26 Energy representation of the metal-semiconductor junction under zero bias, i.e., $V_M = V_{SC}$. The fluxes of electron injected by the metal F_{m-sc} and by the semiconductor F_{sc-m} compensate each other

Since under equilibrium, at zero bias, the Fermi levels of the metal and the semiconductor are aligned, no current flows across the structure (see Fig. 16.26). This means that the currents injected between the metal and the semiconductor cancel each other, and therefore the current density injected by the metal into the semiconductor is known at zero bias:

$$|J_{m-sc}| = |J_{sc-m}| = K\, N_C e^{-\varnothing_B/U_T} \tag{16.87}$$

Conversely, when biasing the metal positively by V_f with respect to the n-type semiconductor, the semiconductor-metal built-in potential is decreased, see Fig. 16.27. Since the barrier seen by electrons in the semiconductor is lowered, their transfer rate into the metal F_{sc-m} will increase.

The electron density at the barrier, in the semiconductor, is now

$$n_B = N_C\, e^{-(\varnothing_B - V_F)/U_T} \tag{16.88}$$

and so the current density injected by the semiconductor into the metal becomes

$$|J_{sc-m}| = K\, N_C e^{-(\varnothing_B - V_F)/U_T} \tag{16.89}$$

On the other hand, the energy barrier seen by electrons in the metal is unchanged since the potential drop occurs almost entirely in the semiconductor, implying that the electron transfer flux from the metal into the semiconductor F_{m-sc} will not change.

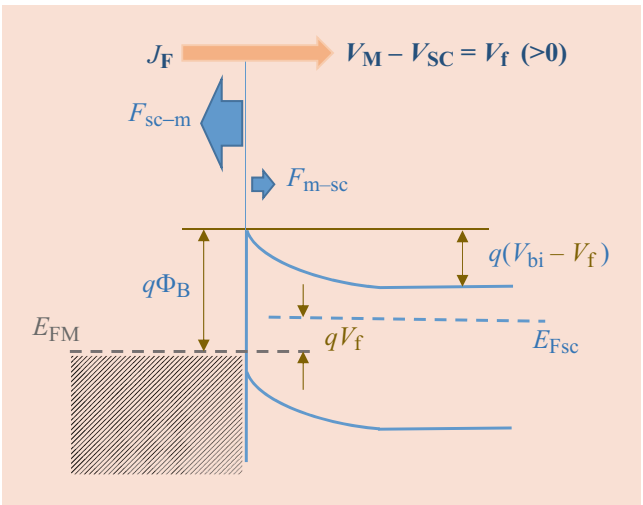

Fig. 16.27 Energy representation of the metal-semiconductor junction under forward bias. The flux of electrons injected by the semiconductor F_{sc-m} dominates with respect to the metal-induced flux F_{m-sc}, giving rise to a net current density J_F across the junction

The current density J_{m-sc} is then still given by relation (16.87).

The case of a negative voltage V_R applied to the metal is illustrated in Fig. 16.28.

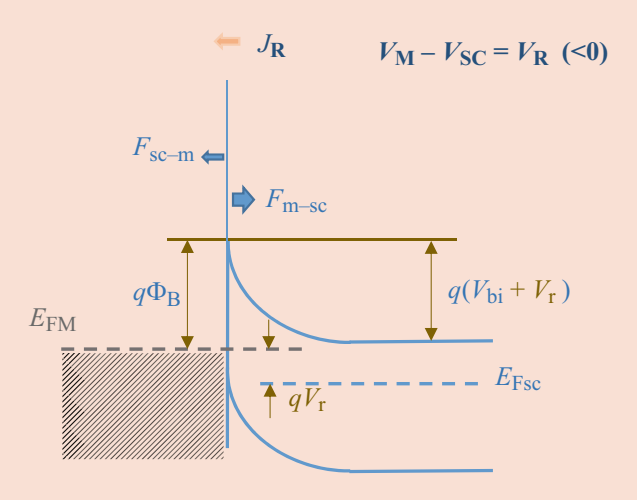

Fig. 16.28 Energy representation of the metal-semiconductor junction under reverse bias. The flux of electrons injected by the semiconductor F_{sc-m} is negligible. The current generated by the flux of electrons F_{m-sc} is the leakage current of the diode

Here the barrier seen by the electrons in the semiconductor is increased by qV_R, meaning that crossing the barrier becomes more unlikely. Conversely, the energy barrier seen by the electrons in the metal, i.e., $q\varnothing_B$, remains unchanged, and so for the flux F_{m-sc}.

The electron current density flowing from the metal into the semiconductor is

$$J = |J_{sc-m}| - |J_{m-sc}| = K N_C e^{-\varnothing_B/U_T} \left(e^{V/U_T} - 1\right) \quad (16.90)$$

Introducing the saturation current density $J_S = A T^2 e^{-\varnothing_B/U_T}$, the current-voltage dependence of the Schottky diode writes

$$J = J_S \left(e^{V/U_T} - 1\right) \quad (16.91)$$

where A is the Richardson constant given by

$$A = \frac{4\pi q m^* k^2}{h^3} \quad (16.92)$$

Relation (16.92) is formally the same as for the pn junction. However, the current in the Schottky diode is made of majority carriers, and therefore no recombination process is involved. This property is beneficial when fast *switching-off* is needed since it gets rid of the time limitation inherent to recombination processes with minority carriers.

16.3.2 Additional Factors

The simplified model derived in this section is an ideal picture of the Schottky diode. In reality, the interface between the semiconductor and the metal is populated with defects that introduce energy levels into the band gap of the semiconductor at that interface. These traps are inherent to dangling bonds, crystal defects, and contaminations at the surface of the semiconductor that are generated during the fabrication process. Their charge state can change dynamically upon bias and modify the electrostatic potential at the metal-semiconductor interface. Traps can also increase leakage current in reverse bias since they intensify electron transfers through forbidden states in the band gap.

In addition, even considering an ideal interface, the barrier potential is still lowered by the presence of electrons in the vicinity of the interface that attract positive charges from the metal. This is known as the image-force lowering concept, whose effect is to reduce the energy of the barrier and hence to increase the current density.

Including these effects goes beyond the scope of this chapter. Interestingly, relation (16.91) remains still valid provided an equivalent Richardson constant A^* is used for the saturation current density.

Abstract

In the following chapter, we will present a summary of the most interesting emerging nonvolatile memories that have been studied in the last two decades. The particular point of view adopted will focus on the advancements achieved by these competing devices and, most importantly, the challenges that these technologies must face in the next years.

We decided to limit the analysis to four main competing technologies, namely, OxRAM (oxide-based resistive random access memory), PCM (phase change memory), STT-MRAM (spin-transfer torque magnetic RAM), and FeFET (ferroelectric field effect transistor). These four best show the development of the research activity on emerging memory devices, going from the most recent FeFET to one of the most mature PCMs. As each technology is based on a completely different physics, the challenges that each must face on are totally different.

The chapter is composed of four sessions. The first one highlights the need to overcome the concept of "universal memory," a longed-for memory device that could be tuned to substitute any memory currently preset in the PC memory hierarchy by minor adjustments and that could thus impose itself as the only memory really necessary. We will see how this concept, although very attractive and seducing, is unrealistic and must be abandoned to be replaced by an application-centric point of view, where each domain dictates the specifications that a memory has to provide and decide at the end what kind of device suits best.

In the second session, the four memory candidates are presented. A very short history of each is sketched and their working principle is briefly depicted.

Session three is the chapter core. The four memory devices are compared to each other; the advantages of each are analyzed along with their main drawbacks and flaws. Each memory, although at a different maturity level, has many challenges to overcome, and the session provides explication of each. The main research axes and strategies are reviewed trying to give the reader the feeling of the effort that developers are putting into solving the memory puzzle. Many trade-offs must be made, and the apparently endless chase between application requirements and device capability makes the path extremely difficult.

The last part of session three is devoted to some innovative applications that eNVM could actually boost. In these cases researches are trying to exploit the device drawbacks as actual advantages. A review of the main of these applications is provided, showing that even for this case challenges are not missing.

In session four a particular attention is posed on one of the emerging applications treated in session three. Neuromorphic applications are indeed of very high interest at the moment, and eNVMs are regarded with very high interest.

17.1 Overcoming the Concept of Universal Memory

In the last years, or we may say last decade, a quite impressive amount of new memory candidates were presented to the scientific and industrial public. In this chapter we will focus on some of them, namely, Oxide-based Resistive RAM (OxRAM), PCM (phase change memory), STT-MRAM (spin-transfer torque magnetic RAM), and FeFET (ferroelectric field effect transistor). Many others were also invented and studied, like CBRAM (conductive bridge RAM), or Mott insulators, or Hybrid RAM (sometimes called HDDRAM). What characterizes all these technologies is what is generally referred to as the Gartner expectation, or "hype," cycle (see Fig. 17.1). Each new announcement of a new memory candidate (but this discussion can easily be extended to different technologies and even different industry at all) was always surrounded by an inflated aura of expectations. This is the beginning of such cycle. The "next" generation of memory is born, and it will be the so-much-longed-for "universal" memory. These statements are accompanied by extraordinary results, in terms of endurance or programming window or low power consumption and so on. Very soon however it appears that all these wonderful characteristics cannot be achieved at the same time and on the same wafer. The overestimated expectations quickly leave place to a much more reasonable and realistic set of characteristics that eventually converge to a real product. This is when the trade-offs are made, and it appears that a gain in endurance or in lower consumption is paid by a lower memory margin or a reduced retention.

A good example is described in [1] with PCM technology. PCMs were first announced almost 10 years ago with great emphasis [2], and these announcements were rapidly followed by a first set of products released by Numonyx

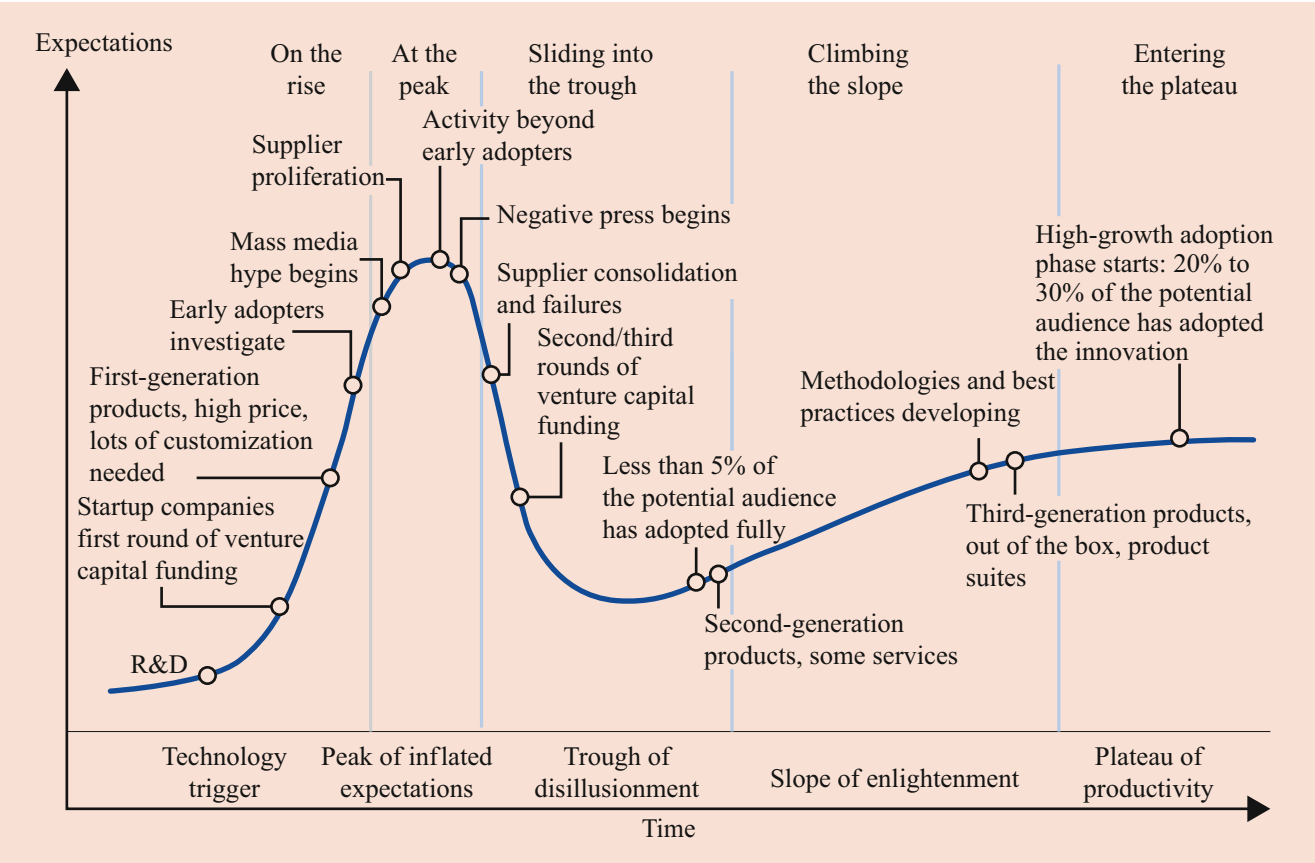

Fig. 17.1 Typical hype curve showing the main phases of appreciation of a new technology. (Figure from [113])

and Samsung. Although the new products guaranteed good sales at the beginning, Flash technology rapidly covered up the distance and reduced drastically PCM market. As a consequence PCMs were withdrawn as quickly as they appeared. Much more recently, and after a long absence of any new announcement, Intel/Micron proposed a completely new product series based on PCM for the storage class memory application [3]. We will come on this very topic later in this chapter.

When a general view is adopted to overview all the existing emerging memories, it appears that the same trade-offs are recurrent even when the physics behind each technology is very different. This kind of analysis was made by both Stanford University (see [4]) and Leti (see [1]). In these studies data coming from different emerging technologies were gathered together and compared in a cross-technology view. The result is that endurance, data retention performance, programming window, and energy consumption are linked by the same rules and appear to obey to a sort of universal law. This law describes the trade-offs that must be made on each technology to find the good compromise between different characteristics to enable a specific application. An explicative example is shown in Fig. 17.2. Here the reader can appreciate the bond that links together the programming window and the endurance performance of technologies that obey to very different switching mechanisms. Endurance always comes at the price of lower programming window. This is particularly true for filament-based memories, like CBRAM and OxRAM [5, 6]. In this case, as a filament is formed and disrupted multiple times, one can imagine that the large memory window that characterizes these devices means the displacement of a relatively large amount of material within the active layer. This is understandably linked to a reduction in endurance characteristic, as the active material is inevitably damaged cycle after cycle. At the opposite end, PCM involves local atom rearrangements in the mushroom region, with much lower net material transfer, and STT-MRAM only relies on spin transfer, with negligible atom rearrangement. Not surprisingly then, PCM features a better endurance with lower resistance window, and STT-MRAM has by far the best endurance at a price of very limited resistance margin. In a similar way, a clear trade-off between write time and endurance can be recognized. In Fig. 17.3 this is elucidated in the case of PCM technology. PCM shows a particularly good example since changing the exact composition of the chalcogenide material has been shown to effectively modify the device characteristics increasing or decreasing different aspects of the cell performance [7]. To improve data retention characteristics generally, materials with higher RESET stability are employed to counter the

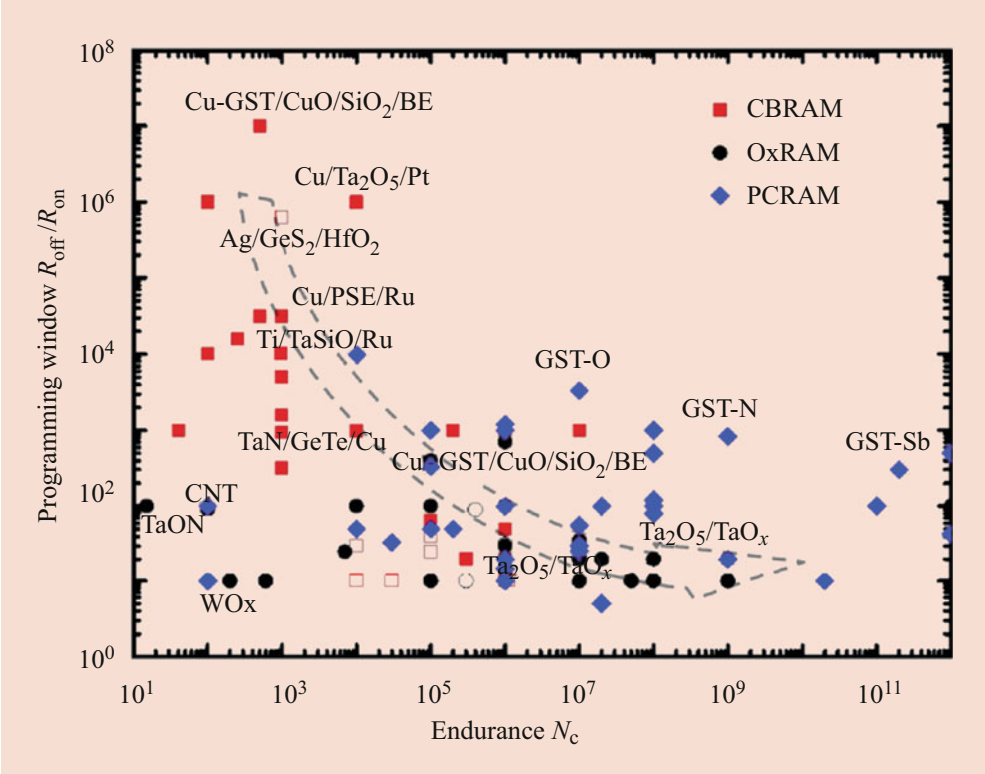

Fig. 17.2 Programming window as a function of endurance for many different emerging memory technologies showing a common cross-technology trend. (From [1])

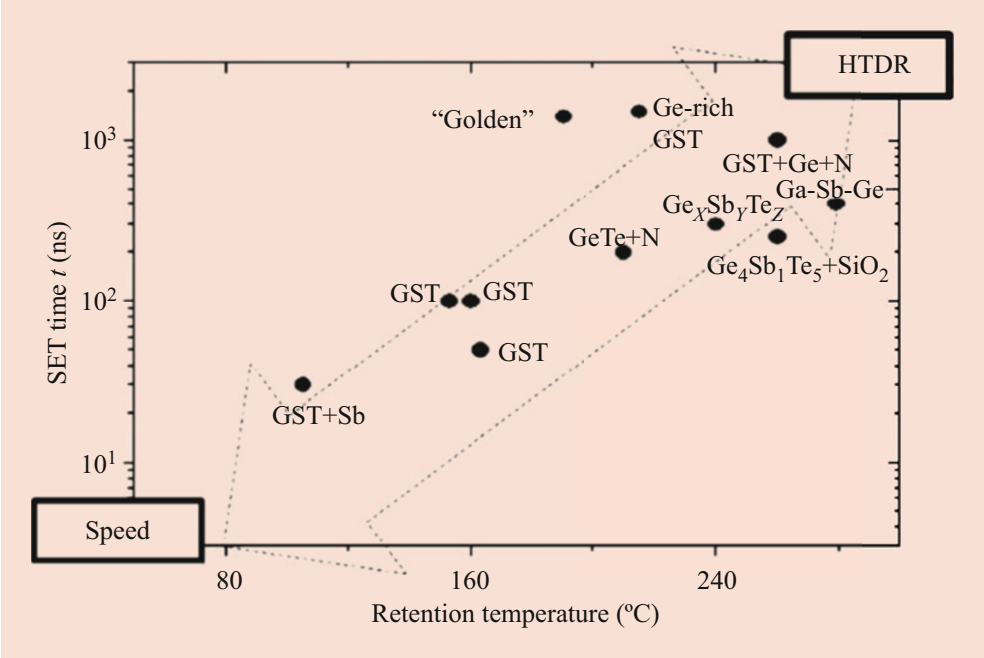

Fig. 17.3 Programming time vs retention temperature for different phase change materials. As speed can be linked to programming energy, the plot suggests that a trade-off between retention and programming energy is obviously to be found. (From [1])

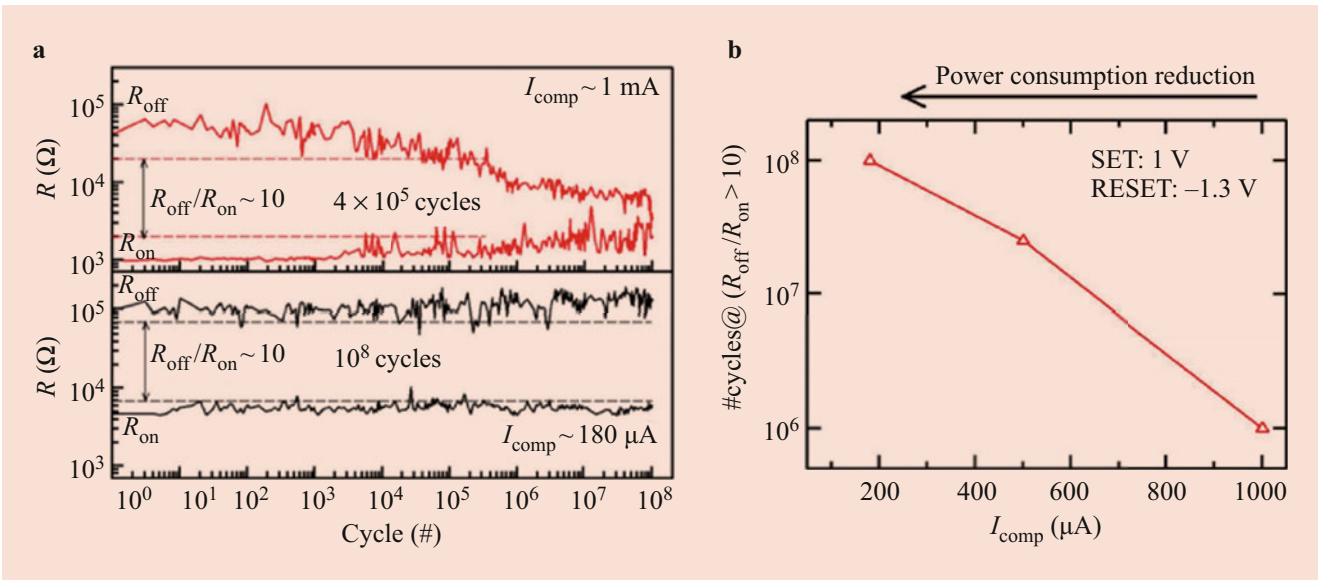

Fig. 17.4 (**a**) Endurance of HfO-based OxRAM; (**b**) endurance vs compliance current used for switching. (Figure from [1])

spontaneous recrystallization of the amorphous phase. This however typically leads to the need of a longer SET time to correctly achieve crystallization. In this sense, Fig. 17.3 shows that a better data retention means a worse endurance. It looks in fact understandable that a more stable RESET, which is necessary to achieve a more robust data retention of the amorphous state, calls for a longer SET pulse to recrystallize the active matrix and that this eventually causes a reduced endurance.

Another trade-off example can be found with HfO_2-based OxRAM where endurance is found to be function of the SET energy [1] as shown in Fig. 17.4a, b. A higher SET energy means a larger SET current (for a fixed program time) which leads to a larger filament and a wider memory window. Quite intuitively, a larger filament means a larger dielectric stress, hence a lower endurance. Understanding these trade-offs leads to the obvious conclusion that each technology must be tailored on the application and that it

looks unrealistic that a single technology would be the good one for very different applications. Some applications will require high endurance (like cache memory) and will need to accept a lower read margin, while others will demand high thermal stability (like embedded memory for code storage, in particular for automotive market) but will probably tolerate a reduced endurance. The main challenge is then to understand which specifications the targeted application requires and tailor the technology to meet these set of constraints.

In the following sections, we will first present the most interesting memory candidates, and we will compare them and analyze the challenge each of them is facing. Next we will focus on applications as the real developing driving force, and we will spend the last section on one of the most recent and demanding ones, the neuromorphic for advanced neural network.

17.2 "NVM Candidates"

In this section we will explore more in detail some of the technology candidates that the actual research is investigating on, among the quite wide NVM panorama. More in particular we will focus on four different flavors of emerging memories, which are by far the most investigated and most promising at the time of writing. We will mention also some other kinds of technologies that are more in an embryonal stage of development and are not quite ready to benchmark themselves on the memory field yet.

As it will be clear very soon, not all the memory technologies under investigation are at the same level of maturity; they are also based on completely different physics and face in general different problems in terms of integration, material, performances, and costs. What is however interesting is that all these technologies turn around the same quest of optimizing many performances at the same time. It should be clear by now that this task is not realistically attainable by any of these candidates, but it will be even clearer that each technology has different degrees of freedom to adapt to different applications. How each technology can adapt to application can make a big deal in which candidate will eventually become a real product, and we will try to show the advantages and weak points of each of them.

Thus in the rest of this section, we will focus on four types of memory candidates, namely, on OxRAM, PCRAM, MRAM, and FeFET which eventually we will shortly describe. First we will briefly recall the working principle of each of these technologies, and then we will show what their potential and weakest point are. We will leave to section three the important task of comparing them, and here we will instead focus on the challenges that each of these emerging technologies is facing with respect to integration, scalability, cost, performance, and readiness. It is almost impossible to cover entirely each aspect of these technologies, each of which could easily be the subject of the entire chapter, not to say of an entire book. However at the end of this section, the reader will have the understanding of the actual status of development for each technology.

17.2.1 OxRAM

OxRAM is a general term to indicate resistive memories that base their working principle on the formation and rupture of a tiny conductive filament shunting an otherwise insulating layer. In other terms, the OxRAM is any capacitor-like device where a dielectric layer is sandwiched between two conductive electrodes. The ability to generate a shunting filament and to restore an insulator layer by proper polarization constitutes the binary behavior that confers the device the memory ability.

OxRAM devices have been studied extensively since the late 1960s and were produced in countless variety and flavors. The number of publications and patents available at the time of writing ranges in the order of tens of thousands (see Fig. 17.5, for instance), and the hype about this promising technology is now starting to fade, as it appears that most of the performances achievable with OxRAM are not, at least not directly, linked to material properties but are rather intrinsic to the structure of the device. This concept will be clarified very soon in the section.

OxRAMs were produced using a large variety of materials. Some of the most studied are NiO_x, HfO_x, TiO_x, Ta_xO_y and perovskite compounds [9, 10]. Other materials were also reported to show resistance switching behaviors like porous Si [11], sulfides [12], chalcogenides [13], and even organic compounds [14]. The main aspects of OxRAM that determined the large research effort we saw are basically the low voltage operation (in the range of a few volts), the ease of integration, the low expected cost adder, and the good data retention performance. As a matter of fact, OxRAM has not yet demonstrated its potential in achieving a real product. This was mainly due to the large intrinsic variability that characterizes in particular the high resistance state (HRS) [15] in addition with other drawbacks that are very specific to OxRAM: the need of a forming process to initiate the resistive switching with a larger potential than the regular operating one, the relatively high current consumption (in the order of 1–100 μA; [16]), and the need of a selector to avoid sneak paths during read and write operations. Another point of attention is the need to reverse the polarity of the programming pulse to restore the HRS, which is a quite common characteristic to many different OxRAMs. This clearly imposes certain constraints on chip design.

Certainly one of the most studied materials for OxRAM has been HfO_2 which has showed good switching behavior

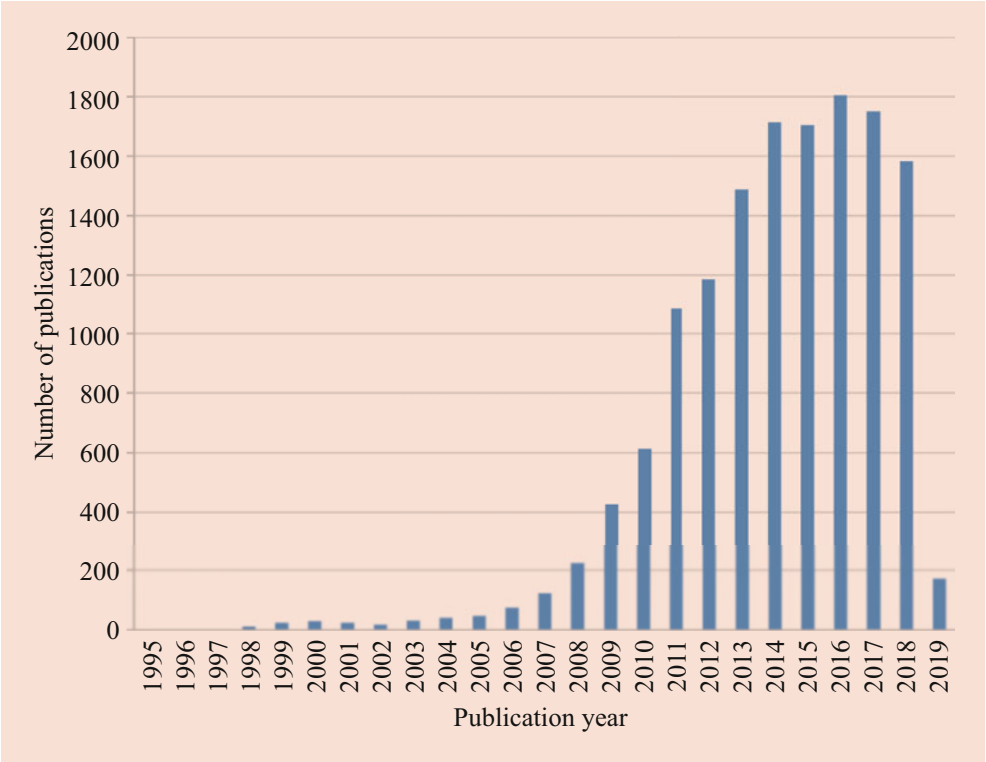

Fig. 17.5 Number of publications for "resistive switching" over the years. (Data from WebofScience [8])

when deposited in a sub-stoichiometric form leading to the presence of oxygen vacancies. HfO_2 deposition was achieved by both ALD and PVD techniques with similar results.

Oxygen vacancies (V_o) are believed to be responsible of the switching mechanism. One of the most accepted theories, even though so far a widely accepted theory is not yet available, proposes that the Vo act as attractive points for O atoms in the surrounding of the active material. O atoms are believed to take the form of negatively charged ions, and thus the electric field promotes the migration of O^- ions and their accumulation in the form of a conductive filament. When a counter polarization is applied, the ions are "pushed" back and forced to recombine at the electrodes causing the dissolution of the conductive path.

More recently, TaO_x [17] and $Ta_\mu O_\mu$ [18] have been investigated more in depth. It is not clear if the switching mechanism still relies on the same O ion migration or more on a local rearrangement of the crystal structure. However Ta-based material shows generally a lower resistance variability but at the same time a lower ration between HRS and LRS.

So far the largest demonstrator chip featuring OxRAM devices had a density of 32 Gb, manufactured in 24 nm technology node [19].

A slightly different flavor of OxRAM is known generally under the name of CBRAM (Conductive Bridge RAM). The main characteristic of CBRAM is the presence of a relatively stable oxide coupled with a reactive electrode. Ions from the electrode can easily migrate within the oxide matrix under the effect of the applied field. The oxide acts as solid electrolyte, while the reactive species are dissolved easily within it. Typical materials for the electrolyte include transition oxides (NiO, TaO, HfO_2), chalcogenides (GST), and silicon [20]. Applying the electric field causes the migration of the reactive species, which are most of the time silver or copper, and the shunting of the dielectric layer when a conductive bridge goes across the entire stack. Reverse polarization causes a back migration of the ions and the dissolution of the conductive bridge. OxRAM and CBRAM are thus extremely similar as both rely on filamentary conductions and obey to similar physics for many reliability aspects. It is noteworthy that while direct observation of the conductive filament in CBRAM was reported multiple times and unmistakably [21], the same is not as obvious for OxRAM, for which a direct observation of an oxygen depleted filament has been extremely difficult and yet de facto unachieved with results as convincing as for CBRAM. So far CBRAM demonstrators feature up to 16 Gb [22].

17.2.2 Phase Change Memory (PCM)

Phase change memories (PCMs) are probably one of the most studied emerging technologies for nonvolatile memories. They were and still are among the most promising

candidates for next-generation memory products. PCMs have in principle the same benefits of OxRAM and CBRAM in terms of low voltage operation, short programming times, and large ON/OFF ratio but are way less affected by intrinsic variability [7, 23, 24]. So far several demonstrators showed the potentials of this technology; in particular it is worth mentioning the results obtained by Numonyx [25] and Hynix [26] which presented a 1 Gb memory array. Samsung [27, 28] also has been very active on developing PCM and reported an 8GB memory array. PCM is seen as a relatively mature technology within the *plethora* of emerging memory devices, and such maturity is demonstrated by the actual presence on the consumer market of PCM products: memory chips in cell phones reported in [29, 30] which use indeed PCM devices.

The very first works on PCM are due to S. Ovshinsky [31] who published back in the 1960s the first results on $Ge_{10}Si_{12}As_{30}Te_{48}$ as a switching material. The physical principle on which PCM relies is the amorphous-crystal transition of a limited volume of phase change material which is thermally achieved. The key PCM features which enable the memory to function are the large difference in electric resistivity between crystal and amorphous phase, the relatively low melting temperature of the alloy, the high crystallization rate, and the good stability of both crystal and amorphous phases. These characteristics allow the PCM to be programmable with short voltage pulses and yet to retain their programmed state long enough to be considered nonvolatile.

The ternary system Ge-Sb-Te (GST) which is now so well-known was introduced later, in the 1980s, along with many different compositions based on the $GeTe/Sb_2Te_3$ group. These new materials allowed faster crystallization which was achievable with rapid pulses in the order of a few tens of nanoseconds [32]. The most known compound is however $Ge_2Sb_2Te_5$ (sometimes called simply 225) [24] which was introduced in the 1990s and had a specific application in optic disks. In that case the property exploited was the high optical contrast between the two stable phases which are achieved by thermal excitation through a laser pulse instead of an electrical stimulation. The step from the optical to the solid-state application was achieved trying to enhance endurance performances and to explore the potential of multilevel programming. [33] demonstrated at the end of the 1990s a very good endurance in the order of 10^{13} program/erase cycles and a relatively good multilevel capability. The main drawback of the 225 compound is however the thermal stability. As a matter of fact, the relatively poor stability at high temperature prevented so far the exploitation of PCM on the actual market. In particular automotive market requires 10 years' data retention at 150 °C which is hardly matched by PCM. Soldering reflow also constituted a problem for PCM, and partly still does, since for security applications data must be pre-coded within the array before reflow of the parts. In this case the thermal budget is 2 minutes at 260 °C. Other than thermal stability, the research focused and yet focuses on current reduction, which aims at cell scaling, and the acceleration of the crystallization phase, again to limit power consumption and cell wear. More recently good results on different GST flavors allowed PCM to gain performances in different directions, and slowly but steadily PCM improved its thermal stability and reduced current consumption. Different stoichiometries in the ternary GST compound as well as dopants were analyzed and proved successful as performance boosters. Still however many trade-offs must be found while choosing the good material. Sb-rich and above all Ge-rich alloys look now as the most promising for applications. Eventually it is worth mentioning the research in progress on different compounds, like GaSb-based materials [34].

17.2.3 MRAM

In the emerging memory panorama, a particular place is reserved to STT-MRAM which improved hugely the conventional MRAM device. In this chapter we will sometime refer to this newer device with the common name MRAM; however the reader must not be confused, as we will only focus on STT-MRAM technology. STT-MRAM implements a spin transfer torque principle which allows to scale the memory cell further and increases the overall device efficiency. The cell structure comes directly from the MRAM precursor, with two magnetic tunnel junctions (MTJ, the active cell part) sandwiched between two electrodes and separated by a 1–2-nm-thick insulation layer. The typical oxide material used as dielectric is MgO. STT-MRAM, just as MRAM, switches between a low and a high resistance state depending on the parallel or antiparallel orientation of the two magnetic layer. Several STT-MRAM products are currently available in various formats [35]. A crucial aspect of STT-MRAM products concerns the magnetic anisotropy [36]. While STT-MRAM with in-plane magnetic anisotropy are already available on market, devices implementing perpendicular anisotropy are still in development with the aim of achieving higher scaling. As we will discuss, scaling is indeed one of the hottest topics for MRAM.

From the performance perspective, MRAM appears as quite mature and really promising [43]. A fast write time (<10 ns) and long endurance (>10^7 cycles) were clearly demonstrated [37, 38], and sufficient data retention has been reported consistently [39]. Bit cell is currently quite large, mainly due to the presence, as for all other resistive devices, of a selector device (most of the times a NMOS). For this reason a possible MRAM application has been seen as SRAM replacement, where the large size of the memory point can be rewarded by the non-volatility of the component.

MRAM still faces difficult challenges. Probably the toughest is being linked to the materials used for MTJ

which are known to be difficult to etch and to clean after etching [40]. This translates in large overhead costs for dedicated machines. In addition, MRAM shows a very small ON/OFF resistance ratio. This means that resistance variability is critically relevant and requires well-designed sensing circuits [41]. This is particularly true in view of scaling the memory point. As density increases and array dimension too, variability is forecast to become a serious threat, and stronger research will be involved to unlock the scaling potential of the technology [41]. Overall, MRAM has various technology challenges to overcome. The manufacturing process is delicate as the device is sensitive to substrate smoothness and encapsulation materials and requires relatively high thermal budget which could have impact of front end. Researchers are spending a considerable effort to improve the technology tolerance and robustness by proper seed layer choice, specific deposition methods, and developing new capping materials. In addition engineers are experimenting with different MTJ recipes, including ferromagnetic multi-layers [42], sometimes interleaved with nonmagnetic metals, and newly developed dielectrics for the tunnel junction.

17.2.4 FeFET

Ferroelectric memories are known and have been studied for at least two decades. Typically the adopted materials are perovskite [44]. Many reasons left ferroelectric memories out of the spotlight, but the main is undoubtedly the excessive active layer thickness and the very difficult, although possible, CMOS compatibility in addition to gate leakage and depolarization [45]. In 2013 however ferroelectricity in Si-doped hafnium oxide was first reported [46], and this was certainly a game changer result. The possibility to exploit Si:HfO_2 gives a path to overcome the integration and scaling limits experienced so far by ferroelectric devices. This is due to the low permittivity along with high coercive field. In addition hafnia is a well-known material for integrators and thus opens the possibility to co-integrate front-end memory along with logic transistors. Different flavors of ferroelectric memory are thus available: a capacitor-like device, 1T1C, and, probably the most promising, 1T. The latter is typically referred to as FeFET. Its working principle, sketched in Fig. 17.6, relies on the polarization change within a ferroelectric Si:HfO_2 gate dielectric obtained by applying a threshold field across the gate stack. This polarization is reversible, by application of a similar field with opposite direction, and modifies the threshold voltage of the Si channel, pretty much as a typical Flash memory but without the need of a floating gate. At the time of writing, a FeFET technology demonstration for 22 nm and 28 nm HKMG was provided [47, 48], which gives interesting outlooks for future developments. The main advantages that FeFET could bring to NVM products would certainly be the a priori high scalability and the low programming voltage, in the range of 1–4 V, along with a very fast programming time (<1 ns) and extremely low programming current, given that during write/erase operations almost no current flows across the device. Moreover it is expected, and to some extent was shown, that FeFET has a remarkable thermal stability, which is one of the main requirements for eNVM. These characteristics would of course make easy for FeFET to find several applications, but as we saw with other eNVM concepts, there are drawbacks. FeFET suffers so far by a limited endurance performance. A typical FeFET leads

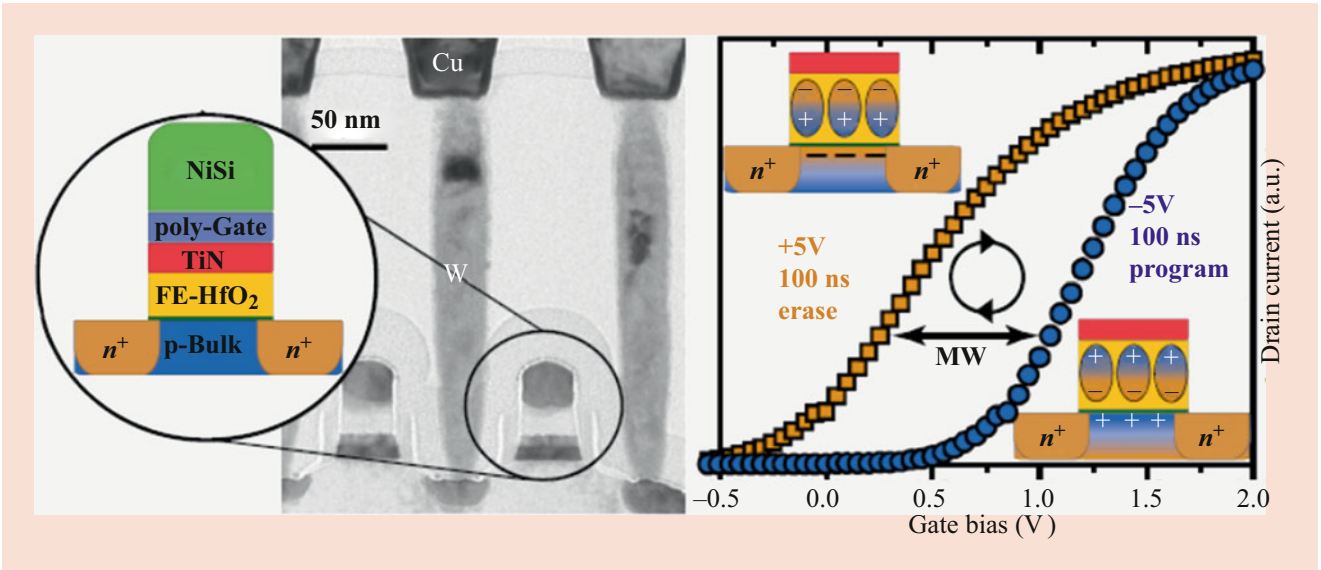

Fig. 17.6 Micrograph of a FeFET device and the typical IdVg curves of erased and programmed states. (From [46])

to 10^4 cycles, even though performances up to 10^7 were reported already in larger 1C (one capacitor) structures. This would still be better or at least comparable to a NAND Flash cell; however FeFET was reported to be read disturb prone, and NOR or AND arrays are therefore preferable for building arrays. Multiple additional metal lines and vias, plus additional access row and column selectors, would then be required, which in turn widely limits the competitiveness of FeFET with respect to NAND devices. Variability has also been shown to be of some issue for FeFET as the Si:HfO_2 ferroelectric crystal features grain sizes of the order of 10 nm. This impacts negatively on the device variability, mainly in terms of remnant polarization, and the problem is further enhanced by the different direction that the internal polarization field can take, leading to a more dispersed channel threshold voltage. Additionally, FeFET show strong trapping phenomena, which require dedicated programming sequence to actively de-trap electrons or holes before the cell can be correctly read [49, 50]. Research is tackling down this issue by specific epitaxial growth of the ferroelectric layer. Eventually, the memory window, defined as the difference between the threshold voltages of the FeFET after write or erase, was shown to be consistently in the order of 1 V, which, given the variability we evoked already, rules out the possibility to store more than 1 bit of information in a single cell.

17.3 How eNVMs Compare to Each Other

17.3.1 eNVMs Comparison

Many review papers compare eNVM together, and the typical table that results out of this quite challenging task is shown as example in Table 17.1 from Yu [51]. It is mandatory to warn the reader that, as the compared technologies are still in development, it is almost impossible to find absolute numbers that clearly explain the actual performance of the device under test. Most of the time, when new data are published, authors tend obviously to highlight the best performance of the DUT, but as we discussed already, many trade-offs are required for an actual memory device to work properly. This means that published tables report performances that are often achieved separately, while the same device is not capable to, for instance, achieve 10^8 cycles while be at the same time soldering reflow compliant and keeping the write potential below 2 V. For this reason, here we preferred to extract performance data consistently from the same chip when possible, but there is no certainty about the actual performance of the DUT. In fact the same device can be operated in different regimes to enhance one feature with respect to one other. For instance, increasing endurance is possible by lowering programming pulse voltage, which however is detrimental for memory margin and hence for array dimension.

Having said that it is undoubtedly possible, and necessary, to compare performances across eNVM data. In Table 17.2 (from [43]), a brief summary of the most important aspects of the eNVM we are focusing on is shown. We must notice that the only eNVM which truly differs in terms of structure is the FeFET, which is the only 1T device. This is of course a key feature for FeFET as it would allow, at least theoretically, to scale the memory device at the same rate of the logic transistor. Most of the other resistive devices are in fact bound to the selector size to be driven at sufficiently large current, while FeFET doesn't require high currents for programming just as a Flash memory. So far some data were provided in literature showing that co-integration of FeFET and 28 HKMG core logic is possible [47], but still quite few data are available to truly estimate the real potentials of FeFET. It is generally agreed that this technology needs research resources to investigate how it can compete with other emerging technologies. At the same time, FeFET is known to be prone to read disturbs and suffers of quite strong

Table 17.1 Table summarizing the main electrical parameters of different memory technologies

	Mainstream memories				Emerging memories		
			FLASH				
	SRAM	DRAM	NOR	NAND	STT-MRAM	PCRAM	RRAM
Cell area	>100 F^2	6 F^2	10 F^2	<4 F^2 (3D)	6 ~ 50 F^2	4 ~ 30 F^2	4 ~ 12 F^2
Multibit	1	1	2	3	1	2	2

Read time	~1 ns	~10 ns	~50 ns	~10 μs	<10 ns	<10 ns	<10 ns
Write time	~1 ns	~10 ns	10 μs–1 ms	100 μs–1 ms	<10 ns	~50 ns	<10 ns
Retention	N/A	~64 ms	>10 y	>10 y	>10 y	>10 y	>10 y
Endurance	>1E16	>1E16	>1E5	>1E4	>1E15	>1E9	>1E6~1E12
Write energy (J/bit)	~fJ	~10 fJ	~100 pJ	~10 fJ	~0.1 pJ	~10 pJ	~0.1 pJ

Data from (Yu 2016)

Notes: F: feature size of the lithography. The energy estimation is on the cell-level (not on the array-level). PCRAM and PRAM can achieve less than 4 qF^2 through 3D integration. The numbers of this table are representative (not the best of the worst cases)

Table 17.2 An over-simplified resume of advantages and challenges on emerging memory technologies

	Main advantages	Key challenges
FeFET	IT cell structure	Material and processing
	Low-power field-driven	FEOL integration
	High performance	Reliability and parasitic effects (e.g., charge trapping)
	Ferroelectric doped HfO_x	
PCM	Maturity	Reliability
	Proven performance	Disturbance
		High switching power
STT-MRAM	High performance	Reducing I_c/Δ (power-stability tradeoff)
	Well-understood physics	
	Novel mechanisms (*e.g.*, SHE, VCMA) to extend capabilities	MTJ patterning and etching
		BEOL thermal budget
RRAM	Simplicity and low cost	Reliability and failures
	High density	Stochastic mechanism and intrinsic variability
	Versatile materials, structures, and behaviors	Forming

From [43]

hole/electron trapping issues. The first problem generally calls for a more robust array structure, which is typically a AND array. This type of array allows each cell to be in parallel along each bitline instead of being in series as in NAND array. There is however a clear drawback in terms of scaling, but it is arguably the bottleneck of the FeFET. It looks in fact natural to compare FeFET with Flash, since both are front-end memories; however as emerging technology, FeFET is actually competing with BEOL memories. With this in mind, AND arrays are quite the obvious solution for resistive memories, since this is the only viable way to prevent sneaking paths during read operations. So the relatively larger AND array that FeFET must be implemented with is not a limiting factor. Still, this will become an issue if this technology was found to be performant enough to pursuit the scaling route. More on the scaling issue comes when dealing with the second problem we evoked: trapping. As a positive programming pulse is applied on the FeFET gate, electron trapping occurs, probably at the interface between the ferroelectric layer and the isolation layer above it [50]. This means that until electrons are actively or passively de-trapped, the device threshold voltage remains unchanged, since the screening effect of the negative charges conceals the internal coercive field. Active de-trap has costs in terms of programming time and energy, but at the moment it is required to allow a fast readout of the memory bit (necessary, for instance, if a program verify must be implemented). Another solution would be enlarging the memory window, which is of course always desirable. This impacts however the vertical scaling quite strongly. The memory window is in fact linked to the dielectric thickness at the first order by $MW = E_c \times t_{ox}$ (where E_c is the coercive field and t_{ox} the ferroelectric layer thickness) [52]. At time of writing, the typical MW is in the order of 1–2 V which looks already quite small if compared to charge trap devices. Vertical reduction of the ferroelectric layer looks thus difficult. In-plane scaling however is not an easier way to go. The ferroelectric HfO_2 has been reported to feature relatively large crystals of about 10 nm size [52]. This granularity immediately impacts the variability of the programmed threshold voltage. This happens in two ways. The first one is linked to the variability in coercive field specific to each grain. As grain size varies, each dielectric gate integrates a different number of grains of different size. This leads to a granularity in threshold voltage that was also reported to be seen in programming. In addition, grains can be oriented differently which means that the polarization field that each grain will apply on the channel is modulated by the cosine of the angle between the remnant field and the vertical z-axis. This causes a further variability in threshold voltage. Another critical aspect of FeFET development is linked to the relatively poor endurance that FeFET demonstrated so far. Typical endurance was reported between 10^4 and 10^6 [49, 53] which depending on the application, as we will further discuss, can be a serious issue. It is believed that the main degradation mechanism consists in the breakdown of the silicon oxide interface between the ferroelectric and the transistor channel. This implies that high endurance requires the silicon interface integrity to be kept during the cell life span. So far however it is not clear how this issue can be tackled while the main research axis points in the direction of decreasing grain size and increasing the coercive field. Another challenge FeFET will have to face is the possibility to be integrated in 3D structure as NAND Flash. This would allow to cope with some of the scaling issues we discussed and to propose a much larger application panel. However to demonstrate the feasibility of going 3D, the most difficult challenge would be the formation of a reliable silicon oxide interface between the ferroelectric hafnium oxide interposed between the two polysilicon structures that constitute the NAND cell series and the gate planes (see Fig. 17.7 [52]). So the 3D route requires major advancements in material development to achieve lower coercive fields and to improve the silicon interfaces. This will only be addressed once that the cell-to-cell disturb and the inhibit schemes required for writing patterns will be proven to be functional.

PCM memory is seen by many as the most mature technology among eNVM. We will show that quite a few demonstrators have been already made available on the market, and this means that most of the technical issues related to PCM have been solved or at least coped with. As we mentioned in the previous section, one of the major challenges that drives the

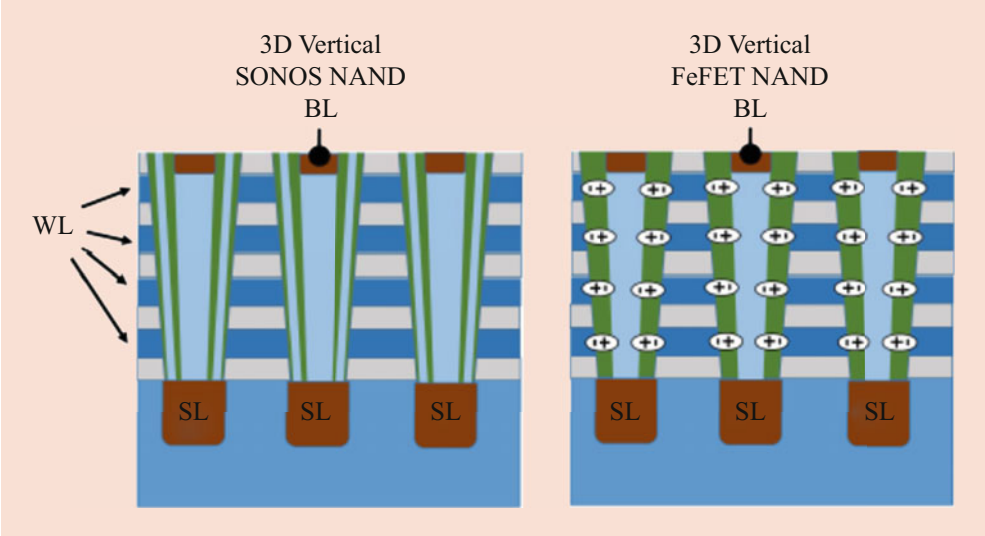

Fig. 17.7 Sketch of SONOS 3D VNAND compared with hypothetical vertical FeFET. (From [52])

development of PCM memories relates to the improvement of the stability of the programmed states. There are two main objectives concerning the thermal stability. The first one is the automotive specification, which is typically 10 years at 150 °C. The second one is probably even more stringent and relates to the pre-encoded data at wafer level. For some applications in fact, it is required that data are encoded on the memory chip before packaging and final board assembly. This is generally due to high security requirements. This however means that the chip will be subjected to additional thermal stress during board soldering reflow. The typical specification is 260 °C and between 2 and 5 minutes.

The stability of the SET and RESET states is very sensitive to the thermal environment of the device. The mechanisms that can compromise the programmed resistances are very well-known and documented and can be summarized in two main points. The first one is the crystallization of the amorphous material. When the amorphous rearranges its atoms, the electrical resistance of the memory bit programmed in RESET state tends to lower as the material becomes more and more crystalline. Eventually this can lead to a fail of the RESET state. A second mechanism of data loss is the structural relaxation of the material (both crystalline and amorphous phases contain imperfections that evolve with time) that causes an increase of electrical resistance. This phenomenon is typically known as resistance drift. RESET is obviously the cell state that is mostly affected by resistance drift as it is inherently disordered and each annealed defect translates into a lower electrical resistance that can be easily spotted in electrical tests. However drift is also observed in SET state, where the material is polycrystalline. Drift is attributed in this case to a structural relaxation of the amorphous residues that are known to exist within the crystalline phase. Grain boundaries are believed to play a role in the dynamics of the relaxation. The inevitable effect of the resistance drift is a fail of the SET state, as the electrical resistance increases gradually until the threshold resistance value is crossed. On the other side, this issue doesn't affect much the RESET state as a higher resistance is desirable but can still cause trouble if the memory is operated in a multilevel way. Research has spent so far a considerable amount of energy and efforts trying to solve both problems, and it is now quite clear that these issues cannot be solved at the same time. Indeed the two mechanisms are deeply linked and appear to be in competition. In [54], for instance, it is shown that materials that improve stability of the RESET state are prone to premature loss of SET state due to higher resistance drift. This eventually means that a trade-off must be found. This is clearly the biggest challenge for PCM.

The second main research axis, key to make PCM successful, is the current reduction during the program pulse. In particular the most current-demanding operating phase of a PCM cell is the RESET. The memory bit being low resistive calls a relatively large amount of current which is required to melt down the crystal material and to sustain the temperature before quenching. To achieve the current reduction task, multiple solutions have been proposed and are under discussion in literature. The first, and probably most obvious, solution would be a bit cell scaling down. A second strategy is the increase of the thermal efficiency of the memory bit by confining the melting heat. This would reduce the power loss allowing reduction of the reset current. A third and probably more difficult path would instead be the modification of the melting material. This approach would mean keep the cell structure and size identical while playing with the material properties. A first way in which the material properties could

be modified would be by lowering the melting temperature Tm of the compound [55]. In [56] instead, the possibility of increasing the electrical resistivity of the crystalline phase is proposed and found to be beneficial while increasing the power generated by the heat source. In [57] another strategy is proposed, consisting in doping the $Ge_2Sb_2Te_5$ matrix with SiO_2, which is found to decrease the reset current by modifying at the same time the thermal and electrical properties of the melting material. It is worth spending a few more words about the microscopic parameters that determine the programming current, in order to allow the reader to better understand the challenge. The main parameter that determines the current necessary for programming is the Joule heating effect that takes place within the phase change material. The power dissipated during the heat up has two contributions as explained, for instance, in [58]. The first one is given by the electrical resistance on the material when it is in the conductive state. This contribution is found to be ohmic. A second contribution is instead non-ohmic and comes from the so-called holding voltage (V_{hold}). These two contributions can be summarized as $P = V_{hold} \cdot I_{prog} + R_{on} \cdot {I_{prog}}^2$.

From this equation it is clear that a lower R_{on} or a higher V_{hold} will cause a higher power dissipation. Both these parameters can be modulated changing the material composition. The second parameter that impacts the current consumption is the heat dissipation during the RESET. This is well described, for instance, in [59] and is shortly summarized in the well-known heat equation (17.1)

$$\rho C_P \cdot \partial T/\partial t + (-k \cdot \mathrm{grad}(T)) = j2/\sigma. \tag{17.1}$$

This equation shows the obvious balance between the heat generation and the heat dissipation. For a RESET to happen, it is necessary that this equilibrium is reached with a temperature above the melting point of the PCM. In [60] it is well explained how modifying the material impacts the melting temperature and how this equilibrium shifts toward higher or lower current demand. Eventually a third effect must be taken into account. It has been reported [61] how the behavior of the material during the cooling phase can impact the programming current. This can indeed happen because if the phase change material features a high growth rate, a dome surrounding the molten mushroom could be recrystallized during the cooling phase. This means that the amorphous material will eventually result as a smaller portion than the actually molten dome. Eventually a larger dome will have to be melted down to achieve the desired amorphous volume, and this is done at the expense of additional programming current. In [61] it is reported how a reduction of Sb/Te ratio in PCM cells based on germanium doped SbTe can lead to a reduction of programming current via a lower growth rate.

MRAM has experienced an impressive progress in the last 5 years, and certainly the development of STT-MRAM devices has further accelerated the research to shorten as much as possible the time to market. We will see in the next session that many chips featuring STT-MRAM technology are currently commercially available. Even so, the magnetic memory still faces quite difficult challenges at the device level and at the circuit level as we already introduced in Sect. 17.2. Here we will focus more on some of these aspects: first the low ON/OFF resistance ratio, which requires extremely accurate and dedicated sensing circuit, and the high write current necessary to accomplish the programming phase of the memory bit. Not only the current is relatively high (typically in the order of a few hundreds of μA) but is also asymmetric between write and erase. Any process variation worsens the situation even further. The low ON/OFF ratio has a clear negative impact on the read latency as longer integration times are generally required. This causes a significant degradation in the memory overhead. In addition any process-induced variation within the reading logic will immediately impact the memory margin which is very small when compared to other emerging resistive RAM. This typically means even longer time for bit reading. As the write sequence is performed with a program/verify sequence, longer latencies on the reading side impact the overall memory latency, given by the sum of read and write latencies. To alleviate the poor ON/OFF ratio problem, various approaches have been proposed. In [62] a self-referencing scheme is proposed to reduce the read errors due to variations in ON and OFF resistances over the array. In a similar direction, in [63] an innovative inverse read is proposed which is proved to reduce read disturb and write power consumption. In [64] the authors investigate the optimization of the sense margin by combining a clamping transistor selector and a reference voltage bias. Eventually it was reported in [65] a reading method based on reference voltage, instead of a current, which proves to increase the sense margin when used to discriminate between ON and OFF states.

The second major challenge concerns the write current. This is a very well-known issue for STT-MRAM, as write current for these devices is high and asymmetric. This is due to the difference in polarization current, which is higher for one of the two logic states, and to the variation of charge current injection. To reduce write current, a new STT-MRAM flavor is under investigation, based on perpendicular magnetic anisotropy (PMA) [66–68]. More than that, a recent discovery of a large change of magnetic anisotropy in a Fe(001)/MgO(001) junction after applying small electric field showed a potential path to reduce current consumption in write procedure. This phenomenon is known as voltage controlled magnetic anisotropy (VCMA) [69]. Eventually we mention a giant spin Hall effect (SHE) reported, for instance, in [70, 71] found in some transition metals which could provide a new source of spin torque less energy demanding. Additionally it could provide a reliable way to separate

writing and reading electrical routes which is expected to positively impact on the device reliability.

OxRAM is still regarded as one of the most promising technologies among the eNVM panorama. We described in Sect. 17.2 some of the advantages of this device. Here we look more into detail to the challenges that this technology must endure before being successful as a real product. An excellent review on this topic can also be found in [9]. As it was already mentioned, the biggest challenge for OxRAM is the poor uniformity of the device electrical characteristics. A very large variation can be found in almost all the electrical parameters that characterize an OxRAM device. Large fluctuations exist in terms of HRS and LRS value and are both temporal (cycle-to-cycle) and spatial (die-to-die or cell-to-cell). Many works deal with the origin of these fluctuations which appear to be clearly intrinsic to the device. It is generally accepted that the stochasticity of the oxygen vacancies or of the ion diffusion is the root cause of the problem. This is discussed, for instance, in [15, 72].

It is quite clear that the variation in the resistance of the LRS (low resistance state) has to be attributed to the existence of conductive filaments of different sizes. Additionally, many report that this can be also caused by the existence of multiple conductive paths. So far, to reduce the variation of LRS distribution, two main routes have been explored: confining the filament in a narrow space and carefully controlling the current during writing process to freeze the formation of CF at a desired resistance value. However the main source of trouble with OxRAM is by far the high resistance state (HRS). In this case in fact, the variability can easily span over two to three decades since the microscopic mechanism that controls HRS is mainly tunneling across the small gap opened within the conductive filament during erase. Since the dependence between the gap dimension and the electrical resistance is exponential, any atomic-level variation within the gap translates into large resistance fluctuations. In addition to that, any defect (for instance, any oxygen vacancy) that remains within the gap can act as a bridge across it; eventually the conductive filament is the sum of many complex percolation paths. As the entropy linked to this situation is extremely high, so is the fluctuation observed. The clear conclusion is that the resistance variation is an intrinsic property of the OxRAM device and little can be done to reduce it. The most investigated approach to palliate this issue deals with the introduction of a capping or an interface layer to better control the interface between the oxide material and its most reactive electrode. In this direction Kim et al. proposed IrO_2 to replace the top electrode of NiO-based OxRAM [73], while several papers published results about TiN electrode buffered with thin Al layer for HfO_x-based OxRAMs [74]. A figure reproducing the remarkable improvement in set voltage distribution is proposed as Fig. 17.7. A second method widely investigated is the concentration of the electric field during set which should focus the conductive filament in a very narrow region. This causes the filament to be forced into the same shape at each cycle, reducing variability. To obtain this result multiple approaches were investigated. Most of them deals with reducing the cell size, as in this work by Lee et al. [75] who scaled the cell size down to 50 nm, or by this work by Fantini et al. where the cell size is as small as 10 nm [76]. This approach shows quite good result with improved set and reset distributions, even if the statistics under test are relatively small (in particular for the 10 nm device). Another research path consists in inserting seeds or extremely sharp edges to enhance the local electric field. In this direction Chang et al., in [77], showed results from TiO_x memory cells with embedded Pt nanocrystals. Similarly Liu et al. in [78] implanted Ti atoms within a ZrO_x matrix. Eventually a cell redesign was also proved to be beneficial at focusing the electric field, thus causing improvement in variability. For instance, Chang et al. in [79] introduced ZnO nanorods across the OxRAM stack in order for them to act as seed and to form filaments protruding out from them. Another example is given by Lee et al. in [75], where a crosspoint architecture is implemented with thin liner used as bottom electrode of a NiO-based device. All the abovementioned approaches showed clear improvements of the device characteristics; still the HRS distribution remains a limiting factor and major challenge for the technology.

Different approaches were also evaluated focusing on the "software" aspects of programmability. Complex program/verify schemes [80], redundancy, differential readings, and a large panel of preconditioning approaches were investigated. Once again, all these efforts although effective were not sufficient to entirely solve the intrinsic stochasticity of OxRAM technology (Fig. 17.8).

In order to summarize what has been described so far, Fig. 17.9 reproduces schematically the most relevant aspects of each technology along with their drawback or issues to be solved. As we saw STT-MRAM are probably the most advanced and promising in terms of performances, and a remarkable effort has been done so far in material and structure optimization. The main axis on which it is necessary to work is related to current reduction, scalability, and cost of manufacturing (see also Table 17.2). Even so, a first commercialization proved the real potential of the technology. A similar situation can be found for PCM, which is again a relatively mature technology with a well-established comprehension of the physical mechanisms of switching and reliability. PCM proved on the market to have a real potential and certainly can find applications. The main issue for PCM relates to thermal stability and power consumption, while good scalability and fast, reliable switching are the main advantages. FeFET is the only 1T device in the emerging NVM panorama. This is certainly its main advantage, since it could conjugate the scalability of a logic transistor with the

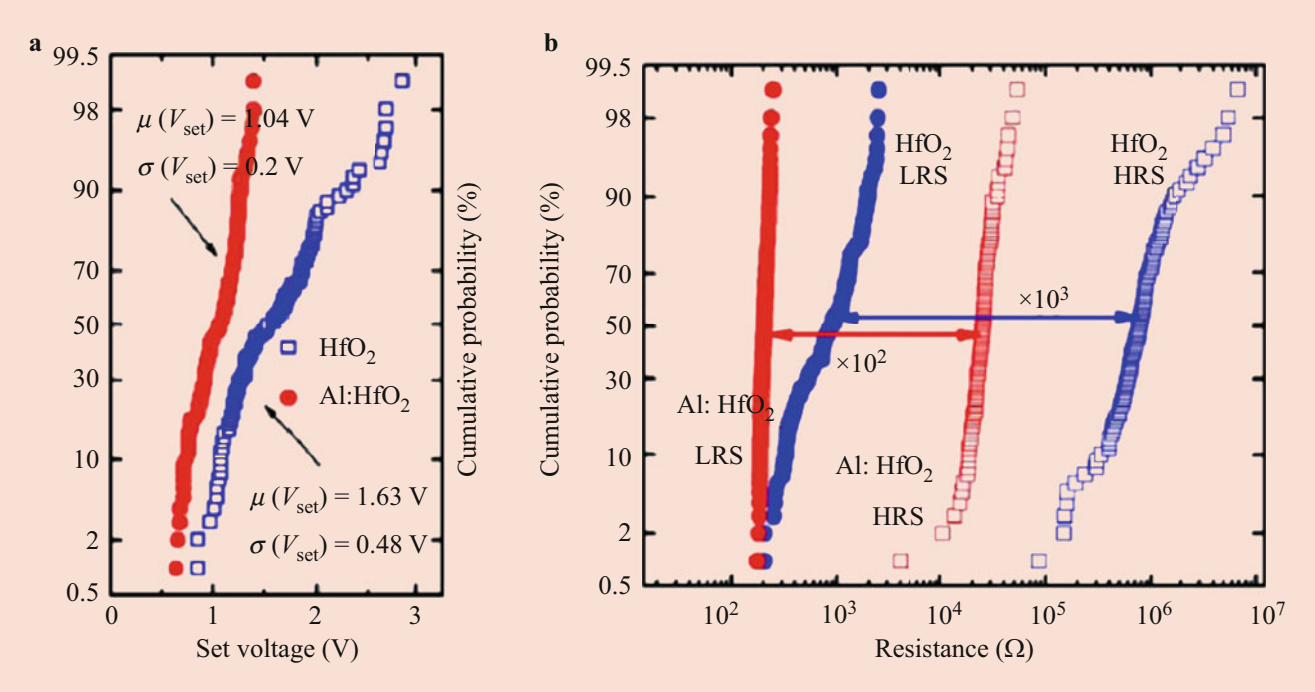

Fig. 17.8 (**a**) Set voltage distributions for HfO_2 and Al-doped HfO_2. (**b**) LRS and HRS resistance distributions. (From [74])

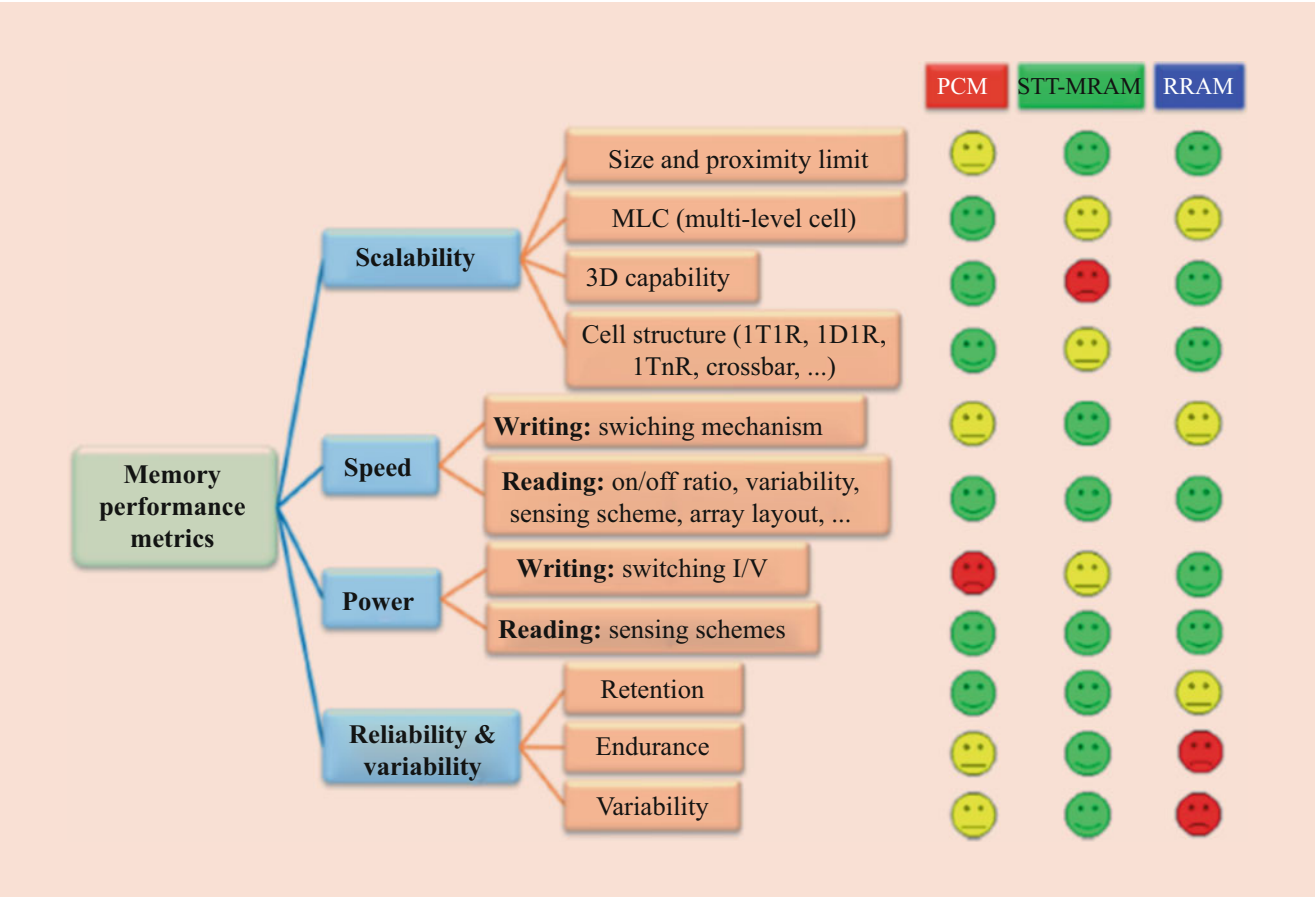

Fig. 17.9 Schematic representation of the main parameters for PCM, STT-MRAM, and RRAM. (From [43])

non-volatility of a resistive RAM. It is, we believe, still too early to understand the true potential of FeFET since much more research is still required. The main other advantages of this technology would be the high speed and a very low energy consumption, in addition to a very high CMOS compatibility. However, high variability, unknown thermal stability, and so far critical endurance are the challenges that FeFET has to face in the next years. It is sure that FeFET is among the emerging NVM the one that needs much more R&D efforts. Eventually OxRAM is probably the simplest device in terms of material and structure. It has been investigated extensively and it is still considered a good candidate for real products. OxRAM has a great advantage in terms of low cost impact, large ON/OFF ratio, and relatively low power consumption but suffers of high variability, which negatively impacts the reliability aspect of the device.

Figure 17.9 effectively summarizes the performance of each NVM described so far. These performances are classed following just four criteria. This is surely reductive as a memory technology must deal with a large number of trade-offs. Process difficulties, additional mask sets, and above all cost are however difficult to evaluate and are so far neglected. The chart classes OxRAM, PCM, and STT-MRAM based on scalability, speed, power consumption, and reliability. Each of these parameters is of course dependent on multiple aspects. Scalability is probably the most difficult aspect to evaluate. How scalable a memory cell is depends on the architecture, on the cell structure, on the selector device, and on the capability to stack 3D array or to use multilevel bits. It must be said however that all emerging NVM, except FeFET, are characterized by similar current consumption and by the need of a selector. This implies that the selector size is probably the most important aspect in determining the scalability of a memory technology. In addition, 3D stack seems to be very premature for any of these technologies and the same goes for the multilevel capability. So far in fact, no strong proof of multilevel programmability was provided on more than a few bits in literature for any of the considered candidates. The speed also depends on multiple factors. The main one is of course the writing mechanism. Although the technologies we considered are very different in terms of physical mechanism, they are relatively close in terms of writing speed. If, in addition, we benchmark these technologies with the typical speed of a Flash memory, it is clear that the memory writing time is not the bottleneck. PCM, FeFET, STT-MRAM, and OxRAM were all demonstrated to be faster than 10 ns on single bit, which is several orders of magnitude lower than a Flash memory (between hundreds of μs and ms). Differences exist however among them. FeFET is supposed to be writable in the ps range, and STT-MRAM can probably match them. OxRAMs were demonstrated writable in 1–10 ns, depending on the voltage applied. PCMs typically require slightly longer time, in particular to set the crystal phase, but newer compound was shown to crystallize in a very short time, in the order of 10 or a few tens of ns. A different situation can however apply for sensing operations. Evaluating the reading speed is quite difficult since it does not only depend on the memory cell itself but on the array architecture also. What is the level or parallelism on the array, how much current it is available for reading, and how large is the array are all parameters that influence the sensing time. Here however we focus on the device itself. The main parameter influencing, at the device level, the read time is the ON/OFF ratio. PCM and OxRAM have a quite large ON/OFF ratio, which makes the reading time possibly very low. STT-MRAM on the contrary are a bit of a challenge on this front, as we discussed previously. Eventually FeFET, since their principle is similar to Flash, have similar characteristics and feature fast reading times. The next parameter reported in the table is the power consumption. It is crucial to underline that power consumption should actually be divided into energy consumption and proper power usage. The first one, the energy, is probably the most important for applications that need to reduce the overall consumption, for instance, portable applications. The second one is instead more important for high performance applications as a high peak power consumption means larger power grids, higher thermal dissipation, and limitations in terms of parallel operations. As last point it must be noted that the energy consumption is the integral of the power absorbed over the time. In these terms, a PCM cell may require more current than a Flash cell but for a much shorter time. Eventually the overall energy required can be similar. Reliability includes many aspects like endurance, data retention, soldering reflow compliance, variability, RTN, read disturb, and others.

17.3.2 Most Relevant eNVM Demonstrators

While most of the research papers available in literature deal with single devices or small arrays, it is necessary to observe what is the actual industry development effort in emerging NVM technology. During the last decade, several demonstrators were proposed by different actors to the scientific and industrial public. Figure 17.10 (adapted from [43]) summarizes some of the most relevant memory chips proposed as technology demonstrators. This plot focuses on PCM, STT-MRAM, and OxRAM. All data reported were published on conferences, and refer to functional arrays which can be considered representative of a real product, although in an early stage of prototyping. In the figure the size of the symbol is meant to be proportional to the technology node used to build the CMOS circuitry of the demonstrator. Each symbol is labelled with the company name, array size, used

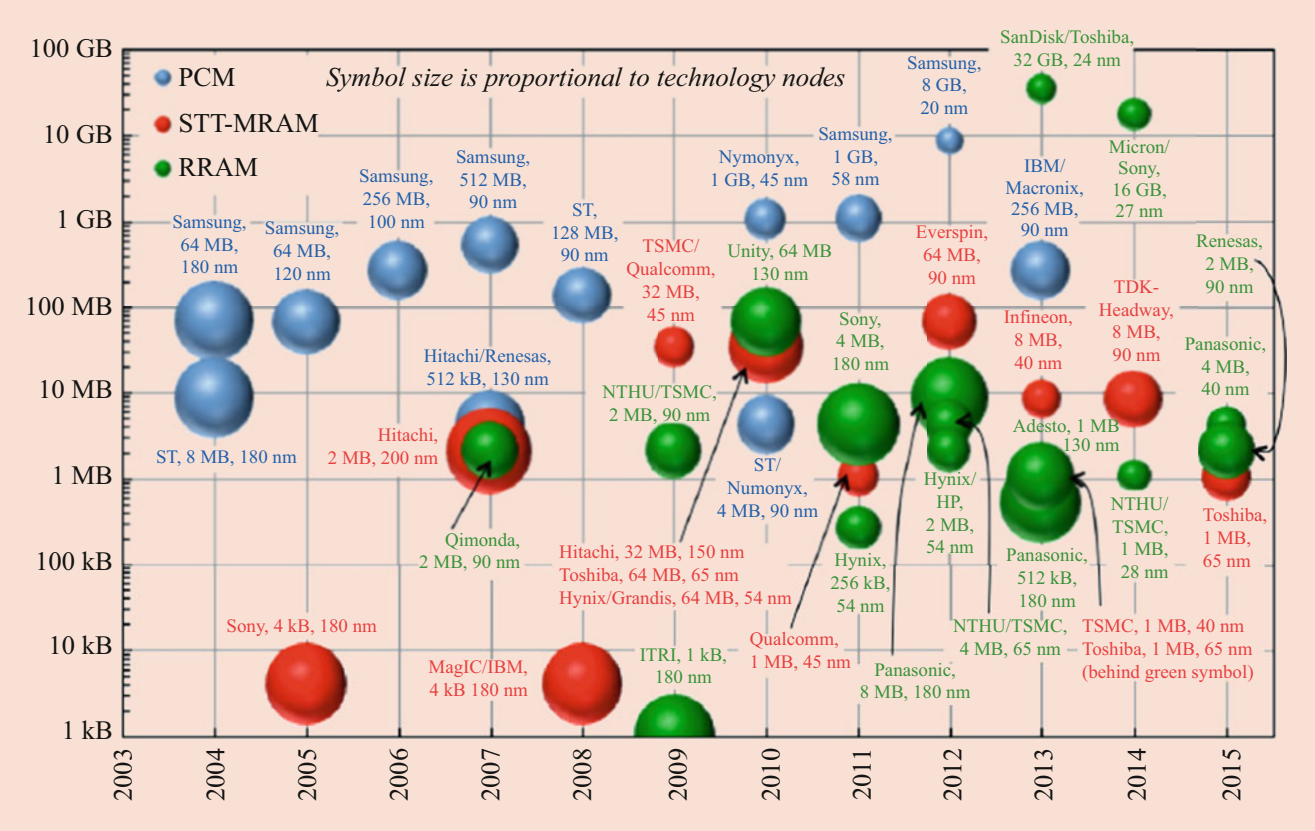

Fig. 17.10 Representation of the fabricated devices over the years based on density and technological node. (From [43])

process, and technology node. Many interesting observations can be made based on these data. The reader will notice that PCM (blue symbols) shows quite a clear trend over the years, with two main actors, Samsung and ST (and its former spin-off Numonyx), proposing increasingly larger memory chips. Also, it appears that PCM technology was the first to achieve a demonstrator stage among the three. The largest PCM array was 8 Gb by Samsung in 20 nm node. Another interesting observation is that STT-MRAM (red symbols) features generally smaller array size compared to PCM. This is due to the different applications STT-MRAM aims at. This device is generally intended for high performance and low size applications (for instance, automotive μC), instead of being oriented to high-density memory. The lowest CMOS technology node used to embed STT-MRAM was in fact 40 nm (by TCMS 1 Mb size). Eventually OxRAM shows very dispersed and inconsistent development path, as different actors aimed at different applications, ranging from μC to neuromorphic to stand-alone. At the same time, it is quite remarkable that so many demonstrators saw the light in a very limited time. Between 2012 and 2015, as many as 11 different test chips were built, showing the high interest that OxRAM attracted in the industry.

17.3.3 Innovative Applications

So far we saw how eNVMs have a wide range of interesting characteristics that drive high interest both in academy and industry. Clearly, new memory devices with innovative aspects with respect to existing technologies open new roads for new applications. In this section we will explore what kind of applications can be envisaged or could be made possible by adopting eNVMs. We discussed the most relevant aspect that characterizes each technology considered so far. For instance, STT-MRAM features a very high speed, while OxRAM is very stable and can sustain high thermal budget. Each eNVM could then ideally be more suited for a specific application based on this description; however as we mentioned in Sect. 17.1, trade-offs are always necessary to enable a specific application, and the success of a technology can only come when several constraints are satisfied at the same time.

The first, quite obvious application that justifies the research of a new memory device is the improvement of the actual products. If we consider, for instance, stand-alone memories (in other words NAND Flash), the typical low voltage operating range of eNVM looks extremely promising since it would remove the requirement of charge pumps

which decrease the array efficiency. At the same time, the high speed typical of eNVM would represent an obvious improvement with respect to Flash. At the end all these aspects represent a cost improvement, which is essentially the driving aspect of NAND Flash. The same reasoning can be applied to SRAM or DRAM, which could in principle be replaced by STT-MRAM or OxRAM, as the first one is characterized by very high speed while the second one is supposed to be very scalable and cheap at production. However the production requirements, the standardization of several products, the needs of the current business, and the justified precaution of customers used since years to a well-established technology represent a high barrier that prevents the adoption of any new device. Two main situations can lead to overcome this barrier. First is a clear and net cost improvement. This scenario is quite unlikely to happen since cost reduction is the result of years of optimizations driven by large demand. Flash technology scales its cost impressively fast and it looks unrealistic that an emerging technology could compete on that. The second situation is related to better performances or entirely new features. The most probable scenario that would lead to the adoption of eNVM is much closer to this one. Emerging memory could compete on performances beyond Flash capabilities – high write speeds, longer endurance, and so on. OxRAM was also demonstrated as a possible solution for flexible and organic electronics. Another sector in which eNVM could penetrate the market is represented by OTP (one time programmable) replacement. OTP, as well as 1T NOR Flash, are often used for code storage in micro-controllers in many different applications. eNVM would bring at lower cost the benefit of re-writability. This is in general true for any embedded application, where standard NVM has difficulties to scale at the most advanced nodes. For instance, Flash technology is hardly achievable below 28 nm, while PCM was demonstrated already at 20 and FeFET at 22 nm. For this purpose however, eNVMs have to show a much improved reliability to become a real solution for embedded applications. In particular automotive market requires very stringent thermal stability and an extremely low defect level. Still many other eNVM characteristics have to be improved before any of the discussed technologies could realistically be embedded.

A second, probably more interesting, domain of applicability of eNVM would be the so-called storage class memory (SCM). The reader may be already familiar with the concept of "memory gap." This term refers to the large difference mainly in terms of speed that can be observed in the current memory hierarchy in computer architecture. The memory close to the CPU is typically SRAM, with access time in the order of ns. DRAM follows with access time in the order of tens of ns, used to catch data and buffer between storage and cache memory. However between DRAM and hard drives, a large gap in speed exists, as the HD works in the ms access time range. Figure 17.11 shows graphically this large gap of

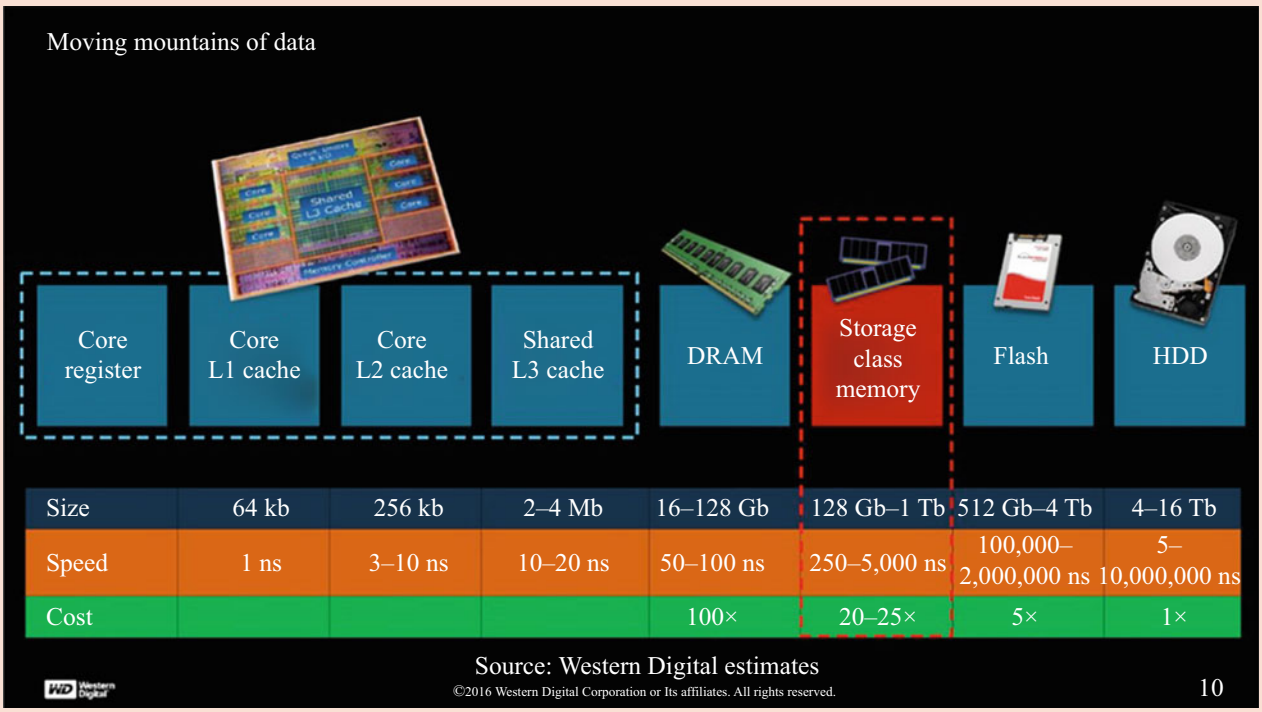

Fig. 17.11 Memory hierarchy. (From [81])

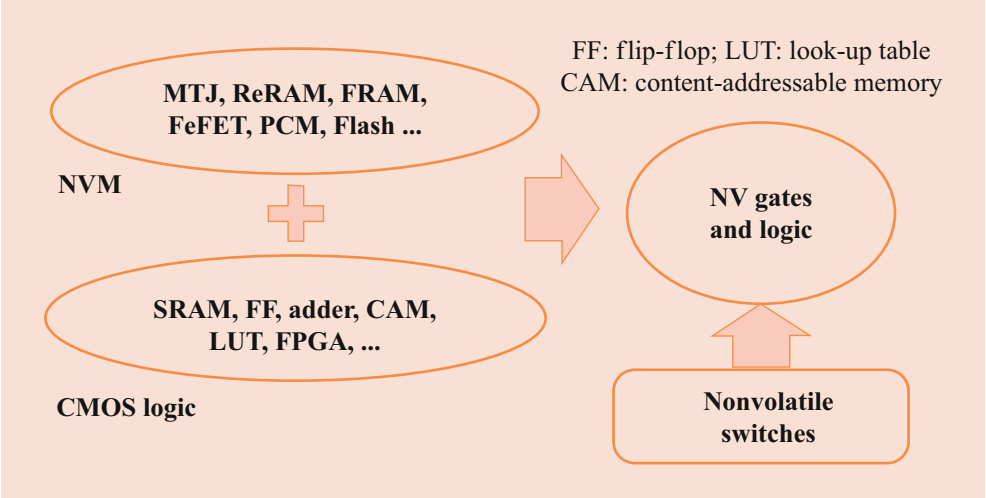

Fig. 17.12 Possible memory implementation for computation. (From [43])

more than three orders of magnitude. The development of NAND Flash as storage memory in SSD drives alleviated this large gap and showed the interest for bridging the leap. A "universal memory" that would have the speed of a DRAM, the non-volatility of a Flash, and the price of a magnetic disk looks extremely attractive but, as we discussed in Sect. 17.1, seems also unrealistic. However, in 2017 the introduction by Intel and Micron of a crossbar resistive memory (with the commercial name of Optane) based on PCM on the consumer market opened and showed the new path. It is still early to assess if commercially this can be considered a success or not, but the electrical behavior of this device indeed boosts the HD performance.

Another potential application that has been scrutinized and could be a market opener for eNVM is the very-low-power application. This class of devices includes those chips that spend most of their lifetime into an off, sleep mode. They only turn on for a short period of time when a trigger event signals the need of an operation. Most devices, while on standby, still consume a relatively high amount of energy, and a significant part of it is used to refresh volatile memory. SRAM cannot be turned off without loss of data, unless, before power down, data are transferred to a nonvolatile support. This has two major disadvantages. First, the data transfer and data writing can take a long time, in the order of tens of ms in the worst cases. In addition, when the trigger is received and the device turns on again, data have to be reverted and SRAM reactivated, causing an additional delay time. Internet of things (IoT) is probably the best example where these devices are required, since power consumption is the main issue. Flash is not a good choice as dumping memory, since its high writing voltage is a big hindrance in low consumption applications and very low-cost devices. For this reason eNVM can be considered as a good candidate as dumping support. Not only eNVM could be used to store SRAM data before standby, but it could also, provided a very good endurance, completely replace SRAM itself. In this case the device could get a high speed, close to actual SRAM but in conjunction with the non-volatility character of eNVM. STT-RAM seems the most appropriate for this scenario, as it can be considered as best performing eNVM currently available in terms of speed and endurance. STT-RAM however has a quite high ON power consumption, and its use can be justifiable only if the saved energy during standby is by far larger than the extra consumption during the ON stage [82].

Many papers also suggest the use of eNVM in the so-called in-memory computing (IMC) approach, where memory bits storing data to be processed are integrated very close to the logic gates that actually process them [83]. By mixing eNVM and logic components, for instance, mixing OxRAM and adders or look-up tables or other logic ports, it is possible to obtain a computational unit with a built-in memory that allows to process data into a nonvolatile environment. This is represented in Fig. 17.12. Some eNVMs look in principle very adapted to this application, for instance, FeFET as it can operate as both a "normal" logic component and as a nonvolatile bit. The use of this kind of architecture, if proved functional, could revolutionize entirely the computing architecture and would benefit of increased speed and reduced power consumption as data transfer would be greatly improved. However the robustness of eNVM has to be quite as high as the logic component, since the memory bits would be used at least as frequently as a classical logic gate, both in reading and in writing mode. Reliability again looks as the biggest constraint.

So far we discussed some applications where eNVM could be preferable with respect to actual technology, and in the last example, we also discussed a potential new application in rupture with the current technology. Some additional ex-

amples must be mentioned where eNVM could have a role as electrical component where the researched characteristic is not its non-volatility but its intrinsic variability or its capability to gradually change its resistance from two or multiple states. The first one is the neuromorphic applications. The interest into this field has been driven by the boost in performance and applications of machine learning (ML). This boost is the result of two main components: on one side the huge amount of data stored in the internet, mainly composed of images, video, music, and text, which can now be used to train artificial intelligence, and, on the other side, the high computational power at our disposal with the advent of parallel computing in conjunction with the ultimate CMOS scaling close to and below 10nm node. At present time, the ability of artificial intelligence in certain tasks, once unique domain of human brain, like image recognition or natural language comprehension has equaled or sometimes surpassed man's ability. The potentials for AI use are endless, from advanced translators to self-driving cars. As we will discuss more in detail in the next section, the limiting factor at developing neuromorphic structure is the difficulties to mimic the actual behavior of a synapse and a neuron. A recent trend in neuromorphic computing is to encode the neuron state into pulses or spikes [84–86], and the information carried over the neural network is represented by the cumulative effect of spikes over time. So far several large-scale neuromorphic systems have been studied and proposed based on the actual silicon technologies. Some examples are Heidelberg's HICANN [87], IMB's TrueNorth [88, 89], or ETH's ROLLS [90] chips. In these examples the neural weight is stored in capacitors or in SRAM cells. Therefore area consumption, energy consumption, and memory volatility are limiting factors. Emerging NVMs are thus considered as very promising candidates to implement synapses thanks to their capabilities to change gradually their resistance, or to switch after a cumulative amount of spikes. This is particularly true for OxRAMs, PCM, and CBRAMs. In addition to this unique feature, the reduced area and power consumption make eNVM ideal for neuromorphic applications. The high variability that characterizes OxRAM could even be considered an advantage in this context as it could promote additional connections in the neural network useful to explore different connection schemes. Even though OxRAM and PCM look so suitable for these applications, actual demonstration of feasibility is limited [91]. The possibility to modulate in a controllable way the resistance of the memory bit has to be improved, and the general asymmetry between write and erase (for instance, SET and RESET in OxRAM are very different) still poses some challenges to easily modulate the reinforcing and depressing learning phases.

In this last section, we discuss some additional explorative applications that are getting more and more attention in recent years. As we saw so far, there are many aspects of eNVM that are unwanted for memory applications. These include resistance variability, switching voltage variability, random telegraph signal noise, and resistance drift, to cite the most important. However for the applications we are about to discuss, these characteristics are actually of interest. These applications in fact profit from the typical stochasticity of most eNVM behavior (mostly OxRAM and CBRAM) to enable some applications in security hardware. In particular we focus on true random number generator (TRNG) and physical unclonable function (PUF).

TRNG are devices that generate a random bit sequence that complies with some requirements that guarantee the actual randomness of the bit stream. The first requirement demands that the bit stream has approximately the same probability to produce "1" as to produce "0." Devices like OxRAM are known to obey to the so-called "time-voltage" dilemma. This means that the probability to switch a cell is a function of both electrical bias and pulse length. If the programming pulses are correctly tuned, the memory cell can work in a range in which the probability to obtain one state or its complementary is equal. This feature enables the generation of true random number streams as demonstrated experimentally in some reports [92–94]. There are two main approaches to exploit eNVM for generating random bit streams. One possibility is to use the variation of write potential, in which the "0" and "1" are produced randomly because the write pulse is close to the switching potential threshold, so that the cycle-to-cycle variation causes the threshold to be higher or lower than the applied potential. The other possibility is to use the variation of the off state which is widely spread in filamentary eNVM. In this case a resistance threshold is carefully placed within the off resistance distribution of the device. As cycle after cycle the off resistance will change, the bit will be read alternatively as a "0" or as a "1." A less explored approach uses instead the signal telegram noise that characterizes the off state of many filament-based eNVM to trigger a random bit sequence [95].

The last application we discuss is PUF. A PUF is a security device that exploits the physical randomness generally linked to uncontrollable process variations to generate a unique, unclonable, stable "fingerprint" of a given chip. PUF must meet stringent specification in order to be implemented as actual source of chip identification. In particular there are three main parameters that quantify the PUF's quality. These parameters are the bias to judge the uniformity of "0" and "1" in the PUF responses, the inter-chip Hamming distance, which tests the uniqueness of the PUF, and the intra-chip Hamming distance which tests the reliability of the device. Using eNVM as PUF means to utilize the intrinsic variation of switching potential as a source of randomness [96–98]. One example is provided in Fig. 17.13a, b. A 1T1R OxRAM array is "challenged" providing two n-bit addresses, and the "response" is given by comparing the bits by pairs,

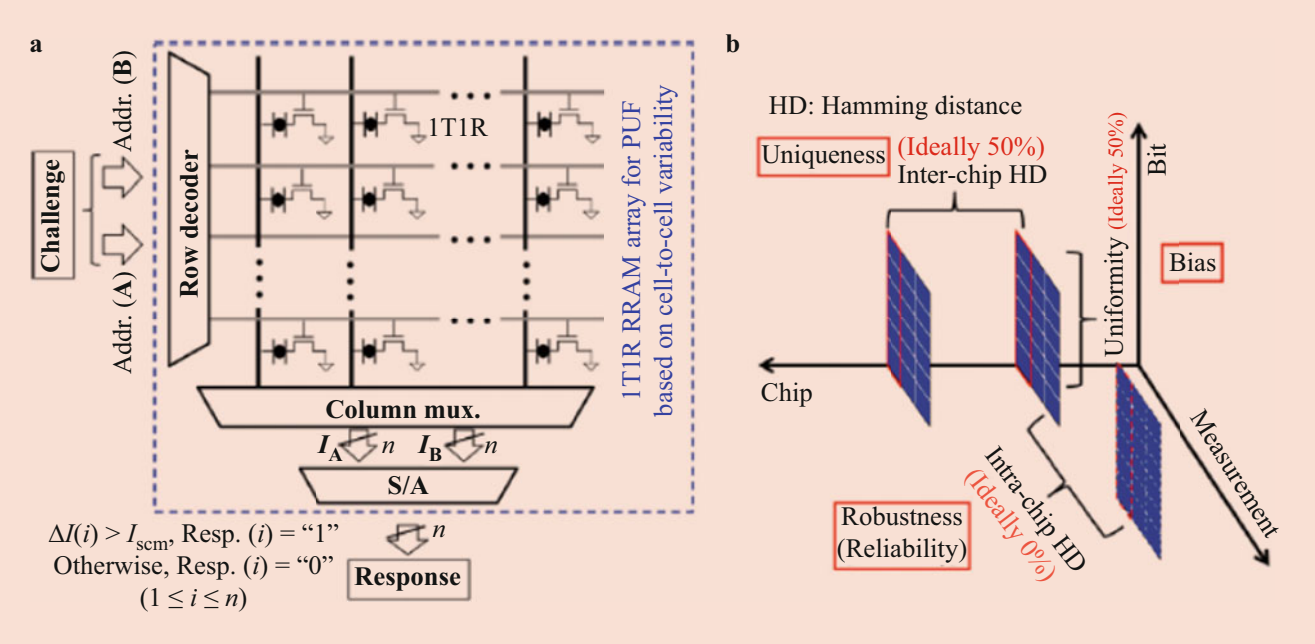

Fig. 17.13 (**a**) Schematic of a PUF based on a 1T1R resistive array. (**b**) Scheme representing how PUF quality is established. (From [96])

which generates an *n*-bit-long word. The randomness and the unclonability are provided here by the intrinsic cell-to-cell variation. OxRAM can present an advantage in PUF design as it allows smaller and less energy-consuming PUFs. Figure 17.13b shows how the PUF quality is established. An equal number of "0" and "1" is to be expected, meaning 50% probability to generate either "0" or "1"; when presented with the same challenge, two distinct PUFs must provide different responses; and when presented multiple times with the same challenge, one PUF must provide always the same response.

For eNVM to function as PUF, some aspects must be considered. The nonideal behavior of filament-based eNVM can be a limiting factor. In particular data retention, thermal instability and read disturb (like RTN, or cell-to-cell cross-talk) can cause the PUF to degrade. PCM and STT-MRAM were also studied as possible PUF devices [99, 100].

17.4 eNVM for Neuromorphic Applications

In this section we describe into more details some aspects of the neuromorphic applications for eNVM. This field is currently one of the strongest drivers of eNVM development, and thus it is relevant for the reader to get some concepts and to understand the main challenges that eNVM must face to enable new neuromorphic features.

As we discussed earlier, quite a few neuromorphic systems have been recently proposed based on silicon technologies. In this case [87–90], SRAM, capacitors, or other standard CMOS components were used to emulate at the same time neurons and synapses. The limitations with this approach are generally the volatility of the neural network and the large area required. Emerging NVM are in this case of great interest for their non-volatility, scaled dimensions, and the possibility to modulate their resistance. In the following part, we propose a short review.

The first example shows the use of eNVM – OxRAM more precisely – for convolutional neural networks (CNN) with supervised learning. CNN are inspired by the structure of the visual systems in mammals [101, 102] and are regarded as very interesting mainly for their relatively small memory footprint. Some significant proof of concepts were provided with software simulations with success in several fields, like the analysis of biological sample images [103], visage detection, optical character recognition (OCR), and human detection in pictures [104–106]. Some on-silicon demonstrators are also available, but, as the computational resources required are extremely high, dedicated SoC are generally used, where FPGAs are optimized to reduce the computational requirements and increase the power efficiency. In [107] an HfO_2-based OxRAM is used as synapses for convolution kernels. This device implements a spike architecture for pattern recognition. The advantage brought by OxRAM is to allow the in-memory computation which is highly time-efficient, leading to lower latency times in pattern analysis when compared to a GPU-based implementation. As can be seen in Fig. 17.14, the CNN architecture is composed of two cascaded convolutional layers (the extraction module) and two fully connected layers (the extraction module). The difference between the two structures is the amount of connections existing between

the layers. In fully connected modules, a large amount of synapses are used to connect every neuron of one layer to every neuron of the next one. Differently, in convolutional networks, a small amount of synapses are shared between the layers reducing the total number of synapses required. The convolutional layer presents several output feature maps. These are connected via the convolutional kernel to some or all the feature maps of the previous layer. The aim of the extraction module is to transform the input image into a feature map, and transferring data from one layer to the next,

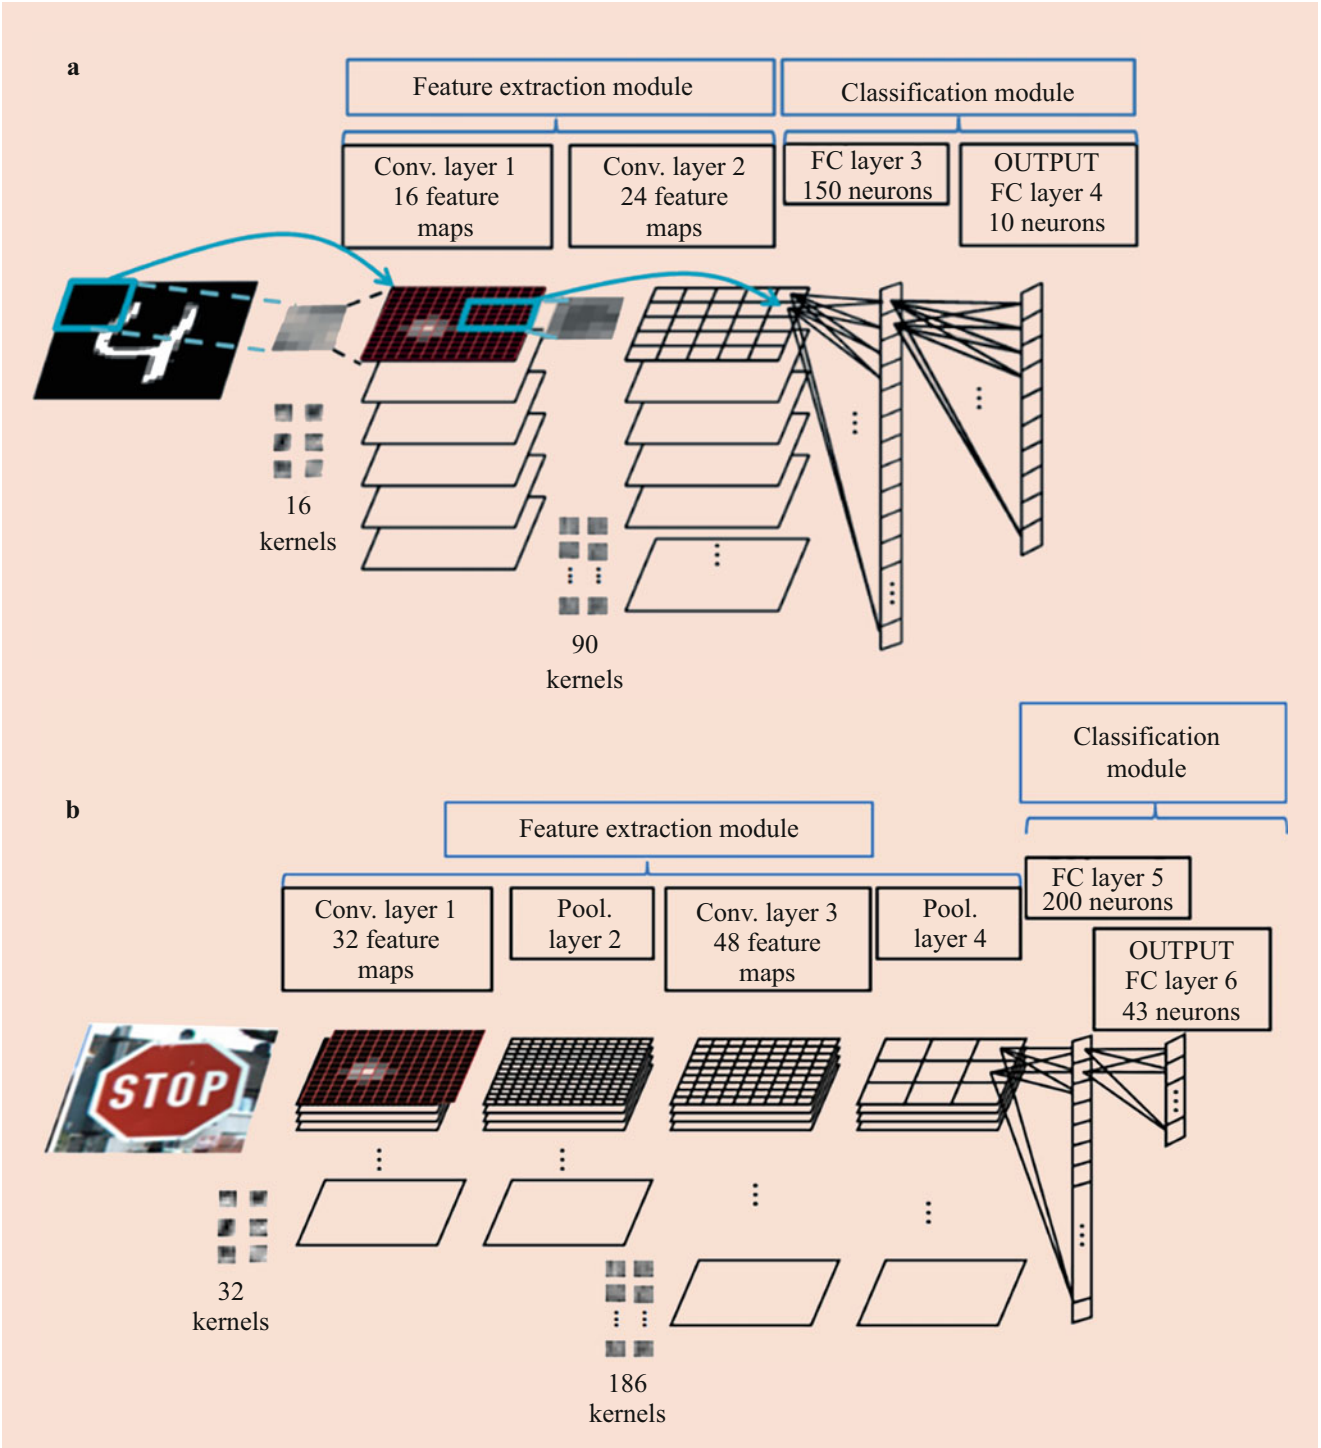

Fig. 17.14 Convolutional neural networks architecture for MNIST database (**a**) and GTSRB database (**b**). The second convolutional layer has each output feature map connected to some only of the input features of the successive maps. (From [107])

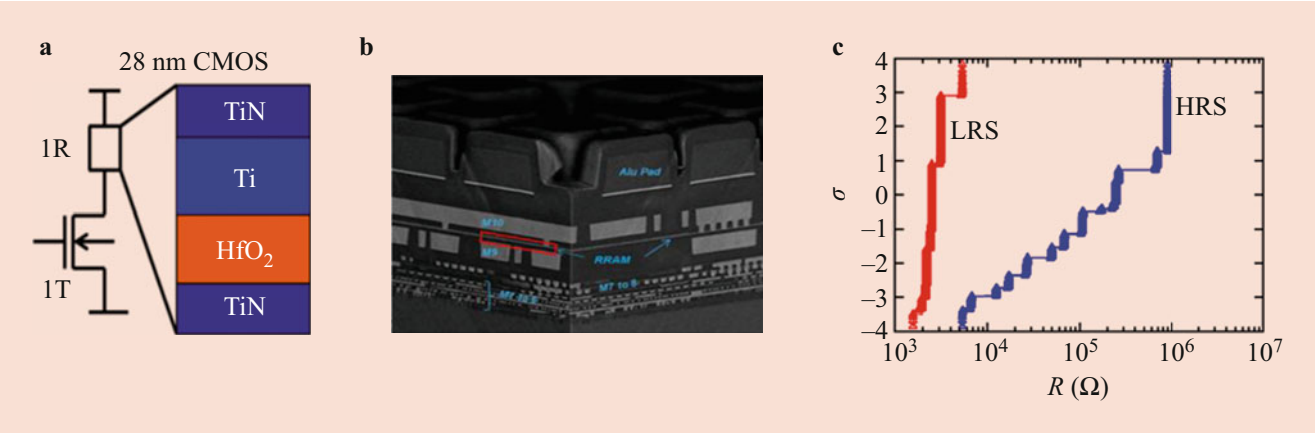

Fig. 17.15 A parallel of 1T1R devices (scheme in (**a**) and SEM image in (**b**)) is taken to build synapses, based on the LRS and HRS distributions of a single device (**c**). (From [108])

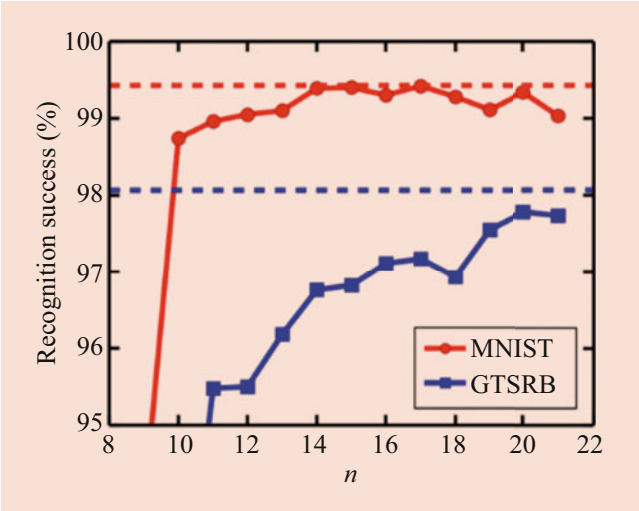

Fig. 17.16 Recognition success rate based on MNIST and GTSRB databases as a function of the number of OxRAM used as synapses building block. (From [107])

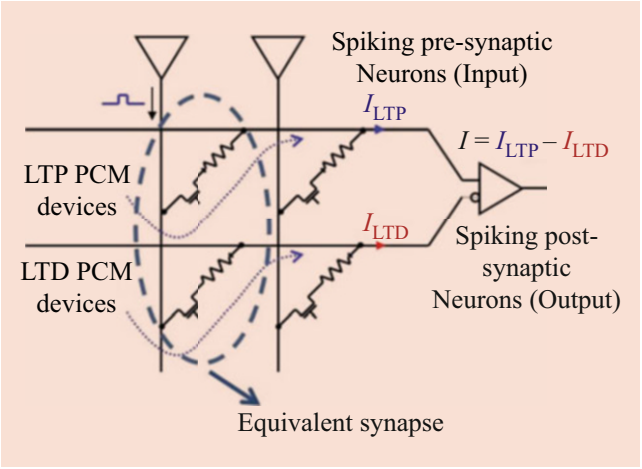

Fig. 17.17 Implementation of a PCM 2 bit cell array used as synaptic device. (From [110])

the set of feature maps gets simplified. Eventually the signal comes to the output neuron layer. The test chip is used to elaborate images from the MNIST (Mixed National Institute of Standards and Technology) database and the GTSRB (German Traffic Sign Benchmark) database containing the 43 German traffic signs. Each output neuron is associated with one category of images. Once an input image is selected belonging to that category, the output neuron is expected to spike out. In Fig. 17.15 the distributions of ON and OFF states of the used OxRAM cells are presented. These cells are connected in parallel in small groups. The amount of cells to be connected in group is computed by simulation and allows to tune the weight of the synapses. The recognition success of this test chip was evaluated by simulation and some results are reported in Fig. 17.16. As the OxRAM groups are enlarged, the recognition success increases since the synapse can be better tuned. With 12 OxRAMs in parallel, 99% pattern recognition of the MNIST database is reached.

Another chance for eNVM applications in neuromorphic chips is given by the unsupervised learning scheme. In the example we saw before in fact, the neural network must be trained and cannot be modified or improved more once the training is complete. If, for instance, a new set of images had to be learned, the training should start over again. Emerging memories as the OxRAM saw in the example can be used to modulate continuously the synaptic weights, de facto implementing the neuron plasticity typical of real brains.

In [109] a PCM device was used to implement a scheme for unsupervised learning in a fully connected neural network. In this case the memory cell can either increase or decrease the synaptic weight to make stronger or weaker connections. This application obviously requires a multilevel capability. Natively PCM shows a strong asymmetry between SET and RESET operations: while SET can be gradually

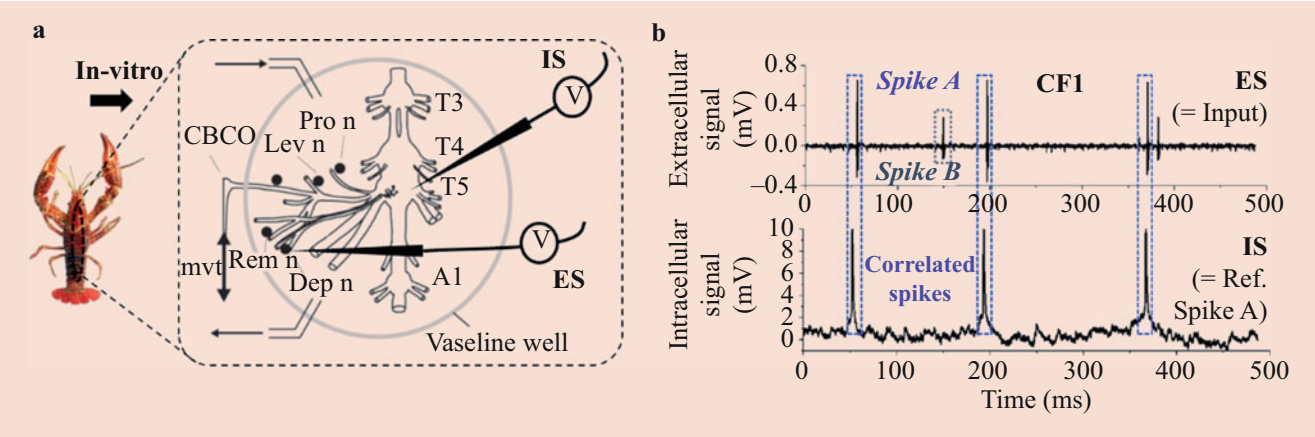

Fig. 17.18 (**a**) Drawing of a ganglion, whose extracellular activity can be recorded in vitro. The recorded signals (**b**) were decoded by a layer of 32 neurons. (From [112])

controlled, as the material crystallizes, RESET is intrinsically abrupt as a quench is generally needed to get the amorphous phase. In Fig. 17.17 a 2 bit synapse is shown, making complementary use of two PCM cells to achieve synapses with the capability of controllable resistance increase and decrease. When actually tested, this system allowed scoring 92% of pattern recognition with a system power consumption during the learning phase of 112 μW. This system was demonstrated for automobile tracking.

Another example of eNVM successfully used in fully connected neural networks is provided by [111]. In this study a CBRAM was exploited to act as synapse in a circuit dedicated to analog signal detection for auditory classification. The exhibited performance was very good along with a reduced power dissipation. The last aspect was indeed the driver advantage of using CBRAM instead of standard CMOS components.

A last example of eNVM for neuromorphic application is given in [112]. In this study low-power neuromorphic computing systems can also be coupled with brain-computer interfaces (BCI). This can allow the development of implants for rehabilitation purposes. The application requires the chip to analyze stream of data for biological sources, make computations, and provide an action in real time based on the input data. OxRAMs were used in a two-layer fully connected neural network able to identify, learn, recognize, and distinguish between different spike shapes of measured biological signals. The device acted without any supervision and was used to decode extracellular activity from in vitro crayfish nerves recorded simultaneously with intracellular data of one motor or sensory neuron of the T5 ganglion (see Fig. 17.18). The biological signal is encoded by 32 frequency band-pass filters. The 32 filtered signals are then full-wave rectified and presented to the input layer of 32 neurons where the analog continuous signals are converted into spikes which are then propagated along the synapses to the 5 output neurons. In this case OxRAM was chosen based on its capability at modulating ON and OFF resistance. This allows the network to keep on training itself by increasing and decreasing continuously the synapses strength in correlation with the input signal.

17.5 Memory Selectors

We have so far discussed about the memory cell; we have seen the different types of emerging concepts, each with their specific performances, challenges, and drawbacks.

In this section we will describe another crucial component of the memory array: the memory selector.

Considering the technology candidates discussed in previous sections in fact, only FeFET can properly work in an array without the need of an additional device that turns ON or OFF depending on which memory cell the system must address. This is possible because FeFET conducts very little current when ground potential is applied on its gate, just as a regular transistor. On the other hand, all resistive devices do not own a gate as they are two terminal devices. This means that in an array, to read a specific word of data, there must be a device that prevents current to be driven by the bits that are not selected, so to access the selected ones only. This task is the role of the memory selector.

Selectors must correspond to a large panel of specifications, the most part of which are summarized in Table 17.3. The most important parameter is the high ON/OFF ratio, but as the reader can easily figure out, the high ON current, the excellent endurance, the correct threshold switching, scalability, and manufacturability are all necessary, and for a selector candidate to fail, only one of these criteria would mean a no go.

Regular transistors, like logic transistors, would look like good candidates for selectors, as they perform well with almost all requirements listed in Table 17.3, except one, the scalability. For an eNVM to be truly considered as successful embedded memory, its scalability is a key ingredient. This is because emerging eNVMs only make sense in advanced nodes as we discussed in Sect. 17.1. Of course this may come with some exceptions, as we will soon see. Ideally, the selector should not take more Si area than the memory cell, which means that the perfect solution would be a crosspoint array. We discussed already in previous sections about the crosspoint array and its first commercial demonstration by Intel with the Optane product series [3]. It is worth noting that a crosspoint array would of course be very beneficial also for all the innovative applications we discussed in Sect. 17.4 and would boost neuromorphic circuits as well as in-memory computing devices or any other memory-intensive application. Even so, different solution can also be envisaged. For instance, the PCM-based solution by STMicroelectronics adopts a MOSFET as selector, in order to provide enough current density for the demanding reset operation in phase change [125]. This solution implies no crosspoint architecture, but it is still performant in terms of density in 28 nm technology for small arrays.

Table 17.3 A list of key parameters and requirement for memory crossbar selectors

Parameters	General requirement
ON/OFF current ratio	Dictated by the array memory size mainly
Scalability	Ideally selector should not taka additional Si area
Theshold voltage	Compatible with the memory device
Polarity	Compatible with the memory device
ON MAX current	As high as possible, dictated by the energy need of selected cell
Manufacturability	Should not require any modification to the standard process
Endurance	Virtually infinite, at least much larger than memory cell
Reliability	Temperature stability higher than memory cell

In this section we will focus on back-end selectors intended for crosspoint architectures, and we will propose a non-exhaustive review of selectors that appeared in literature so far. A basic categorization of selector types can be cleverly given following [114]. Barrier engineering of single junction or multi-junctions achieves step IV electrical characteristics by tuning the band diagram. Typically a multi-junction can be more performant than a single one but necessitates a more complex process [115–120]. Volatile memory components can also be adopted, in which a filament temporarily shunts the two electrodes and dissolves rapidly after polarization is interrupted [121–124]. The main inconvenience in this case is the time required for the filament to spontaneously dissolve, which can be long with respect to the targeted latency. On the other side, a very steep IV curve is achieved. Eventually threshold switching is among the most promising devices as selector candidates. In most cases chalcogenide materials are adopted as they show a sudden increase of conductivity when a threshold voltage is achieved. Below threshold the resistivity can be very high which guarantees an exceptional selectivity. Although chalcogenide materials have been studied for several decades, the actual physics involved in the threshold switching is still subject to debate. In Table 17.4 three main physical pictures summarize the leading physical explanations that are proposed in literature. The first description (first column of the table) uses the nonequilibrium charge distribution across the material to explain the switching: the

Table 17.4 Principle kind of selector based on their working principle

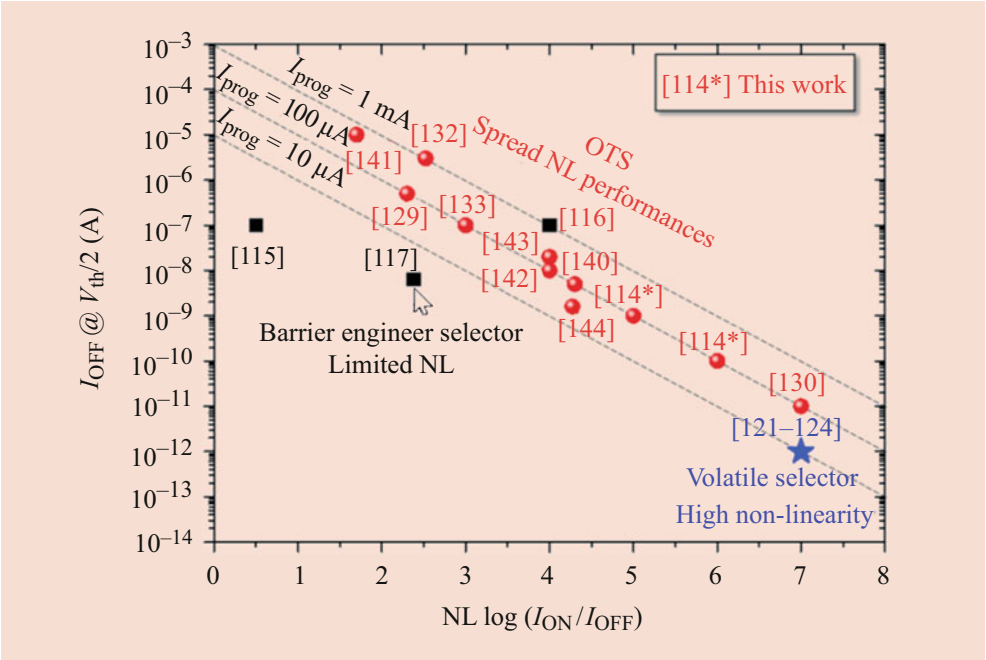

Fig. 17.19 Off current at $V_{th}/2$ vs ON and OFF currents for various selectors in literature. (From [114])

applied field reduces the barrier seen by the electrons in their hopping transport which increases locally the charge's energy. This causes the lowering of electric potential and a further bending of the conduction band near the injection interface, causing a further increase of electron hopping. The system evolves to lower resistivity until the energy relaxation, induced by phonon-electron interaction, saturates the conductivity. A different picture (middle column in Table 17.4) explains the switching as a localized phase change with the growth of a tiny crystalline filament that eventually shunts the electrodes. In this model the growth of the filament is assisted by a locally induced point effect which enhances the field and the temperature at the filament's tip. A third picture (last column in Table 17.4) which applies in particular to Se-based chalcogenide glasses explains the switching as a dipole alignment of metastable bonds.

The principle of a crosspoint selector is very simple. During reading the selector of the selected cell turns on only if the memory bit is in its low resistive state, which causes the reading potential V_{read} to induce switching in the selector. This approach is widely accepted and described, for instance, in [127–134]. Differently, if the memory bit has a high resistance, the read potential V_{read} is insufficient to turn on the selector as most of it drops on the memory bit.

In the next part, we describe the state of the art of OTS selectors mainly in terms of their nonlinearity (ratio between ON and OFF current) and their selectivity (ratio between the ON current in reading condition and the leakage current at $V_{read}/2$), and we focus on some results on read disturb and endurance in the specific case of HfO_2-based OxRAM.

As discussed before probably the most important characteristic of a selector is its ability to prevent sneak paths which would drive current toward unselected cells in a crosspoint array. This means that a selector must feature a very high conductivity in the ON state while also possessing very low leakage current in the OFF state. This is generally referred to as nonlinearity (NL). A good selector shows a very steep IV curve above the threshold potential and a very low parasitic current below it. In Fig. 17.19 the reader can appreciate how different kinds of selectors behave. As it is also clear, a high nonlinearity generally is also accompanied by a lower leakage current, and this general behavior applies for all kinds of selector described in Table 17.3. This is rather obvious as a selector device ON current is upper bound by the application current requirement, and thus its NL is mostly defined by the leakage current amplitude. The OFF current is also critical to determine the tile size of any array, as the leakage current of individual selectors sums up to a total OFF current. As can be seen in Fig. 17.20, multi-MB tiles are possible for OTS selectors.

Furthermore, when a selector in series with a memory cell is considered (1S1R), the programming voltage of the latter is generally dependent on the leakage current of the former. This is true as low leakage OTS is always accompanied by high threshold switching potential. This can be appreciated in Fig. 17.21. In addition, when the selected cell is in its high resistance state, an additional drop of potential appears across it which sums up to the switching voltage of the selector. This leads to a very difficult design of the array, as one must take into account the maximum array size, thus the total

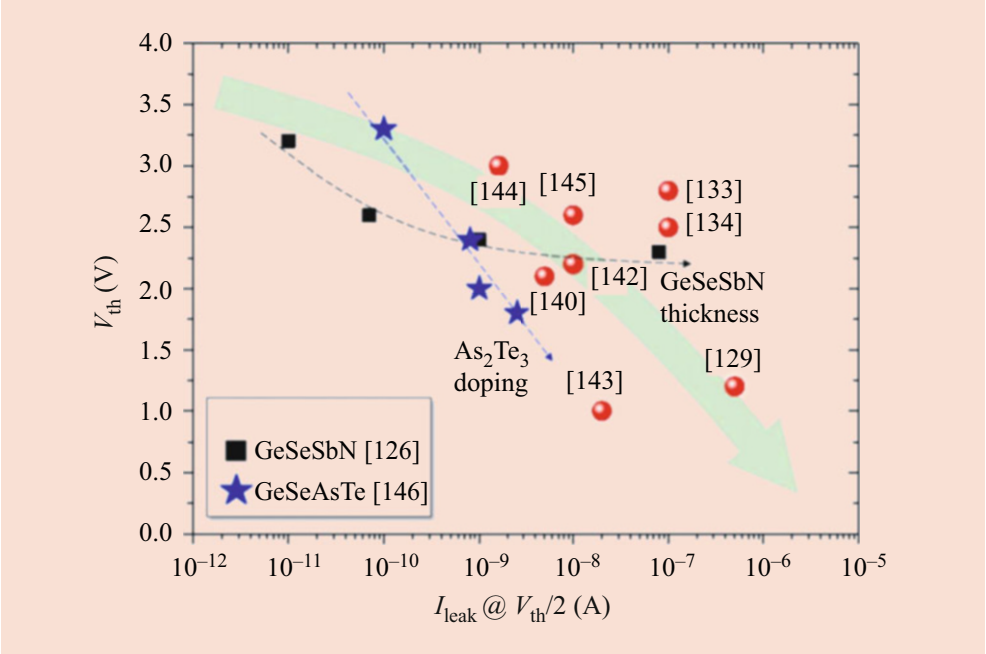

Fig. 17.20 PTS threshold voltage vs current leakage at $V_{read}/2$. Different selector candidates are reported. (From [114])

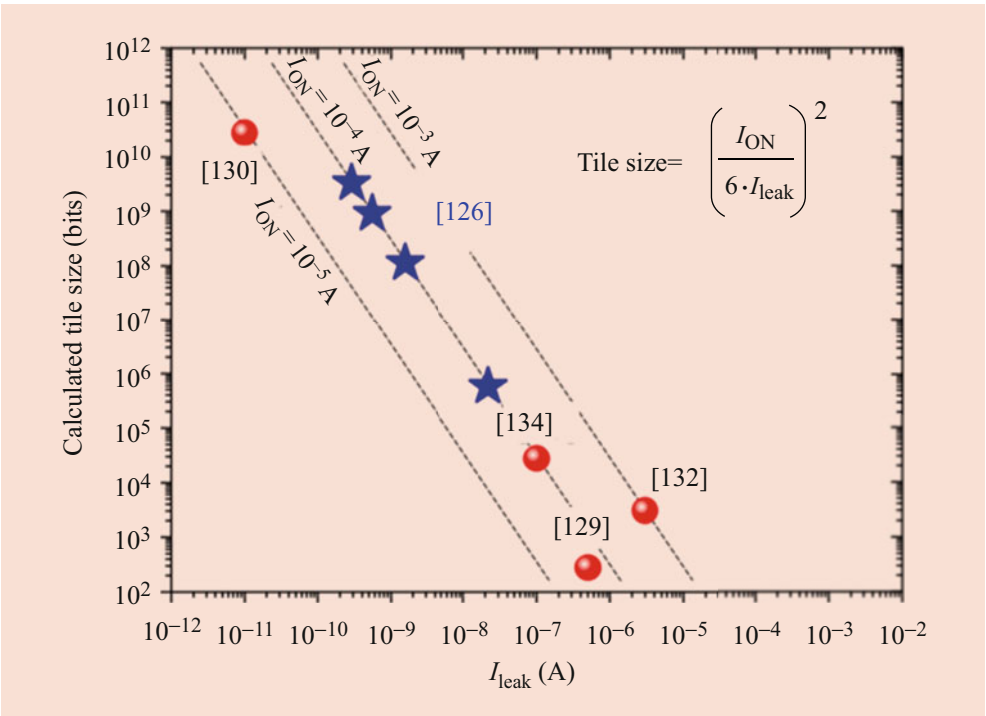

Fig. 17.21 The selector OFF current (and the ON current target) dictates the maximum tile size. (From [114])

leakage current plus the maximum required voltage in the array, which dictates the BL and WL drive transistor type. It seems quite clear that the voltages required in the array are relatively high (in the order of 2–4 V [114]), and this means that thick oxide transistors are likely required. On the other hand, as OTS selectors are built in BEOL, it appears possible to "hide" the driver transistor below the selectors, thus keeping the silicon efficiency to a maximum.

Another figure of merit that surely represents a challenge for OTS is endurance. While for a memory component 10^6 write/erase cycles appear a very reasonable target at array level, a selector must ensure a switch ON/OFF endurance as

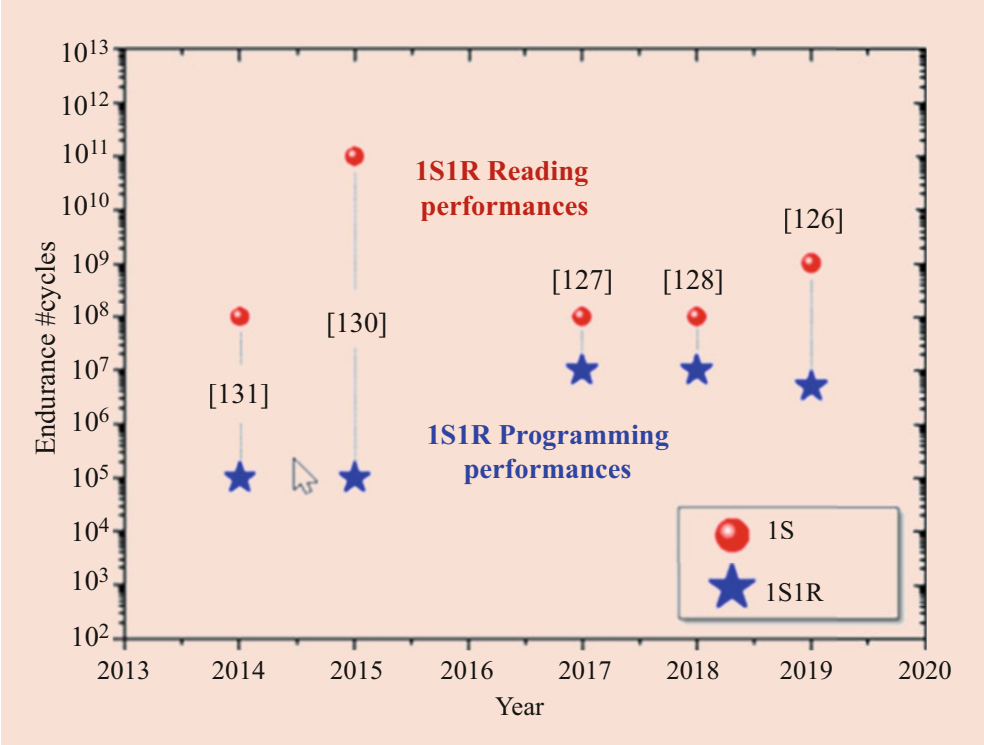

Fig. 17.22 As endurance is one of the most important parameters for selectors, many efforts were spent to improve it. Over the last 5 years, an improvement of X10 was achieved on intrinsic device. (From [114])

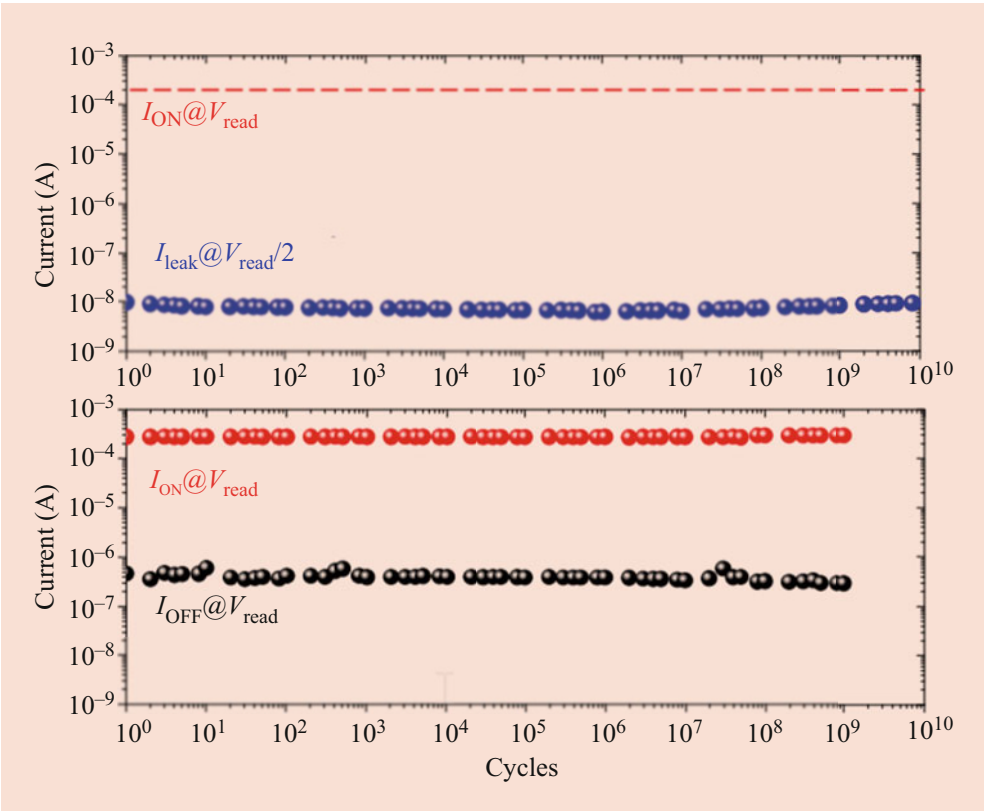

Fig. 17.23 Measured current disturb at $V_{read}/2$ and at V_{read} during endurance test for an HfO_2 OxRAM equipped with a GSSN OTS selector. (From [114])

large as the maximum readings as possible on the memory cell. This means in the order of 10^{10} to 10^{12}. In Fig. 17.22 some results are reported showing the improvement over the years of the read endurance as well as the write endurance of the 1S1R device. More in detail, Fig. 17.23 reports the read disturb at $V_{read}/2$ as well as the readings at V_{read}. These data come from 1S1R device, R being a HfO_2-based OxRAM and the selector being a GSSN OTS device described in [126].

In conclusion, selector development faces as many challenges as the memory devices themselves but has the potential to unlock the ultimate scaling potentials of emerging resistive devices.

Carlo Cagli was born in Italy in 1984. He received a MS degree in Physics in 2007 from Università degli Studi di Milano and a PhD degree in Electronics Engineering in 2011 from Politecnico di Milano. He has 10 years of experience in electrical characterization and modeling of emerging memory technologies. He worked both in industry and in the research environment and he is now with CEA-Leti as permanent member of the staff since 2014. He has published more than 50 papers and conference contributions. His interests include mainly phase change and resistive RAM characterization.CEA-Leti 17 rue des Martyrs 38054 Grenoble Cedex

Luca Perniola received the Laurea in Nuclear Engineering from the Politecnico di Milano, Italy (2002), and the PhD degree from the University of Pisa, Italy, and the INPG of Grenoble, France (2005). In 2005 he joined CEA-Leti, France, where his work mainly focused on device electrical characterization of nitride-based NVM (i.e., SONOS FinFET), phase-change memories, and RRAM. Since 2013 he has been appointed responsible of the Advanced Memory Technology Laboratory in CEA-Leti, dealing with the full value chain from development of optimized technology modules up to simple test chip designs of back-end memories. Starting from 2019 he became Head of Power, Energy & Connectivity Component Section.CEA-Leti 17 rue des Martyrs 38054 Grenoble Cedex

Abstract

In the course of human history, the development of high performance low-cost sensors has been fundamental for the progress of Homo sapiens in many fields. In the last 20 years, the pace of sensor development accelerated thanks to microfabrication techniques typical of semiconductor industry. Automotive was the first market to adopt in high-volume silicon sensors; then thanks to the sensor consumerization wave, silicon sensors spread widely in many products of the consumer market (MEMS, Industry group: 2007 industry report, 2007). Entering the internet of things era and with the advent of artificial intelligence, the importance of silicon sensors will continue to grow.

Sensors are all around us: they are in cars, in smartphones, in factories, in pacemakers, in drones, in smart

speakers, and in many other places, with the ultimate goal to sense and to monitor parameters of importance and interest in our daily environment. They play an essential bridge between electronic systems and the user or environment. This chapter is addressing both the technical and business aspects of the commercially most successful silicon sensors, highlighting also the most common wrong prejudices of this industry.

Firstly, this chapter will detail the most relevant market applications of the silicon sensors and their future use in conjunction with the emerging technologies of artificial intelligence and low-power wireless connections, including 5G. Secondly, it will recap the most important features of the sensors, their taxonomy, their sensing fundamentals, their microfabrication technologies, and the great relevance of the package and testing for the sensors. Thirdly, it will discuss detailed examples of the most commercially successful sensors (MEMS, Industry group: 2007 industry report, 2007; MEMS, Trends, 10, pag. 18, 2012) that we can find all around us.

18.1 Overview

A sensor is a device that detects a change in a physical parameter (i.e., the measurand) and transduces this change into an electronic signal, i.e., a current, voltage, or charge. A sensor is a measurement instrument used to interface with the external world, enabling the sensor user to understand the world more deeply and thus to dominate it. The word sensor comes from the Latin word sensorium, derived from the verb sentire that means perceive with our senses. A man is able to sense the reality with his five senses (hear, see, smell, touch, taste), and since the beginning of his appearance on Earth, humankind, realizing the limits of its natural senses, has been constantly developing better and better sensors. The goal has been always the same: Homo sapiens wanted to become the master of the world.

Time has been the first measurand that humanity has been interested to measure. Two thousand years ago, the Egyptians used large obelisks to track the movements of sun and to measure the passing of time; they developed also water clocks later used by both the Greeks (calling them clepsydrae) and the Chinese, while Japanese were using burning candles to measure time. In the ancient world, time measurement was important for many different purposes, from knowing the exact hour to hold the religious rites for worshipping the gods to the time slot allocated to the defense lawyers in old Rome's courts and to the paid time slot allocated to prostitutes' customers in several brothels [3]. If we exclude few other instruments, like the compass invented in China (used for divination first and later for navigational orienteering around 1050 A.D.), we need to wait for the Scientific Revolution of the seventeenth century, whose foundational Galilean scientific method required the development of many more instruments to challenge the dogmatism of the pre-modern era. Only in the last 40 years a strong boost to sensor massive adoption came from the automotive market (airbags, etc.) and, later, from the consumer and personal electronics market (computers, mobile phones, watches, etc.), thanks to sensors' increased reliability, more affordable cost, optimized power consumption, and miniaturized size.

Sensors are multidisciplinary devices that require the master of many disciplines (physics, engineering, electronics, materials, control theory, etc.) for their design and their production. They are creating new opportunities in many consolidated markets, such as automotive, consumer, and personal electronics, and they are now undergoing a great expansion, owing to the emerging application in industrial internet of things, artificial intelligence, 5G, and future forms of reality (augmented, virtual, and mixed) [4].

The physical dimensions of the different types of sensors span a wide range, from meter scale (i.e., the antennas for space exploration) to microscale (i.e., the ultrasmall silicon-based sensors). The techniques and the materials used to manufacture the different kinds of sensors are also very much different, involving materials such as plastic, ceramics, metals, and semiconductors. The goal of this chapter is to describe commercially successful silicon sensors having two important features:

- They utilize silicon as material, exploiting its excellent semiconductor and thermomechanical properties [5].
- They are realized by means of microfabrication techniques, enabling mass parallelization. When there are 3-D structures in the sensor, realized with micromachining techniques, they are also known with the English acronym of MEMS, i.e., microelectromechanical systems.

These transducers are also known as micro-sensors, since the single smallest dimension is at sub-micrometer scale, though a complete sensor containing both the tracer elements and the electronic ones can be of the order of millimeter. Micro-sensors can be composed of one silicon die containing the transducer standalone (integrated microphone of Akustica) or of multiple dice including also the electronic chip (inertial modules or microphone of STMicroelectronics [6]), all arranged in the same package by means of system in package (SiP) or system-on-chip (SoC) technologies (Table 18.1 and Fig. 18.1).

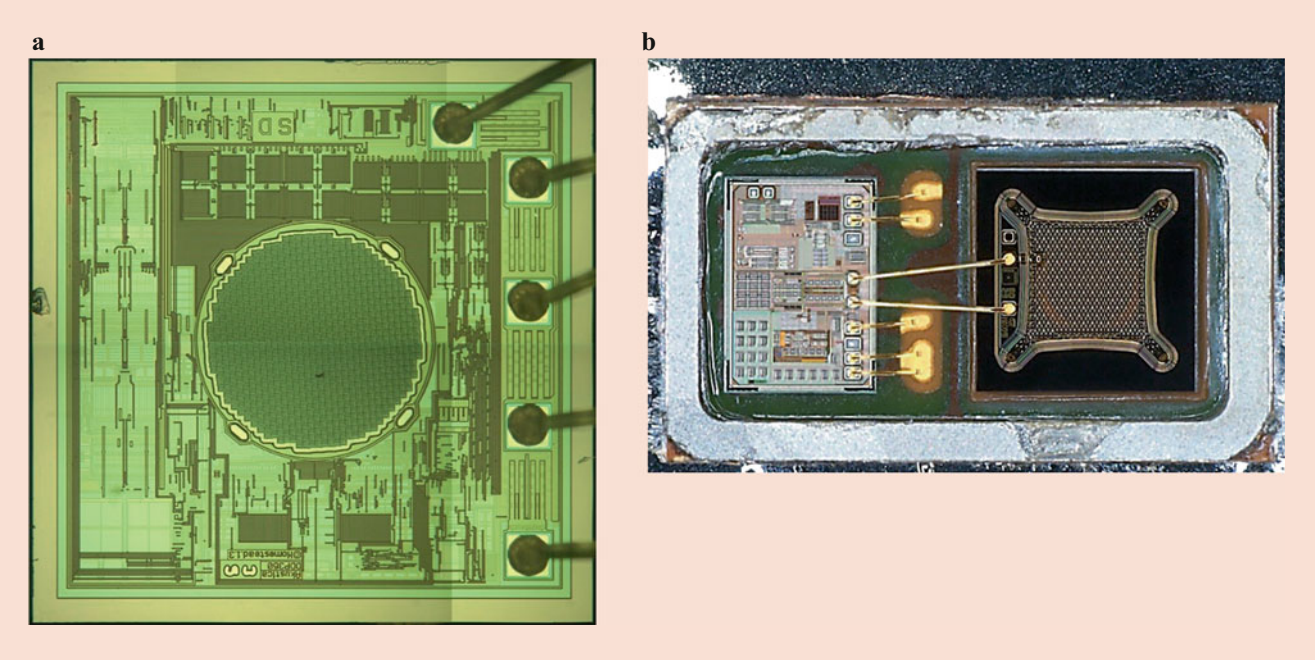

Fig. 18.1 (**a**) Akustica AKU230 integrated microphone is an example of system on chip: membrane is visible in the center, with circuitry all around. Yield strength (10^{10} dyne/cm^2)	7.0
Knoop hardness (kg/mm^2)	850
Young's modulus (10^{12} dyne/cm^2)	1.9
Density (g/cm^3)	2.3
Thermal conductivity (W/cm °C)	1.57
Thermal expansion (10^{-6}/°C)	2.33
Electron mobility at 300 K (cm^2/V s)	1400
Hole mobility at 300 K (cm^2/V s)	450
Energy gap at 300 K (eV)	1.12

Therefore, this chapter will not address the whole world of sensors. It would be a task too huge to be addressed in a single chapter of a book. We will not talk about non-silicon sensors such as zirconia ceramic oxygen lambda sensors, disposable plastic blood glucose sensors, harsh environment pressure sensors with stainless steel membrane, high performance fiber-optic sensors, piezoelectric quartz resonating gyroscopes, pyroelectric single crystalline lithium-tantalite infrared sensors, II–VI semiconductor cadmium selenide near-infrared detectors, giant magnetoresistive read/write heads for hard disk drive on aluminum titanium carbide ceramic substrates, III–V semiconductor indium antimonide Hall sensors, and nano-sensors based on carbon nanotubes. A complete overview of sensors can be found in specific handbooks such as those in Refs. [7, 8].

The silicon semiconductor sensor era officially starts after the visionary talk given by Feynman on December 1959 [9] and with the realization of the first resonant gate transistor (RGT) of Nathanson et al. in [10].

The RGT allowed the incorporation of high Q frequency selection into silicon integrated circuits. It was batch-fabricated in a manner consistent with silicon technology, and it had a vibrating gold beam operating in the frequency range from 1 to 100 kHz, depending on the geometrical dimensions of the resonant gate, with a gate length in the range of few hundreds of micron and few micron-scale thickness.

Since the beginning, micro-sensors used the same manufacturing techniques of the CMOS (complementary metal-oxide semiconductor) industry, whose evolution was dictated by the famous Moore's law. Since the market for silicon sensors has been much smaller than CMOS industry, micro-sensors have been always classified as part of the so-called more-than-Moore (MtM) world [11]. There are many books, articles, and publications on the MtM subject. But considering both the increasing relevance that micro-sensors continue to acquire in the field of internet of things to boost the wider adoption of artificial intelligence (AI) and the strong contribution given by Feynman, envisioning the possibility to miniaturize the sensors and to stack specialized silicon wafers to realize a complex versatile microsystem, the time has come to see the micro-sensors as part of the Feynman

roadmap instead of more-than-Moore roadmap. The authors of this chapter propose the following transition:

More-than-Moore → Feynman roadmap

This chapter addresses market, technical, and fabrication relevant facts of the micro-sensors, highlighting also some of the prejudices that miserably failed on the market.

18.2 Present and Future Market Applications of Sensors

Today sensors are used almost everywhere to sense and monitor parameters of importance and interest in our daily environment. They play an essential role as interface between electronic systems and the user or environment. Because of the large number and variety of devices required for performing different functionalities, the sensor market is huge.

The most successful silicon sensors include capacitive accelerometers, gyroscopes, microphones and pressure sensors, piezoresistive pressure sensors, temperature sensors, Hall effect and magnetoresistive magnetic sensors, CMOS image sensors, time of flight sensors, ambient light sensors, and humidity and gas sensors. They are used across all the market segments from automotive to personal electronics, from industrial to computers [1]. In the last 40 years, we have also seen many micro-sensors abandoning the CMOS plants because of their inability to meet customer requirements in terms of either cost or performances. These examples include the piezoresistive accelerometers and microphones, the electromagnetic and piezoelectric gyroscopes, and, last but not least, many biosensors for DNA analysis (i.e., lab-on-a-chip).

All modern cars have active (i.e., vehicle dynamic control™) and passive safety systems (airbag) based on micro-machined accelerometers and gyroscopes (inertial sensors). Car tires, equipped with pressure sensors measuring constantly the pressure and alerting the driver in case of danger, are widely spread. Pressure sensors are also used to measure the ambient and the intake manifold pressure to optimize the fuel-to-air ratio with the goal to reduce carbon footprint [12].

Sensors are also used in the industrial market for factory automation, preventive machine diagnostics, and post-sales support.

In the last 30 years, accelerometers spread out also in pacemakers to adapt the pacing signal frequency to the physical activity of the patient and in neurostimulators for different purposes.

It is only in 2005 with Nokia N95™ camera phone and in 2006 with Nintendo Wii™ that the world sees the dawn of the sensor consumerization wave. The Nokia N95™ camera phone was designed, indeed, to achieve in many use cases the same experience as a consumer digital still camera (DSC) product, with exceptional quality at resolution of 5 megapixels so the user could edit the images after capture. In 2006, the three-axis accelerometer of STMicroelectronics together with Wii™, the revolutionary game console of Nintendo [13], changed dramatically the way people were interacting with the digital world of electronic games. Now micro-sensors are everywhere from smartphones to laptops, from tablets to high-end digital cameras, from watches and hearable devices such as the AirPods® to shoes and professional or consumer drones. More intuitive user interfaces, step counter, image stabilization, image and video capture, and depth measurements are just a few of the many applications of sensors in the consumer market. The pictures below show the sensor market revenue by final application category and sensor type (Figs. 18.2, 18.3, and 18.4).

Nowadays, inexpensive, highly reliable, energy-efficient, and tiny sensors enabled by the sensor consumerization wave are ready to be coupled with low-power radios (sub-GHz, Bluetooth, Wi-Fi, Sigfox, LoRa, narrowband IoT, 5G, etc.) in certified wireless modules to enable the large-scale deployment of wireless sensor networks. With the smartphone volume growth slightly decreasing, many technical and business experts believe that we are now leaving the nomadic era, to enter the internet of things era, enabled by wireless sensor networks, autonomous robots, 5G ultrashort latency communication networks, and artificial intelligence [1, 14, 15] (Fig. 18.5).

The following three sections discuss briefly the use of micro-sensors in automotive market, the MEMS consumerization wave, and the dawn of wireless sensor nodes era.

18.2.1 Automotive Micro-sensors

Safety, comfort, and environmental control applications have been the three main drivers of wide micro-sensor adoption in all modern cars from the 1970s till the beginning of our century. Only in the last few years there has been a revamp of micro-sensor adoption in the car industry thanks to autonomous car recent developments. Signals from multiple-axis accelerometers, gyroscopes, and pressure, magnetic, and airflow sensors must be fused together to address the needs of several different applications.

In 1974, the first micro-machined silicon pressure sensors started to be used in electronic fuel injection systems to monitor the manifold absolute pressure (MAP), while mass airflow sensor was used to optimize the air-to-fuel ratio, to reduce gasoline consumption. One decade later, in the 1980s, the pressure sensors started to be used to measure atmospheric pressure, fuel pressure, oil pressure, and others. In particular barometers, measuring the drop of pressure at

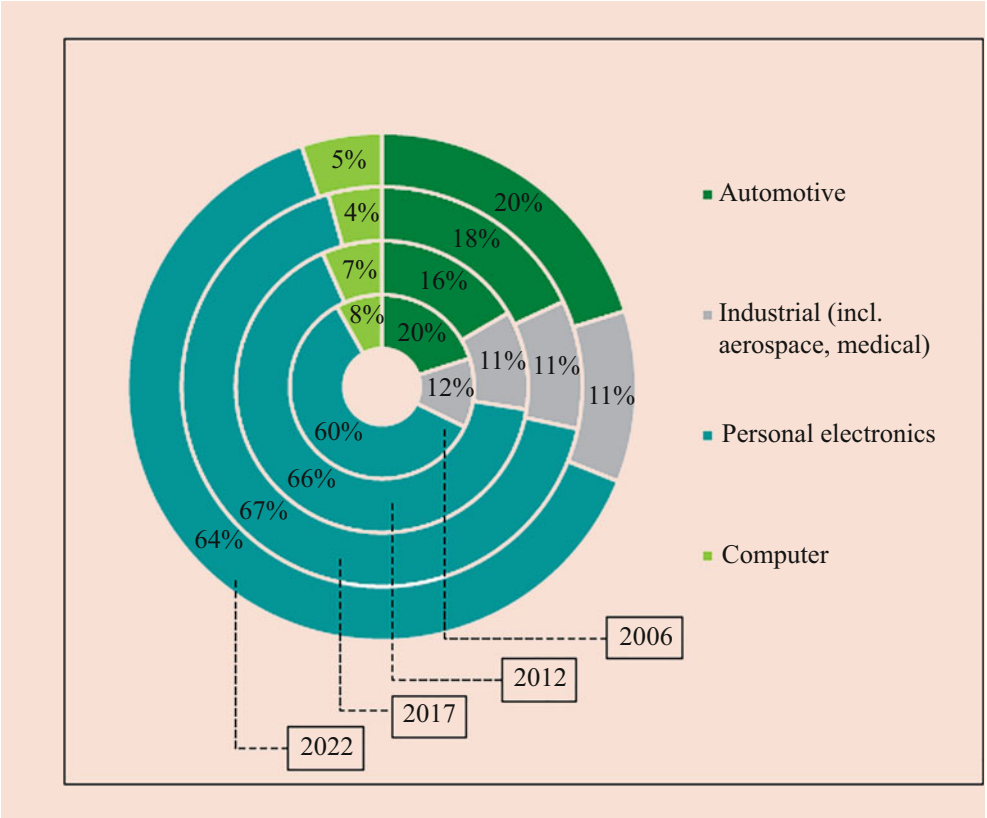

Fig. 18.2 Sensor market revenue by application category (2006–2022). (Source:© 2018 IHS Markit)

different altitude, allowed to increase car engine efficiency, reducing the carbon footprint. Starting April 1, 1989, the US National Highway Traffic Safety Administration (NHTSA) mandated the use of driver-side airbag, and in 1993, dual front airbags in all passenger vehicles were mandated. Few years later, side impact airbags were also required. A microfabricated accelerometer, detecting any sudden change in the vehicle acceleration, in combination with an algorithm, triggers an explosive charge that rapidly deploys the airbag. The airbag accelerometers can be located either in the central part of the car and in this case detect accelerations from 40 to 70 g (g being the acceleration of the Earth's gravity) or in the periphery of the car (satellite accelerometers), with a full scale ranging from 50 to 500 g. After 1996, active safety systems, such as vehicle dynamic control (VDC™) or electronic stability control (ESC®), started to use high-grade low-*g* accelerometers (up to 5 g), yaw rate gyroscopes, and magnetic speed sensors at each wheel. These safety systems help drivers handle a car on icy or rainy roads better, by preventing the dangerous situation of under- or over-steering. After wide adoption of sensors for active safety in European vehicles, in April 2006, the NHTSA mandated the use of ESC active safety systems in all US passenger vehicles, beginning in 2012.

Initial bulky and power-hungry piezoresistive accelerometers, manufactured by Sensonor, and piezoelectric quartz-based yaw rate sensors, mostly manufactured by Panasonic (Japan) or Systron Donner (USA), left the ground to more reliable, lower power, and ultrasmall capacitive inertial sensors (accelerometers and gyroscopes) manufactured by STMicroelectronics, Robert Bosch, and NXP. Micro-machined capacitive sensors, moreover, offered the big advantage to be combined all together on the same package, opening the way to multiple-axes inertial sensors in the automotive safety market, with VTI first, Bosch, and STMicroelectronics later.

After the year 2000, in which the high failure rate of a specific tire brand was implicated in more than 270 deaths and almost 1000 injuries, pressure sensors started to gain momentum for measuring the pressure in the tire and for alerting the driver in case of anomalies. All vehicles manufactured in 2008 or later will have a tire pressure monitoring system. The system consists of a piezoresistive pressure sensor, a simple microcontroller or state machine, and a sub-gigahertz wireless link. It also contains an accelerometer to wake up the systems when the vehicle starts moving.

Last but not least, in car navigation systems based on Global Position System (GPS), receivers also use accelerometers, gyroscopes, and magnetic sensors for dead reckoning

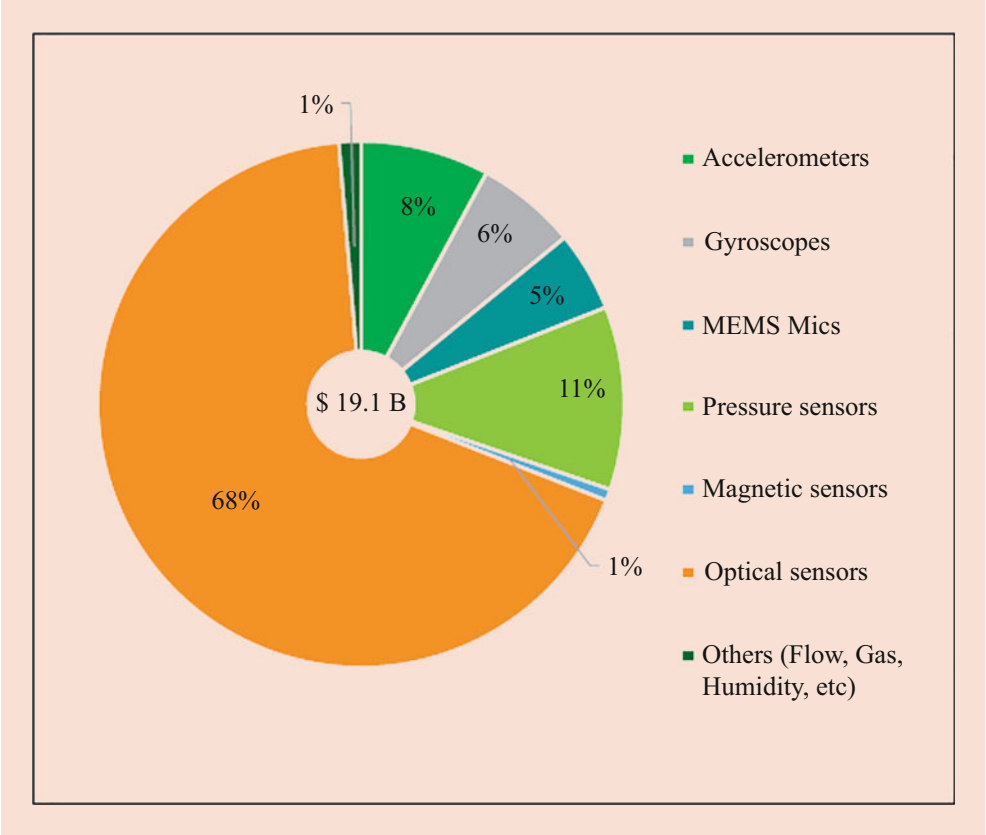

Fig. 18.3 Sensor market revenue by sensor (2017). (Source: © 2018 IHS Markit)

in case urban canyons, tunnels, or blind spots cause a fading of the satellite signals. In year 2012, a big boost to micro-sensor adoption in car navigation systems came from the first available single-package three-axis gyroscope of STMicroelectronics.

18.2.2 The Sensor Consumerization Wave

If the adoption of sensors in the automotive was driven by regulation, vision and imagination triggered the proliferation of micro-fabricated sensors in the consumer market. A few visionary companies, including STMicroelectronics, Knowles Acoustics, and Avago, invested heavily to support the development and manufacturing of sensors, such as accelerometers and microphones, and bulk acoustic wave filters, all suitable for the consumer market [1]. This triggered an extraordinary surge in the number of applications in the consumer market, with user interface applications being the most dominant across several market segments: from remote game controllers to smartphones, from tablets to laptops, from wearable to hearable. Only in the last few years the arrival of artificial intelligence-enabled smart speakers on the market starts to show the full potential of microphones, once seen only as a mere replacement of old electret microphones in the mobile phones. Moreover recently miniaturized motion sensors became a key enablers for a smoother and easier motion control of robots and cobots in industry 4.0 factories.

At the same time, MEMS sensors were spreading all over the consumer market; Nokia N95™ using the 5 megapixel STMicroelectronics CMOS image sensor started to displace the Japanese digital still cameras. And now after 14 years, digital still cameras have been completely replaced by smartphones embedding higher-resolution cameras, up to the recent 48 megapixel cameras of Sony. If at the beginning the CMOS sensors were used for simple video and image capture, now they are used to capture information for application control, multi-shot picture fusion, computational imaging, multi-sensor fusion, and visions applications. Moreover, since the end of 2017, near-infrared CMOS sensors (in iPhone X of Apple) have been used for biometric applications, and just recently some smartphones (like Huawei Mate X) [16] are embedding also time of flight (ToF) sensors for augmented, virtual, and mixed reality applications. Recently announced HoloLens 2 [4] makes also extensive use of indirect time of flight sensors for 3-D mapping of the environment around the user.

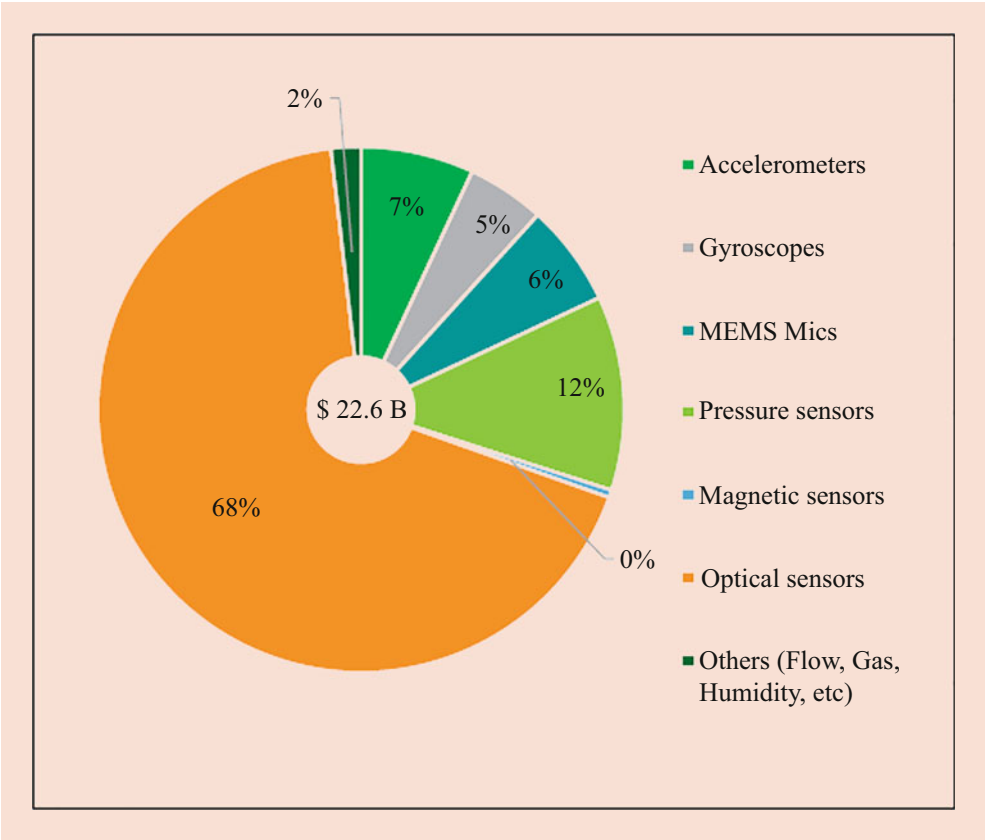

Fig. 18.4 Sensor market revenue by sensor (2022). (Source: © 2018 IHS Markit)

Sensors for User Interface in Game Consoles

May 2006 is definitely a key date for the dawn of the sensor consumerization wave. Before that date accelerometers were used for some medium-volume consumer applications, such as free fall protection in hard disk drives, and gyroscopes were used in digital still cameras and camcorders to improve the quality of recorded video and pictures. The launch of Nintendo Wii™ game console equipped with two single-hand controllers, each with a three-axis accelerometer, represents, without any doubt, the onset of the sensor consumerization wave on a large scale. Some authors of this chapter attended the launch of the Wii™ game console in the Kodak Theater in Los Angeles, and they still remember the thrilling atmosphere in that magic place. Nintendo wanted to leverage an easier user interface to fight against the high processing graphics of Microsoft Xbox and Sony PlayStation. Micromachined accelerometers of STMicroelectronics offered the right solution at the right cost and with the proper performances.

After Nintendo, Sony's PS3™ started to use three-axis accelerometers and one-axis piezoelectric gyroscopes of Murata to realize a more anthropomorphic wireless game controller. Right after, same adoption wave was observed in TV, PC, and set top box remote controllers. In July 2007, Logitech announced a controller called Free Air using a combination of three-axis accelerometer from STMicroelectronics and a two-axis gyroscope from InvenSense to simplify the navigation on a display. This controller was the product that declared once forever the death of piezoelectric gyroscope in the consumer market. Since then all Murata gyroscopes have been replaced by a combination of high performance capacitive gyroscopes and accelerometers (also known as six-axis inertial combo) able to fit in less than 10 mm^3 volume and draining less than 500 μA while enriching the user's experience and device usability (Fig. 18.6).

Sensors for Multiple Functions in Smartphones, Tablets, and Wearables

If sensors are used mostly for user interface in game controllers, they enable multiple applications in personal electronics devices, such as smartphones, tablets, and wearables. The overall smartphone industry owes a lot to Nokia for its wide adoption of STMicroelectronics CMOS 5 megapixel sensor and later micro-machined inertial sensors in their phones. In fact, one of the biggest differences between traditional phones, meant only for phone calls, and smartphones is strictly linked to wide use of multiple types of sensors.

After a pale adoption of smaller and more reliable silicon micro-machined bulk acoustic wave filters from Avago and capacitive silicon microphones by Knowles Acoustics,

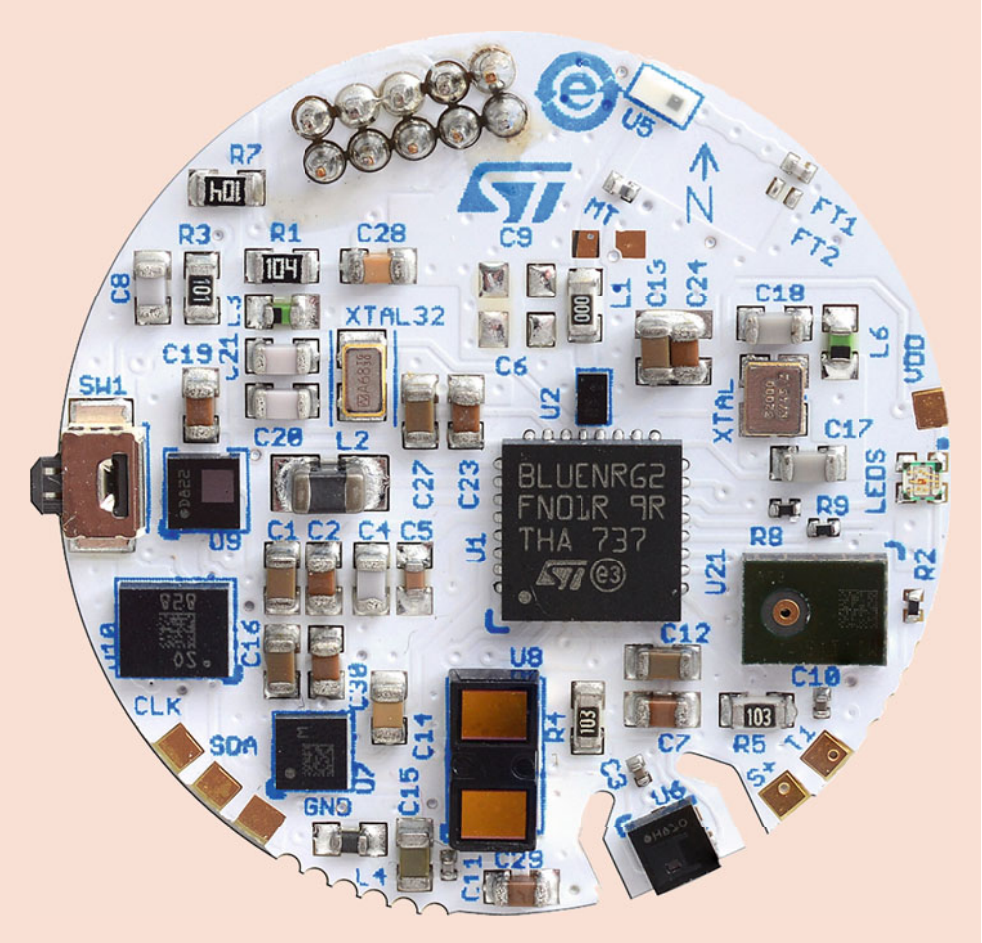

Fig. 18.5 STMicroelectronics BlueNRG-Tile: programmable wireless multi-sensor node. It includes Bluetooth low energy system on chip (center), microphone, humidity and temperature module, time of flight sensor, magnetometer, inertial module, and pressure sensor. (© 2018 by STMicroelectronics)

the big revolution happened in 2006 when three-axis accelerometers were introduced into some mobile phones to simplify the user interface. Initially, this application of sensors was only known to very few people until Apple launched the iPhone™ in June 2007. In this buttonless phone, the accelerometer was key for the new human-machine interface [17]. In fact, the combination of accelerometers, touchscreens, and suitable application software eliminated the need for traditional switches or buttons and thumb wheels for scrolling, zooming, and panning of web pages, e-books, and spreadsheets. The sensors, detecting basic human movements and using them as an input for the mobile phone, allowed passing the limits deriving from the small screens. Nowadays the users can easily navigate through web pages or pan through maps by simply tilting the device in the desired direction. The step from mobile phone to small wearables (like the iPod Nano of Apple of 2009) and big tablets (like the iPad of 2010) was a very easy and obvious one.

However, the pervasion of motion sensors in mobile phones did not stop there, since they started to be used more and more for pedestrian navigation to enable location-based services, so attractive for network operators in constant search of new revenue streams. When navigating

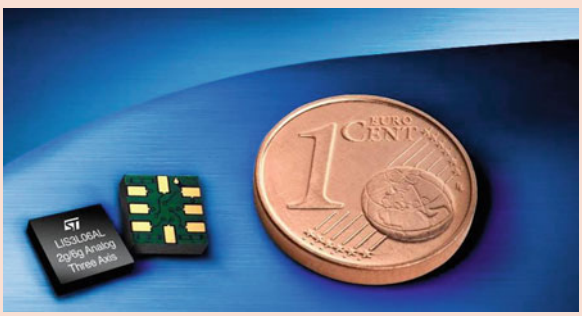

Fig. 18.6 STMicroelectronics LIS3L06AL, first three-axis accelerometer in game consoles, adopted by Nintendo in the Wii. We can also define it as the father of consumer motion MEMS. (© 2018 by STMicroelectronics)

in unknown places, the electromagnetic signals coming from several geostationary satellites and from the cellular network infrastructure can be faded, and thus the GPS function embedded in our phones is not 100% reliable. Tunnels, bridges, and skyscrapers are all obstacles for telecommunications operators who want to sell location-based services such as zone-based advertising and augmented reality experiences. In this context, micro-fabricated low-power and high stability motion sensors can assist and substitute the GPS signal, so that dead reckoning system continues to track people movements. To implement dead reckoning, it is necessary to know the distance and the direction the phone user travelled. An ideal module for personal navigation comprises a three-axis accelerometer plus a three-axis magnetometer plus a three-axis gyroscope and a pressure sensor, everything coupled with the appropriate application software. Often a module like the previous one is also called ten-axis. The accelerometers help to determine the travelled distance and the average speed of the user, the compass picks the heading direction with respect to the magnetic north, the gyroscope measures the change in the direction of user path, and the pressure sensor measures the inclination of travelled path. Emergency services like the E911 in the USA mandate the integration of an altimeter (pressure sensor) in the phone so that in combination with a GPS, it can tell the emergency responders on which floor of the building the caller is. In the last 10 years, many integrated modules have been developed to address this interesting market application, but as of today, we do not have a reliable solution yet. Suppliers are able to deliver highly accurate altimeters and very low-noise magnetic sensors, but we still need a couple of years before we see in the market highly precise and stable six-axis inertial modules suitable to address this long awaited applications. It's also interesting to notice that all the attempts, done by companies such as STMicroelectronics, TDK, and Bosch, to integrate the different sensors in the same modules miserably failed because of the high calibration cost of the final solution. The development of high accuracy six-axis inertial sensors will bring benefits also to future autonomous cars which must rely on digital maps and onboard sensors to navigate in the city jungle.

Before leaving this section, we cannot forget the importance of the sensors in combination with smartphone cameras. If CMOS sensors are used to capture the video and the picture, gyroscopes are used for image stabilization in all medium- and high-end smartphones to avoid blur effects caused by unconscious muscular contractions in the frequency range of few hertz. In the last decade, piezoelectric gyroscopes, mostly manufactured by Japanese suppliers, lost the race against silicon gyroscopes thanks to their smaller dimensions and higher performance in terms of sensitivity and stability. Moreover, silicon gyroscopes can measure angular rates along the pitch and roll axes simultaneously, and, thanks to their reduced dimensions, they can be integrated more easily in the camera module itself (Samsung S8™ smartphone). Last but not least, silicon gyroscopes are sold already calibrated, and thus the final product manufacturer does not have to waste time and money to calibrate the final system, i.e., the full smartphone.

18.2.3 The Internet of Things Era

Micro-fabricated sensors start to be widely utilized in numerous applications both in the industrial and medical market space. Smart factory automation, condition monitoring for preventive machine diagnostics, asset tracking for more efficient logistic services, optimization of water and energy consumption of household appliances, continuous monitoring of people activity, and ambient assisted living are just a few examples of applications in these two markets [18, 19].

Wireless Sensor Networks

Starting from 2013, in the field of wearable electronics , first Fitbit and later other companies like Apple announced products embedding sensors of different types in their watches. The accelerometer was the first sensor used to measure the physical activity; later it was the time of the light sensors to measure the body's function through blood oxygen content measurement. Recently two-lead electrocardiogram (ECG) appeared in the Watch 4 series. Some cardiologists have raised concerns about two-lead ECG: according to them, it is unnecessary for the general population, or it could cause problems, including false positives. At the best, they say, that could result in stress for users and unnecessary visits to doctors, further burdening an increasingly sluggish healthcare system. Even worse, false positives could also lead to unnecessary follow-up tests with the costs and health risks those tests can involve [20]. The next steps are noninvasive glucose monitoring. Several companies are busy in developing and selling add-on devices from blood pressure monitor to a sleep-aiding headband. Last 2019 Consumer Electronics Show in Las Vegas hosted many companies working on digital health. However, mental health has strong impact on blood pressure and ECG readings and thus on a person's overall well-being. Thus, several cardiologists are questioning the usefulness of continuous monitoring in consumer wearable gadgets. The authors share the same concerns.

Global healthcare spending is estimated to reach almost $9 trillion annually by 2020, and this is the field where smart sensors can make a big difference. We will all discover the future of medical wearable devices in the course of next decade; the authors do not have doubts about the successful market adoption of medical-grade wearable devices. It will take time, but it will happen. Figure 18.7 represents an

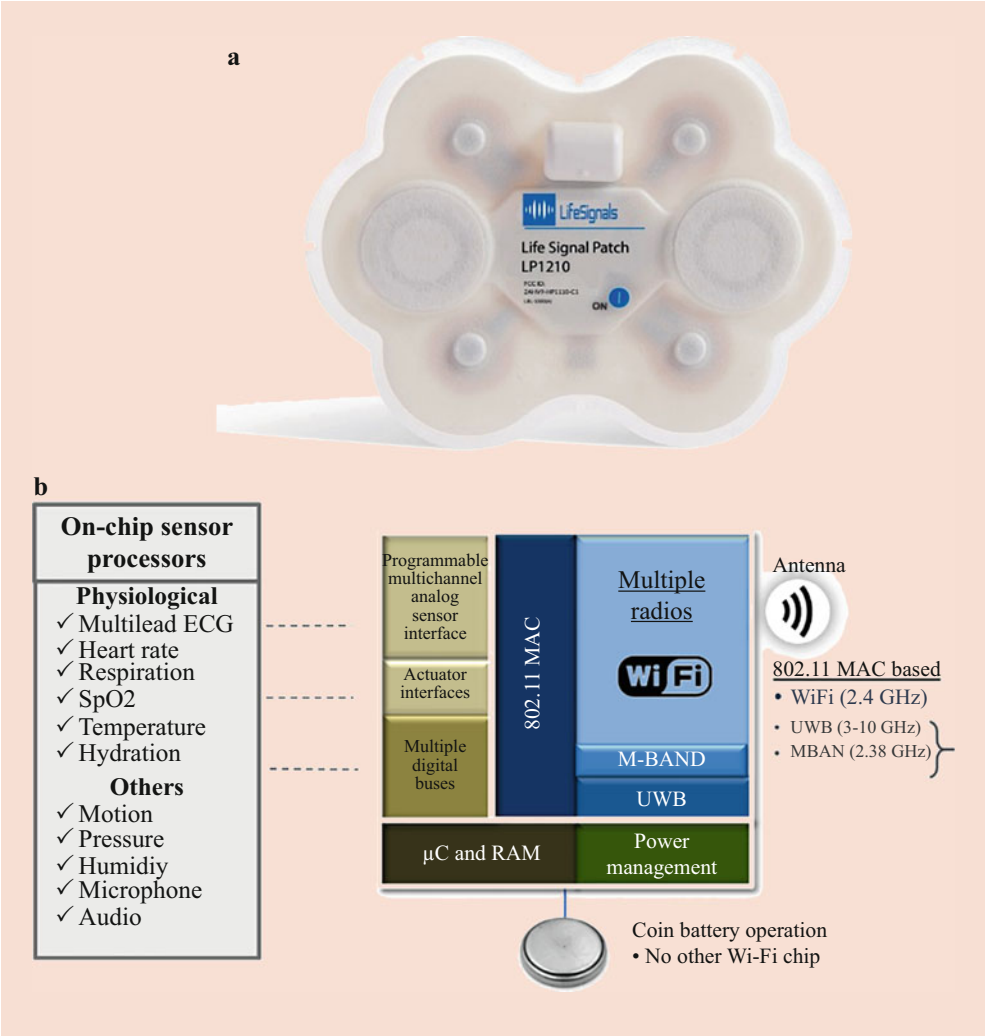

Fig. 18.7 (**a**) LifeSignals ultralow-power wireless patch for professional-grade electrocardiogram (ECG) that can operate with a cheap zinc-air battery at 1.2 V. (**b**) Lifesignal silicon processor chip for patches schematic. (© 2018 by LifeSignals)

ultralow-power wireless patch for professional grade (ECG) developed by Californian start-up LifeSignals in cooperation with STMicroelectronics in the last 5 years [21].

Beyond this growing and essential healthcare market, sensors will leave a sign in the new generation of home and factory robots, including the cobots, and the autonomous cars, enabled by artificial intelligence. The recent market trends in electrification, digitalization, and automation will require more and more the deployment of wireless sensor networks, which today are still in their infancy. A wireless sensor network results from the combination of different wireless sensor nodes (mote), consisting of some combination of a sensor, a microcontroller, a wireless receiver, an antenna and a battery, or even better, an energy scavenger. The potential market for motes is limited only by our imagination, and as soon as overall power consumption of the mote will be lowered (big current technological hurdle), motes will ultimately become a natural part of our lives. Their potential applications range from security and bio-detection to building and home automation, industrial control, pollution monitoring, and agriculture. Moreover, rising concerns for safety, convenience, entertainment, and efficiency factors, coupled with worldwide government regulations in terms of security, could boost sensor usage to unprecedented levels, although not all of them necessarily silicon micro-fabricated. In fact, motes will have to measure real-world variables such as pressure, temperature, heat, flow, force, vibration, acceleration, shock, torque, humidity, and strain as well as capture and record images in the visible and near-IR range. Suppliers must be ready to integrate different technologies in a modular format as well as to achieve high-volume manufacturability of motes. Most of the transducers, with the exceptions of the CMOS image sensors, are coming from advanced 8″ fabs, while the rest of the active silicon components is fabricated in state-of-the-art 12″ fabs. Then, system in package solutions allow a modular and flexible integration of the different

components in a miniaturized and compact module. It is of course not clear which exact application will win in the long run, but it is clear that different new sensors, currently being developed by many companies and research centers, will enable a lot of new applications, driving new revenue streams.

3-D Sensing Solutions

The evolution toward complex stereographic representation or data analysis, for mapping and sensing the surrounding reality using near-infrared (NIR) wavelengths, is now a clear trend in medical, automotive, factory automation, home security, communication, consumer, food, and entertainment markets. 3-D sensing solutions aim to estimate the distance between the object and the sensor. A basic classification of present 3-D sensing solutions (excluding medical diagnostic systems and non-photon-based sensors) are:

- Stereo vision: including active and passive stereo vision, with small volumes in professional industrial applications.
- Structured light (SL): presently widest market adoption through iPhone or professional 3-D scanning systems and originally used by Kinect 1 of Microsoft.
- Time of flight (ToF): including direct (dToF) and indirect time of flight (iToF), with limited volumes in professional industrial applications and growing in automotive for both in-cabin driver monitoring and autonomous driving applications. Kinect 2 of Microsoft represents the highest volume market application of iToF (Fig. 18.8).

Stereo vision and structured light are based on triangulation methodologies and thus they are geometric methods. By triangulation, they estimate indirectly the depth of the scene, calculating the unknown distance knowing the baseline (distance between the two cameras) and focal length. Precise knowledge of the baseline, and therefore precise optical assembly, is key for this methods. Stereo vision is clearly close to human stereographic view, where brain elaborates the signals coming from the two eyes and is able to discriminate 3-D scenarios from pictures and 2-D images. Stereo view works best when the observer is in motion. Geometric systems are on top affected by parallax error (perception of the object depends on the point of view), due to the intrinsic triangulation-based measurement: this issue creates mismatch in object identification. Moreover, depending on the geometry of the object to be measured, there could be mistakes linked to the conic or occlusion shadows, with a consequent misidentification of the shapes and the depth.

Time of flight, instead, is an electronic method that provides a direct measurement of depth without relying on geometrical assumptions. Electrical quantities of the signal, like phase or time delay, are processed to yield a depth value that is independent on the spacing between the components in the system and therefore is compatible with a more relaxed assembly tolerance. Typically, the challenges are signal-to-noise ratio, reaction time, and signal path delays. The advantages are related to the lack of intermediate calculation for geometric systems: electronic methods are simpler, require lower computational power and lower calibration effort, and have lower costs.

All the three 3-D solutions require an application processor. Structured light and time of flight systems require also a light source with related analog drivers. This light source is, in most cases, an IR VCSEL light emitter. In order to avoid the use of visible light, a wavelength of about 950 nm is normally used. Longer wavelength can be chosen to increase the safety for eyes but also to increase the depth of scan, as in the case of LIDAR or RADAR, used in the premium cars.

3-D sensing solutions are bundled with other sensors (inertial sensors, CMOS image sensors, etc.) to move from 3-D to 4-D or synchronous localization and mapping (SLAM): a system that is capable to explore and map an unknown environment while simultaneously keeping track of a subject interacting with and inside that environment. SLAM represents the next step toward virtual reality, autonomous navigation and driving, and next-generation robots and cobots, as showed in Fig. 18.9.

18.3 Micro-sensor Classification and Terminology

Every day we deal with several different types of silicon sensors using several materials (monosilicon, polysilicon, silicon oxide, silicon nitride, etc.) and manufactured with different microfabrication processes. Despite all this variety, sensing the real world always requires dealing with physical variable inputs to be converted in electrical signal variable output. This electrical signal is typically processed in some way, e.g., amplified and/or filtered, and either transmitted, stored, processed further, or converted into a human-readable form, e.g., used to drive an optical display (as shown in Fig. 18.10).

18.3.1 Classification

There are many possible ways to classify the different types of micro-sensors. They can be easily grouped in analog (voltage) or digital (bit stream) sensor families, just looking at the format of their electrical signal output. Moreover, considering that the two key blocks (transducer and electronic processing chip) of a micro-sensor can be realized on the same die or on multiple dice, a classification based on the microfabrication process architecture is also possible. Thus, we can classify sensors in three classes:

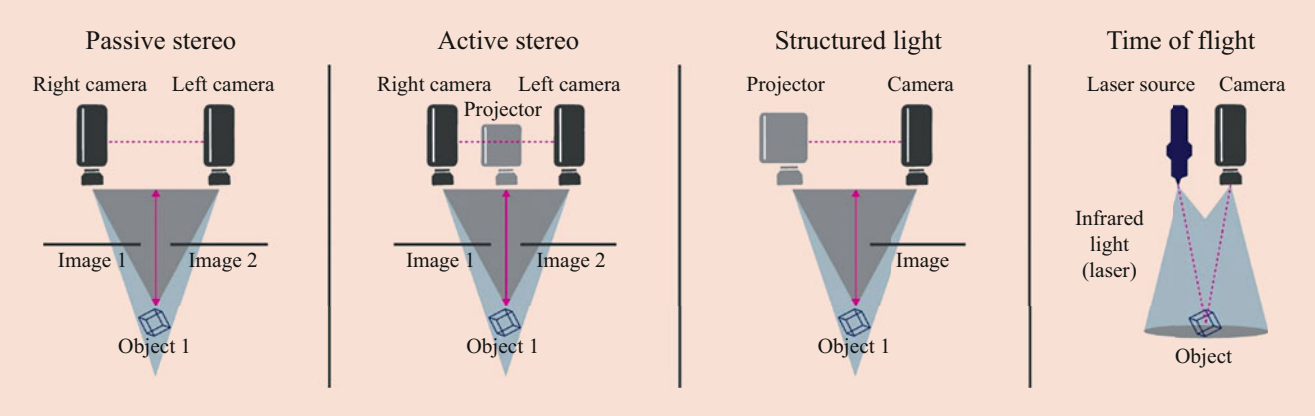

Fig. 18.8 Main 3-D sensing solutions. (© 2018 by STMicroelectronics)

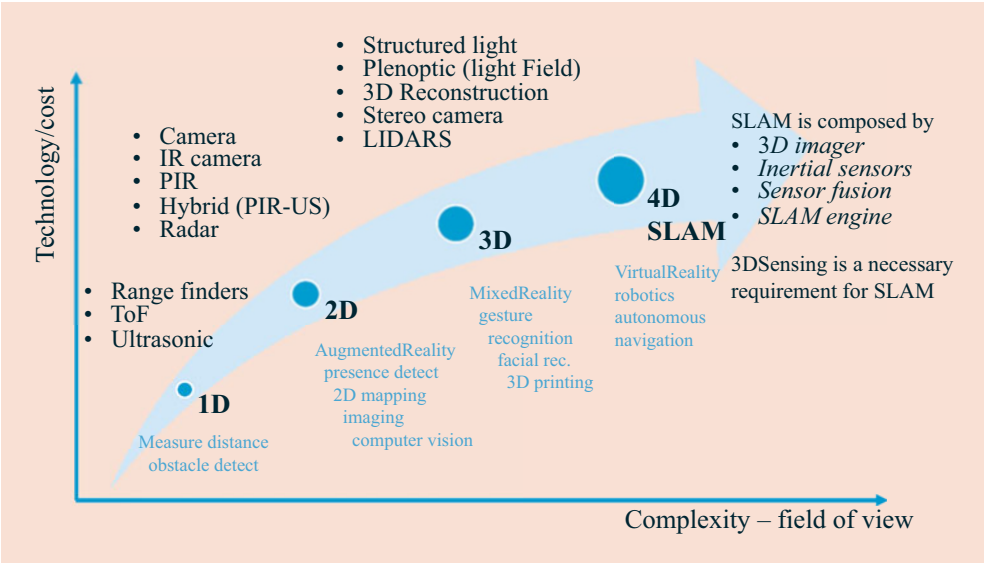

Fig. 18.9 Adoption of 3-D sensing solution across different market applications. (© 2018 STMicroelectronics)

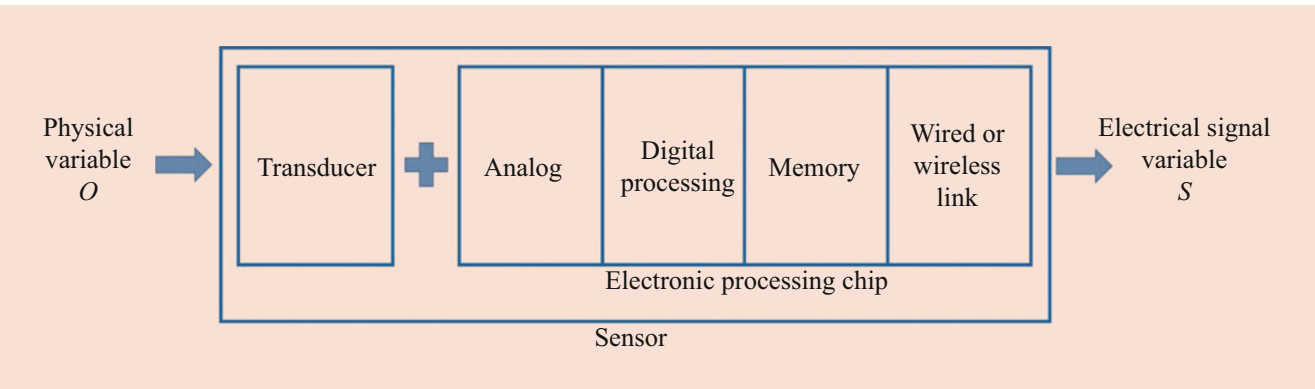

Fig. 18.10 Schematic representation of the transduction and elaboration processes inside a sensor. (© 2018 STMicroelectronics)

1. CMOS monolithic, like the Hall effect sensors of Allegro or the ambient light sensors of AMS or the humidity sensors of Sensirion. The fabrication steps can precede the regular CMOS process (pre-CMOS, like the VENSENS™ process of STMicroelectronics) or follow it (post-CMOS, like the humidity sensors of Sensirion) or can be per-

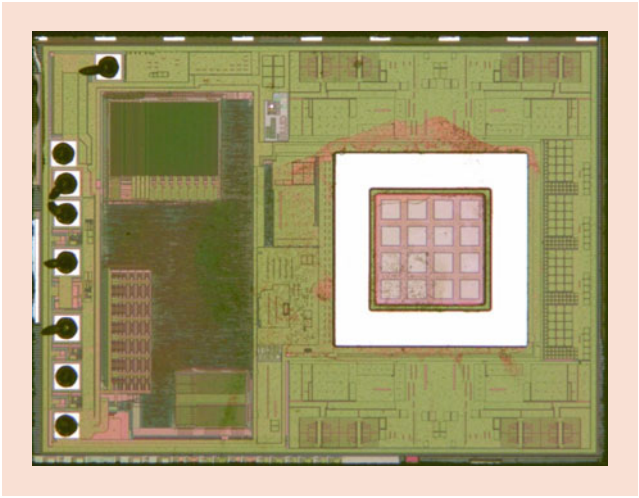

Fig. 18.11 Optical view of AMS color and proximity sensor, realized with CMOS monolithic. (© 2018 ALS and proximity sensor comparison by System Plus Consulting)

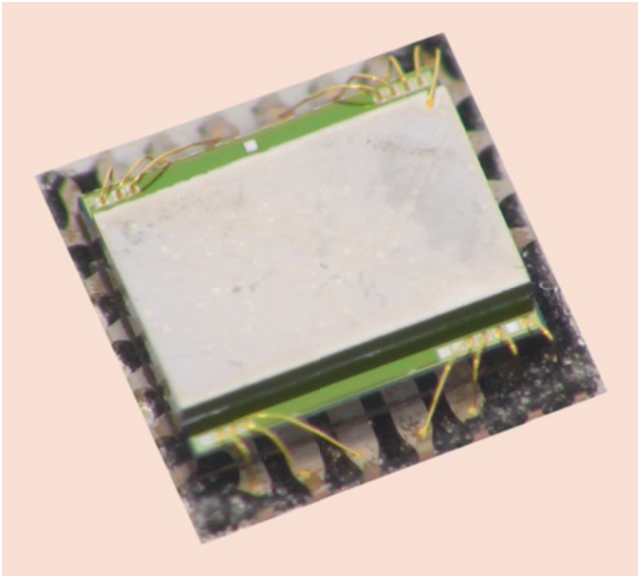

Fig. 18.12 Optical view of InvenSense MPU6500 six-axis inertial measurement unit (IMU): CMOS stacked structure is adopted, with MEMS sensor bonded on top of application-specific integrated circuit (ASIC) with wafer-to-wafer bonding. (©2013 InvenSense MPU6500 six-axis IMU by System Plus Consulting)

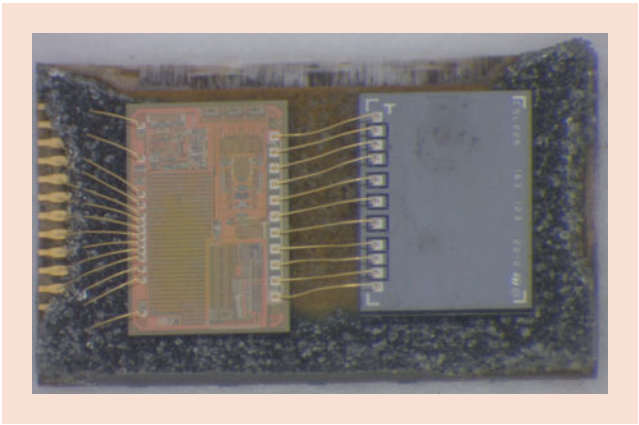

Fig. 18.13 CMOS hybrid: optical view of STMicroelectronics three-axis accelerometer LIS302DL with MEMS and ASIC side-by-side and wire bonded. (© 2017 MEMS Packaging Reverse Technology Review by System Plus Consulting)

formed in between the regular CMOS steps (intermediate CMOS, like the accelerometers of Analog Devices or the Hall effects of Melexis). In the last 20 years, we saw the market failure of many sensors belonging to this class. Akustica microphones are just one example.

2. CMOS stacked, like the gyroscopes of TDK/InvenSense or the backside illuminated CMOS image sensors of Sony. In this case, the wafer containing the different type of transducers is processed separately, and later it is bonded to one or multiple CMOS standard wafers containing the processing electronics by means of wafer-to-wafer metal bonding technologies (aluminum germanium and copper-copper alloys are the most widely used metallurgies).
3. CMOS hybrid or heterogeneous, like the six-axis of STMicroelectronics and Bosch or the microphones of Knowles Acoustics and Goertek. In this case, the transducer itself and the processing electronics reside on two different silicon dice, and later they are connected inside the same package thanks to standard copper or gold wire bonding technologies (Figs. 18.11, 18.12, and 18.13).

Besides the classification criteria suggested above, a convenient way to classify the several types of sensors is in terms of the type of energy they transduce (e.g., mechanical, thermal, and magnetic) into electrical energy. If we exclude nuclear energy and electrical energy (which does not require any transduction), we can distinguish between five basic energy types: mechanical, thermal, radiant, magnetic, and chemical, as detailed in the table below with related example sensors (Table 18.2).

An alternative way to classify electronic sensors is in relation to the conversion process itself. Two categories can be identified: direct/self-generating/active sensors and indirect/modulating/passive sensor. A direct sensor converts one form of energy directly into an electrical signal. For example, a photodetector converts photons (optical energy) into a current and a thermocouple converts radiation into a voltage.

In an indirect sensor, instead, the physical parameter of interest modulates an electrical signal. Time of flight, capacitive, or piezoresistive sensors are a good example. Resistive sensors, for example, are typically biased with a constant voltage, so that the change in resistance due to a change

Table 18.2 Classification of physical parameters and sensors according to the type of energy they convert

Energy	Parameter	Physical effect	Example sensors
Mechanical	Position, velocity, acceleration, force, stress, pressure, strain, torque, stiffness	Piezoelectric, piezoresistive, capacitive, inductive, optical	Accelerometer, strain gauge, load cell, switch, motion sensor, touch sensor, mass flow sensor
Thermal	Temperature, heat flow	Seebeck effect, thermo-resistance, pyroelectricity, thermal noise	Thermal couple, thermal resistance
Radiant (Optical/EM)	Light intensity, wave length, refractive index, polarization, phase	Photoelectric, photovoltaic	Photodiode, photo transistor, photomultiplier tube, position-sensitive detector, CCD
Magnetic	Magnetic field, magnetization	Magnetoresistance, inductance, hall effect	Compass, position, speed sensor
Chemical	pH, humidity, chemical/bioagents, gas	Potentiometry, conductometry, amperometry	pH sensor, gas sensor, humidity sensor

in the parameter of interest (e.g., strain, magnetic field, temperature) results in a modulation of the current flowing through the sensor. In general, modulating sensors are used for the measurement of very weak signals.

Many sensors use displacement sensing to measure a mechanical signal directly, such as acceleration, yaw rate, or sound pressure. Displacement sensing is the most highly developed areas in the field of micro-machined sensors because it can be applied so widely and it is relatively straightforward to implement. All the micro-machined sensor examples provided later in this chapter employ displacement sensing techniques such as capacitive, piezoresistive, and piezoelectric. A detailed explanation of these basic sensing techniques will be provided in Sects. 1.6, 1.7, 1.8, 1.9, and 1.10 in conjunction with the related sensor exploiting it.

Commercially successful micro-machined sensors, also known as MEMS sensor, include accelerometers, gyroscopes, microphones, and pressure sensors. All these micro-machined sensors are passive and detect the physical input signal of interest by means of resistive or capacitive variation induced by a displacement. We do not have yet on the market any commercially successful example of micro-machined sensor measuring an inductive change. Many papers are also published about micro-machined resonant sensors, but authors of this chapter believe that 2 or 3 additional years are needed before having some commercially relevant market examples.

18.3.2 Terminology

There are some key parameters common to all sensors that are specified in their datasheets and have a relevant role in the price of the sensor itself. The reader can find a comprehensive review of sensor terminology in many specialized books like Ref. [7]. The intent of this section is to clarify the meaning of the most critical parameters of any sensor, parameters that often are confused or misused.

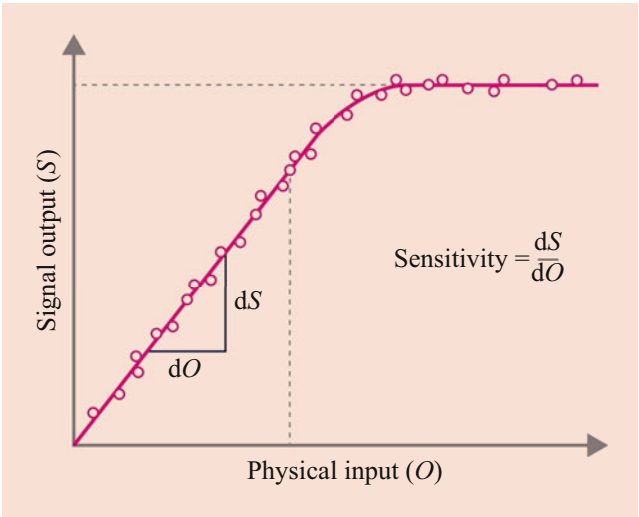

Fig. 18.14 Schematic representation of a calibration curve with illustration of the concept of sensitivity. This example curve has a good linearity in the first part and then deviates from linearity. (© 2018 by STMicroelectronics)

Calibration: Any sensor, before to be used, must be calibrated, so to ensure its correct behavior during its utilization. In fact, the calibration enables to determine the correct relationship between the physical variable input O (observable) and the signal variable output S. The calibration procedure requires the use of a well-known physical input to the sensor and recording the output on a calibration curve accordingly.

Scale factor, most commonly known as *sensitivity,* is the slope of the calibration curve, i.e., dS/dO.

Nonlinearity is the systematic deviation from the straight-line relation between O and S, i.e.,

$$S = \text{sens} * O + \alpha \tag{18.1}$$

where α is the offset, usually compensated (Fig. 18.14).

Dynamic range is the ratio between the smallest $O_{\min}$ and largest physical inputs $O_{\max}$ that can be reliably measured by the sensor.

Resolution is the smallest variation of the measured quantity O that can be detected. Resolution is an important property of the sensor and higher resolution implies smaller minimum difference between two measurements. Often higher resolution is synonymous of higher precision.

Accuracy and precision of the sensor are, maybe, the two most important concepts describing the quality of the sensor itself and making it more or less suitable for the final application.

Accuracy, also called bias in the literature, describes the closeness between the true value of the measurand O^{True} and the measured value indicated by the sensor O^{Measured} [7]. The difference between the true value of the measurand and the measured value indicated by the sensor is called error.

$$\text{Error} = O^{\text{True}} - O^{\text{Measured}} \tag{18.2}$$

The higher the accuracy, the lower the error. Typically, the true value is defined in reference to some absolute or agreed upon standard. Accuracy is especially important when the user is interested in estimating the true value and is less important when measurement repeatability is the critical issue. Common synonyms include bias, systematic error, and trueness, albeit ISO has a different definition of accuracy from the common scientific usage.

Precision, also referred to as variability, describes the closeness of agreement between experimental measured values O_i, obtained by replicating measurements of the same quantity O under specified conditions. Measurement precision is usually expressed numerically by way of standard deviation. Some measurements require high precision, i.e., small variability in the measurement, and may tolerate a constant offset with respect to the true value, which in most cases is easily detectable and removable during the calibration procedure by means of compensation. Common synonyms are precision, jitter, variance, and standard deviation.

Figure 18.15 exemplifies the two concepts in the case of multiple measurements of a certain quantity O, distributed according to a Gaussian probability density function. Accuracy is the difference between the average O^{Measured} of the different measurements and the true value O^{True}, while precision is the measurement variance.

The lack of accuracy and precision of the sensor can be quantified by two types of errors in the measurement data: systematic errors and random errors, respectively [7].

Systematic errors occur always with the same value when acquisition and environmental conditions remain the same. They are predictable and once identified they can be removed through a compensation process.

Random errors are associated with different measurements and can be characterized by a mean and variance value. The variance can be reduced in general by averaging multiple measurements, while the mean can be incorporated with systematic errors, since the central limit theorem ensures that random errors tend to be normally distributed when many independent variables are added together.

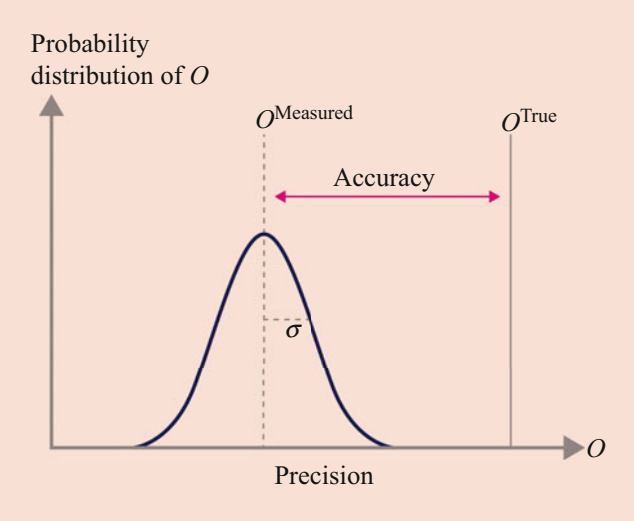

Fig. 18.15 Schematic representation of the concepts of accuracy and precision in a measure. (© 2018 by STMicroelectronics)

18.4 Microfabrication and Micromachining

Miniaturization of sensors thanks to microfabrication technologies typically results in improvements in the response time and the sensitivity of a device and in a reduction in the power consumption. Additional benefits of using micro-fabricated sensors are size, cost reductions, increased performances, improved reliability, and the possibility to integrate electronics directly in the devices, enabling even further reductions in size and cost. Last but not least, micro-fabricated sensors enable the integration of several different sensors on the same platform so that physical quantities can be measured simultaneously and the sensor becomes more accurate. Integration of a temperature sensor is a typical example, where the simultaneous measurement of the signal of interest and of the temperature can increase the accuracy of the overall sensor, thanks to an improved temperature compensation.

Perhaps one of the most powerful concepts facilitated by micro-fabricated sensor technology is that of massive parallelization thanks to either batch manufacturing techniques or possibility to integrate many equal sensors on a silicon die (like the CMOS image sensors). In the past, data describing the spatial variation of a parameter of interest was typically acquired by taking a single sensor and raster scanning it over the area of interest. The main drawbacks of this technique are the complexity involved in positioning the sensor and the time required to acquire the data. An alternative approach is to build an array of identical sensors and use them to

simultaneously acquire an image of the spatial variation of the parameter of interest. This concept has been exploited very effectively in optical imaging devices, such as the image sensor arrays currently found in all the smartphones. Some recently announced phones like the Samsung S10 include up to six cameras.

As we anticipated in the previous section, depending on the CMOS integration level, we have three classes of microfabricated sensors: CMOS monolithic, CMOS stacked, and CMOS hybrid/heterogeneous. The first two classes are also referred to as system on chip (SoC), while the last one is more commonly known as system in package (SiP). In the last 20 years, the market success of SiP approach versus the SoC one has been the subject of many time-consuming speculations written in many technical papers and specialized books and even debated in international conferences attended by experts and/or by financial market analysts. Each company has been arguing the intrinsic benefit of its own process selection. A posteriori all of us can admit that all these discussions were useless. Today most of commercially successful micromachined sensors follow the SiP approach, mostly because of flexibility in the choice of the best process and development time, while temperature sensors, Hall effect, ambient light sensors, and CMOS image sensors use the SoC approach.

Most of the silicon microfabrication processes were developed for the integrated circuit (IC) industry. Processing techniques such as lithography, thin film metallization, photoresist patterning, and chemical etching have found extensive use in the fabrication of micro-sensor. The ability to mass-fabricate many of these sensors on a single wafer (batch processing) using currently available semiconductor processing techniques helped to decrease the unit fabrication costs significantly and to manufacture sensors with increased reproducibility of response.

By combining these two-dimensional processes with three-dimensional micromachining technology, three-dimensional structures can be formed. Different micromachining techniques are available: surface/epitaxial techniques allow fabricating transducer masses with thickness from few up to 100 μm; bulk methods allow the realization of masses with thickness greater than 100 μm.

The techniques used in silicon micromachining fabrication include two key steps:

1. Chemical anisotropic and dry etching. Chemical anisotropic etching is an etching procedure that depends on the crystalline orientation of the substrate. For silicon etching, potassium hydroxide (KOH) and tetramethylammonium hydroxide (TMAH) solutions are most commonly used as etching agents. Dry etching processes include ion milling, plasma etching, reactive ion etching, and reactive ion beam etching. These dry etching processes are not dictated or limited by the crystalline structure and thus enable greater freedom in the design of the sensor. The SF_6 dry etching process invented by Laermer et al. represents a big step forward in micro-sensor development [22].
2. Sacrificial layer method. The active structure is fabricated on a sacrificial layer that is subsequently chemically removed. In this way, the active structure becomes free to move.

18.5 Microsystem Back End

A microsystem is the combination of electrical and nonelectrical function. As we have seen in the previous section, some suppliers integrate the two functions on the same silicon die, while others use two separate silicon dice. These dice may be placed in different ways inside the package itself: stacked or side-by-side as shown in Fig. 18.16. Almost 12 years ago, the use of full molded packages enabled a strong cost reduction of micro-machined accelerometers and thus a wider consumer market adoption. Nowadays, while the package of physical sensors, like magnetic, inertial, and CMOS sensors, is very much cost-optimized, the same does not apply to chemical sensors, like gas sensors. The goal of research and development activity in this field is to continue to move MEMS packaging out of the jewelry space of custom solutions toward standard production rules and controls. The ultimate goal is to minimize manual interventions through utilization of automatic equipment and to lower the bill of material. This step is mandatory to increase both the level of global production and level of quality.

In the last decade, many attempts have been done to move standard wafer-level manufacturing steps to back-end plants (plants running assembly and testing operations). Many great innovative ideas, like package on package (PoP), fan-out, wafer-level molding, bare silicon, and thru-silicon vias (TSV), were proposed in the last decade, but although their beauty and elegance, most of them remained limited in volumes, mostly because of cost reasons. This does not mean they will not resurrect and find their way to the high-volume market, but as of today most of the sensors continue to be assembled with standard assembly processes (Fig. 18.17).

Assembly refers to the collection of industrial processes that are used in a specific sequence to create a package housing of the sensor. Packaging is the process of enclosing the sensor inside a package. The role of the package is to offer a proper interface between the sensor and the printed circuit board, on top of which it is soldered, while providing mechanical and environmental protection, to guarantee reliable operation during all its lifetime.

Testing is the sum of all electrical and nonelectrical tests performed to verify product functionality and to calibrate it properly. Calibration is an important step required by all

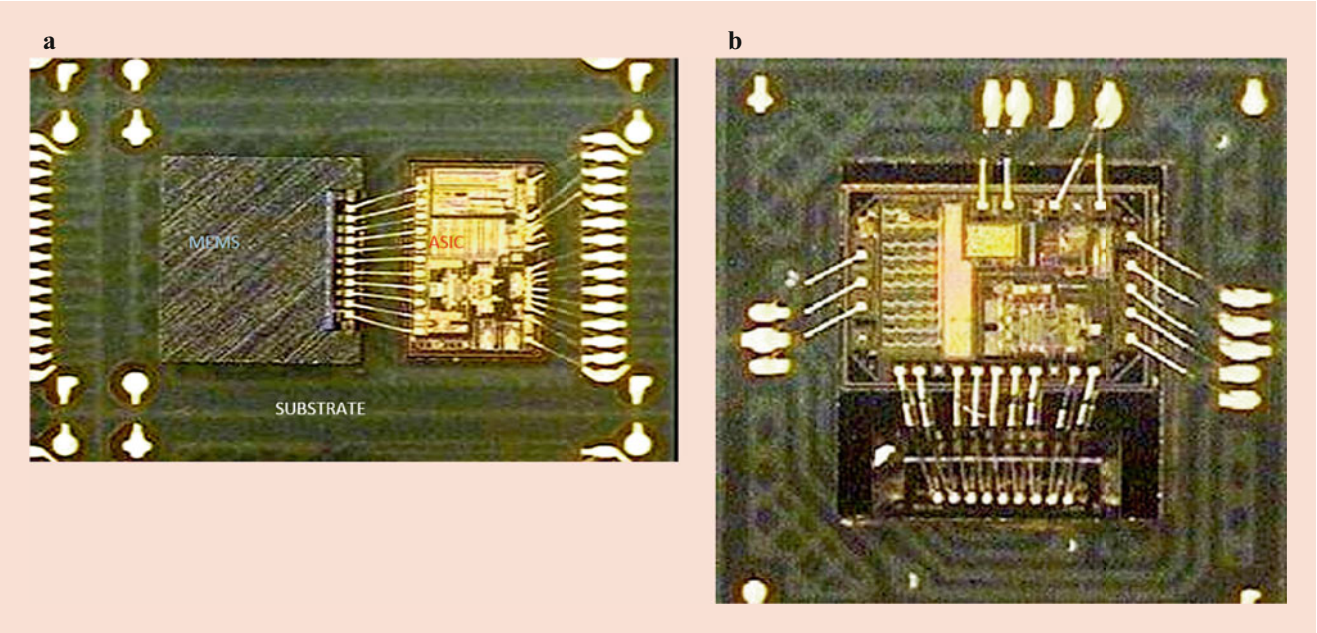

Fig. 18.16 (**a**) STMicroelectronics IMU, example of side-by-side chip configuration. (**b**) STMicroelectronics IMU, example of stacked chip configuration. (© 2018 by STMicroelectronics)

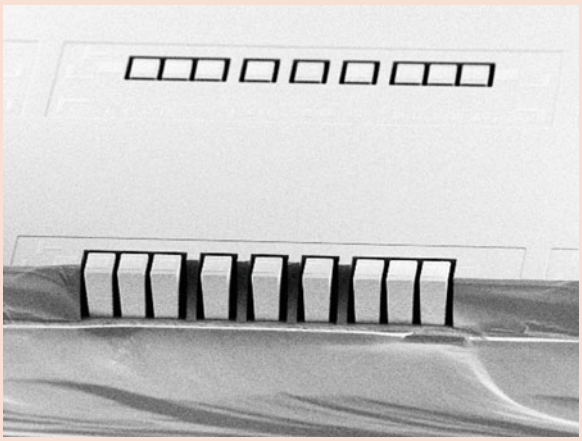

Fig. 18.17 Cross section of a wafer showing thru-silicon vias (TSV) in STMicroelectronics IMU. (© 2018 by STMicroelectronics)

kind of sensors. As explained in Sect. 18.3.2, the calibration curve is key for the usefulness of the sensor itself in the final application. No calibration, no sensor!

Packaging and calibration are extremely important for the sensor performances. Microfabrication technology can enable the best ever sensor performances, but then a wrong selection of the package and/or inaccurate calibration can make the sensor not adequate to its use in the final application. Packaging and calibration of sensors depend largely on the application and on the different type of sensors. For a more detailed discussion of sensor packaging, the reader is referred to Ref. [23].

18.5.1 Micro-sensor Assembly and Packaging

Silicon sensor assembly techniques are mainly derived from those developed for microelectronics . In contrast to integrated circuits (IC), where the package protects the electronics device from the outside world, the sensor package sometimes may need to provide direct physical interaction with the external world. At the same time, package protects the sensor from damage or failures in the assembly line and in the field. According to the different types of sensor packages, three classes can be identified:

1. *Hermetic* packages are intended to protect chips from external environment agents (i.e., particle contamination, moisture-induced corrosion, and stiction) that can prevent the devices from properly working. Inertial sensors, such as accelerometers and gyroscopes, and bolometers are examples of devices that require hermetic packages. In the 1990s ceramic packages were the only possible solution for hermetic packages. This was the case for the accelerometers of Analog Devices, mainly for automotive applications. With the dawn of the sensor consumerization wave, cost-effective solutions based on plastic full molded packages started to appear on the market (i.e., the accelerometer of STMicroelectronics LIS3L02AL used in the Nintendo Wii™ game console), and now full molded plastic land grid array (LGA) package is the standard for inertial sensors. If the package of inertial sensors evolved so much in the last years, the same cannot be said for the bolometers, where only shy attempts of new package

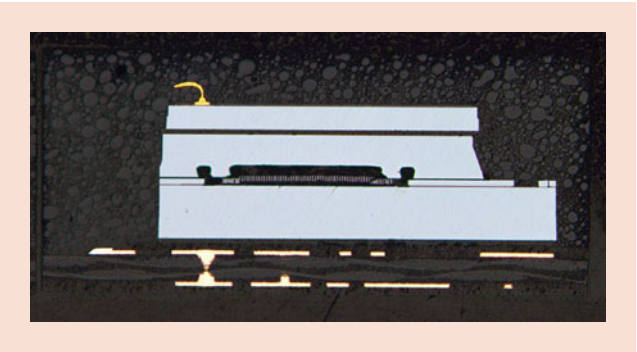

Fig. 18.18 Cross section of a STMicroelectronics inertial module. LGA substrate is visible at the bottom, with sensor in between and ASIC on top. MEMS die is made of a sensor wafer (on top of which suspended mass can be seen) and a cap wafer. Wafer-to-wafer bonding guarantees hermeticity inside sensor die. (© 2018 by STMicroelectronics)

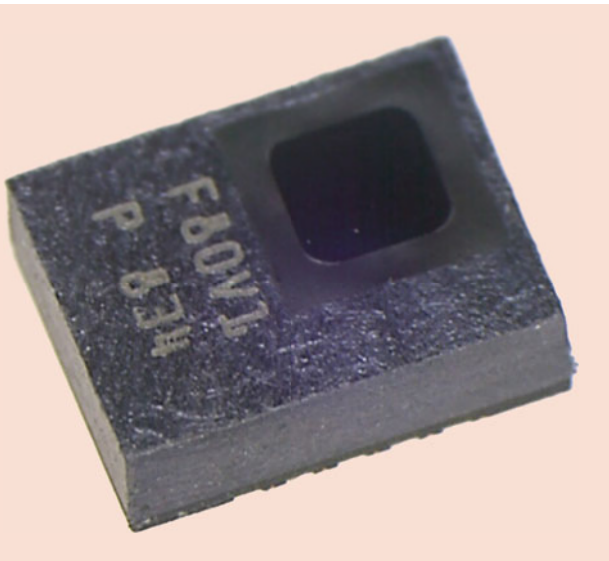

Fig. 18.20 STMicroelectronics optical sensor in plastic package with embedded IR window. (© 2018 by STMicroelectronics)

evolution can be found. Hermeticity of the package is usually guaranteed by low melting point glasses (glass frit) or metal alloys used to join two or more silicon wafers. Alternative techniques include high-voltage high temperature anodic wafer-to-wafer bonding, like the pressure sensor used in tire pressure monitoring systems of Infineon.

2. *Open* packages provide an interface between the sensor and the external world through one or more inlets. Typical examples of open package MEMS sensors are pressure sensors and microphones. Open packages are required whenever the external stimulus requires close physical or chemical contact with the transducer part of the sensor. Moreover, most of open packages are highly customized to fit the specific application they are designed for, and, thus, they involve special manufacturing designs and equipment. The manufacturing industry is still far from the standardization wave that involved hermetic sensor class, but the introduction of the holed land grid array (HLGA™) package of STMicroelectronics pressure sensor in 2013 represented the dawn of a standardization era also for pressure sensors.
3. *Semi-hermetic* packages are in the middle between hermetic packages and open packages. They do not have any inlet, but, being not hermetic, humidity can enter easily, and thus this kind of package is not suitable for stiction-prone sensors with a sensing element containing moving parts. Temperature sensors, magnetic sensors, and optical sensors, all without moving parts, fit into this category of packages (Figs. 18.18, 18.19, and 18.20).

Apart from the functional classification of the different kinds of packages, another fundamental difference exists in the material employed for the package: ceramic and plastic. In the plastic package family, a further difference can be made between full molded and pre-molded packages.

Though the full molded packages are cheaper and more easily scalable in high volume, nowadays there are many different packages on the market, depending on the requirement of the sensor itself.

Today, the manufacturing of high-volume micro-sensors is linked to the use of molded packages. In the field of consumer-related products, the only cost-effective and volume-scalable solutions for inertial sensors are full molded plastic packages. In the late 1990s, lead-frame solution packages based on SOIC (small outline integrated circuit) packaging were the first approach for mass production

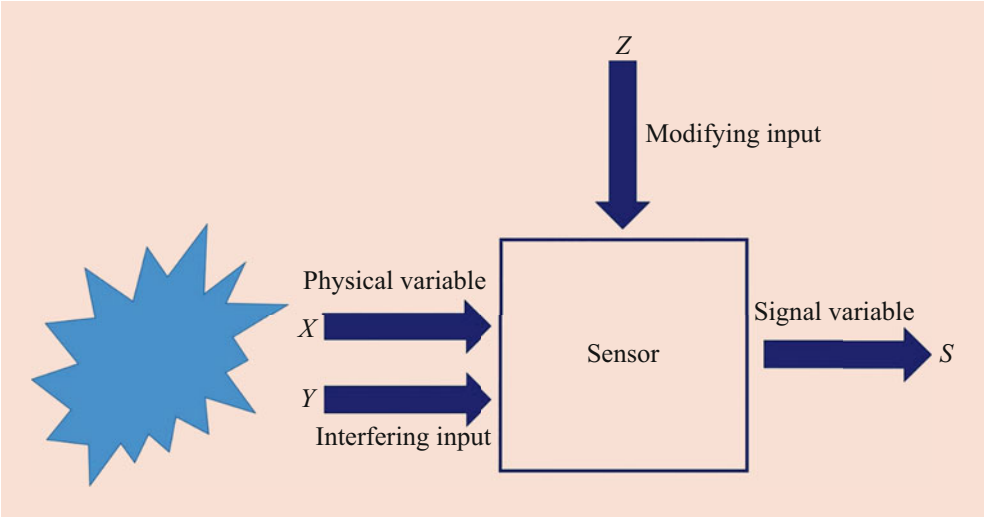

Fig. 18.21 Illustration of how interfering and modifying inputs may affect negatively the calibration curve of the sensor. (© 2018 by STMicroelectronics)

of a full molded package for accelerometers; later, LGA definitely became the standard solution.

MEMS sensors can be capped one by one in the packaging line or directly at wafer level in the clean room with wafer-to-wafer bonding technology process. Glass frit, a low melting point glass, is the most common technique used to seal the microstructure at wafer level. In the 1980s and 1990s, the inertial sensors were assembled and sealed one by one in ceramic hermetic packages, but since this approach did not scale well in mass production and since it induced quality issue (stiction) in the market, it was replaced by a wafer-level low-cost reliable technique, which is now employed by all large MEMS silicon manufacturers [23]. STMicroelectronics and Bosch use it for all their inertial sensors. For this full molded low-cost package transition, several technical challenges were successfully overcome at design level to gain performance in terms of thermal stability (over the required temperature range) and time stability (over the device lifetime), due to changing conditions in humidity and mechanical stress coming from the application board. Sensor suppliers keep experimenting innovative ideas to increase overall accuracy.

18.5.2 Micro-sensor Testing and Calibration

Testing equipment for sensors is designed to provide known physical stimulation to the packaged microsystems. Linear accelerometers must be calibrated by applying an external linear acceleration (measured in units of g, the Earth's gravity acceleration); gyroscopes require the application of an external known angular rate (measured in degree per second, known also as dps); CMOS image sensors require the application of an external known optical source.

While, for standard integrated circuits testing, the equipment apply only an electrical stimulus, the specificity of sensors testing is due to the need of applying to the device a nonelectrical signal. Therefore, a sensor handler is different from any traditional integrated circuit handler. In fact, the device under test (DUT) board must be properly designed to minimize the impact of the interfering or modifying inputs on the calibration curve. (See Fig. 18.21.)

Thus, the handlers and sockets must be customized to minimize any deformation or stress on the sensor element. DUT insertion and socket are key to avoid calibration errors on the curve that could limit the application of the sensor.

Innovative testing technologies typically require dedicated testing equipment, and thus a deep cooperation between sensor suppliers and testing equipment suppliers is required to be successful. In the last decade, testing equipment suppliers in cooperation with sensor manufacturers have constantly increased the degree of parallelism for the sake of higher productivity and thus lower cost. Many progresses have been done in this direction, but the high accuracy requirements imposed by new market application continue to demand further testing advances.

18.6 Accelerometers

MEMS accelerometers are transducers able to convert an acceleration input in an analog or digital electrical output. Acceleration input signal is either a result of a motion of the sensor in an inertial frame of reference, in which case the accelerometer is used as motion sensor, or the projection of the component of Earth's gravitational acceleration on the sense axis, in which case the accelerometer is used as

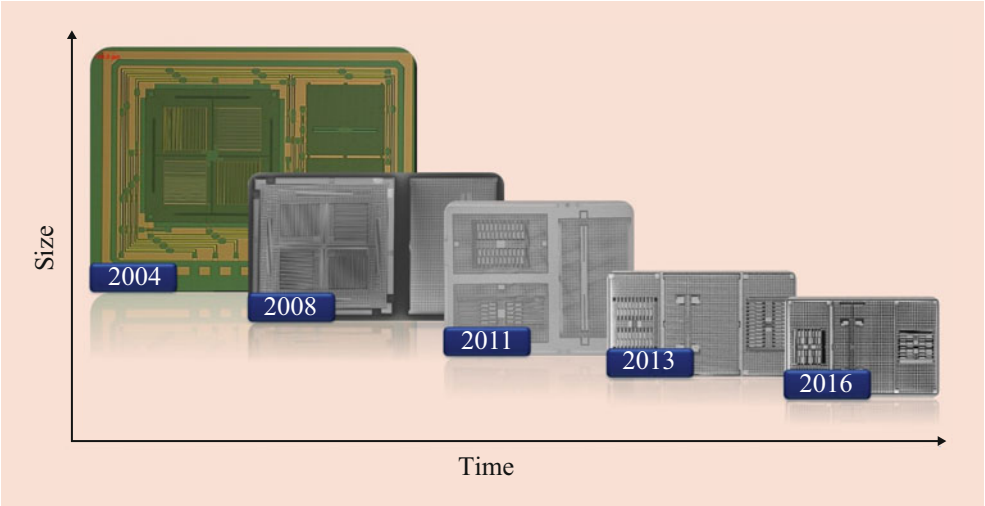

Fig. 18.22 STMicroelectronics three-axis MEMS accelerometers for consumer market: die size evolution (images in scale). Along with impressive die size reduction, capacitive MEMS accelerometer has also experienced a dramatic performance boost since early introduction in the 1990s to present. (© 2018 by STMicroelectronics)

an inclinometer. Acceleration signal is usually expressed in units of g, the common value of Earth's gravitational acceleration at sea level, and converts into 9.81 $\frac{\mathrm{m}}{\mathrm{s}^2}$.

18.6.1 Accelerometers Introduction

MEMS accelerometer was one of the first MEMS sensors to be recognized as potential application of mechanical silicon sensors [5] and one of the first MEMS sensors to achieve commercial success in the early MEMS stage due to its automotive applications to replace switches in airbag deployment. The requirement of high reliability crash sensors at reasonable cost for automotive industry has driven the early development of silicon motion sensors. In 1991, Analog Devices' ADXL50 accelerometer [24] was the first commercially available, high-volume manufactured accelerometer realized with surface micromachining and available in ceramic packages (Fig. 18.22).

As accelerometer was the driver of the first sensor consumerization wave for automotive applications in the 1990s, it led also the second wave of inexpensive, ubiquitous sensor adoption in consumer electronics devices. In the mid-2000s, MEMS accelerometers were adopted in game consoles, smartphones, and laptops in order to enable more intuitive user interfaces.

In this timeframe, MEMS accelerometers changed and evolved their main characteristics to penetrate new markets. Shrinkage of sensor dimensions and lower power consumption were a key driver to enable accelerometer adoption in small, battery-operated consumer devices. Better accuracy and reliability, high flexibility on full scale, and bandwidth are now driving the MEMS accelerometers to challenge traditional piezoelectric sensors in the industrial market.

18.6.2 Accelerometer Specifications

MEMS accelerometers today have widespread applications in all markets, and the target application strongly influences the specifications of the sensor. Key performance indicators of acceleration sensors are full scale, offset, sensitivity, noise, and bandwidth, along with power consumption of the system.

Full scale is the range of input accelerations that can be converted before saturation of the mechanical element or readout electronics. The traditional segmentation of MEMS accelerometers divides them into low-g sensors (with full scale ranging from 1 g to 32 g) and high-g sensors (with full scale ranging from 50 g up to 8000 g).

Offset is the output value of the sensor when no input signal is applied. In accelerometers, offset is usually referred to as zero-g level (ZgL), and its value is calibrated at final testing. The requirement for stability of ZgL during device lifetime, in the complete operative temperature range, can range from fraction of milli-g (mg) in high accuracy inclinometers up to few g in applications where DC acceleration is cancelled.

Output noise value, i.e., the fluctuation of the accelerometer output when input acceleration is not varying, is also differentiating sensors in the different applications. Typical values range from 0.1 $\frac{\mu\mathrm{g}}{\sqrt{\mathrm{Hz}}}$ in seismic exploration for oil and gas to 1 $\frac{\mu\mathrm{g}}{\sqrt{\mathrm{Hz}}}$ in industrial vibration monitoring up to 100 $\frac{\mu\mathrm{g}}{\sqrt{\mathrm{Hz}}}$ in mobile phones and wearable electronics applications.

Bandwidth is the frequency point at which sinusoidal acceleration inputs are attenuated by 3 dB. It is determined by the frequency response of the system, as a combination of the mechanical frequency response of the MEMS sensor combined with the dedicated analog or digital filtering on ASIC. The mechanical bandwidth is a function of the

resonance frequency and the damping ratio of the sensor, gas damping being the dominant dissipation source in several accelerometer designs.

Power consumption of MEMS accelerometers was one of the key advantages of micro-fabricated sensors. Power requirement strongly varies depending on the final application: industrial or automotive applications allow for few mW of power dissipation for each sense axis, while wearable electronics applications require few μW for a full three-axial device. At the limit of power requirement are medical implantable accelerometers for pacemakers or brain stimulators, targeting sub-μW power dissipation.

18.6.3 Accelerometer System

MEMS accelerometers are usually composed of an electromechanical element and a signal conditioning integrated circuit, usually referred to as application-specific integrated circuit (ASIC). The two silicon dice are electrically connected and protected by a dedicated package.

The mechanical element translates the acceleration signal in an electrical quantity (capacitance, voltage, frequency). Several transduction mechanisms were proposed and are used to sense acceleration. The most common sensing mechanism is capacitive, piezoresistive, or piezoelectric. The ASIC is electrically connected to mechanical element, usually by means of wire bonding (Fig. 18.23).

MEMS accelerometers can be operated in open or closed loop. In open loop mode, the signal chain is a single direction stream from acceleration to analog or digital output, the force acting on proof mass is in principle only acceleration, and ASIC has the main purpose of signal conversion (e.g., from capacitance to voltage), conditioning and filtering, and digitalization. Closed loop accelerometers instead apply a force on the proof mass to maintain the position fixed also in presence of external accelerations. This is performed with a dedicated control loop actively steering the sensor by means of electrostatic force. This is also known as force-to-rebalance working principle (Fig. 18.24).

18.6.4 Capacitive MEMS Accelerometers: Design Principles

In capacitive MEMS accelerometers, the acceleration is sensed by measuring the displacement of a movable mass with respect to its rest position in the inertial frame of reference on which the sensor is fixed. This displacement causes a differential capacitance change between a set of fixed electrodes (stator) and a set of movable electrodes (rotor). The change of capacitance is measured by means of a suitably designed readout electronics.

In the literature, different architectures for sensing linear acceleration in one, two, or three directions through mono-axial, biaxial, or three-axial solutions have been reported [25–27]. The most common solution adopted in the industry is to use a mono-axial architecture for each acceleration direction. In the next section, the basic working principle for in-plane and out-of-plane accelerometer is described (Figs. 18.25 and 18.26).

The displacement of an x-axis single-mass device can be modelled through the following 1-degree-of-freedom motion equation:

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + b_x\frac{\mathrm{d}x}{\mathrm{d}t} + k_x x = ma_{\mathrm{ext}} \tag{18.3}$$

where m is the movable mass, b_x represents the damping term, k_x is the elastic stiffness, and $a_{\mathrm{ext}} = 9.8 \bullet g$ is the external acceleration applied to the inertial frame. The equation of motion can be translated to the frequency domain through the Laplace transformation in order to obtain the sensor displacement vs acceleration frequency response; see Fig. 18.27.

In this plot, the flat region corresponds to the sensing bandwidth of the sensors, and it is defined by the combination of the resonance frequency ω_0 and the Q factor. The static response to acceleration can be evaluated by setting all time-dependent terms in the previous motion equation to zero obtaining

$$\frac{\mathrm{d}x}{\mathrm{d}g} = \frac{9.8}{\omega_0^2} \tag{18.4}$$

from which results that the displacement of the movable mass is defined only by the resonance frequency of the mass-spring system. The stator and rotor electrodes form two set of capacitors, which can be expressed as.

$$C_1 = \frac{\epsilon NLt}{(g_0 - x)};\ C_2 = \frac{\epsilon NLt}{(g_0 + x)}; \tag{18.5}$$

where ϵ is the air permittivity, N is the number of parallel plate stator-to-rotor cells, t is the electrode thickness, and g_0 is the stator-to-rotor gap at rest. By combining the previous two equations and linearizing around $x = 0$ position, one can calculate the differential capacitance variation per unit of external acceleration also known as electromechanical sensitivity:

$$\frac{\mathrm{d}\Delta C}{\mathrm{d}a_{\mathrm{ext}}} = 2\frac{\mathrm{d}x}{\mathrm{d}a_{\mathrm{ext}}}\frac{\mathrm{d}C}{\mathrm{d}x}\bigg|_{x=0} = 2\frac{\epsilon_0 NLt}{g_0^2}\frac{1}{\omega_0^2} \tag{18.6}$$

The sensitivity of a MEMS capacitive accelerometer depends on three main parameters:

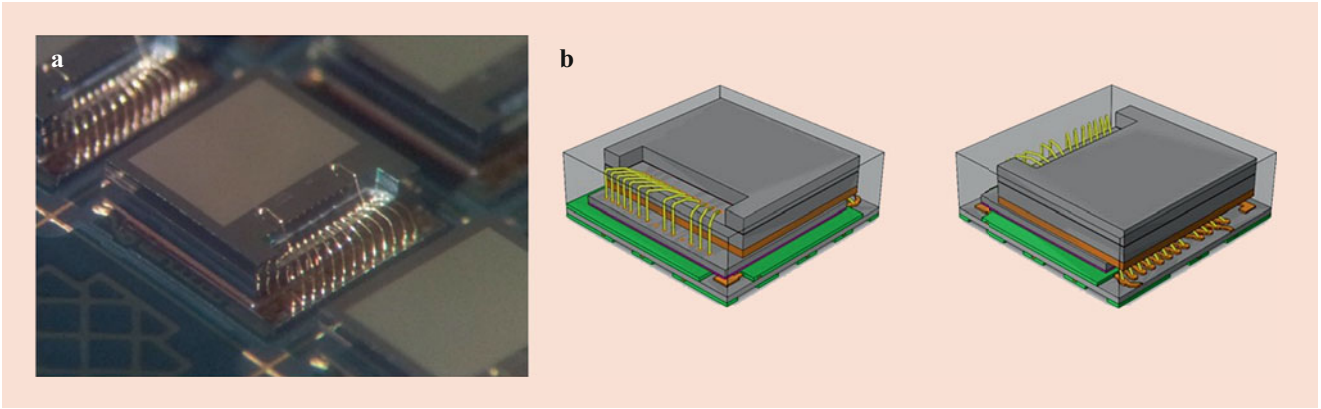

Fig. 18.23 In STMicroelectronics IMUs, the MEMS sensor and the signal conditioning ASIC are two separated silicon dice placed inside the same plastic system in package. The two dice are connected with wire bonding, providing electrical connectivity. (**a**) Image of stacked MEMS and ASIC dice attached to a plastic LGA substrate and wire bonded together, before the molding process. (**b**) 3-D view of the package after molding and singulation. Fig. 18.24 Architecture of a capacitive digital MEMS accelerometer system: LIS2DW12 three-axis accelerometer from STMicroelectronics. The sensor, indicated by the variable capacitors in the blue box, is attached to a multiplexer and to a charge amplifier. The voltage signal from the charge amplifier and the temperature signal for temperature compensation are fed into an analog to digital converter, and the digital signal is then available to be filtered by onboard signal conditioning and elaboration. (© 2018 by STMicroelectronics)

1. The electrodes area NLt, which can be tuned by increasing the die size or increasing the thickness of the silicon.
2. The stator-to-rotor gap at rest g_0, which depends on the minimum critical dimension (CD) defined by the deep reactive ion etching (DRIE) process used.
3. The resonance frequency ω_0, which is defined by the ratio of the elastic stiffness k_x and the movable mass m, which depends on the intrinsic properties of silicon (Young's modulus, Poisson ratio, material density), on the spring geometry, and thus again on the DRIE capabilities.

In general, high sensitivity is required to ensure low noise and low power performance when the sensor is coupled with a dedicated readout circuits as well as to ensure high stability device.

18.6.5 Capacitive MEMS Accelerometers: Process Flow

Capacitive MEMS accelerometers can be manufactured with different micromachining techniques. An example of epitaxial micromachining process developed specifically for MEMS inertial sensors, STMicroelectronics ThELMA MEMS process, is described in the next section.

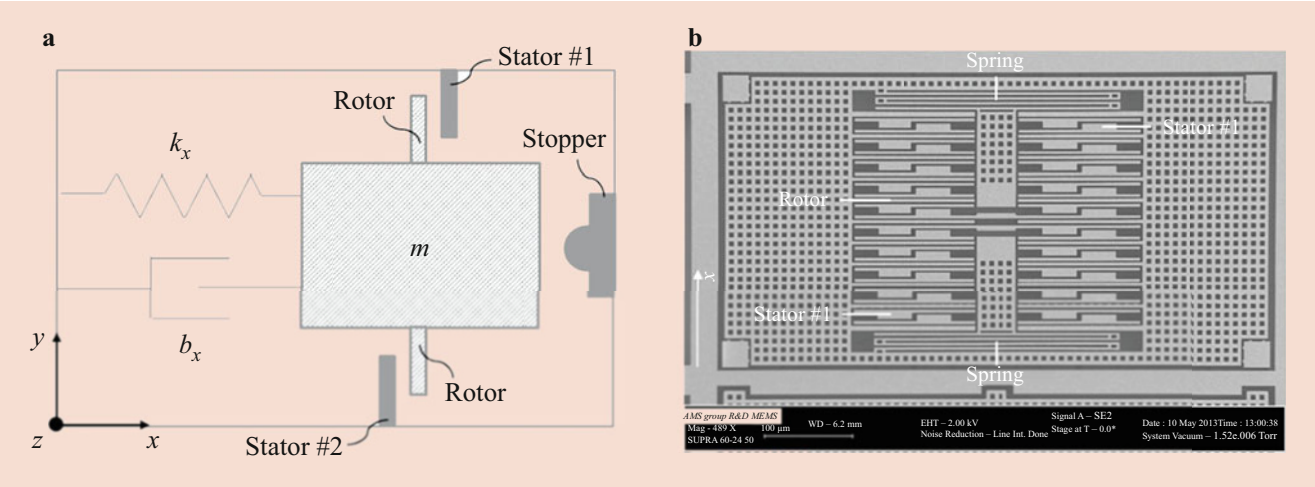

Fig. 18.25 MEMS capacitive accelerometer. (**a**) Schematic representation of an in-plane MEMS capacitive accelerometer based on 1DOF mass-spring-damper model. (**b**) SEM image of the *X*-axis of SK33 a MEMS accelerometer of STMicroelectronics. (© 2018 by STMicroelectronics)

(© 2018 by STMicroelectronics)

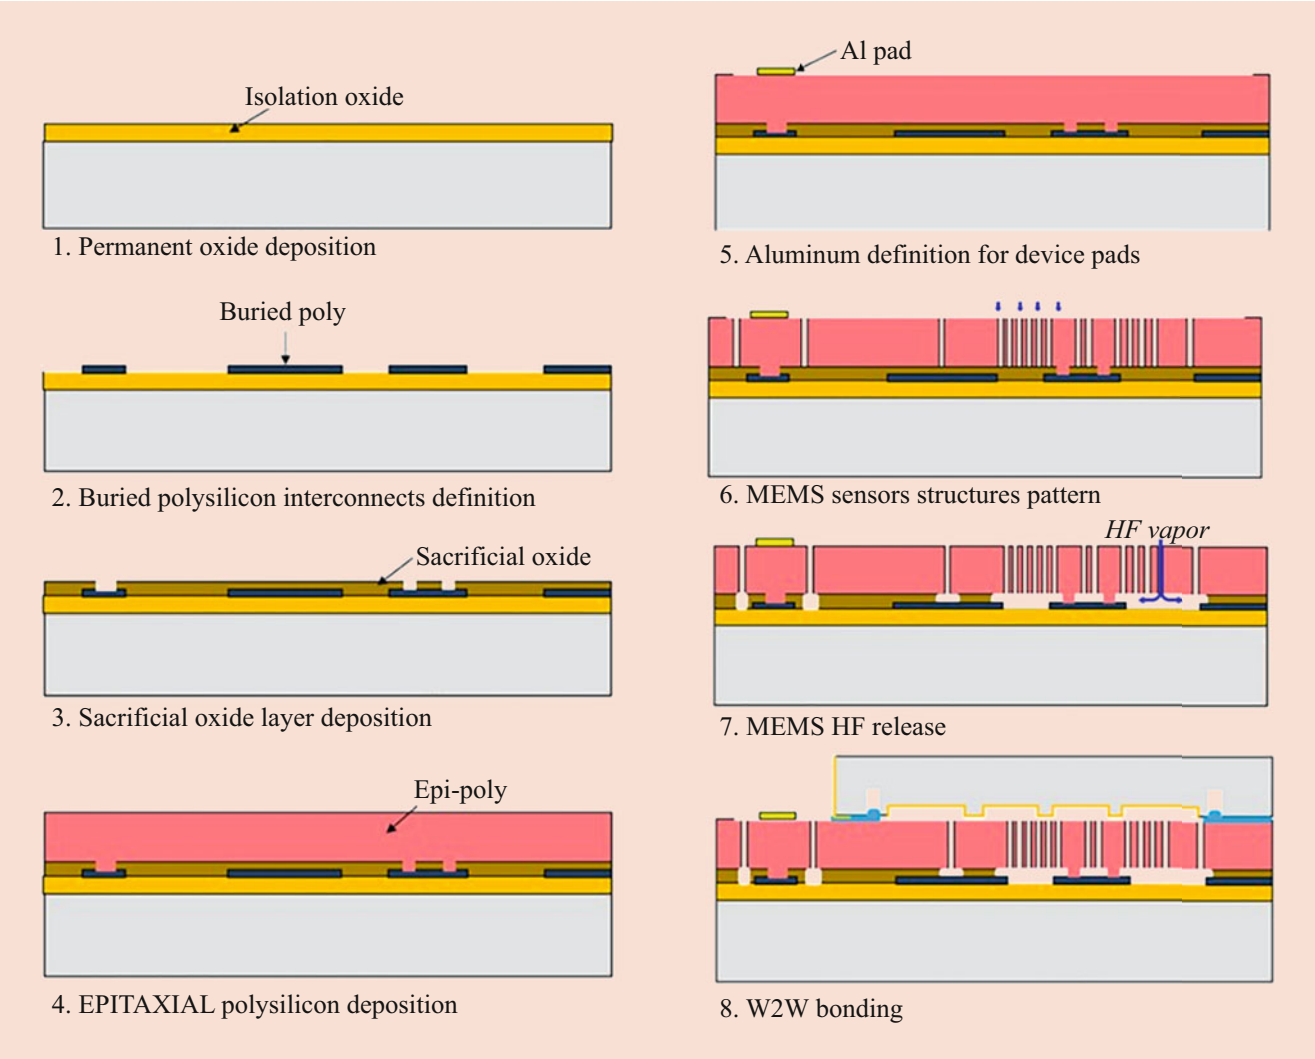

Fig. 18.28 Flow chart of STMicroelectronics ThELMA surface micromachining process for inertial sensors. (© 2018 by STMicroelectronics)

ThELMA is an acronym for thick epitaxial layer for micro-gyroscopes and accelerometers. ThELMA process is based on the fabrication of two wafers: the sensor wafer, which includes the micromechanical components, and the cap wafer. The two wafers are bonded together in the final part of the front-end process. Wafer-level bonding is needed in order to protect the micromechanical elements and enables to use standard back-end technologies like testing, dicing, and packaging, ensuring the reliability of the product over-time. Figure 18.28 shows a schematic process flow for a ThELMA accelerometer.

The sensor wafer process flows start with the growth of a thermal oxide, which is used to insulate the interconnections from the substrate. A thin polysilicon layer is used to design buried interconnections and electrodes for out-of-plane sensing structures. A sacrificial oxide is then deposited and defines the final *Z*-gap between the polysilicon electrodes and the rotor mass for vertical displacements (e.g., accelerometer *Z*-axis). This layer is patterned to define the anchoring areas and the ground areas where the rotor mass is connected to the buried polysilicon and to the substrate. Rotor mass is realized through an epitaxial polysilicon (EPI) growth, and the thickness could vary between 15 and 60 μm according to product requirements. This layer is patterned by DRIE process that defines proof mass, the sensing and driving electrodes, and the device spring. Finally, the sacrificial oxide under EPI structures is removed by HF vapor etching allowing the release of the MEMS sensing structures.

ThELMA technology allows manufacturing both in-plane and out-of-plane actuation and sensing electrodes by exploiting epitaxial polysilicon in the *X*-*Y* plane and buried polysilicon versus epitaxial polysilicon in the *Z* direction.

The cap wafer is a silicon substrate, which typically includes a cavity on the sensing area to allow the out-of-plane displacement of the rotor mass and pad window opening which provides access to the probing pads.

Sensor and cap wafers are then bonded together using glass frit bonding technology. Glass frit is a low melting temperature glass, which can be deposited on cap wafer by screen printing process. During wafer bonding, glass frit is heated and melts at temperature higher than 400 °C. After cooling, the glass frit layer solidifies, providing a hermetic seal joint between the sensor and the cap wafers.

The main competitive advantages of ThELMA versus other commercial technologies are:

1. The use of a thick low stress epitaxial polysilicon film; for high performance applications, thickness values up to 60 μm were implemented in production.
2. The use of the getter layer which improves the vacuum level inside the package; the use of getter allows also to integrate on the same die an accelerometer and a gyroscope (six-axis) working at different pressure values, as reported by Ferarresi [28].
3. A system architecture on which IC and MEMS are manufactured by different technological platforms. In fact keeping MEMS and the IC technologies separated increases technology development flexibility, removing from integration constraints between MEMS and the IC.
4. A long experience coming from more than 10 years' high-volume manufacturing and more than 10 billion devices sold, including accelerometers, gyroscopes, and combo devices.

18.6.6 Reliability Challenges for MEMS Accelerometers

The purpose of reliability is to estimate device lifetime versus device potential failure modes [29, 30].

In an industrial context, the challenge of reliability is to address new product and technology introduction, new material introduction, and manufacturing process change. The general methodology has to address both intrinsic and extrinsic potential failure [31–33]. Intrinsic failure mechanisms are strictly related to products design performance and relative vulnerability. Extrinsic failure mechanisms are related to all the supply chain steps involved in the product fabrication (wafer fabrication, assembly, testing, etc.).

During validation phase, the intrinsic vulnerability is assessed following standard international procedure (JEDEC) [32, 33]. In the specific case of MEMS, stress tests are customized in order to consider additional failure modes related to the strong interaction between environmental condition and mechanical elements that could affect device performances and mechanical robustness.

During MEMS production ramp-up phase, the extrinsic vulnerability is assessed. Generally, a time-reduced stress test is applied on a large amount of devices in order to investigate product marginality vs manufacturing process phase.

Several failure mechanisms have been found to be the primary sources of failure. Typical MEMS three-axis accelerometer failure mechanisms are:

- Lack of hermeticity.
- Parametric stability.
- Adhesion.

Lack of hermeticity is a serious failure mode, caused by presence of voids or cracks in the sealing material (glass frit or metal alloys) that is used to seal cap to sensor. It can be a time zero defect during wafer-to-wafer bonding or induced by thermomechanical stress that occurs during manufacturing (molding, soldering, etc.). Time zero defect can be detected at wafer level performing automatic scanning acoustic microscopy (SAM) control, while at package level it can be monitored submitting the plastic devices to moisture and performing accelerated THS (temperature humidity storage [33]) test. Customized THS is applied during product rump-up or reliability monitoring.

Parametric stability concerns zero-g level offset and sensitivity, and it is strongly affected by thermomechanical interactions between package and MEMS. Package thermomechanical stress induced by hygro-swelling for water absorption or high temperature excursion (e.g., soldering) can cause submicron displacement of movable parts that induces meaningful deviation on output parameters. In order to evaluate intrinsic susceptibility to hygro-swelling, dedicated reliability test should be performed during early qualification phase. This test may consist of putting device in a climatic chamber and monitoring sensor output (device soldered on application board) changing the percentage of relative humidity (Figs. 18.29 and 18.30).

Adhesion, for example, between movable mass and stoppers, is a phenomenon that appears when surfaces adhesion

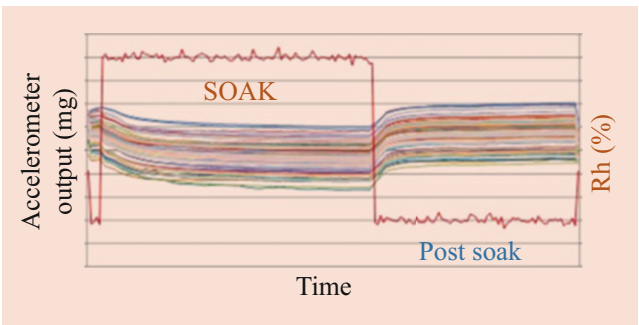

Fig. 18.29 Parametric output of an accelerometer sensor acquired during active soaking of the device in a variable humidity environment. This test has the capability to highlight potential weaknesses due to temperature and humidity – activated interactions between package and MEMS. (© 2018 by STMicroelectronics)

forces (electrostatic attraction, van der Waals forces, etc.) are larger than the mechanical restoring force of a suspended micromechanical element. It may occur during wafer manufacturing or device usage (in this case, it is known as in-use adhesion).

This phenomenon is activated in presence of electrical field, for instance, when device is powered and shocked with a low-g acceleration. Detection and characterization take place performing dedicated capacitance vs voltage (*CV*) measurements at electrical wafer sorting (EWS) and on final devices or monitoring the sensor outputs when a low-g acceleration is applied [34, 35]. This powered shock test is a good reproduction of possible in-use adhesion. In order to reduce the adhesion occurrence, the abovementioned tests are used to improve technology process and design, for instance, optimizing moveable mass stiffness.

18.6.7 Next-Generation MEMS Accelerometers

The evolution of MEMS accelerometers has improved dramatically the trade-off between conflicting requirements such as noise, full scale, accuracy, and power consumption.

Traditionally, high accuracy MEMS sensors were available only with very limited full scale, bulky packages, and power consumption in the mW region. Low-power accelerometers for consumer and wearable electronics applications, instead, offered state-of-the-art power consumption in appealing small packages at the expense of higher noise and limited accuracy.

High-g sensors were almost dedicated to automotive applications (airbag deployment, tire pressure monitoring systems – TPMS), where lower noise and offset accuracy performances could be easily forgiven (Table 18.3).

A clear path in next generation of MEMS accelerometers is the further improvement of the noise and accuracy vs full scale and power trade-off, due to the convergence of consumer, automotive, and industrial requirements [36].

Higher full scale of consumer accelerometers, beyond the traditional 16 g, could unleash a series of potential applications as shock monitor and detection that involves acceleration levels in the order of tens of *g* for human fall detection in wearable electronics equipment [37] up to thousands of *g* in the case of shock detection for mobile electronics. This would naturally be an add-on requirement to the standard accuracy and noise for low-g sensors, to preserve the level of user experience while adding more functionalities. Such high-g accelerometers can also be merged with accurate temperature sensors in order to provide valuable tracking information during shipment of goods.

Capacitive MEMS accelerometers are also tackling traditional applications usually served by bulk piezoelectric sensors. Good accuracy performances, together with high level of integration of the signal conditioning chain, small size, and reasonable cost, offer an appealing solution for industrial applications [38].

Preventive maintenance of mechanical equipment and structural health monitoring of buildings and bridges are key examples where the availability of affordable, reliable, and accurate sensors can make the difference in the cost-benefit analysis of the installation of sensor networks [39–41].

Integration of accelerometers in 6-degrees-of-freedom inertial measurement units (6-DoF IMUs) is today a mainstream direction for consumer and automotive non-safety applications.

18.7 Gyroscopes

Gyroscopes are sensors used to convert rotation rate input in an analog or digital output. Rotation rate, or angular velocity, is the amount of angle travelled in unit time during a rotation and is usually measured in degrees per second [dps].

18.7.1 Gyroscopes Introduction

MEMS gyroscopes are commonly based on Coriolis force, an apparent force arising in presence of a linear movement and a rotation of the frame of reference. The need for active excitation of the linear, or drive, movement and the higher intrinsic complexity in the design and realization of MEMS gyroscopes has slowed their introduction in the automotive and consumer applications, and only a decade after the successful introduction of MEMS accelerometers in the market, MEMS gyroscopes were commonly adopted in automotive and consumer electronics goods.

It was in the first half of 2000 that first quartz tuning fork gyroscopes achieved commercial success, and driver was again, as for MEMS accelerometers, automotive and aerospace industry. The availability of micromachining technology already matured for accelerometers enabled in the first years of 2010s the introduction of silicon MEMS devices matching the performance, size, and cost requirements of consumer electronics manufacturers.

At present, gyroscopes have a huge variety of applications, in the class of motion detection (e.g., in enhanced user interface in gaming consoles and smartphones, in rollover detection in automotive or in inertial navigation systems) or motion control (e.g., in antenna stabilization systems, electronic stability control in automotive or optical image stabilization in camera lens).

As happened for accelerometers, in the past years, MEMS gyroscopes evolved in several performance metrics, leading to small, accurate, and less power-hungry sensors (Fig. 18.31).

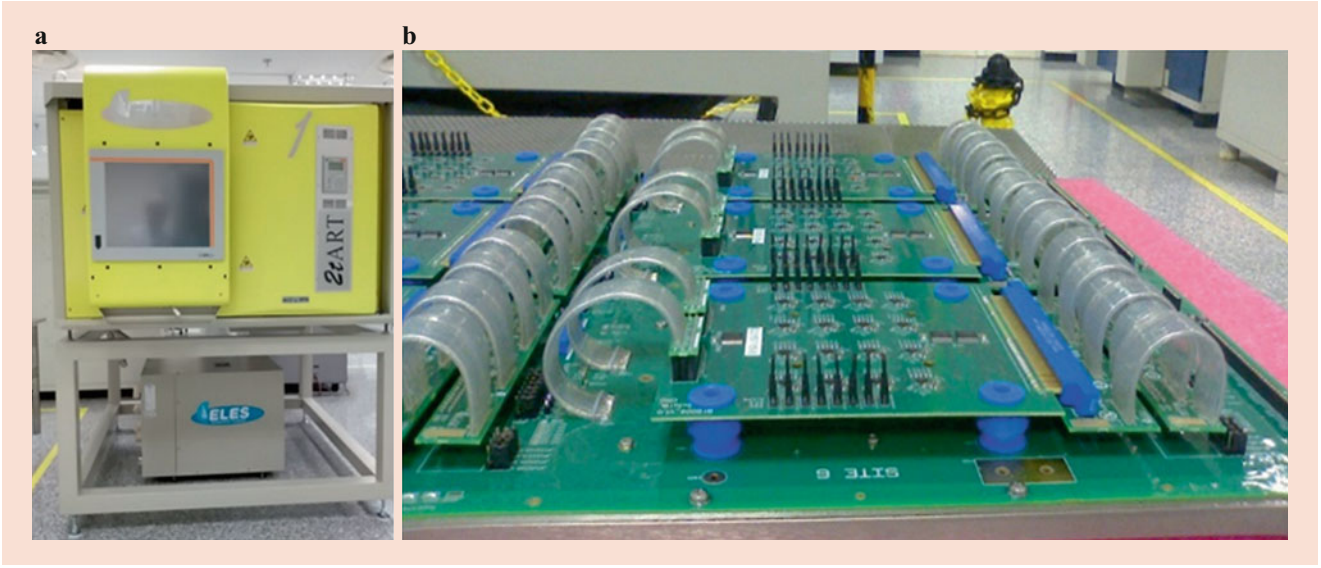

Fig. 18.30 (**a**) Dedicated climatic chamber with compressor outside (**b**) reliability board with adapter (16 parallel sites). Soft gimbals hold the board and flex cables connect board to adapter, minimizing external mechanical vibrations. (© 2018 by STMicroelectronics)

Table 18.3 Performance of Colibrys MEMS V1000 series accelerometers having different full-scale ranges. A great challenge for accelerometers is to break the trade-off full scale vs accuracy and noise, to enable applications based on shock detection without sacrificing traditional user interface functions

18.7.2 Gyroscopes Specifications

Key performance indicators for gyroscopes are similar to the ones described for the MEMS accelerometers: most critical ones are offset or bias, scale factor or sensitivity, noise, and power consumption.

Offset or bias is the output value of the sensor at zero input, usually referred to as zero rate level (ZRL). ZRL

Table 18.4 Bias stability and scale factor accuracy level for gyroscopes as a function of the grade and application. MEMS capacitive gyroscopes have created the consumer market and strongly penetrated the industrial and low-end tactical grades. Strong efforts are still needed for MEMS to be a viable substitute for ring laser gyroscopes (RLG) or fiber-optic gyroscopes (FOG) in the highest grade markets

Grade	Application	Bias stability $\left[\frac{^\circ}{h}\right]$	Scale factor accuracy [ppm]
Consumer	User interface	30–1000	5000–10,000
Industrial and low-end tactical	Guided ammunitions	1–30	100–5000
Tactical	Platform stabilization	0.1–30	10–100
High-end tactical	Missile navigation	0.1–1	1–10
Navigation	Aerospace inertial navigation	0.01–0.1	<1
Strategic	Submarine navigation	0.0001–0-01	<1

and its variation due to temperature, vibrations, or aging are critical parameters for gyroscopes, and they can range from few degrees per second (dps) in low-end systems down to few degrees per hour $\left[\frac{^\circ}{h}\right]$ in low-end tactical applications.

Competing technologies have clearly defined a benchmark for gyroscopes based on the achievable accuracy in the reconstruction of the angular position. Almost all available MEMS gyroscopes are of the rate type (i.e., they measure angular velocity); therefore the motion reconstruction algorithms need an integration to obtain absolute angle information. Errors in offset and presence of noise in the gyroscope output lead to inaccuracy in the integrated signal, strongly limiting the performances of the sensor. As presented in Table 18.4, bias stability is a key performance parameter to differentiate gyroscope performances.

18.7.3 Gyroscope System

Silicon MEMS vibratory gyroscopes are composed of an electromechanical part and a signal conditioning ASIC, encapsulated in a protective package.

The most common transduction mechanisms to actuate the gyroscope and read back the Coriolis signal are electrostatic actuation and capacitance variation, even if few MEMS gyroscopes exploit piezoelectric actuation/readout with quartz crystals or AlN thin films.

A common operation mechanism in MEMS gyroscopes is closed loop driving and open loop sensing. ASIC has the purpose of providing the actuation signal for drive movement,

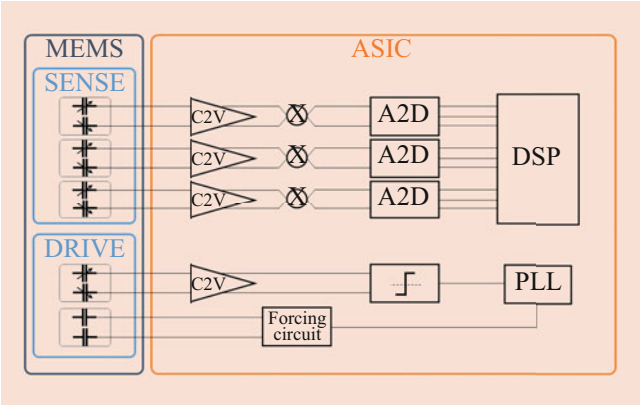

Fig. 18.32 MEMS gyroscope block diagram for sensor and ASIC. A common configuration for capacitive MEMS in consumer applications is closed loop drive and open loop sense. Differently from accelerometers, MEMS vibrating gyroscopes require a coherent demodulation to extract the rate value from the modulated Coriolis signal. (© 2018 by STMicroelectronics)

converting sense signal and operating coherent demodulation and proper filtering.

A feedback loop on ASIC collects the capacitance signal from the sense of drive electrodes, proportional to the MEMS displacement in the drive direction, and converts it to voltage through capacitance to voltage converter (charge amplifier). The signal is then filtered and squared to be fed into a phase locking loop (PLL) in order to adjust the phase difference and provide a forcing signal back to the drive electrodes on the MEMS.

The capacitance signal from sense electrodes is routed to a capacitance to voltage converter (charge amplifier) and then coherently demodulated. The baseband signal is properly filtered and then digitalized through an analog to digital converter (A2D). The digital signal is then processed by an onboard digital signal processor DSP (Fig. 18.32).

18.7.4 Capacitive MEMS Gyroscopes: Design Principles

A Coriolis vibratory gyroscope (CVG) is a classical 2-degrees-of-freedom oscillator. The first degree of freedom is commonly referred as the drive mode, which is kept at a fixed amplitude harmonic oscillation by a controlled closed loop to generate the Coriolis force on the perpendicular direction; the second degree of freedom is known as sense mode, or detection axis. An electrostatic force F_d is applied in the case of the drive mode to sustain oscillation: in most cases, this force is harmonic, of sinusoidal or square wave type, and it is applied at drive resonant frequency.

Regarding the sensing axis, the forcing term is represented by the Coriolis force, which is generated in the non-inertial

gyroscopic frame by the combination of the drive velocity due to harmonic oscillation and the external angular rate. The amplitude of this force F_{co} is.

$$F_{co} = -2mv_d \wedge \Omega_{ext} \tag{18.7}$$

A gyroscope can be seen as a system of two one-dimensional oscillators, one along the drive direction and one along the sense direction. In the case of a gyroscope made up of a two-symmetrical mass system, the above considerations remain valid, and the equation of motion for the drive axis oscillator will be

$$m_d\ddot{x} + r_d\dot{x} + k_d x = F_d \sin(\omega t) \tag{18.8}$$

where m_d, c_d, k_d, and $F_d \sin(\omega t)$ are, respectively, the mass, the damping coefficient, the stiffness, and the force applied to drive. If we introduce the quality factor term and the drive resonance frequency in above equation, we have as solution for the drive displacement amplitude Δx_d

$$\Delta x_d = \frac{\frac{1}{m}}{\sqrt{\left(\omega_d^2 - \omega^2\right)^2 + \left(\frac{\omega_d}{Q_d}\omega\right)^2}} F_d \tag{18.9}$$

where ω_d and Q_d are the resonant frequency and quality factor of the drive oscillator.

In a capacitive Coriolis vibratory gyroscope (CCVG), both the drive and sense axes are, respectively, forced and sensed by means of a set of electrostatic system of capacitors.

The electrodes exploited to actuate and read the oscillation signal of the drive axis are usually of comb-finger type, as showed in Fig. 18.33. This kind of capacitors is arranged as a comb-like interdigitated structure. A voltage difference is applied between the fixed stator fingers and the movable comb structures: this will result in a displacement of the movable mass by means of the electrostatic forces. The force exerted by a set of N comb capacitors is expressed by

$$F_d = \frac{1}{2}\frac{\partial C_d}{\partial x}\Delta V^2 \rightarrow F_d = \varepsilon N \frac{t}{g_0}\Delta V^2 \tag{18.10}$$

Since the dependence of force on voltage is quadratic, to eliminate the constant and the double frequency terms the voltage difference ΔV it is usually made up of a DC plus an AC term so that:

$$(V_{DC} + V_{AC}\sin\omega t)^2 = V_{DC}^2 + V_{AC}^2 \sin 2\omega t + 2V_{DC}V_{AC}\sin\omega t \tag{18.11}$$

The voltage difference is applied to a double differential set of electrodes, driven in antiphase with respect to each other (double differential forcing). According to this scheme, the forcing of the oscillating drive system will become

$$F_d = 4\varepsilon N \frac{t}{g_0} V_{DC}V_{AC}\sin\omega t = 2\frac{\partial C_d}{\partial x} V_{DC}V_{AC}\sin\omega t \tag{18.12}$$

Since the varying dimension is the lateral facing L of the comb fingers, this solution ensures high forcing linearity over the necessary displacement range.

For the same reason, the drive displacement too is read by means of a set of sensing drive electrodes. The capacitance variation, which is commonly fed into a feedback loop, is

$$\Delta C_{sd} = \frac{\partial C_{sd}}{\partial x}\Delta x_d \tag{18.13}$$

The displacement y of the sense electrodes is usually read by a set of parallel plate electrodes, which ensure higher capacitance change with respect to comb structures:

$$\Delta C_{PP} = \varepsilon A\left(\frac{1}{g_0 - y} - \frac{1}{g_0}\right) \approx \frac{\varepsilon A}{g_0^2} y \tag{18.14}$$

In these sensing structures, the variable dimension is the gap; therefore the electrostatic force will be dependent on displacement and nonlinearity. The electrostatic force will be directed along y-axis and its magnitude will be

$$FS = \frac{1}{2}\frac{\partial C}{\partial y}V^2 = \frac{1}{2}\frac{\varepsilon A}{\left(g_{0y} - y\right)^2}V^2 \tag{18.15}$$

The dependency of the force on the position, usually referred to as electrostatic softening, is crucial as it changes the actual elasticity, adding a term of this type to the equation of motion:

$$k_{el} = -\frac{\varepsilon A}{g^3}V^2 \tag{18.16}$$

An example of a ThELMA gyroscope design is the single-mass three-axis gyroscope, better known as the beating heart. Launched in production in high volumes on 2010, this design has been the first three-axis single-mass gyroscope design on the market. The mechanical structure design is explained with the aid of Fig. 18.34.

Four coupled plates, linked by springs, compose the structure; the first vibration modes of the mechanical structure consist in one drive mode and three sense modes: the primary mode (driving mode) is an auxetic expansion of the four masses in-plane. Two opposite masses host the actuation comb fingers used to generate the driving force, while the other two masses are forced to move in phase by the 45° coupling springs. Secondary vibration modes (sensing modes) are identified as pitch and roll modes, in which two opposite

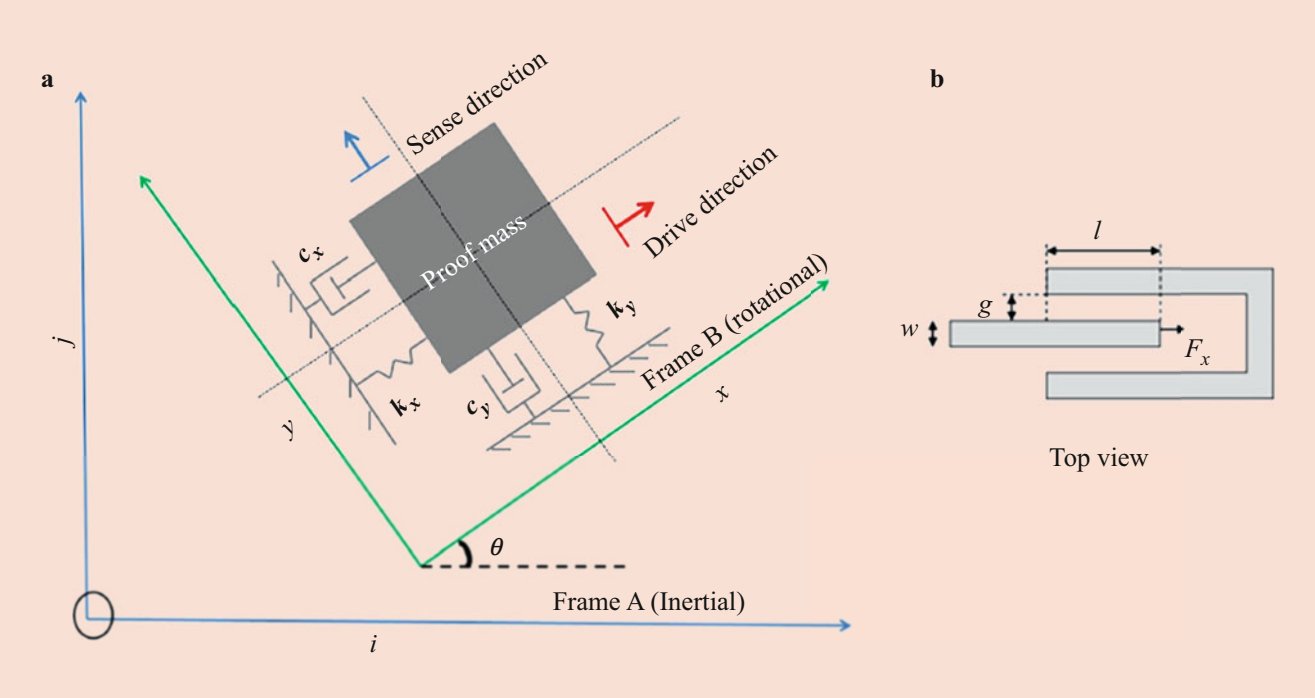

Fig. 18.33 (**a**) 2-degrees-of-freedom spring-mass damper system is shown as a lumped description of Coriolis vibrating gyroscope. Fig. 18.34 Example of STMicroelectronics ThELMA three-axis gyroscope. (**a**) SEM image of the mechanical structure. (**b**) Vibration modes of the gyroscope. (© 2018 by STMicroelectronics)

masses vibrate in antiphase out-of-plane, and yaw mode, in which all the four masses rotate in-phase in-plane.

Sense pickup electrodes are located below the moving masses for pitch and roll modes, while yaw electrodes are constructed with parallel plates standing out from the substrate. The Coriolis force directly excites the sense modes, generating a movement of the proof mass in the sense direction and inducing a differential capacitance change in the sense electrodes [42].

18.7.5 Capacitive MEMS Gyroscopes: Process Flow

A key requirement for the wafer bonding for MEMS gyroscopes is the possibility to achieve low bonding pressure down to few tenths of mbar in the sealed cavity. In fact, the presence of an actuation mechanism in the gyroscope architecture implies a low damping of the drive motion in order to reduce the power consumption of the device.

High vacuum level can be achieved in MEMS gyroscopes thanks to the integration on the cap wafer of a getter layer. This layer allows the absorption of not inert gas species present in the bonding cavity, ensuring the achievement of a bonding pressure lower than 1 mbar and a reduced spread in the cavity pressure. This reduced spread translates also in more uniform electrical performances of the devices across wafer, wafer-to-wafer and run-to-run. In addition, getter films ensure the stability of the vacuum package over time due to film capacity to getter the gas species that are desorbed by the MEMS package surfaces during device lifetime.

18.7.6 Reliability Challenges for MEMS Gyroscopes

Since gyroscope shares with accelerometers a large part of the manufacturing flow, many failure modes are common to both accelerometers and gyroscopes. Some failure mode and their techniques of investigation reported hereafter were already discussed on previous accelerometer section. Nonetheless, gyroscopes have their specific critical issues related to the high Q factor of the resonance modes [31].

For gyroscope, typical failure mechanisms are:

- Lack of hermeticity.
- Parametric stability.
- Mechanical robustness.

Lack of hermeticity is a serious failure mode caused by presence of voids or cracks in the sealing material that is used to seal cap to sensor. It can be a time zero defect during wafer-to-wafer bonding or induced by thermomechanical stress that occurs during manufacturing (molding, soldering, etc.). This failure mode can be detected at wafer or product level, performing automatic SAM control or THS reliability test, as for accelerometers. In addition, since quality factor of gyroscope is strictly related to hermeticity, quality factor is a key parameter to detect lack of hermeticity with high accuracy, and this measurement is done at both electrical wafer sort and final test.

Parametric stability concerns zero rate level and sensitivity and it is strongly affected by thermomechanical interaction between package and MEMS. As said for accelerometer, also for gyroscope any package thermomechanical stress induced by hygro-swelling for water absorption or high temperature excursion can modify gyroscope quadrature having meaningful consequence on ZRL or sensitivity accuracy. One of most important reliability tests to evaluate gyroscope parameter stability against moisture is to put device in a climatic chamber and monitor sensor output changing the humidity. This method is the same used for accelerometer.

Based on our experience, gyroscope performance is influenced by debris produced by mechanical shock [43]. Besides, shock amplitude is amplified due to high-quality factor of gyroscope. Main procedures used to assess mechanical robustness are based on the following three reliability tests: vibration, mechanical shocks, and drops [34, 44].

Vibration test is suitable to reproduce the mechanical effects generated during transportation or normal usage in range of some tens of g. The test is not relevant for the evaluation of robustness versus usage incidents.

Mechanical shocks and drops are instead targeting shock acceleration level up to hundreds of thousands of g, well simulating effect during handheld stresses [35]. Mechanical shock test can be performed using a pneumatic machine, which combines falling height and pressurized air to produce mono-axial and repeatable shock. Adding a special fixture, acceleration level can range from 500 to 20,000 g (see Fig. 18.35).

Drop test is a free fall that can be done on various hard surfaces and from different heights. This method allows reaching very high acceleration levels up to 200,000 g.

Tumble is a rotating machine able to produce repetitive random free fall drops in a controlled repeatable manner (see Fig. 18.35). We exploited it performing drop test on high quantity of packaged gyroscope, allowing characterizing its mechanical robustness more accurately. This methodology can be applied during early qualification phase or reliability monitoring [45].

18.7.7 Next-Generation MEMS Gyroscopes

The evolution of MEMS gyroscopes has two clear paths to be followed: strong reduction of power consumption to enable low-power applications and improvement of sensor performances to tackle high-value applications in the tactical grade market.

Power consumption of state-of-the-art MEMS gyroscopes dramatically improved in last years, falling for consumer sensors more than one order of magnitude for high performance operative mode. The power reduction has been achieved in parallel to great increase of performances in terms of noise and bias stability. Nevertheless, power consumption gap is still huge compared to MEMS accelerometers, preventing gyroscopes to be used in ultralow-power, always-on applications popular in the current internet of things and activity monitoring era. Current state-of-the-art, ultralow-power MEMS capacitive gyroscopes operate with less than half mA current drain, more than two orders of magnitude higher power consumption than low-power accelerometers. The actuation of drive mode and the modulation of the signal over acoustic are fundamental differences between

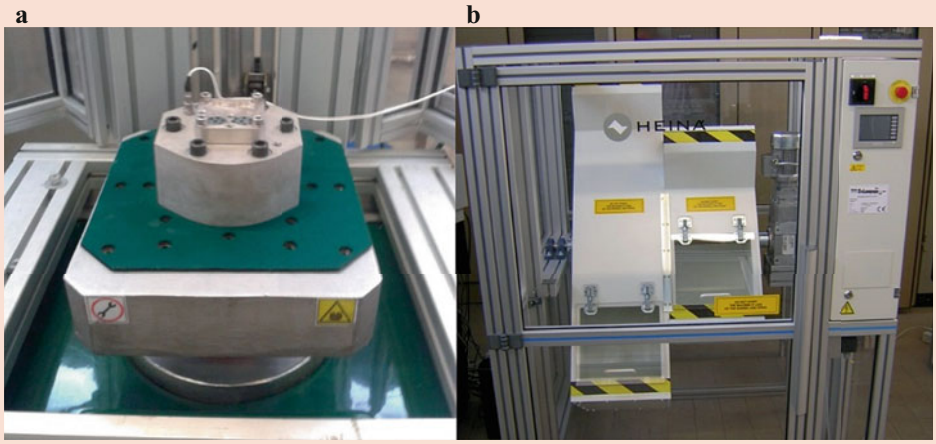

Fig. 18.35 (**a**) Pneumatic shock machine: particular of the carriage and fixture acting as shock amplifier. (**b**) Example of equipment used for tumble test. It is a rotating machine where devices are repeatedly dropped. (© 2018 by STMicroelectronics)

MEMS gyroscopes and accelerometers, limiting the power consumption reduction.

Accuracy improvement is the second trend driving MEMS gyroscopes' development in next years. In the automotive field, ADAS (advanced driver assistance system) and self-driving cars will soon demand performances close to low-end tactical grade sensors. This can be achieved with increased complexity in the architecture, with dedicated quadrature compensation structures and use of closed-loop quadrature cancellation and sense.

Another promising path is to use low-end sensors with good performance capabilities and either redound them or place in a controlled enclosure and compensate drifts of key parameters (bias, scale factor) with an external microcontroller.

Integration of accelerometers in 6-degrees-of-freedom inertial measurement units (6-DoF IMUs) is today a mainstream direction for consumer and automotive non-safety applications.

18.8 Microphones

A microphone is an acoustic transducer able to convert sound into an electric signal. Sound is a pressure wave with frequency in the range 20 Hz–20 kHz (audio band) and pressure that ranges between 20 μPa (audible threshold) and several tens of Pa. In order to detect this physical quantity, microphones need a moving element, usually a membrane, vibrating when reached by sound, and some transduction principle (i.e., capacitive or piezoelectric) to convert this vibration in an electrical signal, i.e., a voltage or charge variation.

MEMS microphones are widely adopted in a large number of devices because of their small size, low cost, good performances, and high part-to-part repeatability. Moreover, a key feature of MEMS microphone success is compatibility with surface mounting, whereas electret microphones require a dedicated and more expensive soldering process.

18.8.1 Microphones Introduction

A MEMS microphone is made of a sensor, an ASIC, and a package, as shown in Fig. 18.36.

Sensors convert sound pressure into an electrical signal. Two transduction principles are commonly adopted in MEMS microphones: capacitance variation or direct piezoelectric effect. Fabrication adopts semiconductor technology blocks and dedicated micromachining process steps. Several possible implementations are possible and will be discussed in detail in Sects. 18.8.2 and 18.8.3.

ASICs have different functions: providing proper polarization to the sensor if needed, performing signal readout, conditioning, and elaboration (i.e., buffering, analog to digital conversion). Both analog and digital output are widespread. Digital signal is usually in PDM (pulse density modulation) format; I2S (integrated interchip sound) is also available.

Package is a key element in microphones. It protects sensing element and IC, as in all MEMS devices, but it also deeply affects performances of the system. Typical microphone package is a cavity, made of a land grid array (LGA) substrate and a metal or organic cap, as shown in Fig. 18.36. Sensor and ASIC are attached to the substrate and electrically connected, usually via wire bonding. A hole in the substrate or in the cap (sound port) allows sound entering the cavity. Dimensions of cavity and sound port have a significant effect on microphone performance.

A brief review of the most significant parameters for a microphone helps to understand the most important constraints in their design and fabrication.

Sensitivity is defined as output signal on input pressure where input pressure is 1 Pa RMS (94dBSPL) at 1 kHz. Unit is dBV (RMS voltage signal at 1 Pa) for analog microphone and dBFS (signal at 1 Pa related to ADC full scale) for digital microphones. Commercial products commonly adopt some standard levels (i.e., −38 dBV for analog microphones and −26 or −41 dBFS for digital microphones) in order to be fully compatible with the readout chain. Part-to-part spread is key: state of the art is sensitivity within ±1 dB.

Frequency response is the output behavior across the frequency range, as shown in Fig. 18.37. All MEMS microphones have a low-frequency roll-off: sensitivity decreases toward lower frequencies. Roll-off point is defined as the frequency where signal is 3 dB lower than its 1 kHz value. This phenomenon is due to the need of a ventilation hole in the membrane to equalize static ambient pressure: without this hole, microphone would act as a pressure sensor, since ambient pressure is several magnitude orders higher than sound pressure. This ventilation hole acts as an alternative path for the sound, subtracting part of the signal from the membrane. Roll-off frequency can be set by ventilation hole design and is usually below 100 Hz (a typical choice is 35 Hz).

At higher frequencies, package acts as a Helmholtz resonator: a resonance peak is therefore present in the range of 15–20 kHz or slightly above 20 kHz, as shown in Fig. 18.37. A wide and short sound port helps to move this peak toward higher frequencies.

Total harmonic distortion (THD) measures the alteration of the signal frequency content. It is given by the formula

$$\mathrm{THD} = \frac{\sqrt{A_2{}^2 + A_3{}^2 + A_4{}^2 + A_5{}^2}}{A_\mathrm{F}} \tag{18.17}$$

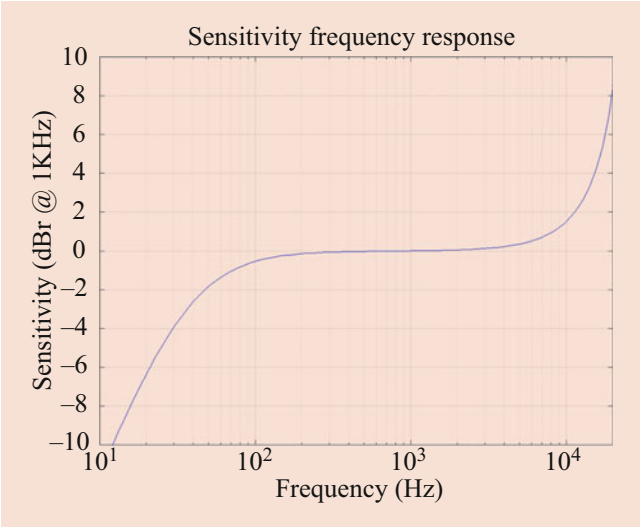

Fig. 18.37 Typical MEMS microphone frequency response. (© 2018 by STMicroelectronics)

where A_f is the amplitude of the fundamental component and $A_2, A_3, \ldots, A_\mathrm{n}$ are the amplitudes of the second, third, …, nth components, respectively. Usually, first five harmonics are included. For a signal at 1 kHz, state of the art for THD is below 0.1% at 94 dBSPL and below 4% at 130 dBSPL. Main contributors to THD are sensors' intrinsic transduction nonlinearity and amplifier nonlinearity.

Signal-to-noise ratio (SNR) is the ratio between sensitivity at 1 kHz and integrated noise floor in audio band (A-weight is usually applied). Noise contributions come from both sensor and ASIC. Sensor noise is generated by different dissipation mechanisms, both acoustic-mechanical and electrical: the most important are fluidic squeeze film damping in capacitive microphones and material losses in piezoelectric microphones.

Package strongly influences microphone performances. Cap cavity adds a backchamber compliance in series to membrane compliance. Backchamber is an additional stiffness that opposes to membrane movement, therefore affecting sensitivity. Backchamber compliance is defined as [48]

$$C_\mathrm{back} = \frac{V_\mathrm{back}}{\rho c^2} \tag{18.18}$$

where V_back is backchamber volume, ρ is air density, and c is speed of sound in air.

Therefore, the larger its volume, the lower the stiffening effect. To increase sensitivity, backchamber volume should be as large as possible: there is an evident trade-off with package miniaturization.

Another acoustic effect related to package is the high-frequency resonance peak described before, physically corresponding to a Helmholtz resonator, due to sound inlet and

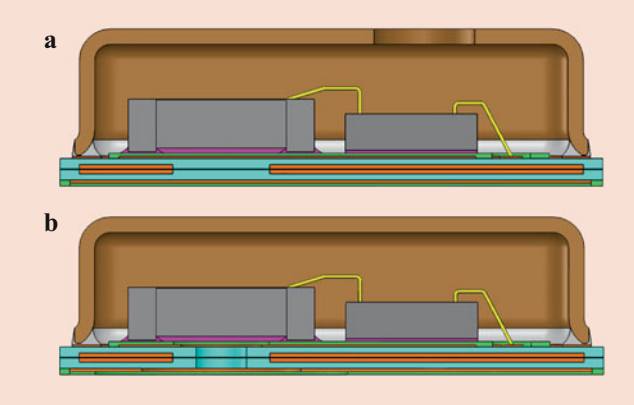

Fig. 18.38 (**a**) Scheme of a top port MEMS microphone. Sound inlet is located in cap. Backchamber is MEMS cavity. (**b**) Scheme of a bottom port MEMS microphone. Sound inlet is located below MEMS. Backchamber is the whole package volume. (© 2018 by STMicroelectronics)

frontchamber. In order to shift the resonance peak toward higher frequencies, frontchamber volume must be as small as possible, and sound inlet should be short and wide.

Microphone packages can adopt a top port or bottom port configuration, as shown in Fig. 18.38. The former has sound inlet in the cap, frontchamber is package inner volume, and backchamber is MEMS internal cavity. The latter has sound inlet in the substrate, below MEMS, frontchamber is MEMS internal cavity, and backchamber is package inner volume.

From what was discussed before, bottom port configuration gives better performances, both in terms of higher sensitivity (larger backchamber) and flatter frequency response (smaller frontchamber, corresponding to high-frequency resonance peak).

To understand microphone behavior and interactions between MEMS and package, it is possible to exploit an electromechanical-acoustic analogy. Interested readers can find more details in Ref. [46–48].

18.8.2 Capacitive MEMS Microphones

Capacitive sensing is the most widely used sensing principle in MEMS sensor industry. It is by far the most successful example of sensors.

A capacitive MEMS microphone is a capacitor where one of the plates is fixed and the other one is the membrane: its movement induces a capacitance variation.

In first approximation, MEMS sensor can be modelled as a parallel plate capacitor. Since plate area is much larger than air gap thickness, capacitance can be calculated as

$$C = \frac{A\varepsilon_0}{d_0 - kP} \tag{18.19}$$

where A is capacitor area, ε_0 is vacuum dielectric constant, d_0 is the initial air gap thickness, k is the equivalent mechanical spring constant of the membrane, and P is the applied acoustic pressure.

Under a sound pressure, membrane movement changes plate distance and capacitance varies accordingly. Capacitance is inversely proportional to displacement, i.e., the relation is nonlinear.

For small gaps, the capacitance change as a function of the displacement can be very large, making this technique suitable for high-resolution sensing of small displacements.

For a capacitor,

$$Q = C * V \tag{18.20}$$

If a constant charge is stored on the plates, a variation of C induces a variation of V: this voltage signal is read by the ASIC and further processed if needed. Constant charge is provided by the ASIC through a charge pump.

The basic structure of a capacitive microphone comprises several elements. A movable membrane acts as the first plate of the capacitor. Many geometries are possible and the membrane can be fully clamped on its entire perimeter or suspended via springs or bumps. Membrane design, materials, and thickness have a strong impact on microphone sensitivity.

The second plate of the capacitor is known as backplate. It must be much stiffer than the membrane since it is the reference side of the capacitor. Therefore, backplate is usually thicker and comprises a large number of acoustic holes for air to pass through. Both membrane and backplate must be conductive or comprise at least one conductive layer (electrode).

Between the two plates, an air gap is present: its thickness defines microphone sensitivity too. The air gap is fabricated using a sacrificial layer, removed at the end of the process.

A ventilation hole must be included to reject ambient pressure. In case of suspended membranes, any small gap between membrane edge and anchored area acts as a ventilation hole: generally, an overlap between membrane and substrate is present, and roll-off point can be controlled with a proper choice of overlap length and distance between membrane and substrate. Holes on membrane can also be added, in case of both suspended and fully clamped membrane.

MEMS sensitivity is determined by:

- Capacitance value, related to membrane area and air gap thickness.
- Membrane mechanical compliance, set by its thickness, residual stress, and spring geometry (if springs are present).
- Backchamber volume.
- Bias applied on the two plates.

ASIC applies a variable bias, so providing a sensitivity tuning. At final test, natural sensitivity of the microphone is measured and calibrated adjusting bias, in order to match tight sensitivity specifications.

All fluidic resistances are associated to a noise source. Main noise sources in the sensor are due to squeeze film damping. Figure 18.39 reports a typical power density spectrum of the different noise sources in the MEMS. A first noise source is the thin air gap between membrane and backplate. Proper design of acoustic holes in the backplate can minimize damping, but there is a trade-off between noise reduction and sensitivity (the larger the holed area, the less the capacitance area). An additional squeeze film damper is the ventilation hole, if membrane edge is not clamped. Sound inlet is a noise source too, even if generally less important.

Since noise is integrated in audio band, resonance peak position plays an important role. Noise transfer function has a resonance peak in the same position of sensitivity transfer function. Therefore, if resonance peak is close to the center of the band, integrated noise value will be higher than if the peak is close to band edge or outside audio band.

Final microphone SNR will depend on both MEMS noise, described above, and ASIC noise.

A typical process flow for capacitive microphones, illustrated in Fig. 18.40, comprises at first a deposition or growth of a first sacrificial layer and its patterning (a): a common choice is silicon oxide. Then the membrane is deposited and patterned (b): this layer must be conductive to act as the movable plate of the capacitor. A common choice is polysilicon or a stack of polysilicon and silicon nitride. This step is followed by deposition and patterning of a second sacrificial layer (c). Thickness of this layer will define air gap thickness. Silicon oxide is often used. Then the backplate is fabricated (d). Materials are usually polysilicon, silicon nitride, or a stack of the two. Silicon substrate etch allows opening a cavity below the active structure (e). This cavity is mandatory to allow sound to flow. Deep reactive ion etching (DRIE) or wet silicon etch can be used. Final release is used to free movable parts (f). HF wet etch is typically used for silicon oxide sacrificial layers.

18.8.3 Piezoelectric MEMS Microphones

Piezoelectricity is a property of several materials with noncentrosymmetric crystal structure. In these materials, a deformation of the structure can change the distance between the atoms, thus creating a polarization and a nonzero electric field (and vice versa).

In a piezoelectric material, a strain across the material induces a charge piling upon its surfaces (direct piezoelectric effect). On the other hand, when an electric field is applied, this generates a variation of strain in the material and, generally, a variation in its geometrical dimensions (converse piezoelectric effect).

Piezoelectric material can be integrated in silicon technologies as thin films: PZT (lead zirconate titanate) and AlN (aluminum nitride) are the most common materials.

Piezoelectric fundamental equations can be written in different forms. We just recall the linear equations in stress-charge form:

$$D_k = e_{kij} \cdot S_{ij} + \varepsilon_{ki} \cdot E_i \tag{18.21}$$

$$T_{ij} = c_{ijkl} \cdot S_{kl} - e_{kij} \cdot E_k \tag{18.22}$$

where D is the electric displacement vector, e is the piezoelectric constants matrix, S is the strain tensor, T is the stress tensor, ε is the dielectric constants matrix, c is the elastic constants matrix, E is the electric field vector in the material, and i, j, and k are matrix indices. From these equations, there is a full electromechanical coupling, i.e., both stress and electrical displacement depend simultaneously on mechanical properties (strain) and electrical properties (electric field). The piezoelectric coefficients e couple strain and electrical displacement: the larger these coefficients, the higher the charge piled up at a given strain.

Piezoelectric MEMS microphones exploit direct piezoelectric effect. A piezoelectric material is present somewhere in the sensor movable area. Membrane movement induces a strain inside the piezoelectric material and this generates charge piling up on the electrodes. Usually microphones are made of movable cantilevers or membranes. Piezoelectric material is on top of these mechanical elements, sandwiched between a top and a bottom electrode. Therefore, the most important piezoelectric coefficient is e_{31}, coupling in plane strain (due to thin structure deflection) and electrical displacement along Z-axis.

Typical embodiments of piezoelectric microphones are cantilever-like structure (not necessarily of rectangular shape) or membranes where piezoelectric material is deposited in the regions where strain is higher. Proper placement of the piezoelectric material is needed to achieve acceptable sensitivity and good linearity. Multilayers of piezoelectric material can be used to increase conversion efficiency. Sometimes the whole structure is made only of the piezoelectric stack, without any sustaining layer.

Most of the acoustic considerations done for capacitive microphones are valid for piezoelectric microphones too. Particularly, the interactions with the package are the same and the need for a ventilation hole is still present. This can be a hole in the membrane or can be the gap between different cantilevers.

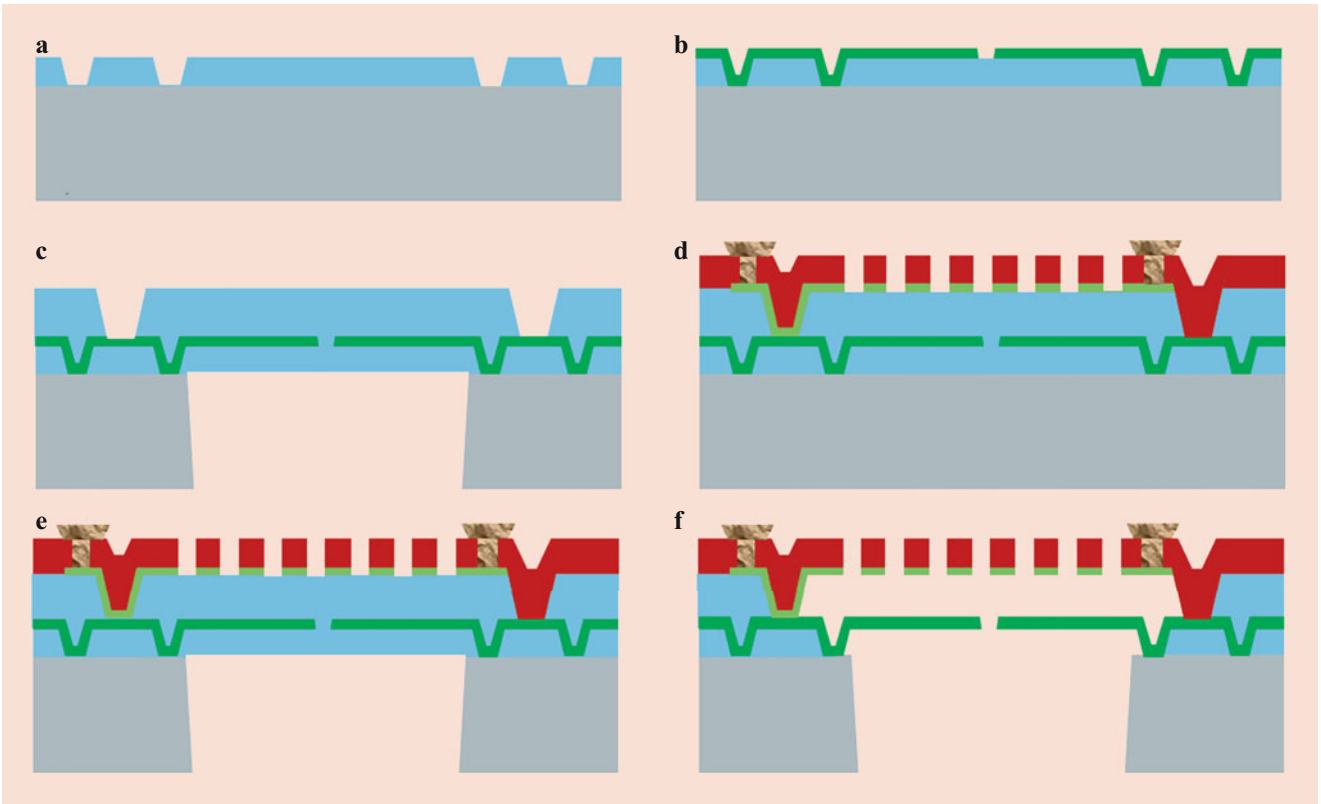

Fig. 18.40 Typical process flow for a capacitive MEMS microphone. Details of each figure in the text. (© 2018 by STMicroelectronics)

As far as noise is concerned [49], piezoelectric microphones generally have just one layer; therefore no squeeze film damping is present. On the other hand, main noise source in these microphones is piezoelectric material losses, i.e., unwanted charge flow from the electrode due to deviation of the piezo layer from the ideal dielectric. For this reason,

AlN is the preferred solution for microphones due to its very low material losses. This noise source can be modelled as a current generator in parallel with piezo capacitance and resistance. Resistance value is given in

$$R_p = \frac{1}{2\pi f C_p \tan(\delta)} \tag{18.23}$$

where f is frequency, C_p is capacitance of the piezoelectric element, and $\tan(\delta)$ is a parameter related to material losses. Noise therefore depends on both material properties and capacitance value.

MEMS sensitivity in piezoelectric microphones is determined by both piezoelectric coupling efficiency and acoustic and mechanical effects. Therefore, sensitivity depends on:

- Capacitance value, related to piezoelectric material area and thickness.
- Piezoelectric coefficients.
- Structure mechanical compliance, set by thicknesses, residual stresses, geometry of springs, and piezo stack.
- Backchamber volume.

No bias is applied by ASIC and sensitivity trimming is achieved only by changing amplifier gain. Proper control of residual stresses, affecting mechanical sensitivity, and piezoelectric coefficients is mandatory.

A typical process flow for piezoelectric microphones, illustrated in Fig. 18.41, comprises deposition or growth of a first sacrificial layer and its patterning (a): a common choice is silicon oxide. Then the active structure is fabricated (b). There can be a mechanical layer with piezoelectric stack on top in selected areas, or the whole structure can be made directly of the piezoelectric stack. Piezoelectric stack is generally made of a bottom electrode, piezoelectric layer, and a top electrode (c). Most common choice for piezoelectric material is AlN due to its very low losses. Common choices for electrodes are Mo and Ti. Multiple stack are possible: usually only unimorph or bimorph stacks are adopted due to technological complexity. Silicon substrate etch allows opening a cavity below the active structure (d). This cavity is mandatory to allow sound to flow. Deep reactive ion etching (DRIE) or wet silicon etch can be used. Usually, final release to free movable parts is not necessary, since there is just one single layer. Therefore, cavity opening is usually sufficient to release movable structure.

18.8.4 Reliability Challenges for MEMS Microphones

MEMS microphone qualification strategy involves both standard ICs tests and dedicated tests based on customer requests. In tests based on standard specifications, common to ICs, test conditions are defined by standards, and parts are measured in socket using standard final testing equipment. Some examples of standard test are HTOL (high temperature operating life), HTSL (high temperature storage life), TC (thermal cycles), ESD&LU (electrostatic discharge and latch-up), and so on.

Tests based on customer specification are usually carried on with parts soldered on quality boards and tested with a dedicated bench setup. Frequently, these tests are aimed to mechanical robustness. Some examples are MS (mechanical shocks), VFV (variable frequency vibrations), free fall, and CAT (compressive air test).

Main failure mechanism for MEMS microphones is contamination. Whereas inertial sensors are hermetic, microphones have a cavity package and a hole in the substrate or in the cap (sound port) and therefore are more exposed to external contamination. This contamination is killer for microphone functionality in terms of reduced SNR and sensitivity. Proper choice of assembly line class is therefore very important.

Another possible failure mode is cap detachment in the cavity package. Cap detachment is typically caused by mechanical overstresses but can also be caused by thermal stresses. Some examples of possible mechanisms causing cavity detachment are:

- Incomplete dispense of the solder paste or glue.
- Wrong reflow profile: if the reflow profile differs from the standard one, the glue on the package can be weakened, losing its fixing capability.
- Free fall over a rigid surface from more than 1 m.
- Wrong cut line in the separation of single components from the strip.
- Force exceeding a threshold (typically 2.5 g) for tape removal.

In the case of cavity detachment, a fail in any audio parameter (sensitivity, SNR, frequency response, THD) can be observed.

Another key aspect for quality and reliability of microphones is mechanical robustness. Smartphones are the main application of MEMS microphone and mechanical overstress related to drop event is common in the field: for this reason phone makers have defined specific tests, such as guided free fall test and tumble test. Such tests are performed with components mounted on a dedicated board with cover to simulate the phone dimensions and weight, in order to reproduce the real mechanical stress on MEMS and to investigate possible failure mechanisms related to package and solder joint reliability. Due to its very thin thickness, broken membrane is one of the main experienced failure modes. Backplate breakage is also possible.

18.9 Pressure Sensors

Pressure sensors have long been in service measuring pressure and flow in a variety of industrial, automotive, and medical applications. Micro-machined pressure sensors are fabricated in silicon with the physical sensing mechanism being either a variable resistance or a variable capacitance. The interface circuitry that converts resistance to voltage or capacitance to voltage can be integrated at chip level or at package level, as for motion sensors. The system in package solution guarantees faster commercialization time and higher flexibility for the customer.

18.9.1 Pressure Sensors Introduction

The fabrication of pressure sensors is either bulk or surface micromachining or a combination of the two. Standard silicon substrates or more expensive silicon-on-insulator substrates are equally used as a starting point [50].

The variable capacitance pressure sensor uses two parallel plates. One is fixed and the other is a thin diaphragm moving in an orthogonal direction to the plane of the chip under the pressure load. A very small change in capacitance then occurs between these two plates. Surface micromachining methods are preferred for this class of pressure sensors.

Piezoresistivity is among the oldest material properties used for the implementation of micro-machined silicon transducers. Since Charles Smith discovered at Bell Labs in 1954 [51] the exceptionally large resistance change in silicon and germanium samples, industry has produced increasingly complex sensors based on piezoresistivity with strain, force, pressure, acoustic, and inertial applications. All piezoresistive transducers operation is based on the deformation due to a load of a mechanical structure, on which piezoresistors are implanted or attached. Typically, a Wheatstone bridge is used to measure the resistance change by converting it in a voltage. Depending on the application, the form and the extension of the piezoresistors will vary together with the mechanical structure subject to the load.

The variable resistance pressure sensor uses the piezoresistive nature of silicon to convert stress in a small diaphragm into a very small resistance change. Bulk micromachining technology was for long the preferred technique. In the last 15 years, companies like Bosch [52] and STMicroelectronics have introduced single wafer surface micromachining processes to create a single crystal silicon membrane and vacuum cavity without any bonding steps.

No ideal manufacturing process exists, but each company follows the micromachining approach that best exploits its experience and its manufacturing assets. Nonetheless, because of the plethora of processes running in different semiconductor fabs, payers in the high-volume consumer market had to accept compromises related to price, size, and performance of the pressure sensor.

The first miniaturized devices had relatively low performance if compared with today's standards. Conventional silicon/glass pressure sensors were fabricated by anodic bonding technique, which translates in output instability in terms of offset drift, hysteresis over temperature, and humidity due to thermal mismatch or bonding interface built-in stress.

18.9.2 VENSENS™ Pressure Sensor

After the introduction of single wafer monolithic membranes, the consumer market became approachable for inexpensive packaged pressure sensors. The VENSENS™ process for pressure sensors by STMicroelectronics enabled high-volume production with 2.5 × 2.5 × 1 mm^3 package. A monolithic MEMS die, shown in Fig. 18.42, with a small

footprint (0.7 × 0.7 × 0.3 mm^3) combined with an ASIC was able to detect the altitude with good accuracy (±1 mbar) over the full temperature (−40 to 85 °C) and pressure (260–1260 mBar) range.

The VENSENS™ process begins with a standard silicon wafer. A proprietary process with successive steps of dry silicon etching, silicon epitaxial growth, and annealing enables the formation of a vacuum cavity layer with on top a single crystal silicon layer. (Fig. 18.43).

The thickness of the vacuum cavity can be tuned to be in the order of few micrometers and the same holds for thickness of the structural layer. The result is very similar to what is possible to get with bulk micromachining wafer-to-wafer bonding, but the big advantage is to have thinner, smaller, and mechanically more robust chips. Moreover, the sealing of the cavity requires no wafer-to-wafer bonding and thus the reliability of the sealing joint is definitely higher.

Because of the superior electrical properties of the monocrystalline silicon, high-quality, stable resistors can be integrated in the structural layer through implantation or diffusion process. Then these resistors are connected with an aluminum metal layer to realize the four branches of a Wheatstone bridge. The bridge is sensitive to pressure changes due to the excellent piezoresistive properties of the monocrystalline silicon layer.

The metal layer is then covered with a standard dielectric, like silicon oxynitride, to provide the required protection against the external corrosive agents.

18.9.3 Bastille™ Pressure Sensor

In addition to the fabrication cost, the sensor performance including output stability has become more and more an important concern. Applications like health and fitness monitoring, indoor and outdoor tracking altimetry, require more and more require accurate devices down to the centimeter of altitude error. In cost-effective consumer microsystem packaging, the sensor is soldered onto a printed circuit board (PCB). Traditional glue-stacked MEMS sensors easily suffer instability induced by packaging stress and thermal drift of the sensing signal. Temperature compensation methods are thus necessary, making the calibration stage the cost bottleneck of these high-volume devices.

Additional to the in-house calibration, soldering subjects a multi-stack device to thermal and mechanical constraints on the composing materials each with different recovery time constraint resulting in a time-varying drift that will compromise the above calibration performance.

Leveraging the VENSENS™ MEMS technology, STMicroelectronics commercialized in 2014 a full molded pressure sensor with only 2 × 2 × 0.7 mm^3 footprint. This technology eliminates the need for soft glue and plastic or metal caps by taking the decoupling task inside the MEMS. The membrane is suspended with a silicon spring, which acts as electrical interface as well. In this structure, thermomechanical external stresses related to soldering are absorbed by the spring resulting in a membrane located inside a stress-free area (Fig. 18.44).

Taking the decoupling complexity inside the MEMS permits to rely on the excellent linearity of silicon springs for drift-free pressure sensors and enables silicon-exposed cost-effective full molded package. The device features a typical absolute accuracy as high as 0.1 mBar in the range of 0–65 °C.

18.9.4 Reliability Challenges for MEMS Pressure Sensors

Main failure mechanisms for pressure sensors can be highlighted by the following reliability trials:

1. Reflow or THS (temperature humidity stress).
2. Mechanical stress test, like tumble or drop.
3. HAST (highly accelerated temperature and humidity stress test) [53] or autoclave [54].

(**b**) Full molded HLGA ($2 \times 2 \times 0.7$ mm^3) top view. Top surface shows exposed silicon and small vent holes. (© 2018 by STMicroelectronics)

Typically, after the test a readout is performed to assess accuracy drift. Some of these tests are specific for environmental sensors; others belong to the standard JEDEC flow.

Typical failure mechanisms are particles and corrosion.

A particle, which is a portion of material of a variable dimension, can be generated by process manufacturing flow or penetrate from the environment through the vent holes located on silicon cap. When they reach sensor area, they can potentially cause a pressure accuracy drift. Generally, this issue can be detected applying a thermal stress (reflow simulating soldering process).

Another possible failure mode is related to corrosion and can be studied via HAST or autoclave, also known as pressure cooker test (121 °C/100% RH). These tests are able to activate any potential leaky path through the whole structure, causing the contact between humidity and the exposed metal. Damages induced by corrosion cause electrical malfunction, typically an accuracy drift of a physical dimension (pressure, in our case).

Thanks to proper qualification process, very low return rates can be achieved. For pressure sensors, one-digit ppm (parts per million) return rate has been reached. Reliability plan includes both tests based on international standards (e.g., JEDEC) and customized trials with the aim to stress mechanical elements.

18.10 Magnetometers

Several different technologies and transduction mechanisms are used to measure magnetic field, since different applications require different sensor features.

18.10.1 Magnetometers Introduction

For instance, an e-compass needs a sensor highly sensitive and accurate in order to resolve the Earth's magnetic field change of direction, which means capability to solve very small fields, in the range of few hundreds of nT. Just as an example, an accuracy on field better than 0.4 μT is mandatory to guarantee a heading accuracy better than 1 degree at temperate latitudes. Full scale for e-compass from 1.6 mT to 5 mT is enough, just to avoid saturation in case of disturbing fields superimposed to the Earth's field.

On the other hand, magnetic sensors very appealing for industrial and automotive applications, like current or position sensors, have generally to measure larger magnetic fields and require larger full scale, i.e., tens or even hundreds of mT. In this cases, the magnetic sensor is generally placed quite close to the source of magnetic field (a magnet in the case of position or angular sensor, or a current line) in order to work in a region where the field to be sensed is larger enough than the expected disturbing fields. Also for these sensors, accuracy is important, but, differently from the case of compasses, it is possible to play with relative position with respect to the magnetic field source.

Furthermore, for some applications, like e-compass or position sensing, the possibility to sense magnetic field in any direction (three-axis) is mandatory, while for angular sensors two-axis sensing is generally enough, and for current sensing a mono-axial sensor is usually employed.

Among the transduction mechanisms exploited for magnetic sensing, magnetoresistive sensor (anisotropic, tunnel, or giant magnetoresistive sensor: AMR , TMR, and GMR, respectively) is particularly suited to solve small magnetic fields, as required by compass application. Indeed, combining high performing magnetic sensors based on magnetoresistors with three-axis accelerometer is possible to obtain six-axis modules especially suited for e-compass.

Furthermore, magnetoresistors can be employed also as angular sensors, as they are intrinsically sensitive to the direction of internal magnetization of a ferromagnetic layer and thus to the external magnetic field angle with respect to a reference direction. On the other hand, since magnetoresistances saturate for small magnetic fields, other technologies as Hall sensors are much more suited for position or current sensing. Since Hall sensor is based on a well-known working principle and can be easily integrated even in the same chip with electronic circuits used for processing sensor signal, they are very popular even for applications in which the Hall sensing is limited by its small sensitivity, as e-compass.

Hall effect and magnetoresistivity are the main transduction mechanisms employed in products for magnetic sensing provided by semiconductor companies, like STMicroelectronics, Infineon, Allegro, NXP, AKM, and Melexis. Other interesting mechanisms of transduction are based on the change of magnetization of a magnetic core in an inductance (magneto-inductive sensors) or in a core of a transformer (fluxgate). In the first case, it is possible to monitor the frequency of an LC tank whose L changes due to magnetization induced by the external magnetic field to be sensed. In the case of fluxgate, the transduction mechanism is more complicated and based on the change of coupling between primary and search coils, due to magnetization of the core induced by the magnetic field to be sensed.

Magneto-inductance and fluxgate can be very accurate and sensitive to small magnetic fields; thus they have been proposed for compass but generally require a larger power consumption and larger dimension than other magnetometers. Furthermore, in their version compatible with typical semiconductor fabrication processes, they can be at most two-axis sensitive.

A last interesting transduction mechanism for magnetic field leads to the only magnetometer that is really a MEMS, in the sense that is based on moveable parts. This last mechanism is based on Lorentz force. If a current line of length l is designed on a moveable part, it is possible to generate a force $\boldsymbol{F}$ on the mass, by driving a current $\boldsymbol{I}$ at a proper frequency, when an external magnetic field $\boldsymbol{B}$ is directed in proper direction:

$$\boldsymbol{F} = l\boldsymbol{I} \times \boldsymbol{B} \tag{18.24}$$

In this way, the movement of the mass is proportional to the magnetic field to be detected, modulated by the current signal driven by a proper ASIC conditioning the sensor. A signal proportional to the movement can be extracted via a capacitive sensing as typically done for inertial sensor and then demodulated to extract a signal proportional to the magnetic field. The driving frequency can be at resonance frequency or at a chosen mismatch to optimize sensor performance. Main semiconductor companies do not use Lorentz force magnetometers in their products, but very good performance has been shown in recent publications [55].

In the following, we will focus on the main sensing mechanism used in semiconductor industry to fabricate magnetic field sensors, i.e., Hall sensor and magnetoresistive sensors, with particular attention to AMR (Fig. 18.45).

18.10.2 Hall Sensors

Hall sensors work because of Lorentz force [55] too, but in this case, the force deflects the trajectory of electron or holes flowing in a semiconductor. Looking at the Lorentz force acting on the single charge q moving at a velocity $\boldsymbol{v}$, the force $\boldsymbol{F}$ deflects the trajectory of the charge according to

$$\boldsymbol{F} = q\boldsymbol{v} \times \boldsymbol{B} \tag{18.25}$$

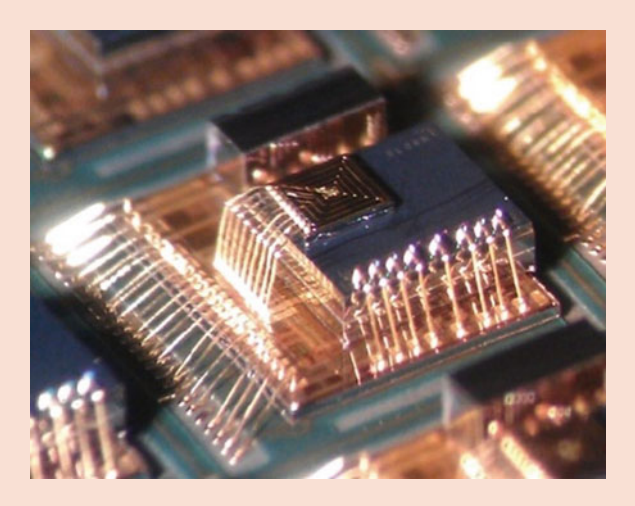

Fig. 18.45 Example of 6× modules for e-compass from STMicroelectronics (3× magnetometer + 3× accelerometer) in production from 2012. (© 2018 by STMicroelectronics)

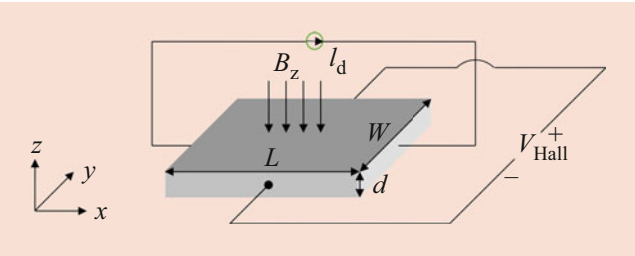

Fig. 18.46 Ideal structure for a Hall sensor. (© 2018 by STMicroelectronics)

Now, considering a flow of charges in a semiconductor plate as in Fig. 18.46, if a current I_d flows between two terminals of a four-terminal structure, at the other two terminals, electric fields perpendicular to current flow are generated by the charge distribution change, due to Lorentz force-induced trajectory deflection.

It is possible to calculate the hall voltage V_{hall} starting from previous equation and fixing the condition of equilibrium between electric field and Lorentz force. In case of a bias current, I_d, we have

$$V_{hall} = \frac{1}{qnd} I_d B_z \tag{18.26}$$

where n is the number of charge q flowing in the plate, d the plate thickness, and B_z the magnetic field perpendicular to the plate. In case of driving a voltage V_d instead of a current, we have the equivalent formula:

$$V_{hall} = \frac{1}{qnd} I_d B_z = \mu \frac{W}{L} V_d B_z \tag{18.27}$$

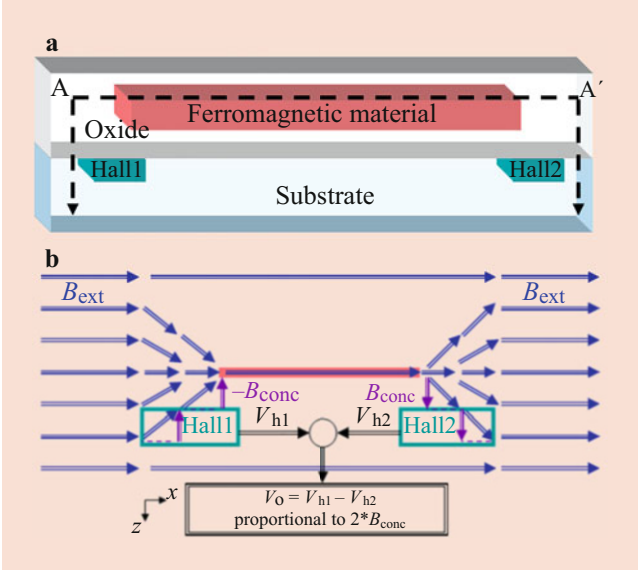

Fig. 18.47 Working principle of a magnetic field sensor based on hall sensor with an integrated magnetic concentrator. (© 2018 by STMicroelectronics)

where W is plate width, L the length, and μ the carrier mobility.

A Hall sensor is easily implemented in a silicon-integrated process, by introducing a diffused well, or by using a well already available in the process. The well is a region of silicon with a majority of carrier n type or p type. Generally, to maximize the mobility of the carrier and thus sensitivity, n-type well is used with a low concentration of dopants.

In this way, Hall sensor can be used to detect magnetic field perpendicular to the chip (Z-axis), but not parallel to the chip (X and Y). This could be a limit, for example, if three-axis sensing is required, as in case of position sensing and compass. A common solution [56] is to integrate on top of the chip a ferromagnetic patterned layer able to deflect planar magnetic flux line so that part of the magnetic field is deflected in direction perpendicular to the chip (Fig. 18.47) and, finally, the Hall sensor can sense fields parallel to chip surface. By properly placing a couple of Hall sensors with respect to the ferromagnetic material, in-plane magnetic component generates magnetic field of opposite sign on the two hall cells, so that the effect due to the magnetic component perpendicular to the chip can be rejected as a common mode.

18.10.3 Magnetoresistive Sensors

Magnetoresistive sensors are based on ferromagnetic materials whose resistance depends on magnetization direction with respect to the current, or on a stack of ferromagnetic layers, whose resistance depends on the orientation of a

soft ferromagnetic layer with respect to a reference hard ferromagnetic layer.

In the first case, we speak about anisotropic magnetoresistance (AMR), while in the second we have tunnel magnetoresistance (TMR, also known as magneto-tunnel junction MTJ) and giant magnetoresistance (GMR).

AMR are generally made of NiFe resistors, whose resistance changes due to the angle θ between magnetization vector M and current density J flowing in the resistor. The resistance R can be written approximately as [57]

$$R = R_0 - \Delta R \sin^2\theta \tag{18.28}$$

where $\Delta R/R_0$ is the maximum change in resistance, which can vary from 2% to 3% for NiFe, depending on thickness and fabrication. In other words, when magnetization and current are perpendicular to each other, scattering for carriers in the resistor is minimum and so is the resistance, while when magnetization is parallel or antiparallel to current, the scattering is higher, and resistance is maximum. Typically, AMR are made of thin sputtered NiFe layer of thickness in the range of tens of nm.

On the other hand, GMR and TMR are basically stacks of at least three layers: a ferromagnetic hard layer, a nonmagnetic layer, and a soft magnetic layer. Current conduction occurs trough the nonmagnetic layer, which can be an electrical conductive layer in the case of GMR, or a thin insulating layer in case of TMR, so that in the first case a standard current conduction occurs while in the second case a tunnel-effect conduction takes place. In the most simplified structure (Fig. 18.48), the first ferromagnetic layer is a hard ferromagnetic material, also known as pinned layer, which shows very high coercive field, i.e., requires a very huge external magnetic field to change direction and or magnitude of magnetization. Thus, it cannot be changed by an external magnetic field and it is fixed during the fabrication process, unless such a field is extremely high. Instead, the second ferromagnetic layer, the free layer, can change direction under the effect of an external magnetic field in the range of measurements of the sensor. Therefore, resistance changes due to the interaction between magnetization and the electron spin. Considering electrons with spin 1/2 and spin −1/2, scattering of electrons at each interface is dependent on magnetization direction and spin, so that if pinned layer and free layer have magnetization antiparallel direction, electrons with positive spin are scattered back at the first interface, while electrons with negative spin are scattered back at the second interface. On the other hand, if the magnetizations are parallel, at least one of the two groups of electrons (positive or negative spin) is much less affected by scattering, so that the resistance is significantly reduced going from an antiparallel to a parallel direction of magnetization [57, 58]. Practically the free layer magnetization rotation can close or open a valve for the electron passage. Typically, GMR/TMR layers are very thin, in the range of few nm.

18.10.4 Anisotropic Magnetoresistive Sensors

AMR sensors exploit the fact that some materials as NiFe change their resistance depending on the angle between magnetization and current as shown in Ref. [58]. Nickel/iron ratio is usually set to have both good sensitivity ($\Delta R/R_0$) and low magnetostriction coefficient, i.e., to have no sensitivity to mechanical stresses introduced by the package. This is an important advantage with respect to Hall sensors, which show a non-negligible dependence on stresses through piezoresistive effect, being Hall sensor generally very similar to a diffused resistor as shown in the dedicated section. Typical nickel/iron ratio to obtain both good magnetic sensitivity and low sensitivity to stress is 81/19 [57].

NiFe layer for AMR is anisotropic in the sense that the hysteresis of film magnetization M vs magnetic field depends on the direction. Generally there is a direction, the so-called easy axis, along which the magnetization is easily aligned,

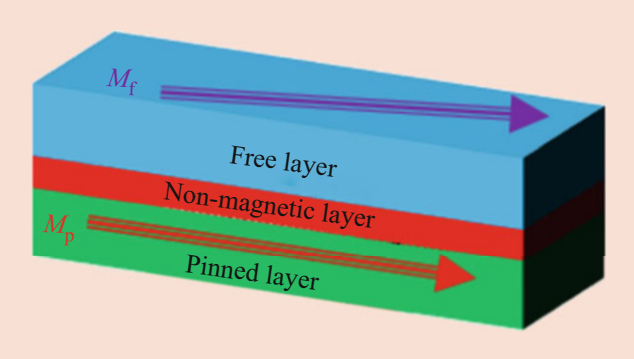

Fig. 18.48 Typical stack for a spin valve magnetoresistor (GMR, TMR). (© 2018 by STMicroelectronics)

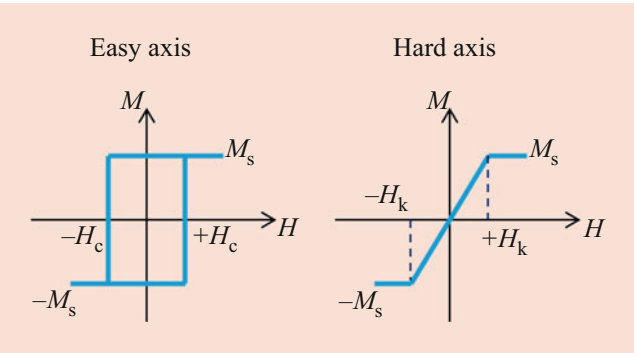

Fig. 18.49 Different behavior of magnetization vs magnetic field for easy and hard axis. (© 2018 by STMicroelectronics)

as well as a second axis, orthogonal to the first one, along which the relationship $M(H)$ is at least in a certain range linear and with very low hysteresis (Fig. 18.49). In a thin film, the easy axis direction lays always in-plane, i.e., parallel to chip surface.

The anisotropy/easy axis direction of a patterned layer is generally fixed by the contribution of material anisotropy and geometrical anisotropy [57–59]. Geometrical or shape anisotropy is due to the fact that in a patterned film, due to the discontinuity between ferromagnetic and not ferromagnetic material, layer magnetization inside the magnetoresistor is not uniform, but is reduced. This reduction can be modelled by a demagnetizing field. Without going too much into details of demagnetizing field calculation, if, for example, a magnetoresistor is much longer than wide (Fig. 18.50a), demagnetizing field is much larger along the width than along the length of magnetometer. Thus, geometrical anisotropy leads the preferred direction of magnetization along length of resistor, even if material anisotropy is in another direction. A magnetoresistor like the one in Fig. 18.50a, after a first magnetization cycle, would have a magnetization aligned along X or along $-X$. Thus if a field in sensitivity direction (Y) rotates M with respect to current J, a change of resistance would occur, according to chart in Fig. 18.50b. The only problem of a simple element like the one in Fig. 18.50b is that resistance as a function of the angle and, consequently, as a function of the external magnetic field is not linear. Moreover, a simple magnetoresistor like this cannot discriminate external magnetic field direction ($\pm\theta$ rotation gives the same resistance variation).

To obtain linearity and sensitivity to field direction, a solution is to use the so-called barber poles, i.e., a conductive and not ferromagnetic layer as copper or aluminum, with conductivity much higher than ferromagnetic layer used as magnetoresistor. By depositing this layer directly on the NiFe and by patterning barber poles at 45° with respect to the ferromagnetic layer, the current direction in the ferromagnetic layer is rotated following the barber pole orientation so that the angle between magnetization and current is 45°, when external magnetic field is 0 (Fig. 18.51a). As shown in Fig. 18.50b and following Ref. [58], around this working point, the dependence of resistance on angle is linear. Furthermore, playing on barber pole orientation is also possible to set the initial angle between magnetization and current to −45°. Therefore, still following Fig. 18.50b, it is possible to have a first set of magnetoresistor showing an increase of resistance for a certain magnetization rotation and a second group whose resistance decreases of the same value with the same magnetization rotation.

This allows to design four magnetoresistors, two with initial angle between magnetization and current to −45° and the other two with initial angle 45°. Consequently it is possible to connect these magnetoresistors in Wheatstone bridge configuration.

Another element useful for AMR sensor is the auxiliary coil to set the initial state of magnetization. A set of the

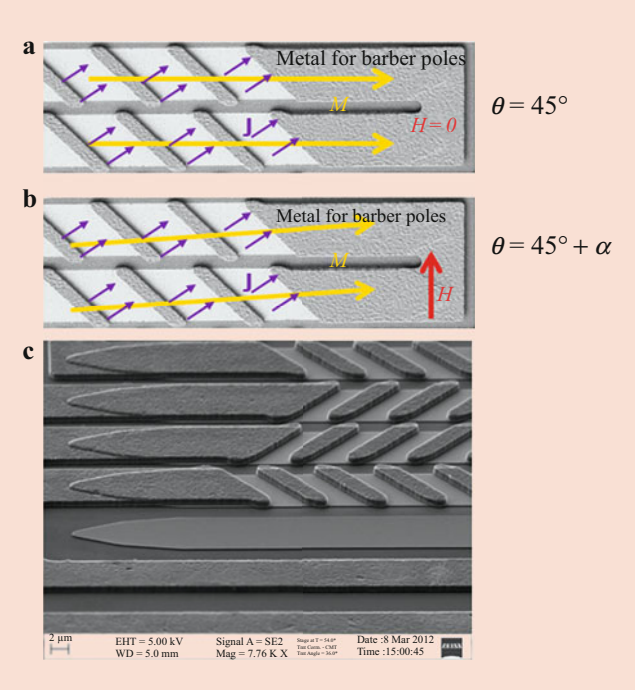

Fig. 18.51 Barber poles structure (dark gray layer) in a real STMicroelectronics sensor; added in purple the expected direction of current, in yellow magnetization, and in red external field. (**a**) Case with external magnetic field 0; (**b**) case with external field not zero; (**c**) perspective view of barber poles and NiFe stack from a STMicroelectronics device. (© 2018 by STMicroelectronics)

magnetization is required at the start-up of the sensor and periodically during sensor working to recover the correct operating point in case of high magnetic field exposure. A schematic example of the coil is shown in Fig. 18.52. When the magnetization set is needed, a short pulse of current is driven through the coil (direction following red arrows in Fig. 18.52) generating a pulse of magnetic field H_{set} (direction following black lines in Fig. 18.52). The amplitude of the pulse should be enough to set the magnetization M of the magnetoresistor and to ensure that it remains set after the removal of the pulse if external magnetic field is 0. Figure 18.53 shows a detail of a typical metal for set coil.

Set coil enables also another important feature of AMR sensors, i.e., the possibility to cancel the offset. Considering a magnetic field with a component H in sensitivity direction as in Fig. 18.52, after a set pulse, initial magnetization of the four magnetoresistors in the Wheatstone bridge is set so as the output of Wheatstone bridge and can be written as

$$V_{out} = SH + V_{offset} = \Delta R/R_0 * f\,(W, t, H_k)\;\; H + V_{offset} \tag{18.29}$$

where V_{offset} is the offset of the Wheatstone bridge, due to geometrical asymmetries among magnetoresistors and independent on magnetization condition of magnetoresistors, while S is the bridge sensitivity. Sensitivity is proportional to $\Delta R/R_0$ and to a function dependent on width W and thickness t of magnetoresistor, while length L is negligible if $L \gg W,t$. Sensitivity S depends also on the anisotropy field H_k, a magnetic property of the ferromagnetic film which can be defined as in Fig. 18.49 as the field required to saturate the flat film with a magnetic field oriented along the hard axis.

If, after a first measurement performed following the set pulse, a second current pulse is driven along the set coil in an opposite direction (reset pulse), the magnetic field pulse on Wheatstone bridge is in opposite direction with respect to the one in Fig. 18.52, so as magnetization direction inside magnetoresistors is reversed too. This results in a change of the initial angle between current and magnetization, which becomes 45° for resistor whose magnetization orientation was −45° after the first pulse, and −45° for resistor whose magnetization orientation was 45° after the first pulse.

Thus, sensitivity to H is still S but with opposite sign. If V_{os} is the output after the first (set) pulse and if V_{or} is the output after the second (reset) pulse, the two outputs are

$$V_{os} = SH + V_{offset} \tag{18.30}$$

$$V_{or} = -SH + V_{offset} \tag{18.31}$$

$$\frac{V_{os} + V_{or}}{2} = SH \tag{18.32}$$

The difference between these two consecutive measurements allows dynamically cancelling the offset, as well as its drifts and temperature dependence. Such AMR sensor feature is fundamental to obtain magnetometers with high accuracy.

18.11 Silicon Image Sensors and Evolutions of CMOS

Silicon is a material suitable for imaging application due to its crystalline properties and band structure. When light hits silicon, energy can be transferred to electrons generating a current flow and paving the way to a very wide range of applications for silicon imaging sensors.

18.11.1 Introduction

Silicon crystallizes into a diamond cubic crystal structure in which the atoms are covalently bonded. Silicon is a group IV element in the periodic table and is a semiconductor with a bandgap of 1.12 eV at 300 K. Semiconductors are

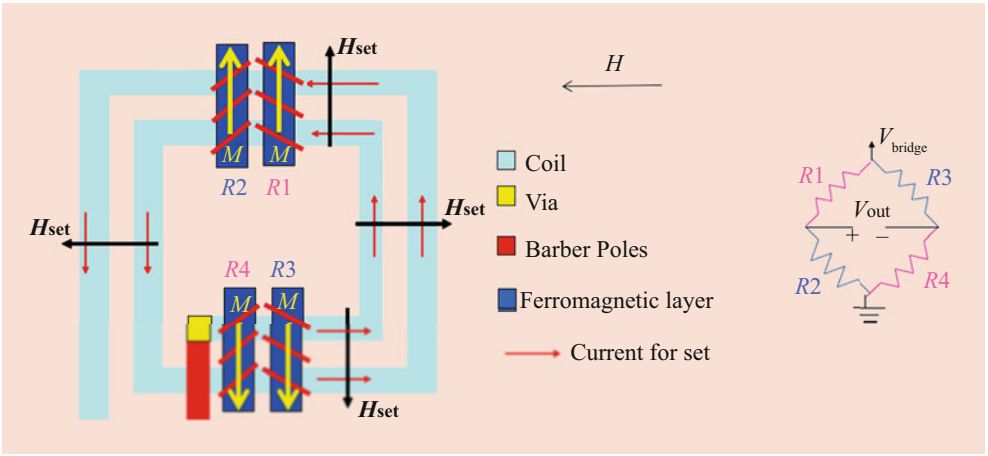

Fig. 18.52 Schematic representation of an AMR bridge with its set coil. (© 2018 by STMicroelectronics)

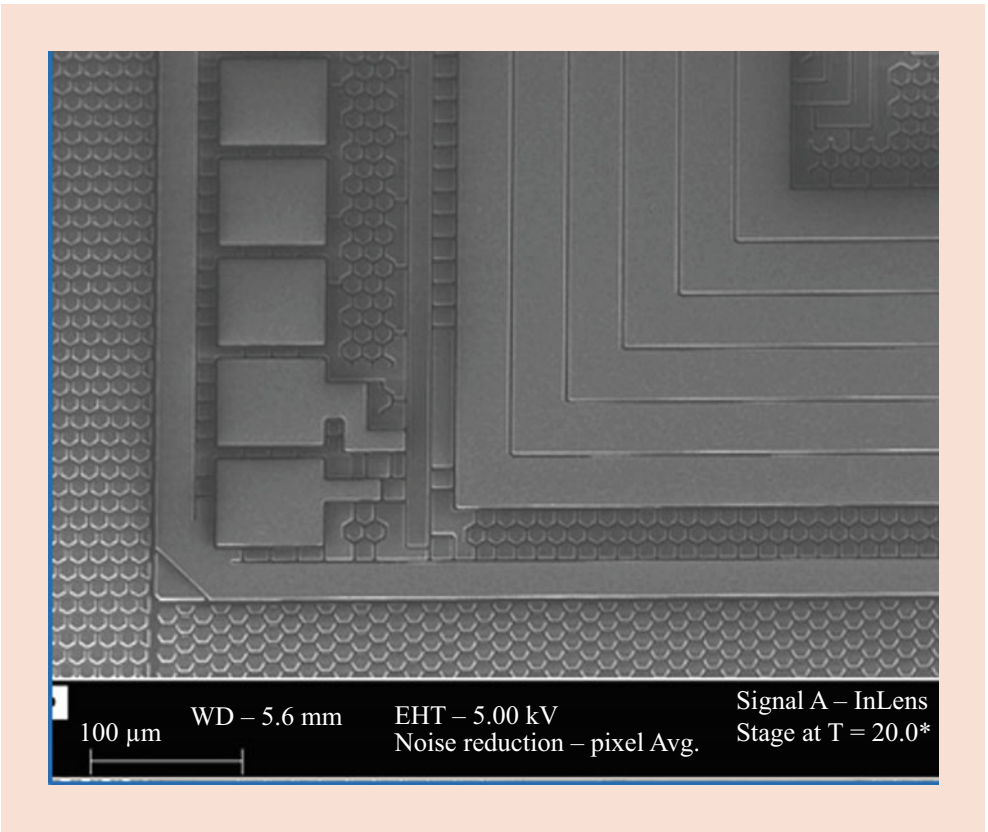

Fig. 18.53 Thick metal coil detail from a STMicroelectronics device. (© 2018 by STMicroelectronics)

materials that have electrical conductivities in between those of conductors and those of insulators. Doping, temperature, or illumination can modify the behavior and the electrical properties of silicon. For example, when silicon is exposed to light, several effects of interactions can occur, depending on the impinging photon energy. The energies of interest for everyday applications range from near infrared (NIR) to visible light and ultraviolet (UV), corresponding to a wavelength from 1100 nm to 200 nm. In order to calculate the energy of the radiation E_{ph}, the following formula can be used:

$$E_{\text{ph}} = h\nu = \frac{hc}{\lambda} \tag{18.33}$$

where ν is its frequency, λ its wavelength, h Planck constant, and c the speed of light.

The UV-NIR domain corresponds to energies between 1.12 eV and 6.2 eV. In this energy range, the dominant interaction mechanism is the creation of an electron-hole pair (EHP). When a photon is absorbed, its energy is transferred to the crystal, allowing electrons to jump to conduction band and move into the silicon lattice. An electron-hole pair is thus created. This mechanism can happen if the energy of the imping photon is higher than the energy gap. In this case, we have an internal extrinsic transition, which is the base of photo transduction in silicon, exploited by image sensors in the above domains.

EHP generation can occur in all semiconductors. Different materials can be chosen in order to detect also photons with lower energies (infrared) or photons with higher energies only. For infrared detection, germanium (Ge) and some III–V semiconductors (i.e., InGaAs) can be used, and dedicated doping can improve performances. Interest in this low-frequency range is due to several applications, such as material identification with optical spectrographs and lasers for LIDAR or 3-D scanning.

Every time an EHP is generated, the two charge carriers tend to recombine. The average time before the recombination of a hole in an n-doped region or an electron in a p-doped region is defined as minority carrier lifetime or recombination time τ. This recombination time is proportional to the diffusion length L, which is the distance minority carriers are able to travel before recombination:

$$\tau = \frac{L^2}{D} \tag{18.34}$$

where D is the carrier diffusivity.

EHP are also generated by thermal energy that may create band to band transition at temperature above the absolute zero (indirect silicon transition). This creates an undesired current, known as dark current, that must be taken into account as a critical design factor. Defects in the reticle (crystalline grid dislocation), chemical impurities, and dangling bonds at silicon interface promote spontaneous generation of EHP at low temperature and may increase dark current. These thermally generated carriers are the main responsible for noise in photodetectors and can be reduced by reducing defects.

Another important parameter for a photodetector is the spectral responsivity R, which is a sort of factor of merit or yield of the photodetector. It measures the output electric signal (voltage) with respect to the impinging radiation energy (in joule) per unit of area (square mm). The impinging radiation energy is computed considering the charge collection time or photocurrent integration time (T_{int}).

The spectral responsivity is directly related to quantum efficiency, defined as the number of electrons collected per incident photon per unit of area. This depends on the probability of an impinging photon to generate an EHP and on the probability of the electron to reach a determined sense node region without recombination.

The quantum efficiency (QE) as a function of wavelength is expressed by

$$\mathrm{QE}\,(\lambda) = \frac{J_{\text{ph}}}{q\Phi_{\text{ph}}\,(\lambda)}$$

where J_{ph} is the current density due to the generation of EHP resulting from the absorption of photons with energy E_{ph} greater than the semiconductor bandgap E_{g}, q is the elementary charge, and $\phi_{\text{ph}}(\lambda)$ is the impinging photon flux per unit of area.

18.11.2 CCD and CMOS

The first industrial proven photodetectors saw the light in 1970 as charge-coupled device (CCD) . The initial concept was to use an array of MOS (metal-oxide semiconductor) capacitors where charges, generated by light, shift from one cell to the contiguous one for the entire length of the array. In a modern CCD, an array of closely spaced MOS capacitors shifts data (in the form of packets of electrons) in a serial bit stream. The electrons finally reach a chip-level output amplifier where a charge to voltage conversion takes place.

At the beginning, independent readout paths for each pixel element were present; then this structure was replaced by one single readout path for each column of pixels, as this was advantageous to reduce the fixed pattern noise (FPN), afflicting the output signals. Good FPN was the stronger advantage versus the CMOS image sensors (CIS) structure for many years (Fig. 18.54).

Due to this shift-out mechanism in multiple stages, in a CCD there is a trade-off between transfer efficiency and frame rate.

CCD aim is image optimization; therefore it has only few integrated output amplifiers, with no other integrated circuitry, as the readout and the conversion stage are not in the same structure. On the other hand, CMOS continued to evolve toward smaller features (enabled by progresses in lithography) and integration of additional components, including readout circuits, that is not possible in the CCD structure. This feature and the strive for cost reduction were strong drivers toward wide spread of CMOS for imaging. In the late 1990s, CMOS technologies, optimized for image detection, started to be competitive in efficiency and cost when compared to CCD.

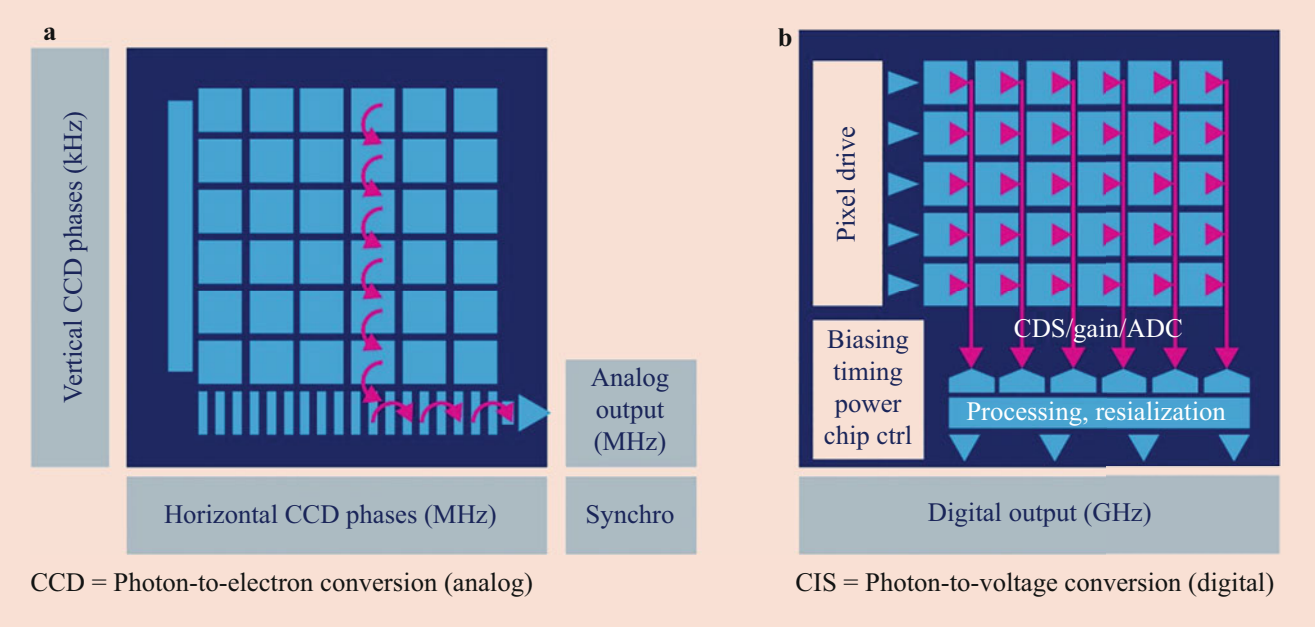

Fig. 18.54 Signal collection mechanism for CCD vs CMOS image sensors. (© 2018 by STMicroelectronics)

CMOS Structure: From Photodiode to Pixel Readout

The key element of a CMOS image sensor is the pinned photodiode (PPD). As depicted in Fig. 18.55, the PPD is formed by an n-well layer sandwiched between a P-type Si substrate and highly doped pinning P+ layer at the Si surface and connected to ground together with the P-type substrate. The concentration of the n-well layer is defined in such a way that it becomes fully depleted in reverse bias conditions. The P+ layer saturates (passivates) the dangling bonds at the silicon surface, drastically reducing the thermal EHP generation and the noise contribution from electron trapping and de-trapping mechanism. The PPD is associated to a polysilicon transfer gate (TG) which isolates it from a N+ output floating diffusion (FD). Generally, a small negative bias is applied to TG in order to suppress the dark current generated at the Si-SiO2 interface state under the gate itself.

In order to design a good PPD, signal-to-noise ratio (SNR) should be considered. SNR indicates the ratio in decibels between the signal level and the equivalent generated noise. If N_{sig} is the signal level in electrons and n_{sig} is the total noise at the given signal level, SNR can be calculated as

$$\mathrm{SNR} = 20\log\left(\frac{N_{sig}}{n_{sig}}\right)[\mathrm{dB}] \qquad (18.35)$$

At low signal levels, the readout noise is dominant, while at higher signal levels, the sensor noise, which is equal to the square root of the signal, becomes the dominant noise source.

SNR is related also to dynamic range (DR). Dynamic range is the capability of an image sensor to represent both high lights and dark shadows before to reach the full saturation. It is defined as the ratio between the maximum signal of a pixel and its dark noise level (typically expressed in decibels).

If V_{sat} is the saturation signal level in volts (which is related to the well capacity or the total charge each pixel can hold during integration time), V_{dark} is the dark noise or noise in volts at the output, N_{sat} is the signal charge at saturation in electrons, n_{dark} is the pixel noise floor in electrons (calculated by dividing the dark noise in volts by the image sensor's conversion gain without illumination and representing the smallest detectable input signal of the sensor), and then the DR can be expressed as

$$\mathrm{DR} = 20\log\left(\frac{V_{sat}}{V_{dark}}\right) = 20\log\left(\frac{N_{sat}}{n_{dark}}\right)[\mathrm{dB}] \qquad (18.36)$$

V_{sat} can be limited by the saturation of the readout electronics or by the full well capacity (FWC) of the detector, which represents the maximum amount of charge that can be collected by pixels.

A four transistors (4T)-based pixel, whose function is to transfer the charges generated into the space charge region (SCR) into the output stage, works in different steps. Once the TG and the reset transistors are both "on" (a U_{high} signal is applied to the gate of both reset transistor and TG), an electric field will be generated and will enable charges to move from the active region of the PPD to the FD. Those charges will cause a progressive voltage increase in the PPD region U_{PDD}, until the maximum voltage, related to the doping of the

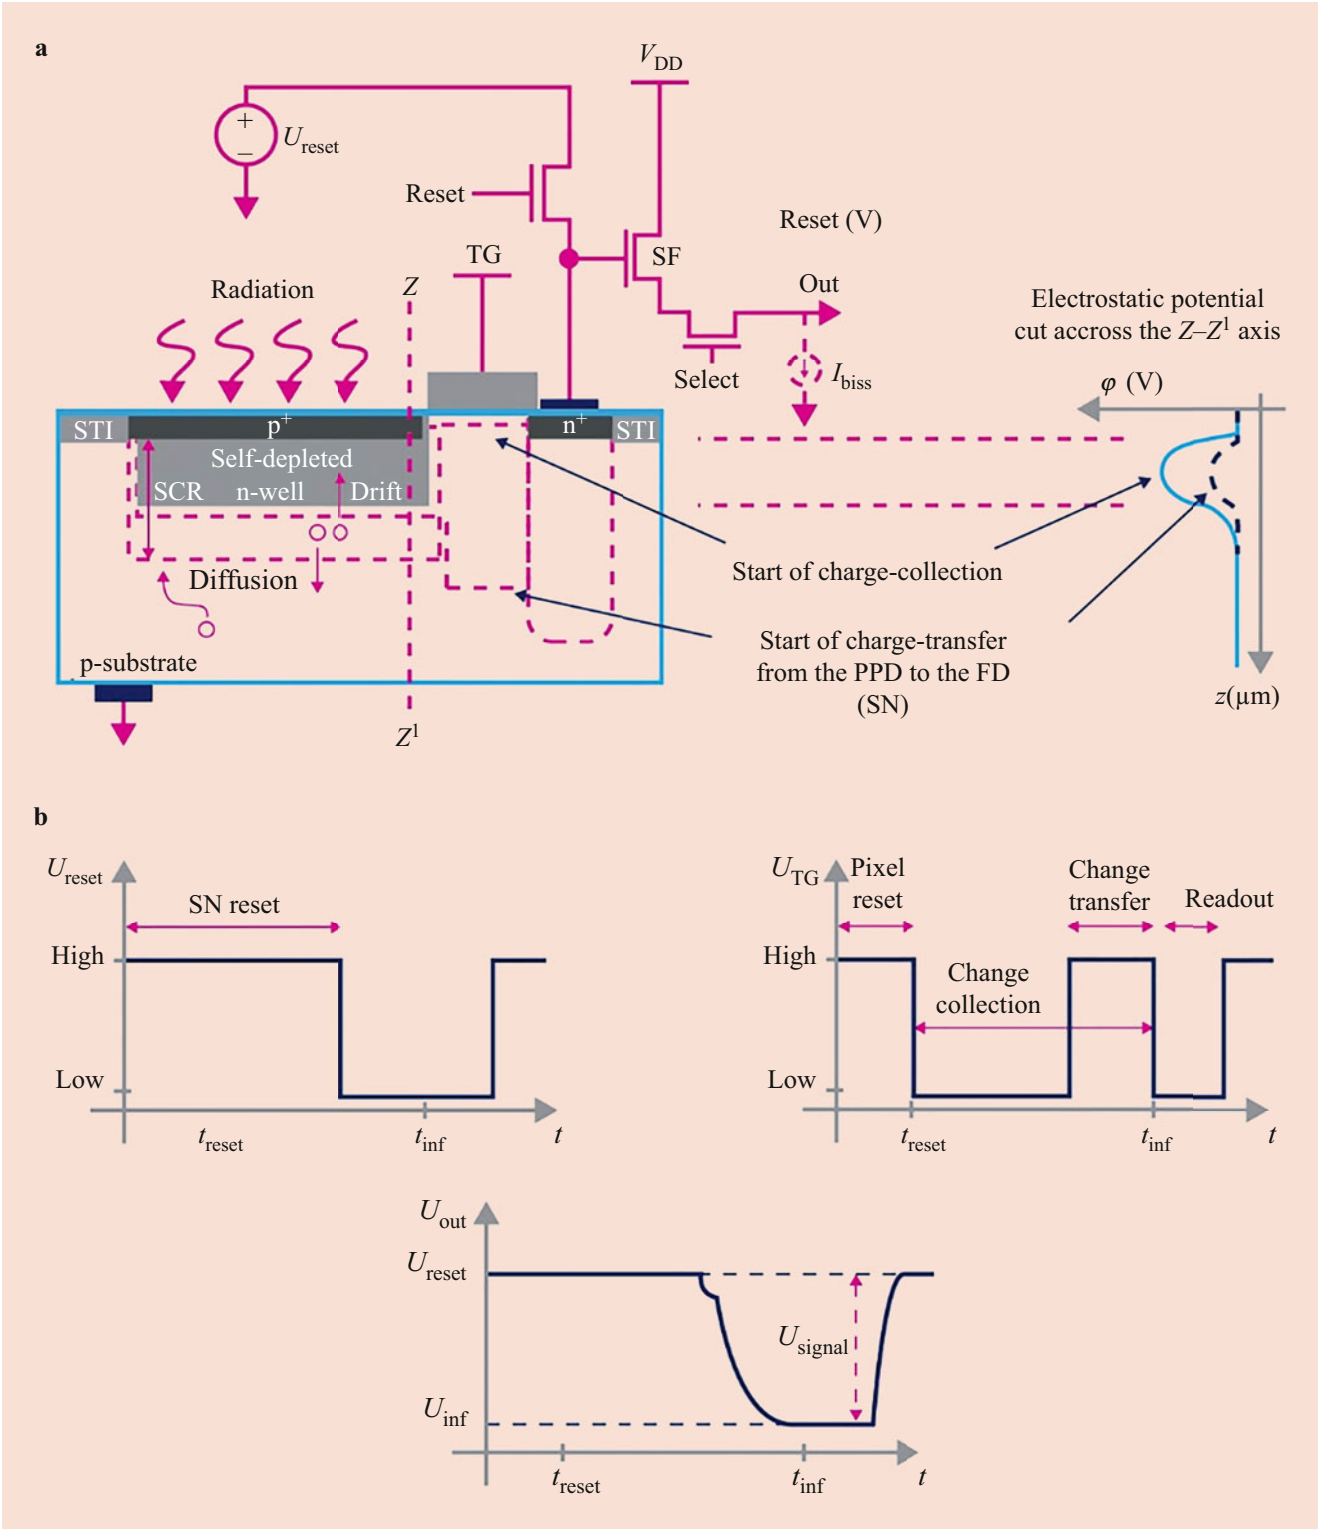

Fig. 18.55 Scheme of the charge transfer process. (© 2018 by STMicroelectronics)

different regions, is reached. When this maximum voltage or pinch-off voltage ($U_{\text{pinch-off}}$) is reached, the pixel is ready to register another event: pixel reset is concluded, and TG is set to "off" mode (U_{TG} is low).

To transfer the charges to the output, the FD remains in reset mode (U_{reset} is high), while the TG signal is low (TG is in "off"); thus the active region is electrically decoupled from the sense node (SN). In this case both thermally generated

and photo-generated electrons are physically in the active region, and its electrostatic potential starts decreasing below the $U_{\text{pinch-off}}$.

At a certain moment, defined by the sensor frame rate, the reset transistor is set to "off" mode and FD is left floating, while TG is on. At this point the output signal is collapsing to a minimum value before to be transferred to the output by putting in "off" mode also the TG, transferring all the charges to the output through the source-follower (SF; used as amplification stage), and saved at the input of the analog chain that will at the end process the signal. In general, a correlated double sampling operation (CDS) should be performed for noise optimization, and the signal must be stored at the input of CDS stage.

The capacitance of the SN can be tailored in order to increase the charge to voltage conversion factor, which at the end represents the pixel gain. FD also can be optimized and consequently designed as small as possible to minimize dark current and other leakage current contributions mainly linked to silicon substrates.

The reset K_{B}TC noise (where K_{B} is Boltzmann constant) originates from the statistical fluctuation of the potential across equivalent SN capacitance after reset. Its contribution depends on the mode of operation and on the pixel design and can be optimized with a trade-off.

The transistors of the readout chain also participate to the fluctuation of the output signal, with both low-frequency noise (1/f flicker noise) and white thermal related noise. During charge collection, in fact, the 1/f noise is primarily generated by the photodiode. It is due to surface recombination of carriers, and the fluctuation in bulk carrier mobility. For a reverse biased photodiode, the 1/f noise is not directly related to the total current. Instead, it is a function of the dark current, and it is typically much smaller than the dark current shot noise, and can thus be ignored. Different situation is happening in the readout circuit where the flicker noise is higher and increasing with the readout time.

FD design is also crucial for retention time, another important feature of the CMOS sensor. It should retain the signal information up to a desired time (several milliseconds) in order to collect the information to the readout: this retention time, reached with a proper design and equivalent capacitance dimensioning, is of essence for global shutter (GS) application, obtained with a (minimum) 4T architecture and by capturing the image simultaneously with all the available pixels. Today, most imaging devices have adopted GS mode to avoid distortion and artifacts; thus we can define GS efficiency as the difference between the original signal information and the signal change rate over time. CMOS image sensors using GS functionality are used in a variety of areas, including broadcasting, automotive, drone, and surveillance applications, as they can provide a perfect image of a moving object.

If pixel is not adopting a GS, then the image is sequentially scanned (from one side of the sensor, usually the top, to the other side, on a line by line basis), and we speak about a rolling shutter (RS)-based image sensor. In RS the pixels are registering a sequence of images rather than a complete synchronous image per pixel as in a GS. This time difference in RS results in specific error, especially for moving images.

Unfortunately, also GS system is suffering a specific error. When we acquire a frame and then suddenly close the shutter of the camera, the following frames should ideally be completely dark. In reality, this is not happening and we have what is defined the image lag error: after closing the shutter, we may observe a sort of ghost image, which slowly fades away as the successive frames are acquired.

SPAD and SiPM

If we consider the evolution of the sensor and the use of photodiodes, many applications arise including both image capturing and environment scanning to provide a tridimensional scansion. The possibility to have a photodiode able to detect single photon (SPAD: single-photon avalanche diode) is opening new possibility especially for 3-D scanning and particularly for time of flight solutions.

Both PPD and SPAD are reverse biased p-n junctions, but SPAD is operating in the so-called Geiger mode, in which the diode is biased slightly above the breakdown threshold voltage, where a single electron-hole pair, generated by absorption of a photon, can trigger a self-sustaining strong avalanche. The current rises swiftly to a macroscopic steady level in the milliampere range. If the primary carrier is photo-generated, the leading edge of the avalanche pulse marks the arrival time of the detected photon. The current continues until the avalanche is quenched by lowering the bias voltage below the breakdown threshold voltage; the lower electric field is no longer able to accelerate carriers to impact-ionize with lattice atoms; therefore current ceases. In order to be able to detect another photon, the bias voltage must be raised again above breakdown. This operation requires a suitable circuit (usually referred to as a quenching circuit), which has to:

1. Sense the leading edge of the avalanche current.
2. Generate a standard output pulse synchronous with the avalanche buildup.
3. Quench the avalanche by lowering the bias down to the breakdown voltage.
4. Restore the photodiode to the operative level.

The simplest quenching circuit is commonly called passive quenching circuit and comprises a single resistor in series with the SPAD. The avalanche current self-quenches simply because it develops a voltage drop across a high-value ballast load R_{L} (about 100 kΩ or more). After the quenching

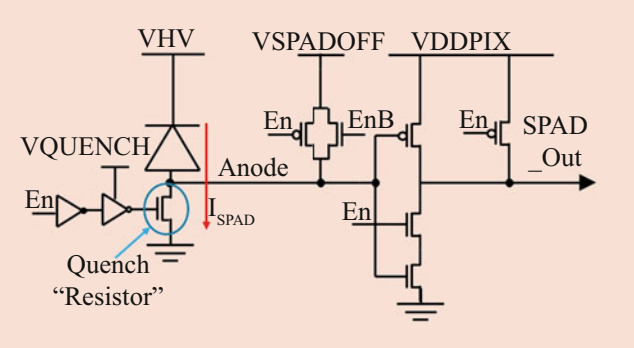

Fig. 18.56 SPAD circuitry with active recharging system. (© 2018 by STMicroelectronics)

of the avalanche current, the SPAD bias slowly recovers to above breakdown voltage, and therefore the detector is ready to be ignited again. A more advanced quenching is a scheme called active quenching. In this case, a fast discriminator senses the steep onset of the avalanche current across a 50 Ω resistor (or integrated transistor) and provides a digital output pulse, synchronous with the photon arrival time. The circuit then quickly reduces the bias voltage to below breakdown (active quenching) and then relatively quickly returns bias to above the breakdown voltage ready to sense the next photon (Fig. 18.56).

SPAD Structure

Not all photodiodes are able to work as SPAD. The structure must be designed in such a way to avoid concentration of the electric field, particularly at the edges; a circular guard ring, visible in red on the left of Fig. 18.57, must be designed to separate SPAD active region from the surrounding area. Particular manufacturing technology steps must be implemented to obtain very good quality of the silicon in terms of crystallographic defectiveness and to minimize the concentration of generation centers and traps levels, in order to reduce the rate of thermal generation of carriers.

SiPM

A silicon photomultiplier (SiPM) is an array of SPAD connected in parallel, where each pixel represents a group of connected SPAD. For specific applications, SiPM is not integrating the entire processing element, typically integrated on the CMOS, but just the photodetector.

Listed in the following are the common reading errors associated with the SPAD:

- Time jitter: The total uncertainty of a SPAD coupled to a time measurement device. It represents the incertitude in the time of the measurement linked to the fact the V_{op} is reached in a time that is not deterministically computed but based on a Gaussian. Since V_{op} is reached in a certain time distribution probability, a time error is included in the measurement.
- Dead time: After an avalanche a SPAD is unable to detect a further photon up to when free carriers will be eliminated and recharge, and quenching will reset back the SPAD to V_{op}. The time necessary to put back the SPAD in operation after a measure is representing the dead time. Dead time cannot be considered in reality an error.
- Electrical cross talk: A large number of connected SPAD with a shared V_{op} line fire at the same time, so any drop or increase in the voltage may cause a decrease of the V_{op} or a registration of an event, with a correspondent reading error.
- Optical cross talk: Can originate from photons emitted during the avalanche or coming from other sources (i.e., a VCSEL used for active illumination or a non-perfectly isolated circuitry from the external environment). Normally this is happening with highly and densely packed SPAD arrays.

18.11.3 CMOS Image Sensor: A Complete Solution

The key components in a CMOS image sensor (CIS) are:

- Photodiode (PD) and pixel readout.
- Circuit for analog to digital transduction.
- Micro lens and optic module.

A light sensor element (pixel) includes a light-sensitive element and a readout circuit. The sensitive element is usually a pinned photodiode, but also a SPAD can be used. Floating diffusion, source-follower, and other transistors form the pixel readout. Signal conditioning is composing the rest of the CIS as reported in the block diagram here below (Fig. 18.58):

The most widely implemented pixel design is known as an active pixel sensor (APS). Three to six transistors are commonly used and they provide gain or buffer the pixel from large column capacitance.

A color filter is used to separate out the red, green, and blue (RGB) components of reflected light. Finally, the micro lens gathers light from the inactive portion of the CIS and focuses it down to the photodiode (Fig. 18.59).

A pixel can be defined as a sensor converting photons into voltage, while the signal processing circuit function, embedded in the image sensor, is similar to that of other sensors. This signal processing stage must guarantee high speed, low consumption, and reduced noise. All of these requirements are strongly linked to the circuit design of CMOS image sensor, particularly to analog signal processing and analog to digital converter (ADC) embedded in the CMOS.

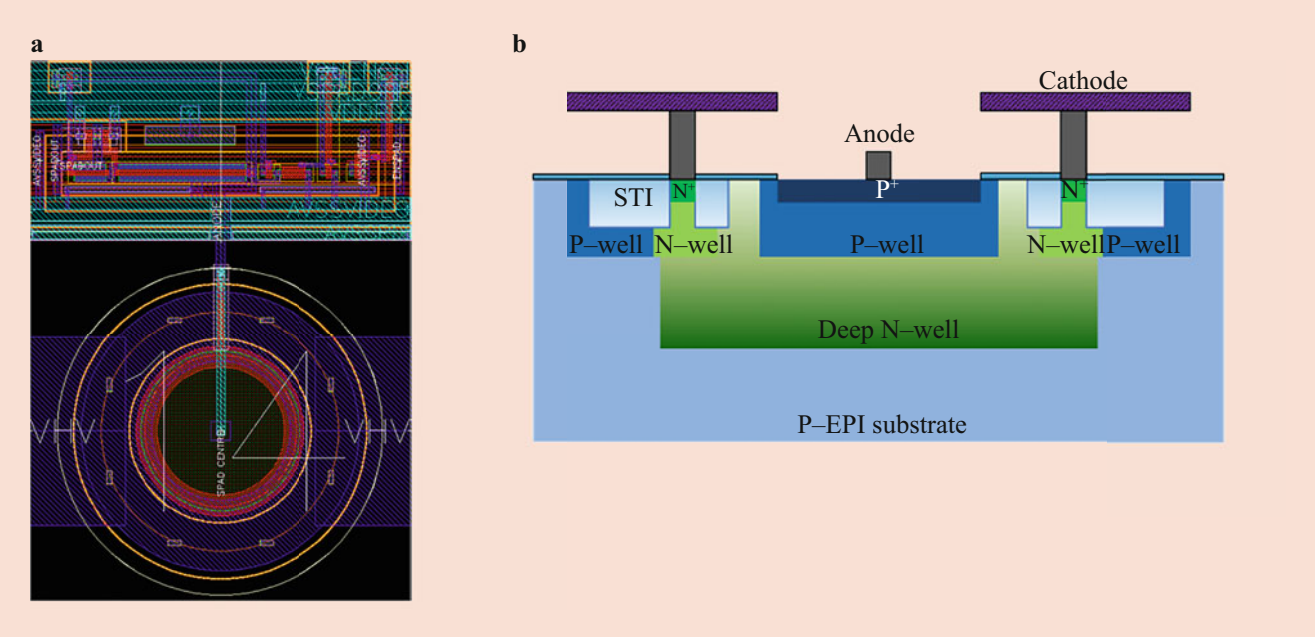

Fig. 18.57 (**a**) Real SPAD structure with guard ring visible in red. (**b**) SPAD schematic cross section. (© 2018 by STMicroelectronics)

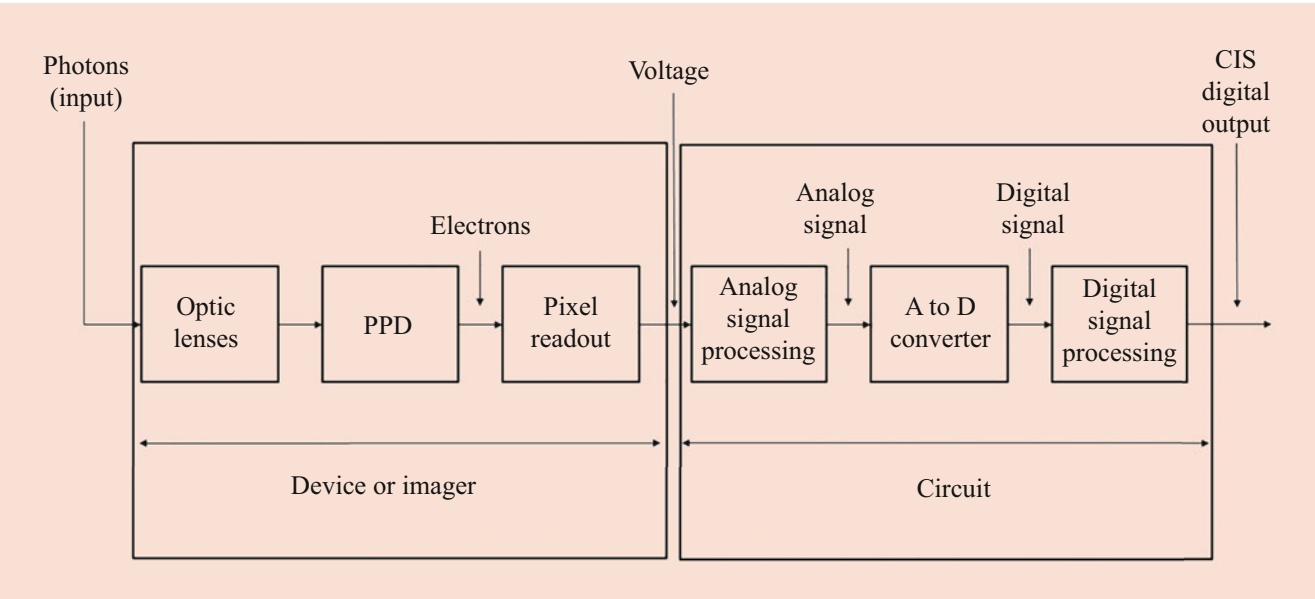

Fig. 18.58 CMOS image sensor block diagram. (© 2018 by STMicroelectronics)

In order to achieve good SNR, different sampling methods and amplifier designs are adopted, according to different specifications and design architectures. Normally, this processing chain is implemented as column circuitry. In CMOS image sensors, correlated double sampling (CDS) is widely used to reduce reset noise and offset. Different sampling technologies have been proposed for noise reduction.

Analog to digital conversion of the pixel output affects image quality, frame rate, power consumption, and form factor. According to their location, ADCs can be sorted into three categories:

- Chip-level ADC: Connected at the output of the analog signal of the sensor. This methodology is not allowing high-speed processing, as all pixel outputs are time-multiplexed to the input of the global ADC.
- Column-level ADC: Ideal for high speed and high resolution, as the input of the column-level ADC is connected

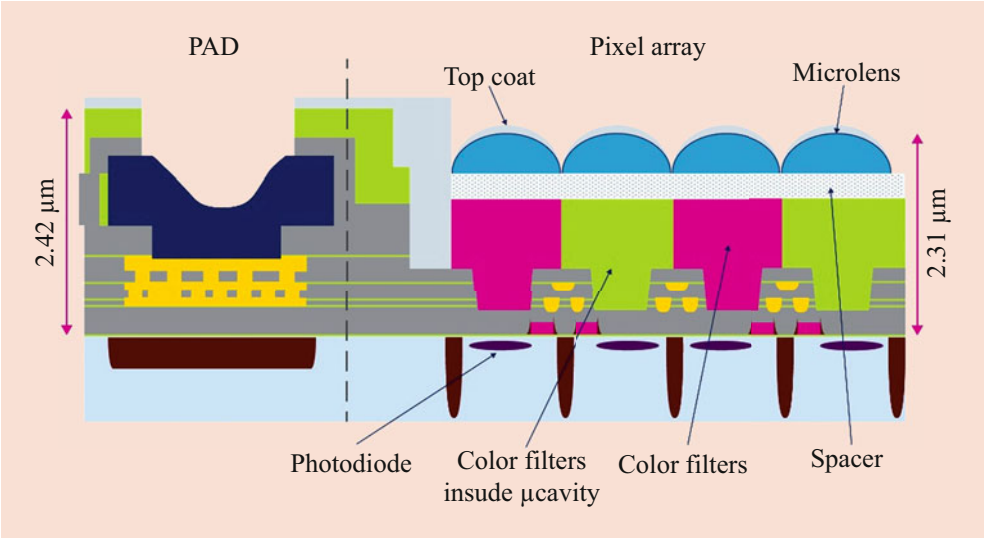

Fig. 18.59 Schematic cross section of a CMOS image sensor, including micro lenses and color filters. (© 2018 by STMicroelectronics)

to one group of the column circuit outputs. By increasing the number of ADCs working in parallel, frame readout time is reduced. The main challenge of this design is due to the insertion of the ADC in the layout: its width should be smaller than corresponding pixel pitch. Therefore, this solution is in contrast with pixel shrinkage trend.

- Pixel-level ADC: When ADC is included at pixel level, SNR can be increased, since conversion occurs at single pixel and only digital data are transmitted. Additional advantages include low power and high speed. Since every pixel includes an ADC, the fill factor of the pixel decreases.

CMOS and Sensor Integration

In conclusion, CMOS presents some advantages if compared with CCD:

- Higher integration: As already mentioned, the CMOS image sensor can integrate readout circuit, ADC, and even the digital signal processing module in one chip.
- Lower cost: CMOS technology is taking advantage of lithography roadmap, whereas CCD cannot. System integration in one chip can further decrease area, with manufacturing cost reduction. Moreover, CMOS diffusion in different markets and multiple applications is a driver for photolithography reduction and miniaturization, with strong scale economy.
- Power consumption: Since CCD requires multiple power supplies per column, a CMOS image sensor can achieve lower power consumption.
- Speed: CMOS image sensor can achieve a more flexible readout integrated mechanism, which results in a higher speed for reading the light than CCD, also with the advantage to integrate memory directly in the pixel. CMOS is the favorite choice when high speed is necessary: this is the case, for example, of 3-D cameras for industrial, consumer, and automotive application.

The real limit of the CMOS image sensor is actually the higher level of integration, limiting the access of photon to the active area of the pixel. To minimize this problem, primarily optimization of metal layers was implemented, and then few other options were experimented, in particular BSI and hybrid or 3-D stack options.

Pixel Manufacturing, FSI, BSI, and 3-D Stack

In the classic structure known as frontside illuminated (FSI) structure , metal contacts on the top surface of CMOS devices limit the amount of photons impinging the pixel. Moreover, light travelling from lenses to photodiode must cross passivation and dielectric layers, and this causes losses, due to reflections, and cross talks, due to light scattered from adjacent pixels. All these effects decrease QE and SNR.

Some optimizations have been implemented in order to increase the efficiency of the sensor. Some of those changes conceived to improve the CMOS performance include:

- Increasing and optimizing lens surface to increase the amount of photons impinging the active area.
- Reducing the distance from the lens to the PD in order to reduce the optical path and increase the amount of photons per area of the PD, avoiding also inter-pixel cross talk.

Micro lenses optimization in form factor and efficiency is key. Micro lenses array fabrication includes two methodologies:

- Direct: The lens is formed using the principle of surface tension effect, when the material used is in a thermoplastic transition or in liquid state (typically induced by heating in controlled atmosphere). Normally this process is very efficient in cost and performance, but, when complex shapes are needed, is not effective. Thermal reflow, microplastic embossing, or microdroplet jetting are all direct techniques.
- Indirect: Lens is fabricated via injection molding or hot embossing using a preformed concave shape. This methodology is more expensive and is chosen for complex geometries.

The basic process is obtained starting from a classical photolithography step followed by a thermal treatment in controlled atmosphere. The melting is obtained with a consequent controlled shape of the formed lens (Fig. 18.60).

A certain amount of QE may be lost for cross talk due to the fact a photon is hitting the active area of another adjacent pixel (cross talk). Therefore, optical isolation between all the PD must be designed. Cross talk can be split into [60]:

- Spectral cross talk: related to color filters properties.
- Optical cross talk: happening when an EHP is generated in the active area from an impinging photon collected by an adjacent pixel.
- Electrical cross talk: electrical charges (electrons or holes depending on the pixel type) that may diffuse among adjacent pixels.

The evolution of the different image sensors to obtain this optical isolation moved from the initial simple shallow trench isolation (STI), characterized by a higher cross talk, to a barrier created with a dedicated p+ deep implant, to vertical deep diode up to deep trench isolation (DTI). DTI guarantees a higher level of immunity and is widely used in CIS (Fig. 18.61).

Deep trench isolation is normally obtained by etching a trench to isolate two adjacent pixels and filling it by oxide in order to create a SiO_2-Si interface, after the formation of the shallow trench isolation (STI). Then around the trench a sidewall implantation (SWI) is made. Thermal treatments and annealing process are necessary to clean up the interface around the trench and minimize dark current.

Sidewall implantation is an improvement able to guarantee a higher immunity to dark current. By this flow, 1:25 aspect-ratio trench can be achieved and it is also used as passivation methodology. Thanks to both DTI and SWI, average dark current is reduced by an order of magnitude, with a net improvement for QE.

A further improvement is capacitive deep trench isolation (CDTI) in which the trench is filled with SiO_2 and polysilicon, allowing a very effective solution for active suppression of cross talk due to diffusion or photo-generated carriers. We can consider CDTI as an active sidewall passivation as, to operate, must be activated. Activation is made by biasing the structure with a negative voltage in order to obtain an equivalent SWI along the whole vertical length of the trench. When negatively biased (around -1 V), CDTI is actively creating hole barriers along the whole trench in a well-controlled and thin region, with a minimal impact on the FWC and PD active area.

In conclusion, CDTI can improve dark current, full well capacity, and indirectly QE, as the active area of PD is optimized. Both SNR and dynamic range increase.

CMOS photolithography node has been progressively shrunk, requiring a drastic improvement related to metal options and their connections. Copper metal process has been introduced to reduce the form factor and increase where possible power density. Copper introduction allowed a further acceleration to photolithography reduction, but the use of copper requires some specific intermediate dielectric layers, whose effect to some specific wavelength is equivalent to the one of an optical filter. This intrinsic problem related to copper metallization is one of the most important issues limiting the CMOS node shrinkage on image sensor, whose race to miniaturization is slowing down compared with standard CMOS.

Despite all the improvements in pixel isolation, pixel reduction is also limited because in FSI the optical path may be extremely reduced. Some possible solutions include reducing metallization layers and creating preferred optical paths to increase the number of impinging photons per area in the PD. For the latter technique, one of the most adopted solutions is the so-called light pipes: they are channels obtained by deep vias filled with material at high reflective index, leading the light from the micro lenses directly upon the PD.

These techniques are often very complex due to small pixel dimension: to overcome this problem, a backside illuminated (BSI) structure has been conceived. In this structure, photodiode is directly exposed under the chip lenses (Fig. 18.62).

BSI optimized structure can be obtained through a complex process flow, implementing some specific manufacturing techniques. Standard diffusion allows realizing PD and interconnections. Then some dedicated process steps are performed:

- Wafer-to-wafer bonding: Surface is cleaned by chemical-mechanical polish (CMP) and micro-roughness is critical for bonding quality. After CMP, surfaces are plasma-activated and direct bonding is performed.
- Wafer thinning: Made on the flipped wafer. Good surface finishing and thickness control are key in this process.
- Passivation of the PD: One method is to implant the wf backside with a shallow P+ implant. The implant

(© 2018 by STMicroelectronics)

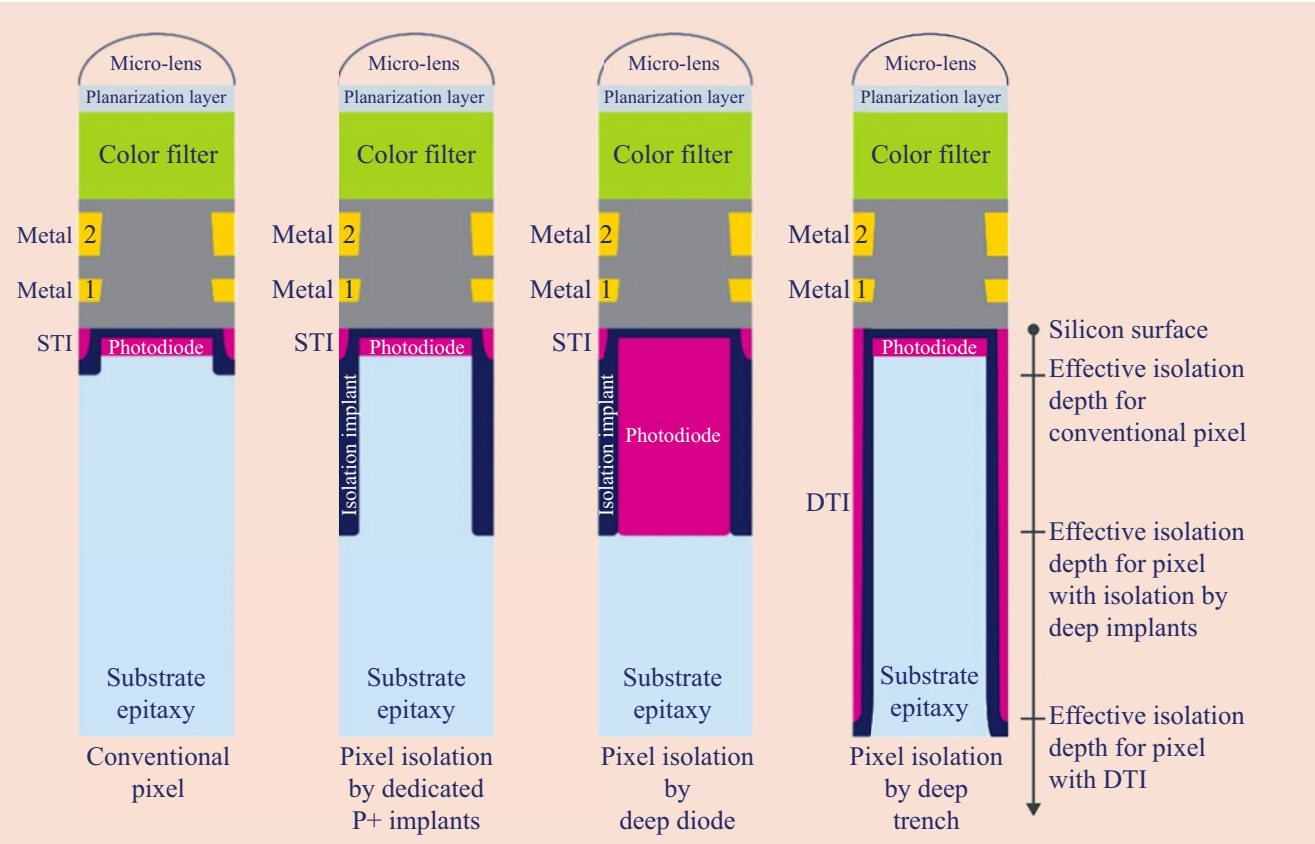

Fig. 18.61 Evolution of the techniques for pixel isolation. (© 2018 by STMicroelectronics)

is annealed and activated by a powerful laser beam pulse, capable to provide high energy for 100–200 ns. In this way, a localized thermal treatment is applied, and the temperature in the metallization area of the wafer does not change. Despite this methodology being now consolidated for CMOS, the equipment to perform laser annealing are expensive and not standard for regular CMOS foundries. Another option is the deposition of high K passivation (Ta_2O_5 on HfO_2 or Al_2O_3) materials. These materials are optimized as antireflective coating (ARC) in order to increase quantum efficiency (Fig. 18.63).

Adopting a BSI flow, the photodiode is directly below the lens and the filters, with the metallization located in the back of the flipped wafer.

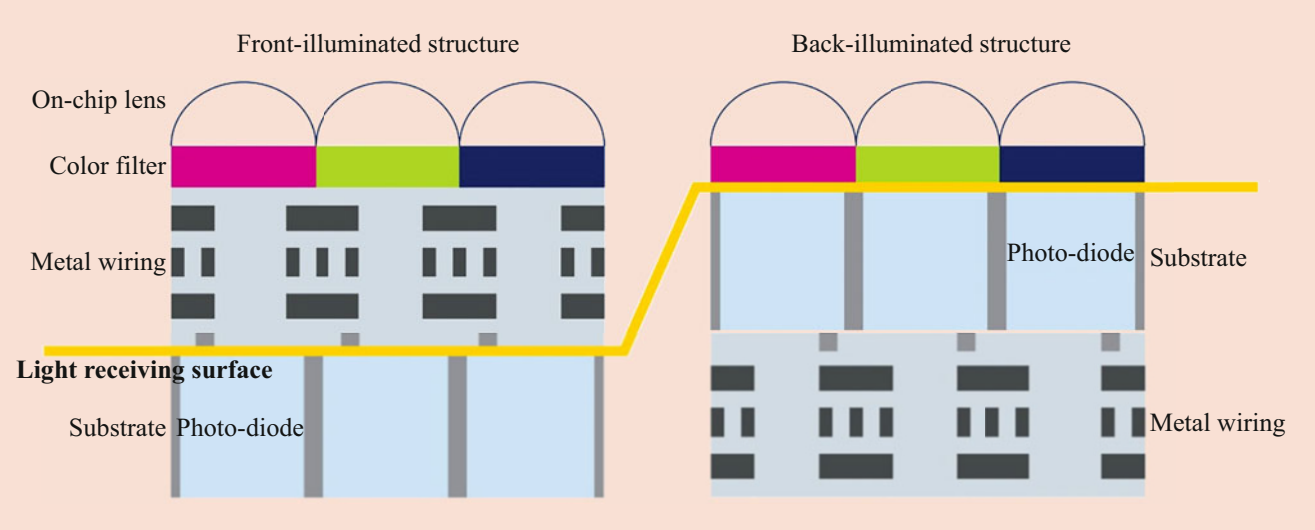

Fig. 18.62 Schematic cross section of a FSI and BSI CMOS image sensor pixel. (© 2018 by STMicroelectronics)

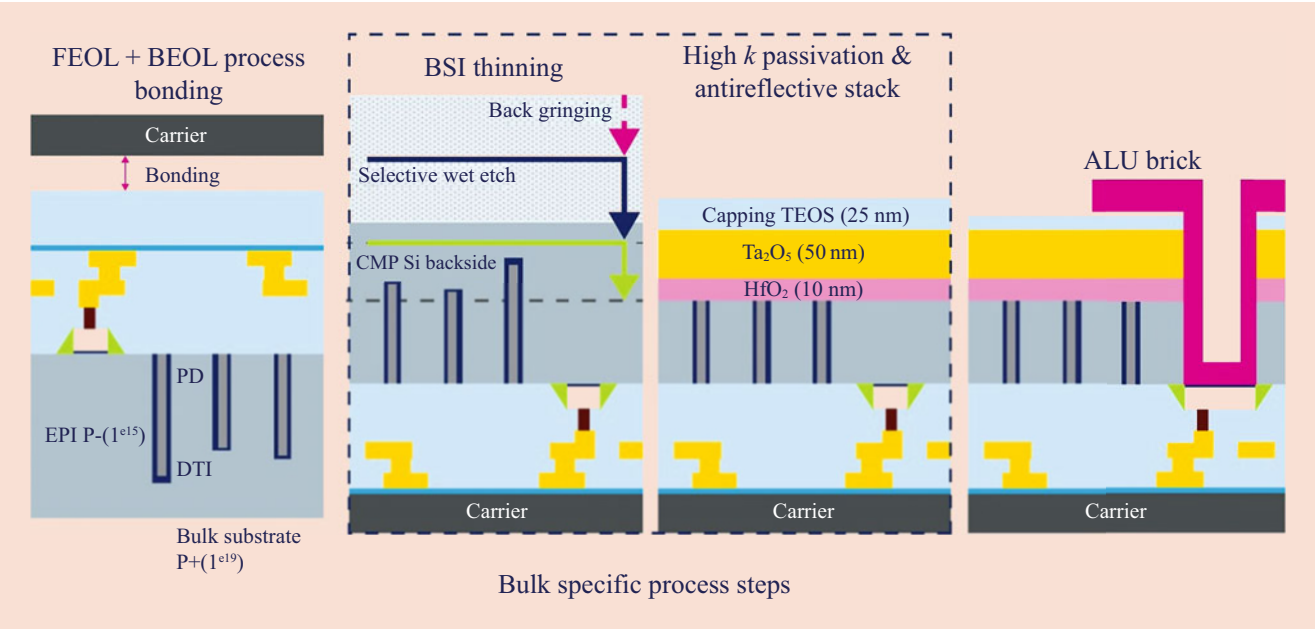

Fig. 18.63 Illustration of BSI schematic process flow with high *k* passivation. (© 2018 by STMicroelectronics)

The advantages of BSI are several: quantum efficiency increases (more photons reach the active area), and a higher fill factor can be obtained; metal backscattering is suppressed and losses are reduced; chief ray angle is improved.

3-D Integration

CMOS evolution takes advantage from lithographic node reduction, while in CMOS for imagers, this evolution is limited by the search for QE, and, despite the new BSI option, there are still manufacturing limitations.

3-D integration is the technique to stack wafers, whose technology may be also completely different, in multiple layers (heterogeneous integration), to form a single device monolithically packaged (Fig. 18.64).

In the past, this integration was obtained with techniques showing several limitations. Wire bonding interconnections have limited maximum current density, electromagnetic interference issues in case of high frequency in operation, and reliability issues. Flip chip is an expensive process and only two dice can be assembled.

Nowadays, more sophisticated manufacturing options are available and 3-D integration can even reach a pixel-level scale. A pixel can be made of a BSI imager stacked on a CMOS die containing the analog and digital circuitry

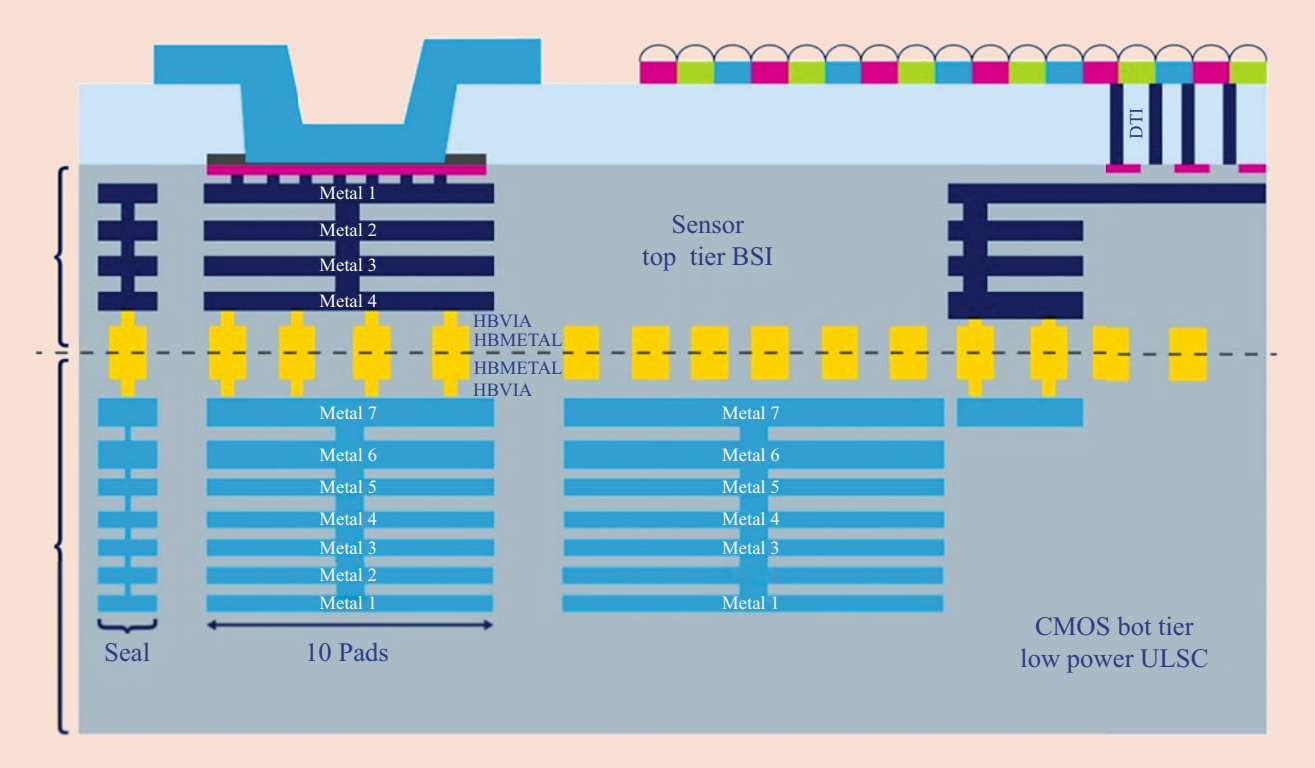

Fig. 18.64 Example of heterogeneous integration of multiple layers in a single device. (© 2018 by STMicroelectronics)

(sometimes including also a memory). The alignment of the wafers is crucial to avoid a drastic reduction of QE and optimize the SNR (Fig. 18.65).

In 3-D stacked BSI, wafer-to-wafer alignment is done with specific equipment allowing a precision in the range of about 0.2 μm. Wafer-to-wafer bonding includes two phases. In the first step, after surface preparation by plasma activation, direct bonding of the silicon oxide on the surface of the two wafers is performed. This process is also known as molecular bonding. Then an annealing induces copper thermal dilatation and coalescence between copper metals of the two wafers. This methodology can guarantee a scalable process for pixel pitch up to 1 μm (Figs. 18.66 and 18.67).

3-D Sensing

3-D sensing is a depth sensing technology that augments camera capabilities for facial and object recognition in augmented reality, gaming, autonomous driving, and a wide range of application. 3-D sensing can be achieved using a number of different technologies among which are stereo light, structured light, and time of flight.

Stereo Light

Stereo light is split into two clusters: active and passive stereo vision. The main advantage, using this technology, is the possibility to obtain 3-D images with a very high resolution and to use the multiple cameras already present, for example, in the top models of mobile phones to obtain a complete 3-D vision with a good depth resolution. In most cases, it is used for professional applications, as this modality requires a high computation from the main video processor and increased depth resolution is strictly dependent on the base line increase as per the following formula:

$$\Delta z \propto \frac{z^2}{b \cdot f} \tag{18.37}$$

where Δz is depth error, z is depth of point of interest, b is the baseline, and f is the focal length.

To avoid the several mistakes associated with parallax error, a tight calibration is required; for this reason, there could be systems where active light option is used, bundled with a time of flight system. Most probably, the 5G and higher performances in the processor, together with some specific entertainment applications (3-D high-resolution scanning, interactive movies), may boost this system. For nomadic systems the calibration costs, power consumption, and baseline form factor will remain in any case a limitation versus other options. On top, depending on the environment, the system can make systemic mistakes if in presence of plane structures with the same color scale (i.e., a white desk with a white wall in the back). In this case, an active stereo solution may be required or, in order to avoid too complex solutions, a ToF can be used.

Structured Light

This is also a geometric system, but, different from stereo light, in general a low-resolution camera is adopted. The measurement is made projecting a finite number of dots (dot matrix or pattern) using the active illumination system (in general a VCSEL with a diffractive lens), creating a pattern in the area/geometry to be measured. The measure is the deviation between the expected position of the dot and the real observed position.

In this case, the baseline is the distance in between the light source and the sensing element, so the same formula for stereo light reported before is still valid. Consequently, the baseline is of essence to increase the distance of the measurement.

One of the most intuitive uses of the structured light is face recognition: the higher the number of dots, the better the image depth precision is. This method implies a lighter processing with respect to the stereographic view and allows higher precision at shorter distance, making the system ideal for face recognition in the front camera of the mobile phones and in security applications.

In addition, this technique requires a rigid calibration with very low tolerances, high precision, and stability in order to guarantee measurement precision in the whole range of operative conditions. Calibration can be simplified by using integrated modules with both sensor and light emitter integrated. This solution is widely adopted in consumer and mobile applications, even if there are limitations due to baseline dimension.

In general, a low-resolution camera QVGA is used bundled with near-infrared (NIR) VCSEL. NIR is ideal to have a detection with different light environment; a flood illuminator may be required to mitigate the external light when very intense. With respect to ToF, in this case, scanning speed and accuracy are higher at lower distance, but processing is more intense than ToF, and calibration is much more complex. Since the light is rigidly controlled, interference with other similar projectors illuminating the same image is less frequent than with time of flight system, assuring a better immunity.

Time of Flight

Time of flight solutions are based on sensor elements that can measure a distance by analyzing the reflected light emitted by a punctual light source (a LED or a VCSEL in general). The illuminator is projecting a controlled light on an object that reflects it. A receiver (SPAD) captures reflected light. Analyzing the reflected light and the time occurred from the emission to the reception of the light, the system is capable to measure the distance. Each pixel encodes the distance to the corresponding point in the scene (Fig. 18.68).

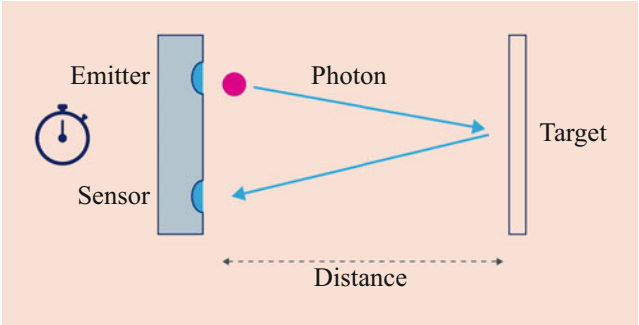

Fig. 18.68 Time of flight principle. (© 2018 by STMicroelectronics)

The methodology is not triangulating any distance as in the previous examples; thus the calculation of the video processor and the calibration are simplified.

The unique sensing architecture of the ToF camera means that a raw depth image contains both systematic and non-systematic bias that have to be resolved for robust depth imaging. The most frequent problems are related to low depth precision and low spatial resolution, as well as errors caused by radiometric, geometric, and illumination variations of the environment, including also interferences due to the contemporary presence of several ToF. We can consider time of flight a valid and reliable solution with fast scanning, low consumption post-processing, and easy calibration, even if less accurate than other methods and generating some specific errors. Other advantages are relaxed mechanical tolerances and rigidity requirements (not relying on geometrical assumptions), simpler calibration, stability during lifetime, and less power-consuming self-calibration.

Main disadvantage is that ToF cameras today typically have a relatively low resolution (maximum 1MP and often much lower). Therefore, to create a 3-D high-resolution image, a composition and post-processing software solution must be used, increasing the computational power again. Ultimately for short distance range (about 1 m), structured light gives higher accuracy at higher speed and, for this reason, is used in the frontal camera of some mobile phone top brands.

Direct Time of Flight and Indirect Time of Flight

Time of flight can be split into two groups, depending on the way the system is measuring the distance: direct and the indirect time of flight (respectively, dToF and iToF).

In dToF, the system measures the time t_d of the echo returning from an object and derives distance z as

$$z = \frac{c \cdot t}{2} \tag{18.38}$$

where c is the speed of light.

In the iToF that requires modulation, the phase shift between outgoing and incoming radiation is measured, and the distance is computed according to the following formula:

$$z = \frac{c \cdot \varphi}{2 \cdot 2\pi f} \tag{18.39}$$

where f is the frequency of the modulated signal (in general a square or sine wave modulation is adopted).

A maximum operating range exists, due to the possibility of ambiguous signals. If the light travels back and forth during a period longer than the period of the modulated light, then the distance calculation will be wrong, as the sensor is not capable to make a difference between a signal coming back from a far distance and another signal coming back from a closer distance with the same phase shift (Fig. 18.69).

In particular, if λ_m is the wavelength of the modulated signal, this critical distance is the following:

$$d = \frac{\lambda_m}{2} = \frac{c}{2f} \tag{18.40}$$

The unambiguous range is the one-way distance and equals half of the maximum distance the light can reach during a period. For example, at 15 MHz it will be 10 m.

Evolution of sensors and high capability of integration in particular on CMOS technology made ToF easy to miniaturize, adopting ultrafast photodiodes, a global shutter, and an analog storage capable of 100 frames per second. The global shutter with the storage system must collect the image got from the sensor, while the sensor must be synchronized with a fast light source emitter.

Optical Parameters and Field of View

In ToF, light is generally coming from a source (LED or VCSEL) operating in the near-infrared range. The sensor is sensitive to the ambient light over-imposed. A high ambient light value will lower the signal-to-noise ratio (SNR). Typical signal shows a plateau, due to environment and dark current, and a peak, corresponding to the signal. Thus, the noise is distributed in time and can be consequently filtered.

Several noise sources can be identified in the complete optical module, related to signal transmission and reception (Fig. 18.70).

In order to gather light reflected from the scene, a lens is adopted, determining the field of view (FOV) of the sensor and the consequent amount of modulated light that this lens will gather on the sensor to create the depth image.

Focal length is the distance from the back of the lens to the plane of the image formed of an object placed infinitely far in front of the lens. The angular field of view of a lens is related to the focal length as for the following equation:

$$\mathrm{FOV} = 2\tan^{-1}\left(\frac{h}{2f}\right) \tag{18.41}$$

where f is the focal length and h is the horizontal dimension of the lens.

The shorter the focal length, the shorter the distance needed to obtain the same FOV compared to a longer focal length lens. The lower the focal number, the better the SNR.

Another issue in ToF is the problem of occlusion shadows, a limiting factor for 3-D vision. FOV is strictly affecting this issue since the critical distance of the object projecting a shadow is related to the FOV.

A last important effect that may produce artifacts is the motion blur. Motion blur is linked to relative motion of the camera with respect to the target, causing errors in the calculation of the depth.

Non-systematic errors can also occur:

- Light scattering: Different levels of illumination in two different objects at different distance may cause a depth distortion.
- Multipath error: Linked to the quoting of concave shapes. In this case the captor is not coherently interpreting the reflection coming from adjacent points, giving back a distorted image.
- Object boundary error: When the edge of an object in foreground and a wide background have similar color, the edge of the object in foreground is distorted.

ToF has also systematic intrinsic depth errors in particular due to:

- Amplitude ambiguity: The amplitude of an IR signal depends on the distance but also on the color of the measured object. This may lead to misinterpretation of the phase shift and consequent distance errors.
- Integration time based: Longer integration time is giving higher accuracy.
- Temperature and IR demodulation.

In conclusion, we can compare the different systems for the 3-D sensing solution using the following table (Table 18.5).

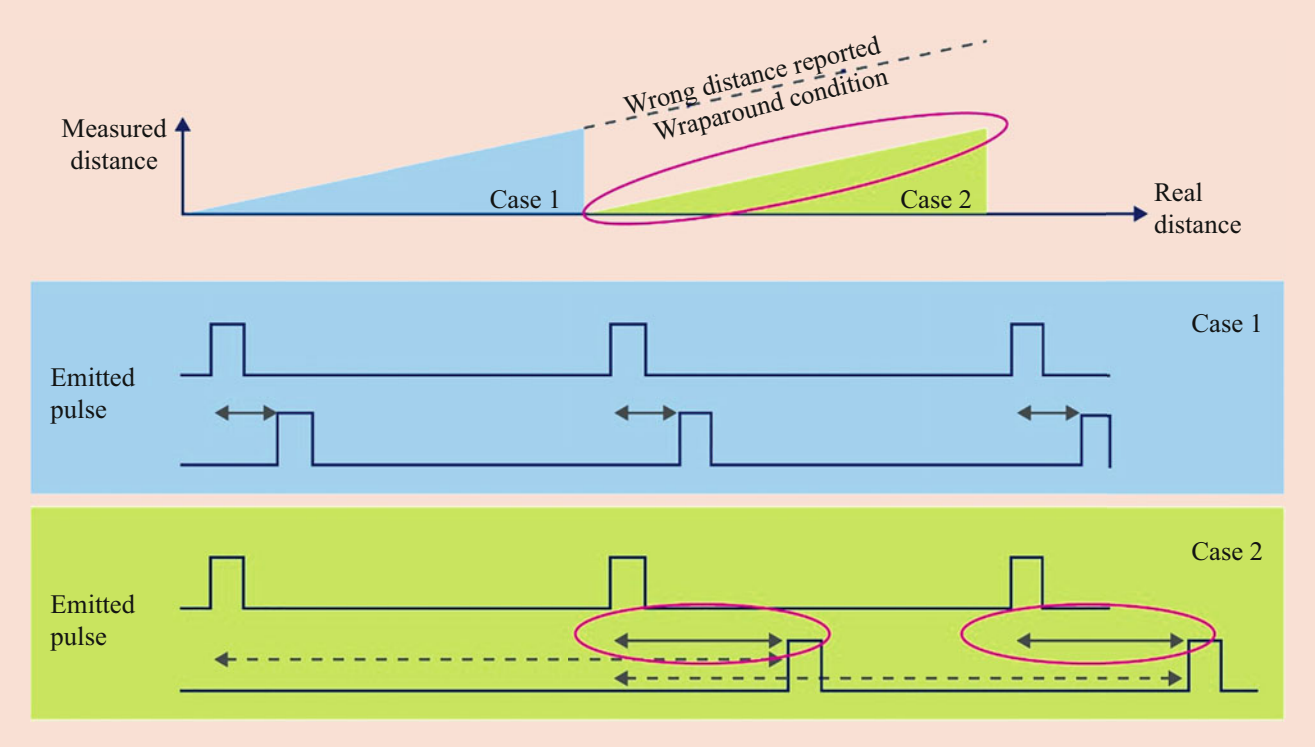

Fig. 18.69 Representation of the issues related to modulating period. (© 2018 by STMicroelectronics)

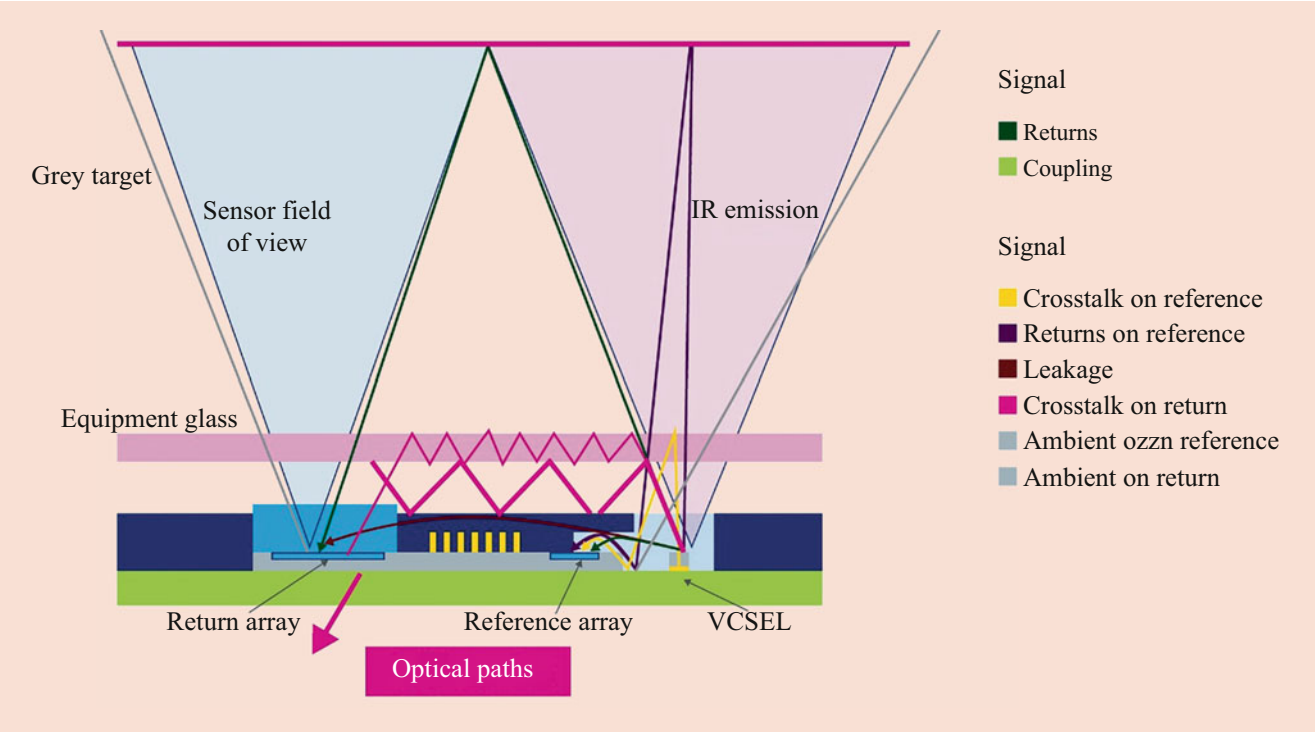

Fig. 18.70 Schematic representation of signal and noise paths. (© 2018 by STMicroelectronics)

Table 18.5 Comparison between different 3-D imaging techniques

Key feature	Stereo	Structured light	dToF	iToF
Baseline constraint	Yes	Yes	No	No
Mechanical alignment	Yes	Yes	No if all-in-one package	No if all-in-one package
Calibration cost	Much higher	Much higher	Much lower	Much lower
Optics	Standard	Standard and dedicated	Standard and dedicated	Standard and dedicated
Illumination	None, or diffuse	VCSEL, with coding lens	VCSEL, pulsed	VCSEL, modulated
Imager technology	Standard	Global shutter	SPAD	Fast photodiode
Number of pixels	Several Mpxl	1–3 Mpxl	< 100 Kpxl	100 kpxl to 1 Mpxl

Total system cost may vary, but we can affirm that ToF is about 30–40% cheaper than structured light. On the other hand, structured light is more accurate and more suitable for secure application (i.e., payment with people identification), allows an easier 2-D extraction (ideal for eye tracking in cabin driver monitoring), offers higher resolution, and is less prone to ToF errors.

Acknowledgments With great pleasure and appreciations, the authors acknowledge the great support of Silvia Adorno, Paolo Ferrari, Carlo Valzasina, Alessandro Tocchio, Luca Falorni, Enri Duqi, Lorenzo Baldo, Dario Paci, Giorgio Allegato, Federico Vercesi, Lorenzo Corso, Alessandro Balzelli, Fabrizio Speroni, Fabio Banfi, Marcella Capezzuto, Giuseppe Bruno, and Michele Vaiana. In addition, many stimulating and interesting discussions with many colleagues at STMicroelectronics were important cornerstone for the content of this chapter. Thank you all very much.

Abstract

In this review chapter, we present the current state of the art of photovoltaic device technology. We begin with an overview of the fundamentals of solar cell device operation, and the nature of the solar energy spectrum and light absorption in devices. We then go into detail of the basics of solar cell operation, and the effects of various factors on the primary figures of merit, the open circuit voltage, short circuit current, and fill factor. In particular we focus on recombination, both in terms of the photocurrent and the dark current affecting the cell voltage. We then discuss heterojunction solar cells, and the general concept of carrier selective structures, which improve solar cell performance. We summarize the main single junction technologies and their efficiencies historically, starting with Si wafer-based technology and GaAs, then thin film technology, and organic solar cells, ending with recent developments of hybrid perovskite-based solar cells.

The limits of solar cell performance in terms of energy conversion efficiency are discussed, where we introduce the concept of detailed balance to derive the Shockley-Queisser limit for single junction cells. Methods of circumventing this single gap limit are discussed, which set the stage for discussing multijunction or tandem solar cells which currently hold the record for highest conversion efficiency in any solar technology. We then discuss nanotechnology in general, and how it is increasingly incorporated in modern solar cells. In this context, we discuss the use of nanostructures in improving light management in solar cells by enhancing light trapping beyond the classical limit. We discuss quantum dot/nanoparticle-based cells such as dye-sensitized solar cells and nanowire solar cells. Finally, we conclude by discussing advanced concept solar cell structures such as intermediate band, multiexciton generation, and hot carrier solar cells, and their theoretical capability of greatly exceeding the Shockley-Queisser limit.

19.1 Background and Basic Operation of Solar Cells

Solar cells are semiconductor-based devices primarily, which convert sunlight directly to electrical energy through the *photovoltaic effect*, which is the appearance of a voltage and current when light is incident on a material. The photovoltaic effect was first reported by Edmond Becquerel in 1839, who observed a voltage and current resulting from light incident on electrochemical cells. Later in the 1800s, the first solid-state solar cells were developed based on platinum-selenium junctions. The first semiconductor-based pn junction cell was developed in the late 1930s and patented in 1946 by Russell Ohl at Bell Laboratories. The first practical solar cell devices utilizing the solar spectrum were demonstrated in 1954 at Bell Laboratories. While too expensive at the time for terrestrial applications, the burgeoning space industry found the first commercial applications of solar cells, as lightweight and long lifetime power sources replacing traditional battery technology for spacecraft in the late 1950s. Photovoltaics has since developed into the fastest growing source of terrestrial renewable energy, with an installed global capacity of over 600 GW peak energy by the end of 2019. This growth in capacity has been driven by the exponential decrease in the manufacturing cost for photovoltaic panels, which has dropped from $75/watt in the late 1970s to under $0.30/watt today, as a result of continuous improvements in materials, device efficiency, and manufacturing scale-up. Coupled with this dramatic cost reduction, the lifetime of solar panels is in excess of 25 years, which has dramatically reduced the levelized cost of electricity (LCOE) from photovoltaics, with some recent utility-scale installations priced below $0.02/kWhr, cheaper than any other current source of electricity.

Figure 19.1 illustrates the photovoltaic conversion process in a *pn* homojunction (same material on each side). It shows the energy band diagram (representative of the potential energy of electrons) as a function of position across the junction, where E_c is the minimum energy of the *conduction band*, which is primarily in unfilled state, and E_v is the maximum energy of the valence band which is almost completely filled. They are separated by an energy gap, E_g (1.12 eV in the case of Si at room temperature, the dominant semiconductor material), where no states exist in the ideal material. The junction occurs between an n-type semiconductor material (intentionally doped with donor atoms that contribute electrons to the conduction band) and a p-type material doped with acceptors, which remove an electron from the valence band, leaving behind a positively charged *hole*, which behaves as a positive charge carrier. The degree of filling of either the conduction band by electrons or the valence bands by holes is represented by the Fermi energies on the n- and p-sides, denoted E_{fn} and E_{fp} in the figure. At equilibrium, the Fermi energies are the same across the junction. At the junction, because of the huge gradient of positive charge on one side and negative on the other, a *space charge region* (SCR) is established at the junction, which is devoid of free carriers, and has a high electric field which opposes the flow of free charge from the n-region to the p-region and vice versa. As shown in Fig. 19.1, this results in a potential barrier for electrons on the n-side (right side) to cross the junction, while it is likewise a potential barrier for holes from the p-side (left side) to move across (since the diagram is of electron potential energy, increasing hole potential and kinetic energy is downward).

In the quantum mechanical description of photovoltaics, photons (quanta of electromagnetic radiation) are absorbed if their energy, $h\nu$ (ν is the frequency of the incident light), exceeds the bandgap, and, in so doing, excite an electron from a filled state in the valence band to an empty state in the conduction band, creating *electron-hole pairs* (EHPs) as shown. Photons below the bandgap are not absorbed, which is the first major loss mechanism in terms of conversion of optical to electrical energy. The photoexcited electron and hole each have an excess kinetic energy above or below the conduction and valence band edges, respectively, and on a very short time scale (picoseconds), they relax to the their respective band edges through thermal losses to the underlying semiconductor material (through phonon emission, where quantum mechanically, phonons are quanta of the wave-like vibrational motion of the crystal). Hence, all the excess energy of the photon above the bandgap is lost, which is the second major loss mechanism, limiting the conversion efficiency of a solar cell as discussed in Sect. 19.5.

Once an EHP is created by absorption of a photon, what is required is charge separation of the electron and hole to opposite contacts to establish a *photocurrent*. This process requires some sort of symmetry breaking in the material, which is provided by the SCR shown in Fig. 19.1, where, as shown, the photoexcited electron on the p-side, if it reaches the edge of the SCR through diffusive motion, is swept across by the high electric field contributing to the photocurrent. The corresponding hole of the initial EHP sees a barrier at the junction on the other hand and so preferentially finds its way to the contact in the p-type material where it is extracted. The opposite process occurs for photons absorbed on the n-side but with the result of a photocurrent in the same direction. If the electron or hole created on a given side of the SCR *recombines*, i.e., the conduction band electron annihilates a

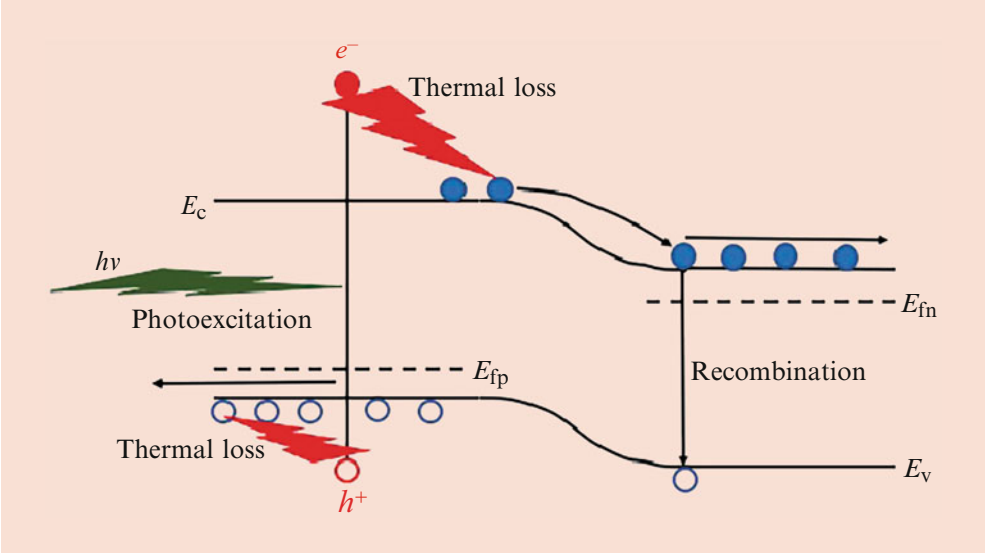

Fig. 19.1 Illustration of the physics of the photovoltaic effect in a *pn* junction solar cell

hole in the valence band either through being trapped in a defect state (Shockley-Read-Hall recombination) or directly via band to band recombination and light emission (radiative recombination), then that EHP is lost to the photocurrent generation process. Therefore, another contribution to the overall conversion efficiency is the competition between extraction of the carriers and recombination before carriers are separated by the junction.

In terms of the solar cell delivering power to an external load, Fig. 19.2 illustrates the equivalent circuit model for a solar cell and its load. It consists of an ideal current source corresponding to the photocurrent, I_{ph}, in parallel with a diode, representing the *pn* junction. For a *pn* junction in the dark, when it is forward biased with a positive voltage applied to the p-side with respect to the opposite side, a large current can flow, due to the lowering of the potential barrier in Fig. 19.1, whereas in reverse bias, this barrier is increased by the bias, creating a large barrier to charge flow and hence small current. The general form of the diode current for junction devices is exponential

$$I_D = I_0 \left(e^{qV_D/nkT} - 1\right) \tag{19.1}$$

where V_D is the voltage across the diode (the same as V, the voltage across the load in Fig. 19.2), q is the charge of an electron, n is the ideality factor which varies between 1 and 2 usually, and I_0 is the reverse saturation current, which physically is a result of recombination of electrons and holes in and near the junction. As discussed in Sect. 19.3.1, recombination can be radiative, where a photon is emitted when an electron decays into a hole state; it can occur through intermediate trap states in the bandgap, or through Auger processes, and typically has an exponential dependence on the bandgap over the thermal voltage, i.e., $-E_g/kT$. Eq. 19.1 shows that for positive V_D the current increases exponentially whereas in reverse bias, for negative V_D, the current goes to a small value, I_0. In terms of the equivalent circuit in Fig. 19.2, under short circuit current conditions ($R_L = 0$), the short circuit current equals the photocurrent, $I_{sc} = I_{ph}$. As the resistance of the load increases from zero, there is an increasing voltage across the diode, $V_D = V = IR_L$, due to the photocurrent which forward biases the diode, increasing I_D, and hence decreasing the net current to the load. The load current decreases until it goes to zero, corresponding to open circuit conditions when $R_L = \infty$. Under open circuit conditions, $I_D = I_{ph} = I_{sc}$. Equating the diode current with the short circuit current in Eq. (19.1) at open circuit voltage conditions, $V_D = V_{oc}$, leads to

$$V_{oc} = \frac{nkT}{q} \ln\left(\frac{I_{sc}}{I_0} + 1\right) \tag{19.2}$$

The open circuit voltage depends most importantly on the reverse saturation current, I_0, characteristic of the *pn* junction, and, as mentioned above, decreases exponentially with bandgap. Hence the open circuit voltage scales linearly with bandgap, increasing for increasing bandgap materials, and empirically is found to be about 0.4 V less than the bandgap for a given material in well-developed technologies, i.e., $V_{oc} \approx E_G(in\ volts) - 0.4$ V.

Figure 19.2 also illustrates the current-voltage characteristic of the solar cell in the dark, and under illumination, where the convention has been used of defining the net solar cell current, I, as flowing into the device, corresponding to negative power in terms of the product of IV, or power generation. As can be seen, the I-V characteristic under illumination is

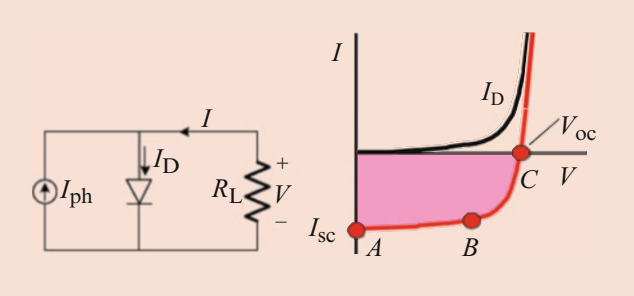

Fig. 19.2 Equivalent circuit of the solar cell and the corresponding current-voltage characteristics and important points along the *I-V* curve

shifted rigidly downward, which illustrates the assumption of *superposition*, that the dark current and photocurrent can be treated independently, which is not generally the case. The points *A*, *B*, and *C* along the curve denote the short circuit current, the maximum power point, and open circuit. The maximum power at point *B* is $P_m = I_m\, V_m$, which is less than the product $I_{sc}\, V_{oc}$, due to the "roundness" of the *I-V* curve as seen in Fig. 19.2, characterized by the *fill factor* (*FF*), i.e., $P_m = \mathrm{FF} I_{sc}\, V_{oc}$. In terms of the total optical energy incident on the device area, P_{in}, the optical to electrical conversion efficiency, η, is given by

$$\eta = \frac{V_{oc} I_{sc} \mathrm{FF}}{P_{in}} \tag{19.3}$$

The optical to electrical conversion efficiency,η, I_{sc}, V_{oc}, and the fill factor, FF, are all figures of merit related to the performance of different photovoltaic technologies, discussed in more depth throughout the rest of this chapter. In what follows, we go into more depth into the materials and physics of present-day photovoltaics technology, starting with the properties of the solar spectrum, and then beginning with Si-based solar cells that are currently the dominant technology worldwide, and continuing through thin film and organic technologies. Due to space limitations, we only provide the basics of solar cell device physics, which are covered in more detail in [1]. We then look at what limits the efficiency of conventional solar cells, and look at more advanced approaches to high efficiency performance in terms of multiple junction solar cells, as well as advanced concept approaches, and implementations thereof using nanotechnology, and some perspectives on future developments in the field.

19.2 Solar Spectrum and Optical Properties

In the present section, we first introduce the properties of the solar spectrum in terms of its blackbody characteristic from the sun incident on Earth, and atmospheric absorption and scattering effects on the corresponding terrestrial solar spectrum which are relevant for solar energy conversion at different locations on Earth. We then discuss the physics of optical absorption in semiconductors, and some basic design considerations for solar cells in terms of maximizing absorption and the corresponding photocurrent.

19.2.1 Solar Irradiance

The solar spectrum in space is modeled to a high level of accuracy by Planck's blackbody radiation law, where the intensity as a function of wavelength is given by

$$I(\lambda) = R_{sun}^2/D^2 \times \frac{2\pi hc^2}{\lambda^5 \left(\exp\left(\frac{hc}{\lambda kT}\right) - 1\right)} \tag{19.4}$$

where R_{sun} is the radius of the sun, D is the distance from the sun, T is the temperature of the sun, λ is the wavelength, c is the speed of light in vacuum, h is Plank's constant, and k is Boltzmann's constant. In terms of the photon flux associated with this intensity, the number of photons per unit time per unit area is simply found by dividing by the photon energy.

$$N(\lambda) = I(\lambda)/(h\nu) = \frac{\lambda I(\lambda)}{hc}; \quad \lambda\nu = c \tag{19.5}$$

where N is the photon flux in terms of number per unit time per unit area per unit wavelength.

Figure 19.3 shows the ideal blackbody intensity assuming a temperature of 5250 C in Eq. (19.4) (the solid curve), compared with the solar spectrum at the top of the Earth's atmosphere, where the difference is quite small. The red curve shows the actual spectrum somewhere on the Earth's surface, where absorption and reflection losses from atmospheric constituents (water, CO_2, etc.) as well as Raleigh scattering (at shorter wavelengths) reduce the intensity of light, particularly at certain preferential absorption wavelengths.

Integration of Eq. (19.4) over all wavelengths (assuming the temperature of the sun is 5762 K) gives a value of 1366 W/m^2, referred to as the *solar constant*, representing the maximum available solar power reaching the Earth. The intensity on Earth is reduced due to atmospheric absorption as evidenced in Fig. 19.3. While local fluctuations in intensity occur due to various local atmospheric effects such as clouds and humidity, in general, the solar intensity at the surface is reduced due to the increasing path length through the atmosphere, and consequent absorption and scattering, which increases with increasing latitude. The increase in path length is characterized by the *air mass*, which is defined as the ratio of path length through the atmosphere normalized by

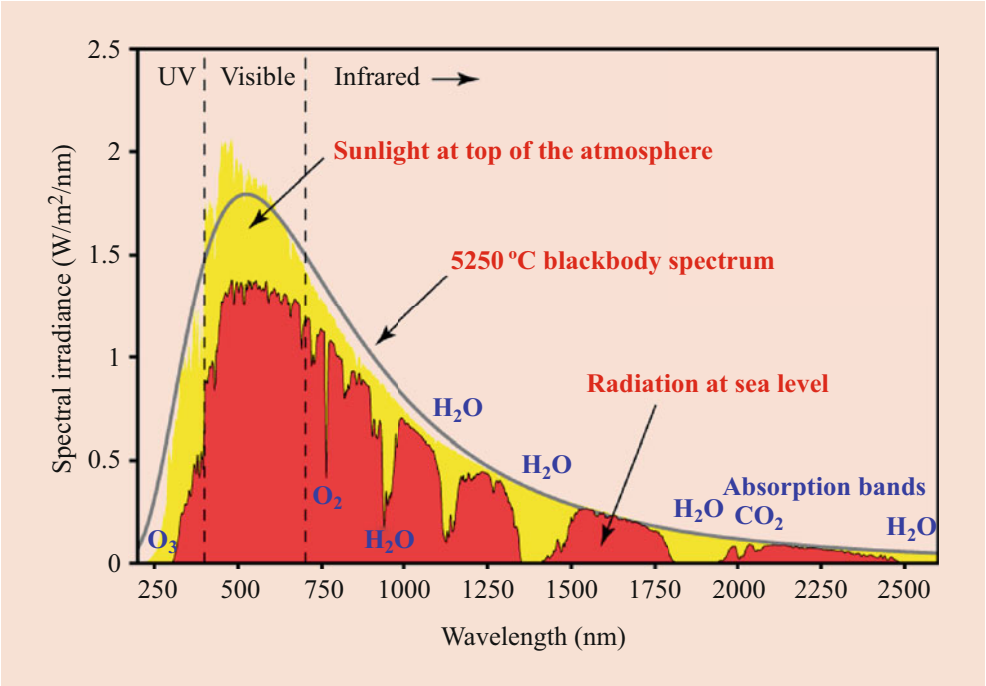

Fig. 19.3 Solar spectrum showing the incident power versus wavelength in outer space and on the Earth's surface. The solid curve is the ideal blackbody spectrum. (Source: the Wikimedia Commons)

the shortest path length at the equator. Geometrically, the air mass is approximately given by

$$\mathrm{AM} = 1/\cos(\theta) \tag{19.6}$$

where θ is the angle between the sun at a given latitude and the normal to the atmosphere at the equator. Equation (19.6) comes from just the geometrical increase in path length in a rectangular geometry. If the curvature of the atmosphere itself is included, and empirical correction to Eq. (19.6) is given as

$$\mathrm{AM} = \frac{1}{\cos(\theta) + 0.50572(96.07995 - \theta)^{-1.6364}} \tag{19.7}$$

AM0 is top of atmosphere, therefore AM = 0. For the sun directly overhead, AM = 1. Given the air mass, AM, the solar intensity at any point is given by the approximate formula [1]

$$I \approx 1.1 \times 1366(0.7)^{\mathrm{AM}^{0.678}} \tag{19.8}$$

A widely used air mass is AM1.5, corresponding to a latitude of 48.2°, representing an average latitude of temperate zones in either the northern and southern hemispheres. The AM1.5 intensity is approximately 930 W/m^2, significantly reduced from the solar constant. Because of atmospheric scattering (Raleigh) as well as dust particles, water vapor, etc., a fraction of the radiation incident on the solar panel is indirect, in the form of diffuse radiation, which comes in from all angles rather than directly from the disk of the sun itself. Both components, diffuse and direct, should be considered in modeling of photovoltaic system performance.

19.2.2 Optical Properties of Photovoltaic Materials

In the previous section, we discussed the intensity and spectral content of solar radiation. For describing solar cell design and operation, what is critically important is the absorption of the incident photons as a function of wavelength, described by the absorption coefficient of the semiconductor described in more detail below.

Optical absorption in semiconductors depends on band to band transitions from the valence band to the conduction band. Due to the quantum nature of light, the absorption of photons can only occur when $h\upsilon > E_G$ (although in fact sub-bandgap photons can be absorbed through impurities and other states in the gap). The nature of such transitions and the strength of absorption depends on whether the semiconductor is a direct or indirect gap material. In the former case, transitions occur directly from valence to conduction band leading to strong absorption when the photon energy exceeds the bandgap. For indirect materials, the conduction and valence

band minimum and maximum, respectively, occur at different crystal momentum, and therefore at the bandgap, a second-order phonon-assisted process is required, and hence absorption is reduced until a direct conduction band minimum is bridged by the photon energy.

The quantity characterizing absorption is the absorption coefficient, α, which is basically the inverse of the average depth a photon penetrates a material before being absorbed. Mathematically, this may be written

$$N_{\mathrm{ph}}(x) = N_{\mathrm{s}} \mathrm{e}^{-\alpha x} \tag{19.9}$$

where $N_{\mathrm{ph}}(x)$ is the photon flux at distance x relative to the surface and N_{s} is the photon flux incident on the surface. The change in the number of photons gives the generation rate, such that

$$G(x) = -\frac{\mathrm{d}N_{\mathrm{ph}}}{\mathrm{d}x} = \alpha N_{\mathrm{s}} \mathrm{e}^{-\alpha x} \tag{19.10}$$

The above equation for the generation rate shows that G varies not only with the wavelength of light but also with distance into the material. Figure 19.4 plots the absorption coefficient as a function of wavelength for several materials. As can be seen, the absorption coefficient for Si is weaker compared to GaAs and InP due to its indirect bandgap for the same relative photon energy to the gap itself (similarly for thin film materials like CdTe), with the consequence that the thickness of Si required for high quantum efficiency (i.e., the number of electrons collected per incident photon) is much higher than for direct gap materials like GaAs.

As illustrated in Fig. 19.4, the absorption coefficient is weakest for a given material for long wavelength photons just above the bandgap in energy, while shorter wavelength photons are absorbed within a short distance from the surface. Thus, the design of a Si solar cell reflects the spectral nature of the absorbed photons. This is illustrated in Fig. 19.5 for a basic Si cell design, where longer wavelength red light has a relatively long absorption depth, whereas short wavelength blue light is absorbed near the surface.

The structure of a commercial Si solar cell device (left panel of Fig. 19.5) typically has a thick base region (here p-type), a narrow emitter layer that is highly doped to minimize lateral resistance, heavy doping near the back contact to reduce recombination of photogenerated electrons there (back surface field), and a grid top contact to the emitter

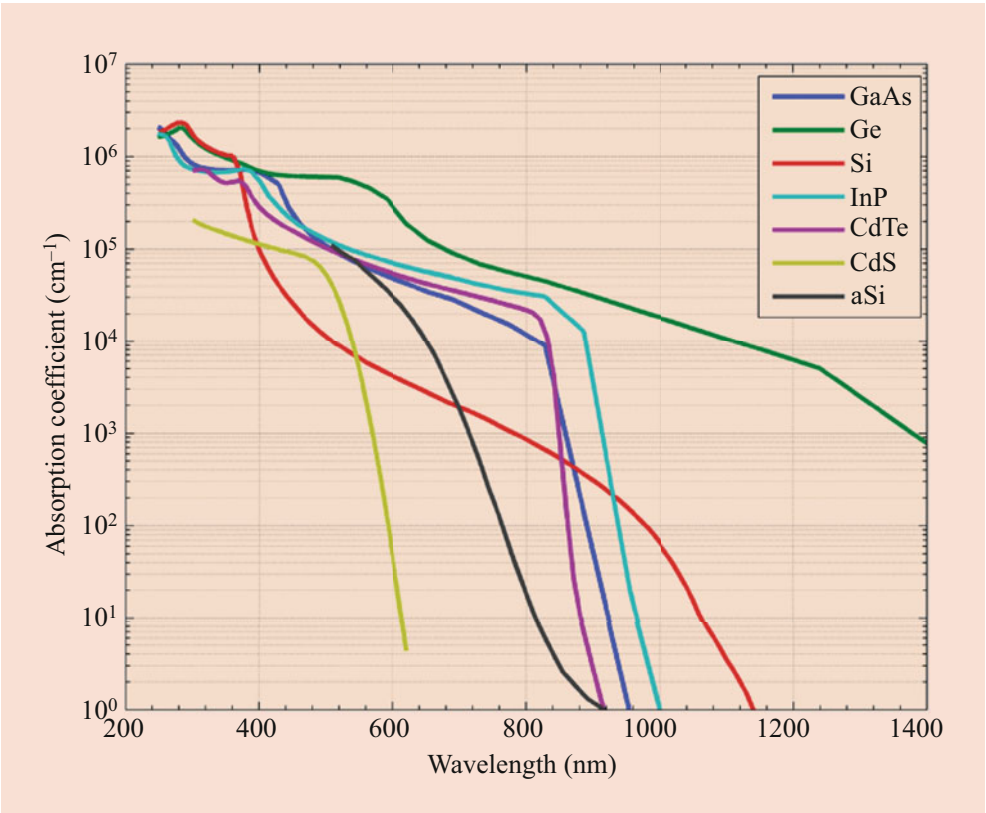

Fig. 19.4 Absorption coefficient versus wavelength for several direct gap materials (GaAs, InP, CdTe, CdS) and two indirect gap materials (Ge, Si) as well as amorphous Si. (With permission from PVEducation.org)

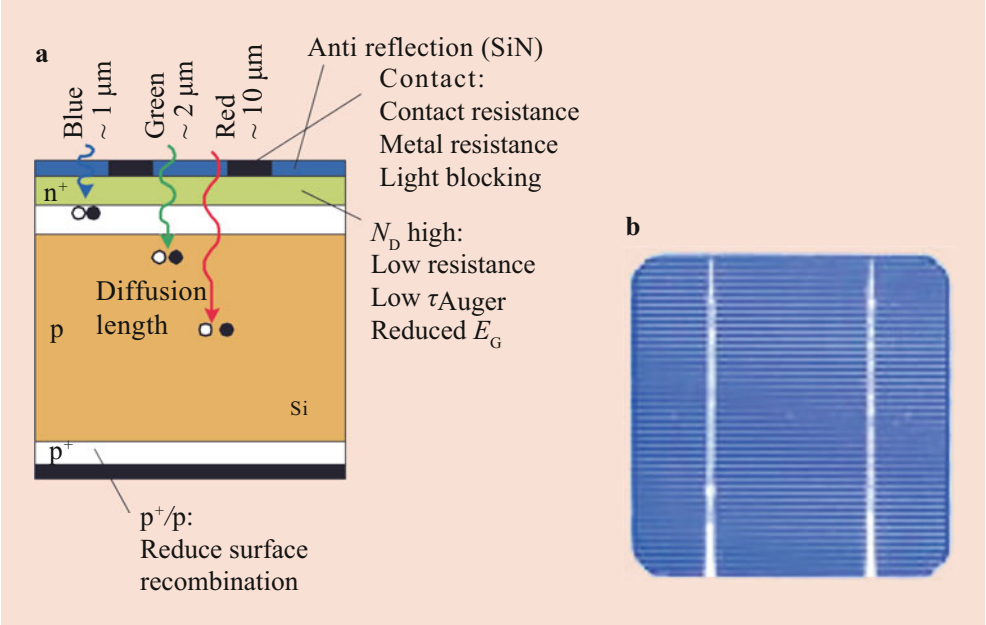

Fig. 19.5 Cross-sectional view showing the structure of a typical Si homojunction solar cell (**a**) showing the penetration of different metallization allowing light absorption and carrier collection with minimal shading (**b**)

which has narrow fingers to minimize optical reflection (right panel is a top view of the grid structure). The design of the top grid involves a trade-off between the shading due to the area of the grid, which reduces the optical absorption through reflection, and the lateral spreading resistance due to current flow in the emitter (n^+) region toward the fingers. Another optical consideration is the reflection of light from the semiconductor surface due to the refractive index difference between the cell and the air (or glass). As shown in Fig. 19.5, the design of the basic cell structure includes an antireflection (AR) coating of a material with refractive index between that of the semiconductor and air (here, e.g., silicon nitride), with the thickness optimized for minimum reflection across the solar spectrum (Fig. 19.3). A number of different wide bandgap insulating materials are used for AR coatings such as SiO_2, MgF_2, and others. Additionally, transparent conducting oxides (TCOs) are often employed, especially in more advanced solar cell architectures, which are wide bandgap materials ($E_G > 3$ eV) and typically heavily n-type self-doped materials due to defects and other sources. In addition to providing a role as an AR material, they provide a conducting surface layer which mitigates spreading resistance effects. As discussed in more detail in Sects. 19.3.2 and 19.7.3, other schemes under the general category of *light management* are employed to increase the path length of light within the semiconductor and thus increase absorption, including a back optical reflector and texturing the front surface to deflect normal incident light into random angles inside the absorbing layer.

19.3 Theory of Operation of Conventional Solar Cells

Homojunction solar cells are basically *pn* junction solar cells from conventional single crystal or multi-crystalline semiconductor wafer-based materials such as Si and GaAs that some authors [2] have referred to as first generation due to their early appearance in the historical development of photovoltaics discussed earlier. Here we provide a brief introduction to the theory of homojunction solar cells but refer the reader to more in-depth treatments of the subject in a number of textbooks [1, 3–6].

As discussed in Sect. 19.1, the overall current-voltage (*I-V*) relationship for a solar cell under illumination is assumed to be a linear superposition of the dark *I-V* of the underlying *pn* junction and the light-induced photocurrent which flows in the opposite direction. The dark current is ultimately dependent on minority carrier (i.e., holes in n-type material) recombination (including the contacts themselves), and as such, an understanding and control of this phenomena are critical to high performance. The photocurrent depends on both the optical generation process discussed in the previous section and on collection of the photogenerated carriers at the junction (shown in Fig. 19.1), which converts minority carriers into majority carriers. The collection process itself depends on minimizing recombination before the carriers reach the junction. The superposition approximation turns out to be well obeyed in state-of-the-art Si and III–V

technologies, although less so in thin film and organic-based technologies, where the nonlinear dependence of recombination on intensity and other factors leads to a breakdown of this approximation. Nevertheless, we begin by considering recombination and its effect on dark current, followed by the photocurrent and control of series resistance effects, and then look at advances in performance through heterojunctions and carrier selective contacts, ending with a discussion of current performance limits of single crystal and multi-crystalline Si and GaAs technology.

19.3.1 Dark Current and Recombination

In the following, we discuss the various recombination mechanisms in semiconductors, and the role of recombination in the dark current of conventional junction solar cells.

Recombination and Minority Carrier Lifetime

Solar cells are highly dependent on the effective minority carrier lifetime, such that the minority carrier lifetime is one of the most important parameters in a solar cell. Solar cell technology can be described as maximizing the effective minority carrier lifetime, given practical constraints such as cost or scalability. The minority carrier lifetime affects both the short circuit current and open circuit voltage as mentioned above. Note that the effective minority carrier lifetime includes the effect of surfaces.

The minority carrier lifetime is dependent on multiple parameters, including the processing history of the material, the type and number of defects in the material, the solar cell operating point, and other device parameters. Here we seek to develop equations and values for the minority carrier lifetimes in terms of relevant material parameters.

The term *minority carrier lifetime* can refer to different physical recombination mechanisms. We define the general term to refer to the effective minority carrier lifetime, which is a combination of both bulk and surface recombination mechanisms. The effective minority carrier lifetime is related to the minority carrier lifetime from individual physical processes by the equation below

$$\frac{1}{\tau_{\text{eff}}} = \frac{1}{\tau_{\text{Auger}}} + \frac{1}{\tau_{\text{radiative}}} + \frac{1}{\tau_{\text{SRH}}} + \frac{1}{\tau_{\text{Surf}}} \tag{19.11}$$

where the four lifetimes correspond to Auger recombination, radiative (direct) recombination, trap-based recombination (Shockley-Read-Hall), and surface recombination. The effective minority carrier lifetime is the parameter, which is usually measured and then de-convolved into its individual components by either additional measurements or by fitting calculations.

Radiative recombination is proportional to the density of electrons in the conduction band, and the density of holes in the valence band, expressed as

$$R_{\text{rad}} = Bnp \tag{19.12}$$

where R_{rad} is the radiative recombination rate of electron-hole pairs (EHPs), the proportionality constant, B, is the recombination coefficient, while n and p are the electron and hole concentrations, respectively. The net radiative recombination of *excess* minority carriers is the total radiative recombination minus the radiative recombination at equilibrium (where $np = {n_i}^2$, with n_i the intrinsic concentration of the material)

$$U_{\text{rad}} = R_{\text{rad}} - R_{\text{rad}}^{\text{eq}} = B\left(np - n_i^2\right) \tag{19.13}$$

The minority carrier lifetime for radiative recombination can be found by

$$U_{\text{rad}} \equiv \frac{\Delta n}{\tau_{\text{Rad}}} = B\left(np - n_i^2\right) \tag{19.14}$$

Letting $n = \Delta n + n_0$ and $p = \Delta n + p_0$, where n_0 and p_0 are the equilibrium carrier concentrations, and using $\Delta n = \Delta p$ (due to charge neutrality) gives

$$\tau_{\text{Rad}} = \frac{1}{B\left((n_0 + p_0) + \Delta n\right)} \tag{19.15}$$

For low-level injection in n-type material ($n_0 \gg \Delta n$ and $n_0 \gg p_0$), where $n_0 \cong N_{\text{D}}$, the donor concentration, the minority carrier recombination due to radiative recombination becomes $\tau_{\text{Rad}} = 1/BN_{\text{D}}$, while for the same case in p-type material, $\tau_{\text{Rad}} = 1/BN_{\text{A}}$. Thus under low injection conditions, the value of the lifetime depends on the doping, but it does not depend on the number of carriers, which is determined by the injection level (the voltage of the solar cell).

For high-level injection on the other hand, $\Delta n \gg (n_0 + p_0)$, and $\tau_{\text{Rad}} = 1/B\Delta n$, which means the radiative lifetime decreases with increasing injection level, which is one way to differentiate this type of recombination in experiments such as time-resolved cathodoluminescence in which the injection level is controlled with the pump beam intensity.

Auger recombination is a three-particle interaction which occurs via two similar processes: (i) the recombination of an electron in the conduction band with a hole in the valence band, where the excess energy is given to an electron in the conduction band, and (ii) the recombination of an electron in the conduction band with a hole in the valence band, where the excess energy is given to a hole in the valence band.

In the first case, the particles involved in the recombination process are two electrons and a hole, and in the second, it is two holes and an electron. In each case, we subtract the recombination at equilibrium. The overall Auger recombination rate for these two processes is then

$$U_{\text{Auger}} = C_{\text{n}} n \left(np - n_i^2\right) + C_{\text{p}} p \left(np - n_i^2\right) \tag{19.16}$$

where C_{n} and C_{p} are the Auger recombination coefficients. Since Auger is often calculated in highly doped or highly excited material, we can usually neglect the $n_i{}^2$ term to get

$$U_{\text{Auger}} \cong C_{\text{n}} n^2 p + C_{\text{p}} p^2 n \tag{19.17}$$

Using the simpler form above and substituting $U_{\text{Auger}} \equiv \frac{\Delta n}{\tau_{\text{Auger}}}$, and also writing $n = \Delta n + n_0$ and $p = \Delta n + p_0$ and using $\Delta n = \Delta p$ (due to charge neutrality), gives

$$\tau_{\text{Auger}} = \frac{1}{C_{\text{p}} \left(n_0^2 + 2n_0 \Delta n + \Delta n^2\right) + C_{\text{n}} \left(p_0^2 + 2p_0 \Delta n + \Delta n^2\right)} \tag{19.18}$$

We sometimes only need the sum of these terms and this is called the ambipolar Auger coefficient C_{a}.

Similar to the radiative case above, under low-level injection conditions, the minority carrier recombination due to Auger in low-level injection becomes

$$\tau_{\text{Auger}} = \frac{1}{C_{\text{p}} N_{\text{D}}^2} \qquad \tau_{\text{Auger}} = \frac{1}{C_{\text{n}} N_{\text{A}}^2} \tag{19.19}$$

for holes in n-type material and electrons in p-type material, respectively. Here the Auger lifetime decreases as the square of the doping concentration, which imposes a limitation in terms of high doping. Under high-level injection conditions, the lifetime depends inversely on the square of the injected carrier concentration (i.e., Δn large)

$$\tau_{\text{Auger}} = \frac{1}{\left(C_{\text{p}} + C_{\text{n}}\right) \Delta n^2} \tag{19.20}$$

Finally, *Shockley-Read-Hall* (SRH) *recombination* is recombination mediated by traps. It is derived by considering the downward and upward transitions for an electron (hole) in a single trap level located at energy E_{T} with density N_{t}. Electrons in the conduction band are assumed to be captured with a rate proportional to the capture cross section, σ_{n}, traveling with a thermal velocity $v_{\text{th}} = \sqrt{3kT/m^*}$

$$\frac{1}{\tau_{p0}} = v_{\text{th}} \sigma_{\text{p}} N_{\text{t}} \tag{19.21}$$

with a similar expression for holes in the valence band. Exponential activation of electrons out of the trap to the conduction band (and electrons from the valence band to the trap level) is assumed as well, leading to the SRH recombination rate

$$U_{\text{SRH}} \equiv \frac{\Delta n}{\tau_{\text{SRH}}} = \frac{np - n_i^2}{\tau_{\text{p0}} \left(n + n_1\right) + \tau_{\text{n0}} \left(p + p_1\right)} \tag{19.22}$$

where

$$n_1 = n_i \exp\left(\frac{E_{\text{T}} - E_i}{kT}\right); p_1 = n_i \exp\left(\frac{E_i - E_{\text{T}}}{kT}\right) \tag{19.23}$$

where E_i is the intrinsic Fermi energy (approximately midgap). For low-level injection, and assuming the trap is located at the intrinsic level, i.e., midgap, the electron and hole minority carrier lifetimes reduce to τ_{n0} and τ_{p0}, respectively.

Surface recombination occurs due to traps at an interface or surface, with a two-dimensional density of trap states. Such states occur intrinsically due to the breaking of the translational symmetry of the crystal, and from dangling or differently bonded states on the surface. Since surface recombination occurs at a plane at a definite location, rather than distributed through the bulk of the solar cell, its effect in terms of the net recombination rate due to surface recombination depends on the distance from the surface. For that reason, the effect of surface recombination is often treated as a boundary condition on the flux due to recombination

$$D_{\text{n}} \frac{\text{d}n_{\text{p}}}{\text{d}x} = S_{\text{n}} \left(n_{\text{p}} - n_{\text{p0}}\right) \tag{19.24}$$

where for minority carrier electrons (n_{p}), D_{n} is the diffusion coefficient and S_{n} is a parameter called the surface recombination velocity, which is a proportionality constant between the excess carrier concentration at the surface, Δn_{p} (the rhs), and the flux toward the surface (lhs). S_{n} itself is proportional to the density of traps at the surface. An ohmic contact, in which equilibrium is established in the contact, can be thought of as surface recombination with an infinite recombination velocity (i.e., $n_{\text{p}} = n_{\text{p0}}$).

Dark Current

A *pn* diode is characterized by the presence of a space charge region (SCR) at the junction between the n- and p-regions due to the balance between the forces of carrier drift (due to electric fields) and diffusion (due to concentration gradients) between the different regions. The SCR is ideally assumed to be devoid of free carriers across its width W, with a fixed charged density due to ionized acceptors and donors for the p- and n-regions, respectively. This charge density is responsible for an electric field across the junction, which opposes the diffusion of carriers into the SCR (within the drift diffusion model of carrier transport), which in turn leads to a built-in potential between the two sides

$$V_{\mathrm{bi}} = \frac{kT}{q}\ln\left(\frac{N_{\mathrm{D}}N_{\mathrm{A}}}{n_i^2}\right) \tag{19.25}$$

and a corresponding width of the depletion region assuming an abrupt doping profile

$$W = \sqrt{\frac{q\left(N_{\mathrm{D}}+N_{\mathrm{A}}\right)\left(V_{\mathrm{bi}}-V_{\mathrm{D}}\right)}{\varepsilon_{\mathrm{s}}N_{\mathrm{D}}N_{\mathrm{A}}}} \tag{19.26}$$

where ε_{s} is the permittivity of the semiconductor, and we have included for generality the forward voltage, V_{D}, applied to the p-side with respect to the n-side.

Under forward bias conditions in the dark, the conventional description of behavior of a *pn* junction device is that the equilibrium state of the semiconductor is broken, leading to a quasi-equilibrium in which excess minority carriers are injected across the junction from their corresponding majority carrier n- and p-regions, due to the lowering of the built-in potential across the junction, as given in the equations above. The dark current in a *pn* junction device then arises from recombination currents due to this excess carrier, both in the bulk of the n- and p-regions through diffusion outside the SCR, as well as recombination within the SCR.

The quasi-equilibrium approximation assumes that the effect of the forward bias is to increase the minority carrier concentrations on either side of the junctions at $x = 0$ and $x' = 0$, as shown in Fig. 19.6, which illustrates an *n* (emitter) and *p* (base) structure. Under low-level injection conditions, the concentrations at these two points may be written

$$n_{\mathrm{p}}\left(x=0\right) = n_{\mathrm{p0}}\mathrm{e}^{qV_D/kT};\; p_{\mathrm{n}}\left(x'=0\right) = p_{\mathrm{n0}}\mathrm{e}^{qV_D/kT} \tag{19.27}$$

where $n_{\mathrm{p0}} = n_i^2/N_{\mathrm{A}}$ and $p_{\mathrm{n0}} = n_i^2/N_{\mathrm{D}}$ are the equilibrium concentrations of minority carrier electrons and holes on the p- and n-sides, respectively.

The regions outside the SCR defined by W in Fig. 19.6 are assumed to be charge neutral with no electric field. Hence, we can solve the semiconductor minority carrier diffusion equations in both regions

$$\begin{aligned} D_{\mathrm{n}}\frac{\mathrm{d}^2n_{\mathrm{p}}(x)}{\mathrm{d}x^2} - \left[U_{\mathrm{n}}(x) - G_{\mathrm{n}}(x)\right] = 0;\; D_{\mathrm{p}}\frac{\mathrm{d}^2p_{\mathrm{n}}\left(x'\right)}{\mathrm{d}x'^2} \\ - \left[U_{\mathrm{p}}\left(x'\right) - G_{\mathrm{p}}\left(x'\right)\right] = 0 \end{aligned} \tag{19.28}$$

where $U_{\mathrm{n,p}}$ and $G_{\mathrm{n,p}}$ are the recombination and generation rates for minority carriers, with $G_{\mathrm{n,p}}(x)$ given by Eq. (19.7), and the holes are solved in the x' coordinate system on the left (positive x' to the right). The solutions require two boundary conditions (BCs); Eq. (19.24) for the excess carrier concentration injected across the boundary serves as BCs at $x, x' = 0$. At the other boundaries, we assumed the surface recombination conditions

$$\begin{aligned} D_{\mathrm{n}}\frac{\mathrm{d}n_{\mathrm{p}}}{\mathrm{d}x}\bigg|_{x=W_{\mathrm{p}}} &= S_{\mathrm{n}}\left(n_{\mathrm{p}}\left(W_{\mathrm{p}}\right) - n_{\mathrm{p0}}\right); \\ D_{\mathrm{p}}\frac{\mathrm{d}p_{\mathrm{n}}}{\mathrm{d}x}\bigg|_{x'=W_{\mathrm{n}}} &= S_{\mathrm{p}}\left(p_{\mathrm{n}}\left(W_{\mathrm{n}}\right) - p_{\mathrm{n0}}\right) \end{aligned} \tag{19.29}$$

For the case of the dark current, $G_{\mathrm{n,p}}(x) = 0$, the general solutions are in the form of hyperbolic functions due to the combination of exponential solutions to the ordinary differential equations above.

The current densities on either side of the junction are expressed in terms of the diffusion current of charge carriers diffusing away from the junction in terms of the carrier gradients

$$J_{\mathrm{n}} = qD_{\mathrm{n}}\frac{\mathrm{d}n_{\mathrm{p}}(x)}{\mathrm{d}x};\; J_{\mathrm{p}} = -qD_{\mathrm{p}}\frac{\mathrm{d}p_{\mathrm{n}}\left(x'\right)}{\mathrm{d}x'} \tag{19.30}$$

The total current is the sum of these two in the general form of Eq. (19.1)

$$J = J_0\left[\mathrm{e}^{qV_{\mathrm{D}}/kT} - 1\right] \tag{19.31}$$

where the reverse saturation current density, J_0, is given in general by.

$$\begin{aligned} J_0 = \Bigg(& \frac{qD_{\mathrm{n}}n_i^2}{L_{\mathrm{n}}N_{\mathrm{A}}}\cdot\frac{\cosh\left(\frac{W_{\mathrm{P}}}{L_{\mathrm{n}}}\right) + \frac{D_{\mathrm{n}}}{S_{\mathrm{n}}L_{\mathrm{n}}}\sinh\left(\frac{W_{\mathrm{P}}}{L_{\mathrm{n}}}\right)}{\frac{D_{\mathrm{n}}}{S_{\mathrm{n}}L_{\mathrm{n}}}\cosh\left(\frac{W_{\mathrm{P}}}{L_{\mathrm{n}}}\right) + \sinh\left(\frac{W_{\mathrm{P}}}{L_{\mathrm{n}}}\right)} \\ & + \frac{qD_{\mathrm{p}}n_i^2}{L_{\mathrm{p}}N_{\mathrm{D}}}\frac{\cosh\left(\frac{W_{\mathrm{N}}}{L_{\mathrm{p}}}\right) + \frac{D_{\mathrm{p}}}{S_{\mathrm{p}}L_{\mathrm{p}}}\sinh\left(\frac{W_{\mathrm{N}}}{L_{\mathrm{n}}}\right)}{\frac{D_{\mathrm{p}}}{S_{\mathrm{p}}L_{\mathrm{p}}}\cosh\left(\frac{W_{\mathrm{N}}}{L_{\mathrm{p}}}\right) + \sinh\left(\frac{W_{\mathrm{N}}}{L_{\mathrm{p}}}\right)}\cdot\Bigg) \end{aligned} \tag{19.32}$$

where $L_{\mathrm{n,p}} = \sqrt{D_{\mathrm{n,p}}\tau_{\mathrm{n,p}}}$ is the diffusion length for electrons (*n*) and holes (*p*), which is the average distance they diffuse before recombining, and the equilibrium minority carrier concentrations, n_{p0} and p_{n0}, have been written in terms of the doping concentrations on either side of the SCR, $n_i^2/N_{\mathrm{A,D}}$, respectively. Here the form of the diode equation has an ideality factor $n = 1$. In the more general case including recombination in the space charge region and high-level injection at high bias, the ideality factor can vary between $n = 1$ and 2 depending on the bias.

The above expression simplifies in two cases, one in which the thicknesses of the emitter and base regions W_{n} and W_{p} are much larger than L_{p} and L_{n}, respectively (short base/emitter), and the other, which corresponds to the opposite, in which the regions are so short that no recombination occurs (short-/base), further assuming ohmic contacts with infinite S_{p} and S_{n} (short base/emitter). This may be written generally as

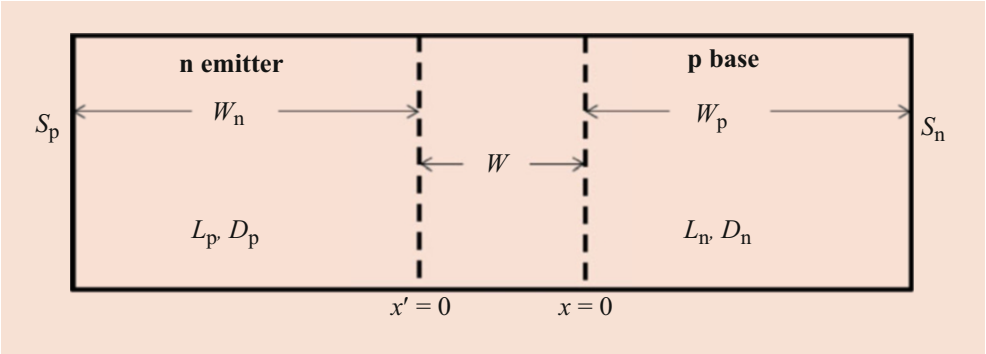

Fig. 19.6 Solution domain for the minority carrier diffusion equations for an *np* junction device

$$J_0 = \left[q\frac{D_n n_i^2}{X_n N_A} + q\frac{D_p n_i^2}{X_p N_D} \right] \tag{19.33}$$

where $X_{n,p} = W_{p,n}$ for the short base/emitter case and $X_{n,p} = L_{n,p}$ for the long base/emitter case.

The open circuit voltage given in Eq. (19.2) can be rewritten in terms of the current densities as

$$V_{oc} = \frac{nkT}{q} \ln\left(\frac{J_{sc}}{J_0} + 1\right) \tag{19.34}$$

Clearly V_{oc} depends on minimizing the dark current, characterized by J_0, which arises due to recombination in the various regions and surfaces. Several general trends can be observed from the expression for J_0. Increasing the doping on both sides increases the built-in potential and correspondingly $V_{oc.}$ However, the diffusion coefficients, $D_{n,p}$, are proportional to the carrier mobility, which degrade with increasing doping due to ionized impurity scattering. Further, for very high doping, there is increased recombination due to Auger processes which decreases the diffusion lengths, as well as bandgap narrowing effects, which increase n_i due to its exponential dependence on the bandgap. Figure 19.7 shows the dependence of the open circuit voltage on doping in a conventional architecture, where the degradation of the diffusion length with doping correlates with a degradation of V_{oc}.

The above analysis did not address specifically the role of surface recombination on the open circuit voltage, but looking at Eq. (19.30), with infinite recombination velocity, the dark current is clearly much larger than the case limited by the diffusion length. Thus, reducing $S_{n,p}$ through *passivation* of the front and back surfaces is critical in good cell performance, particularly considering that in state-of-the-art Si solar cells, the diffusion length is typically much longer than the entire wafer thickness.

Figure 19.8 illustrates the solution of the minority carrier diffusion equation in the limit that the based width W_p is much less than the diffusion length, L_n, in Fig. 19.6, where the solution is just a straight line. In the case of a conventional ohmic contact, where $S_n = \infty$, the minority carrier concentration goes to zero at the boundary, and the current is given by the slope of the line times the diffusion coefficient for minority carrier electrons, D_n. As S_n decreases, so does the slope and the corresponding minority carrier current. Asymptotically, the solution goes back to the long base solution as $S_n \to 0$.

Reducing the minority carrier current extracted through the front and back is therefore a major strategy in the design of solar cells for maximizing V_{oc}. However, at the same time, we have to extract majority carriers through low resistance contacts, which is somewhat of a contradiction. Design of contacts which have high majority carrier extraction but low minority carrier extraction is the goal of carrier selective contact design, discussed in more detail in Sect. 19.3.4.

A traditional strategy for reducing minority carrier recombination in the contact region is the use of a back surface field (BSF), which usually involves having a higher doped region in the vicinity of the back contct. The isotope junction formed between a p^+ and p-region results in a SCR with a field that opposes the flow of electrons toward the *p* contact, reducing the effective surface recombination velocity. This results in a V_{oc} increase of several tens of mV.

The above analysis has considered the current density in a one-dimensional analysis, but another approach to reducing the effective recombination on the back is to minimize the contact area laterally through selective contacts to the base with local BSFs, where the rest of the back surface is highly passivated by a dielectric layer. Here the ratio of the passivated area is high compared to the actual contact area, with a commensurate reduction in dark current. This structure is the basic architecture of the PERC (passivated emitter and rear contact) solar cell, which is presently (in 2020) the dominant commercial Si technology, and has demonstrated cell efficiencies greater than 24% [7].

19.3.2 Photocurrent

The short circuit current density, J_{sc}, is directly related to the photocurrent density, resulting from light absorption in the solar cell, and is equal to this quantity when nonideal effects such as shunt and series resistance are minimized. Maximizing the short circuit current involves two main design factors: one is absorbing the maximum amount of light above the bandgap, and the other is maximizing the collection of light-generated carriers throughout the volume of the cell.

Maximizing the amount of light absorbed involves minimizing reflection both from the metallic front contact grid and from the surface of the cell where light is transmitted. As mentioned earlier, minimizing the front contact grid shading is a design optimization between the spacing and width of the fingers and the spreading resistance of the top layer which

impacts the fill factor of the cell. Minimizing reflectance involves the design of an optimal AR coatings based on the spectral response characteristics of the cell as discussed in Sect. 19.2. In addition to the optical coating, texturing of the front (and back) surfaces is employed in commercial Si solar cells to increase the capture of light into the cell. Finally, either the thickness of the cell has to be sufficiently thick that light is not lost through the back side of the cell due to incomplete absorption, or light trapping techniques have to be employed so that photons make multiple passes through the absorber. The most straightforward approach is simply having an ideal reflecting back side, so that photons make at least two transits of the cell thickness. Texturing of the front surface leads to a high probability of being scattered again back into the cell rather than exiting the front surface. The maximum number of passes is expressed in the classical light trapping limit [8] for the maximum optical path length in the cell, $\langle l \rangle = 4n_s^2 W$, where n_s is the index of refraction of the absorber and W is its thickness. Light trapping is discussed in more detail in Sect. 19.7.3. Reflection and absorption depend on characteristics of sunlight, solar cell optical properties, E_G, and solar cell thickness, so that the optimum design is a nontrivial task.

The second important quantity associated with the short circuit current is the collection probability of the cell for the photoexcited carrier distribution, which is nonuniform and wavelength dependent due the wavelength dependence of the absorption coefficient. The collection probability is illustrated in Fig. 19.9. It represents the probability that an electron generated at some point relative to the SCR will be collected, where in the SCR it is commonly assumed that 100% of the carriers are collected due to the high electric field there.

In terms of the collection probability, the short circuit current can be written as an integral

$$\begin{aligned} J_{sc} &= q\int_0^{W_s} dx G(x) CP(x) \\ &= q\int_0^{W_s} dx \left(\int d\lambda \alpha(\lambda) N_s(\lambda) e^{-\alpha(\lambda)x} \right) CP(x) \end{aligned} \tag{19.35}$$

where Eq. (19.7) has been substituted for the generation rate, and we have integrated over all wavelengths. The upper panel of Fig. 19.9 illustrates the overlap of the generation rate and the collection probability for one wavelength. As mentioned earlier, shorter wavelengths have a generation rate profile close to the top surface, whereas longer wavelength photons result in generation throughout the structure. The dependence of the collection probability with distance relative to the SCR depends on recombination, both bulk and surface recombination, through the solution of the minority carrier diffusion equations, as discussed below. Qualitatively, the effects of low and high bulk recombination, as well as low and high surface recombination (often referred to as the degree of surface *passivation*), are illustrated in Fig. 19.9, where the realization of high short circuit current requires both a high minority carrier lifetime in the bulk and well-passivated front and back surfaces.

A simple case in which analytical expressions can be derived is considering the solution of the minority carrier diffusion equations again on either side of the junction, with a constant G (both in terms of position and wavelength) throughout the device, which would be the case of a light source with a small absorption coefficient relative to the width of the cell. The minority carrier diffusion equations in Eq. (19.25) then have a simple inhomogeneous constant, which, in the limit of the diffusion lengths being much shorter than the widths of the emitter and base regions, gives the analytical form for the current density as the sum of the dark and light currents

$$J_{total} = \left[q\frac{D_n n_i^2}{L_n N_A} + q\frac{D_p n_i^2}{L_p N_D} \right] \left[e^{qV/kT} - 1 \right] - qG\left(L_n + L_p + W\right) \tag{19.36}$$

where W is the width of the SCR, and it has been assumed that all the carriers generated in the SCR are collected. This analytical model gives the simple interpretation that all the carriers generated within a diffusion length of the edge of the SCR on either side of the junction are collected in addition to those generated within the SCR, and the short circuit current is the sum of these three contributions. Qualitatively, this situation corresponds to the collection probability profile illustrated in Fig. 19.9 for the low diffusion length case. As mentioned earlier, in state-of-the-art crystalline Si solar cells, the diffusion length is actually greater than the width of the base region, and passivation of the front and back surfaces plays a critical role in both the photocurrent and dark current.

An important characterization of the photocurrent response of a solar cell is in terms of its *quantum efficiency* (QE), which is defined as the ratio of electron-hole pairs collected to incident photons on the cell within a certain wavelength interval. Once the QE is known, the short circuit current density can be obtained from the integration of the QE with the spectrally resolved incident photon flux

$$J_{sc} = q\int_0^{\infty} d\lambda N_s(\lambda) \, QE(\lambda) \tag{19.37}$$

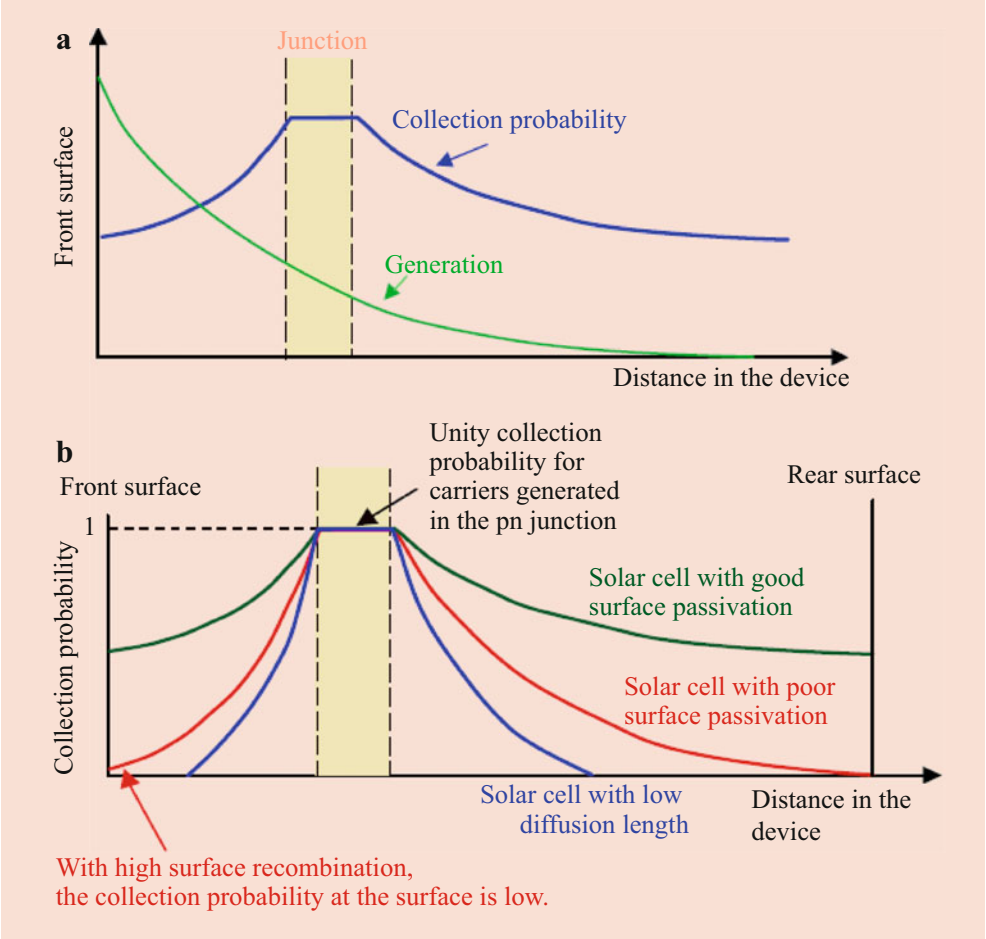

Fig. 19.9 Sketch of the collection probability versus distance in the device. The shaded region represents the SCR where the collection probability is unity. The panel (**a**) compares the collection probability with the generation rate, while the panel (**b**) shows the effect on the collection probability of surface passivation and diffusion length. (With permission from PVEducation.org)

The quantum efficiency provides useful information on the limiting mechanisms controlling the short circuit current. Fig. 19.10 shows a typical QE versus wavelength plot. The ideal quantum efficiency is zero below the bandgap and then jumps to unity above the bandgap and remains constant. In reality, there is reflection from the front surface, which depends on wavelength (in addition to the uniform loss due to the grid pattern, which reduces QE). At long wavelengths, the QE degrades due to the increased absorption depth of photons close to the bandgap energy, where they either are lost due to being absorbed further than a diffusion length from the junction or from not being absorbed due to the cell being too thin. For short wavelengths in the blue region, carriers are absorbed very close to the front surface, where surface recombination exists resulting in loss of collection in a traditional Si cell architecture. Thus, the quantum efficiency of a solar cell is an important characterization used in the optimization of the cell design.

19.3.3 Series Resistance

The simple equivalent circuit model of a solar cell shown in Fig. 19.2 neglected two important parasitic effects that degrade mainly the fill factor defined in Eq. (19.3), that of shunt and series resistance. Figure 19.11 shows the modified equivalent circuit including these two effects modeled simply as linear lumped parameter elements. In general, these resistances are nonlinear, depending on the operating point of the device, but for analysis of the main effects, the linear model is sufficient.

The effect of the shunt resistance is to effectively short the junction, leading to a parallel leakage current component which degrades the ideal diode behavior, with a corresponding degradation of the fill factor. Ideally, the shunt resistance is semi-infinite in a good device. Shunt leakage paths can originate due defects such as dislocations or grain boundaries that bridge SCR leading to a current transport separate from the ideal recombination currents discussed

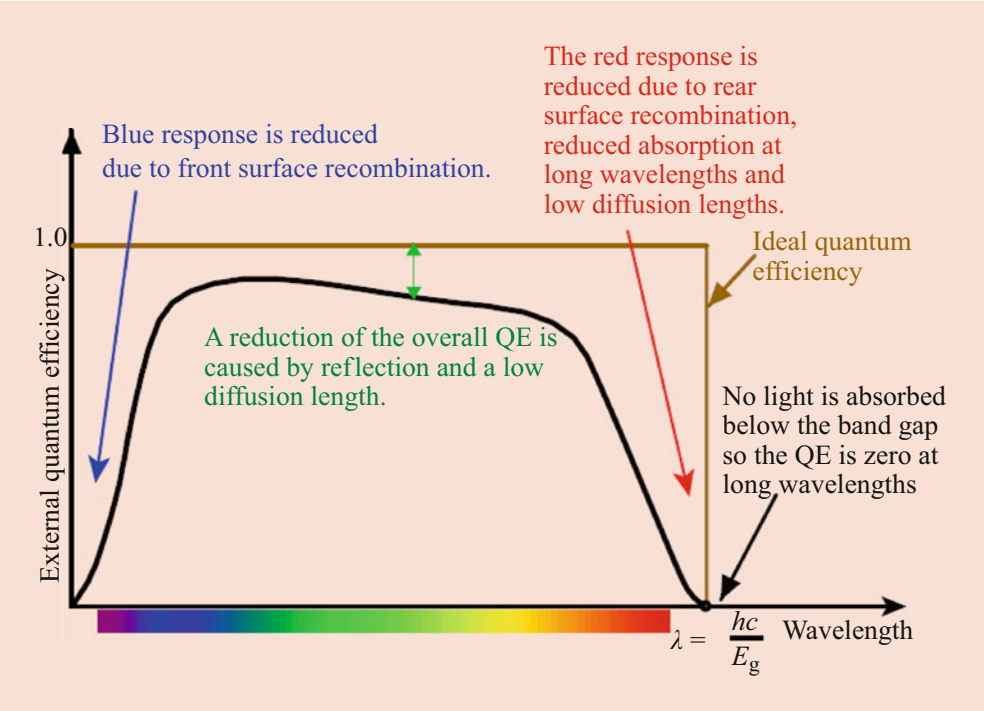

Fig. 19.10 Illustration of the quantum efficiency of a solar cell compared with the ideal quantum efficiency illustrating the various factors affecting its wavelength dependence. (With permission from PVEducation.org)

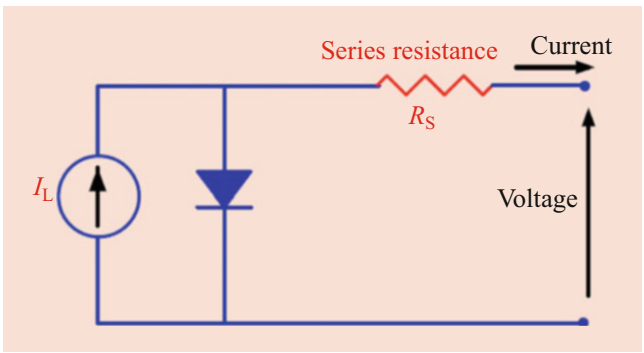

Fig. 19.11 Solar cell equivalent circuit including both shunt (R_{sh}) and series resistance (R_s). (With permission from PVEducation.org)

earlier. It can also originate from leakage around the edges of the cell due to poor isolation and potential metallization problems with the final cell design.

Series resistance can arise from the bulk resistance, contact resistance, the resistance of the metal top grid in the fingers, and importantly the spreading resistance in the emitter as the current spreads laterally to reach the fingers of the top contact metallization, illustrated in Fig. 19.12. Typically, the base resistance is small in comparison to the spreading resistance as the cross-sectional area is quite large. The metal contact resistance between the metal and the semiconductor, defined in terms of the specific contact resistance, is usually well behaved in commercial solar cells as well, and not the main source or resistance loss, while the resistance of the metal itself is not problematic if the finger width is sufficiently large. So the main component of series resistance of concern is usually the emitter spreading resistance, and the design of the finger spacing to minimize the power loss due to this resistance.

The emitter is typically quite thin, and current transport is primarily lateral in this layer. Therefore, it is more usual to talk about the sheet resistance of the emitter in terms of

$$R = \frac{\rho_e L}{tW} = \rho_{sh}\frac{L}{W} \tag{19.38}$$

where ρ_e is the bulk resistivity of the material, t is the thickness, while L and W are the length and width of the material that current is passing through. The quantity ρ_{sh} is the *sheet resistance* in ohms/square (Ω/□).

The problem requires solving the resistive power loss associated with the distributed current flow problem in which the current density is changing in the y direction relative to the grid finger as illustrated in the geometry shown in Fig. 19.13. The incremental power loss in a section dy is given by

$$dP_{loss} = I^2 dR; \quad dR = \rho_{sh} dy/b \tag{19.39}$$

The current flowing into the left finger is zero in the middle and increases linearly as y increases

$$I(y) = Jyb \tag{19.40}$$

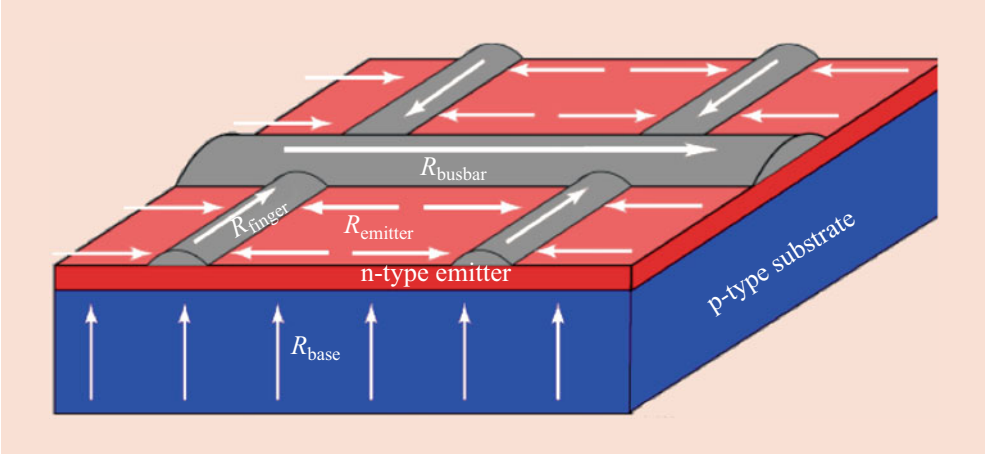

Fig. 19.12 Illustration of the different components of series resistance in a solar cell. (With permission from PVEducation.org)

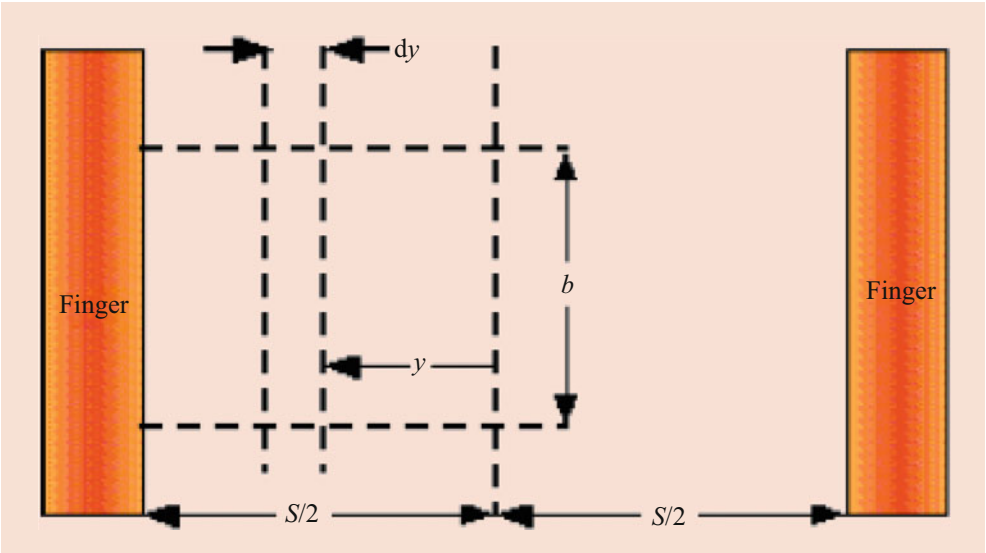

Fig. 19.13 Schematic of the finger geometry for calculating the spreading resistance in the emitter of a photovoltaic device. (With permission from the PVEducation.org)

The total power loss due to the current flowing into the left finger is therefore

$$P_{loss} = \int dRI(y)^2 = \int_0^{S/2} \frac{J^2 b^2 y^2 \rho_{sh} dy}{b} = \frac{J^2 b \rho_{sh} S^3}{24} \quad (19.41)$$

At the maximum power point, the generated power is given by

$$P_{gen} = J_{mp} b \frac{S}{2} V_{mp} \quad (19.42)$$

where J_{mp} and V_{mp} are the current density and voltage at the maximum power operating point of the current-voltage characteristic of Fig. 19.2. Therefore, the fractional power loss is given by

$$P_{\%loss} = \frac{P_{loss}}{P_{gen}} = \frac{\rho_{sh} S^2 J_{mp}}{12 V_{mp}} \quad (19.43)$$

As S increases as well as the sheet resistance, so does the fractional power loss. For ρ_{sh}=40 Ω/□, J_{mp} = 30 mA/cm^2, V_{mp} = 450 mV, $S < 4$ mm is necessary for less than 4% total power loss. The optimal grid design minimizes this power loss while simultaneously minimizing shading loss.

19.3.4 Heterojunction Cells and Carrier Selective Contacts

Here we discuss heterojunction solar cells and the efficiency improvements due to the heterojunction, followed by a more general discussion of carrier selective contacts, of which heterojunctions can be considered a subset.

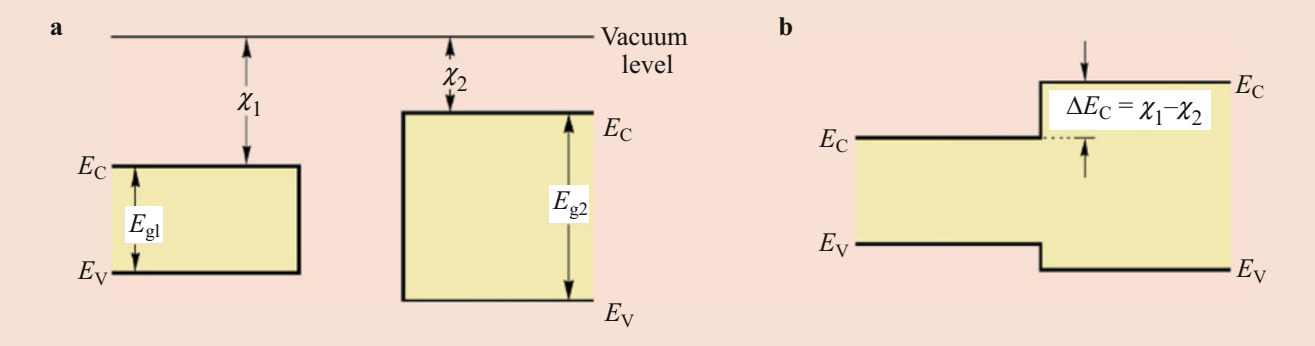

Fig. 19.14 Band diagram of (**a**) two separated semiconductors and (**b**) two different semiconductors in contact. The semiconductors have bandgaps E_{g1} and E_{g2} and electron affinities χ_1 and χ_2

Heterojunctions

The highest efficiency solar cell technologies, either single junction or multijunction, employ heterojunctions between dissimilar semiconductor materials. Figure 19.14 illustrates the ideal band alignment between the two materials based on the electron affinity rule or Anderson model. This model assumes that the vacuum level can be treated as a reference level, which is assumed continuous in forming the heterojunction band diagram. The band offset in the conduction band is then the difference between the two electron affinities, $\chi_1 - \chi_2$. The conduction and valence band alignment can either be such to confine both electrons and holes (type I), either electrons or holes (type II), or staggered such that the VB of one material overlaps the CB of the other (e.g., InAs/GaSb). This model works well for some systems, e.g., InAs/GaSb and Si/Ge. However, deviations from Anderson model generally occur due to interface dipoles which allow the electrostatic potential to change discontinuously. Typically the band offsets are determined experimentally from capacitance voltage, photoemission, photoconductivity, and other techniques.

There are a variety of heterojunction structures in photovoltaics used in high performance devices in various technologies. In the context of conventional wafer-based technologies such as Si and GaAs, these include amorphous Si (a-Si)/c-Si (crystalline Si) heterostructures as a passivating as well as carrier selective contact (discussed in the next section), as well as TCO-based heterostructures, for example, ITO (indium tin oxide)/Si structures and a-Si/c-Si structures. GaAs typically employs $Al_xGa_{1-x}As$ ternary compounds as a heterojunction "window" layer to mitigate surface recombination and serve as a carrier selective contact.

From the standpoint of the ideal diode equation for the dark current as discussed in Sect. 19.3.1, the derivation can be slightly modified to account for the difference in bandgaps, which results in different intrinsic carrier concentrations, n_i, on either side of the junction. The modified reverse saturation current is then given by

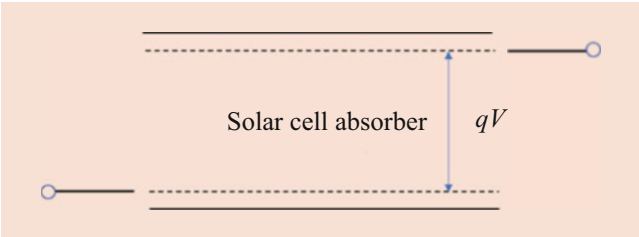

Fig. 19.15 Band diagram of an idealized solar cell as modeled in detailed balance. The solar cell absorber material generates a quasi-Fermi-level separation due to light-generated carriers, which are extracted from the device at the quasi-Fermi level

$$J_0 = q\left(\frac{D_{p1}n_{i1}^2}{X_{p1}N_{D1}} + \frac{D_{n2}n_{i2}^2}{X_{n2}N_{A2}}\right)\left(e^{qV_D/kT} - 1\right) \qquad (19.44)$$

where the parameters have the same definition as Eq. (19.32) except that the intrinsic concentrations are different and significantly reduced in the wider bandgap material by a factor

$$\frac{n_{i1}^2}{n_{i2}^2} = Ae^{-\Delta E_g/kT} \quad \Delta E_g = E_{g1} - E_{g2} \qquad (19.45)$$

Hence, one component of the minority carrier reverse saturation current is exponentially reduced by a factor involving the bandgap difference, leading to an increase in V_{oc}. In general, however, reductions in J_0 may be realized by selective controlling the minority carrier injection, which is the basis of the general topic of carrier selective contacts in the next section.

Thermodynamic and Detailed Balance Definition of Ideal Contacts

The ideal thermodynamic or detailed balance solar cell structure consists of an absorber material with a given quasi-Fermi-level separation, with the light-generated carriers extracted from the material at the quasi-Fermi-level energy as shown in Fig. 19.15 (see Sect. 19.5).

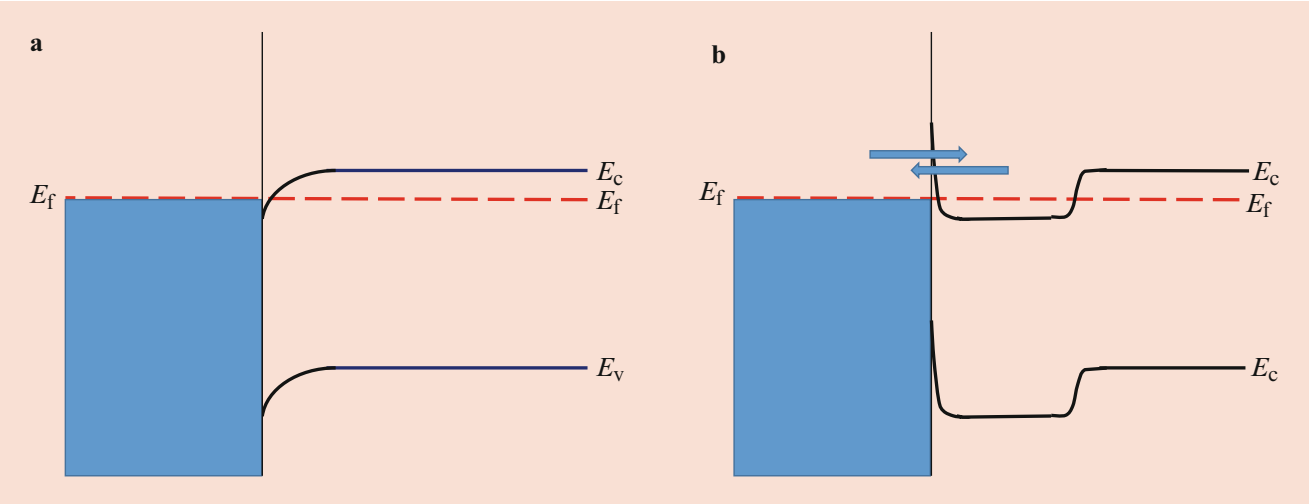

Fig. 19.16 Band structure of an ohmic contact. (**a**) The ideal band diagram of an ohmic contact. (**b**) Practical implementations of an ohmic contact. In all cases, there is a large density of allowed energy states in the contact (a metal), such that there the concentration of minority carrier is low and the quasi-Fermi level is identical to the Fermi level

However, such a structure encounters several practical barriers relating to extracting the light-generated carriers. An ohmic contact (with the band diagram shown in Fig. 19.16) has high recombination for minority carriers, and therefore the carriers are extracted at the Fermi level rather than the quasi-Fermi level. This fact drives the need for a *pn* junction; we need to have two different Fermi levels in the semiconductor, and hence we need the *pn* junction used by the majority of solar cell structures.

The thermodynamically ideal contact for a detailed balance structure was termed a selective carrier contact by Würfel [5]. It consists of a contact which allows one type of carrier to be extracted, with the band diagrams shown in Fig. 19.17, consisting of a Fermi level in the contact material aligned with the quasi-Fermi level in the absorber material. The band structure has a large number of allowed energy states *above* the Fermi level in the contact material, and no allowed energy stated below the Fermi level of the contact material. The band structure diagram shows that a selective carrier structure is the "inverse" of the band structure of an ohmic contact.

Detailed balance and thermodynamic calculations also show that even a carrier selective contact incurs substantial losses in that extracting carriers from a carrier population with an energy given by a quasi-Fermi level loses substantial energy as the quasi-Fermi level is near the bottom of the energy distribution, and hence the higher energy of some carriers is lost. Solar cells which extract carrier at energies above the quasi-Fermi level are generally called hot carrier solar cells, and the contacts to such device are called energy selective contacts. They are discussed in Sect. 19.8.3. Their band structure is similar to a carrier selective contact structure, except that the allowed density of states is a narrow band.

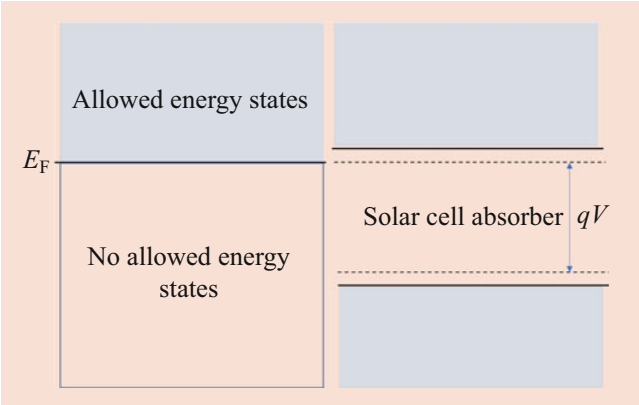

Fig. 19.17 Ideal band structure of a selective carrier contact

Overall, the type of contacts indicated by thermodynamic or detailed balance analyses is shown in Table 19.1.

A substantial optimization in solar cells has centered on minimizing the nonideal recombination associated with an ohmic contact. This involves addressing two features: (1) ensuring that the Fermi level is close to the quasi-Fermi level and (2) minimizing the recombination at the metal-semiconductor interface. Increasing doping, particularly using higher doping near the contacts, is an effective way to minimize both effects. However, high doping itself introduces non-idealities including bandgap narrowing and increased Auger recombination. The introduction of selective carrier contacts, initially through the HIT (heterojunction with thin intrinsic region) and later through a greater variation of structures such as TOPCon, has allowed solar cell efficiencies to more closely approach thermodynamic ideals. The

Table 19.1 Overview of contact approaches

Type of contact	Ideal structure	Energy at which carriers can be extracted or injected	Implementation
Ohmic contact	Fermi level of the metal aligns exactly with Fermi level in semiconductor	Carriers are extracted or injected at the Fermi level; quasi-Fermi level is equal to the Fermi level at the contact	Ohmic metal-semiconductor contacts
Carrier selective contact	Fermi level of the contact aligns with the quasi-Fermi level of the semiconductor	Carriers are extracted or injected at the quasi-Fermi level	Passivated contacts; heterojunction contacts
Energy selective contact	Fermi level of the contact is above the quasi-Fermi level and Fermi level in the material	Carriers are extracted as "hot" carriers – i.e., they have not equilibrated with the lattice or other carriers	Quantum dot contacts; resonant tunneling contacts

next subsection describes the implementation of a selective carrier contact in the constraints of commercial silicon solar cell technologies, and examples of silicon selective contact solar cells.

Silicon-Based Selective Carrier Contact Solar Cells

The ideal implementation of a carrier selective contact consists of a material with a zero density of states below the Fermi level of the contact material, and a large density of states above it. There are several ways in which we can approximate such a band structure. The conceptually simplest way is to use a very wide bandgap semiconductor with quantum well used to adjust the Fermi level to the quasi-Fermi level in the absorber material. This is similar to a hot carrier contact in which the requirement of a narrow band for the density of states is relaxed to a wide band for the density of states above the lowest energy level, and hence quantum wells can be used instead of quantum dots.

In practice, however, particularly for large area silicon and thin film solar cells, a quantum well contact is not readily commercially feasible. A far simpler implementation is to use a very thin wide bandgap layer. The bandgap of the material needs to be wide enough such that there are theoretically no allowed states near the silicon band edge as shown in Fig. 19.18a. However, adjusting the Fermi level of this wideband material by doping is typically not useful, as the introduction of allowed energy levels from the dopants introduces energy states, which increase recombination. Further, because of the difficulty in doping wide bandgap materials or oxides, even with high doping, such materials are unlikely to have sufficient conductivity to avoid large resistive losses given the large currents from a solar cell. Instead of doping, we adjust the Fermi level in wide bandgap region adjacent to the solar cell by putting a doped wide bandgap semiconductor on top and using band offsets to achieve large band bending. The separation of an ideal selective carrier into two layers introduces the need to examine the transport, usually by tunneling and/or thermionic emission across the thin wide bandgap region.

There are several solar cell architectures which meet the above requirements. One group of solar cell structures uses silicon heterojunctions, initially developed using amorphous Si layers on a crystalline Si solar cell. These approaches are often called HIT solar cells (heterojunction with intrinsic thin layers) or SHJ (silicon heterojunctions). The HIT structure is shown in Fig. 19.20. It achieved an efficiency of 24.7% in 2014 [9], reaching the previously long-standing silicon efficiency record from the *pn* junction-based PERL solar cell. Since then numerous improvements have allowed solar cells based on silicon heterojunctions to reach 26.6% [10] in an interdigitated back contact structure (Fig. 19.20). Several companies have large-scale commercial production of HIT solar cells, including Panasonic and Tesla Solar. Key challenges for broader adoption of SHJ solar cell relate to the consistency in large-scale manufacturing and more expensive metallization for these solar cells. Metal screen printing for HIT solar cell uses different pastes and processing since SHJ require low temperature processes, and cannot use the high temperature sintering steps in conventional solar cells. A variety of other metallization processes are used to address these issues including using wires (SmartWire), copper plating, or metal stencils.

Overall, a selective carrier contact for a commercial solar cell generally consists of several features (Fig. 19.19): (1) a wide bandgap material often called a membrane with (a) sufficiently low interface defects where the defects have a minimal impact taking into account the band bending at the Si surface and (b) thin enough to support high tunneling/thermionic emission currents; (2) layers on the surface of the wide bandgap to adjust the Fermi level and to support lateral transport to the contacts; and (3) an approach in the silicon absorber to reduce the impact of interface defects.

Another selective contact technology is the TOPCon technology [11]. It is used as a rear contact approach for solar cells in which the emitter already closely approaches the ideal structure shown in Fig. 19.21. In the TOPCon structure, SiO_2 is used as the membrane wide bandgap region. The Fermi level is adjusted by a polysilicon doped layer on the SiO_2, and reducing the impact of interface states is accom-

plished by a thin doped layer in the silicon (which is diffused through the oxide). TOPCon solar cells have achieved 25.7% efficiency [12].

19.4 Performance Comparison of Single Junction Technologies

In the following, we compare the performance of different single junction technologies, including Si, the III–V materials, II–VI and chalcogenide materials, and finally organic and perovskite-based cells. All are referenced to the conversion efficiency versus time of the various technologies, as discussed below.

19.4.1 Performance Limits of Si- and GaAs-Based Technologies

A primary performance metric for solar cells is the solar to electrical energy conversion efficiency, defined earlier by Eq. (19.3). The National Renewable Energy Laboratory (NREL) publishes annually a comparison of the efficiencies of all solar cell technologies versus time shown in Fig. 19.22. Silicon solar cell technology dominates 95% of the current world photovoltaic market, through both single crystal and multi-crystalline Si technologies [13], as shown by the various blue curves in Fig. 19.22. The current high efficiency record (as of 2020) reported for single junction Si device technology under 1 sun illumination to date is 26.7%, based on a heterojunction HIT structure (see Sect. 19.3.4) using a crystalline Si substrate with thin layers of amorphous Si (a-Si), which forms a heterojunction due to the larger bandgap of a-Si (~1.7 eV) [10]. This cell record was demonstrated on a large area device, with an interdigitated back-side contact as shown in Fig. 19.20.

The highest efficiency for any single junction technology was reported by Alta Devices for a heterojunction AlGaAs/-GaAs single crystal solar cells where they achieved 28.8%, as shown by the purple curves in Fig. 19.22 (see Ref. [14] for discussion). III–V semiconductor solar cells are normally too expensive for terrestrial flat plate solar applications due to the costs of the substrate materials. However, III–V-based cells, as well as their multijunction realizations (shown in purple below), are standard technologies for space applications, where radiation tolerance and efficiency versus weight are the main performance drivers.

19.4.2 Thin Film Technology

The Si and III–V technologies described in the previous section are mainly wafer based, which is a major contribution to their cost in terms of materials. Thin film solar cells, in contrast, are deposited using thin film technology onto a low-cost substrate material such as metal or glass. Since the quality (as characterized by its minority carrier lifetime and surface recombination velocity) of the deposited material is inferior to that of single crystal materials, thin film cells typically have lower efficiency but lower fabrication and material costs, thus achieving lower $/W cost, the other main metric of solar cell technology. Amorphous Si (a-Si) thin film solar was the dominant thin film technology several decades ago but has since been supplanted by II–VI CdTe heterostructure technology. A schematic cross section of a CdTe cell is illustrated in Fig. 19.23. Typically a heterostructure is used, with a wider bandgap "window" layer (here CdS with a bandgap of 2.5 eV), while CdTe has a bandgap of 1.32 eV. The structure is an inverted structure in which glass is used as the supporting substrate, followed by a thin transparent conducting oxide as the front contact through which light enters the cell. The wider bandgap CdS layer is deposited first followed by the polycrystalline CdTe layer (typically a few microns thick), and finally rear contacts. As shown in Fig. 19.22 by the green sets of data, CdTe cells have demonstrated over 21% performance by First Solar [15], and this is the basis for a number of large (>200 MW) utility-scale solar installations worldwide. Chalcogenide-based materials such as CIGS ($CuInGaSe_2$) have demonstrated even higher efficiencies >23% [16] and are competing for market share.

19.4.3 Organic Solar Cells

Organic solar cells are basically thin film solar cells based on organic semiconductor materials rather than inorganic semiconductors. In analogy to the energy band diagram of Fig. 19.1, organic materials are defined by their HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital) levels, which play the same role as the valence and conduction bands in inorganic semiconductors, respectively. A heterojunction is formed due to the lineup of the HOMO/LUMO levels of the two different materials (called donor and acceptor materials), rather than through doping in a *pn* junction. Excitonic effects play a strong role in organic materials; photoexcitation of an electron from a filled HOMO level to an empty LUMO level creates a strongly bound exciton, which diffuses as a bound (neutral) state to the heterointerface, where it dissociates at the barrier into separate free electrons and holes on either side of the heterojunction, which are then collected at the contacts giving rise to a photocurrent. Typically the lifetime of the exciton is quite short, leading to short diffusion lengths,

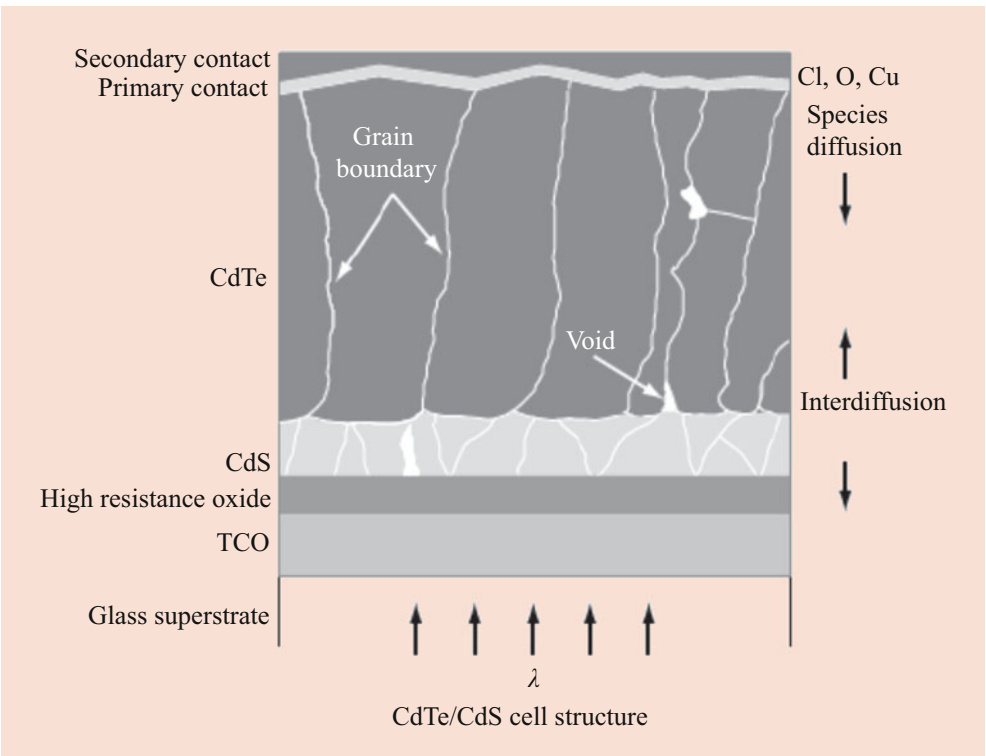

Fig. 19.23 Schematic of the structure of a CdTe-based thin film solar cell

and hence problems with charge collection. To circumvent this diffusion limitation, *blended heterostructures* with the donor and accepter materials interdiffused into a random network are employed, which provide better charge collection and short circuit current. A conventional organic solar cell includes P3HT (poly(3-hexylthiophene)), which acts as a donor material, and PCBM (6,6-phenyl-C61 butyric acid methyl ester), which acts as an acceptor material [17]. While efficiencies are generally lower than inorganic thin film approaches, the fabrication process for organic is much less expensive; organic layers can be sprayed or spun on, hence not requiring vacuum deposition or high temperature processing. Recent high performance organic cells have increasingly used more conventional thin film processing, however [18]. The improvement in efficiency with time of conventional organic cells is shown by the solid red circuits in Fig. 19.22 and tandem (discussed in Sect. 19.6) organic cells by the red triangles.

While research work on commercial ventures in niche markets continues on all organic photovoltaics, including incorporation of advanced concept and nanotechnology-inspired approaches discussed in more detail in Sect. 19.7, remarkable advances in performance have been achieved over the past decade on cells fabricated from hybrid organic-inorganic perovskite materials. These hybrid perovskite materials have the general perovskite crystal structure ABX_3, most commonly methylammonium lead trihalide, $CH_3NH_3PbX_3$, where A is the organic methylammonium, B is Pb, and X is a halogen (I, Br, or Cl) [19]. The bandgap ranges from 1.55 eV to 2.3 eV depending on the halide, where $CH_3NH_3PbI_3$ corresponds to the lower value. This bandgap is well suited for terrestrial photovoltaics in terms of its maximum theoretical efficiency discussed in the next section. Perhaps more importantly, the transport properties of the hybrid perovskites are superior to those of the typical organic materials discussed in the preceding paragraph, with electron and hole mobilities comparable to inorganic semiconductors, and diffusion lengths on the order of microns. Excitonic effects are relatively weak as well. The early high performance results report for perovskite solar cells was based on the nanostructured dye-sensitized solar cell architecture [20], discussed in Sect. 19.7.2, in which the hybrid perovskite is infused into a mesoporous wide bandgap TiO_2 structure which acts as an electron acceptor from the perovskite, while holes are extracted in an electrolytic liquid cell structure. This efficiency was greatly improved by replacing the liquid electrolyte with a solid organic hole transport layer (spiro-MeOTAD) [21], which is the basis of the current high efficiency cells shown in Fig. 19.22. In a further breakthrough leading to high efficiency cells, the Cambridge group further demonstrated that high performance devices may be fabricated in a planar structure in which $CH_3NH_3PbI_3$ is essentially a polycrystalline semiconductor [22], resembling an organic thin film solar cell. As seen in Fig. 19.22, the performance of perovskite solar cells has one of the steepest slopes of any technology over a very short time period, reaching a record as of today of 25.2% at the Korea Research Institute of Chemical Technology (KRICT)/MIT, surpassing that of thin film inorganic technologies such as CdTe and CIGS. The advantage of perovskite technology is the low manufacturing cost, similar to those of organic and thin film processing, where solvent spin coating and vapor deposition are the two main synthesis methods. The main barrier to commercialization presently is issues related to the long-term stability, where degradation occurs due to the sensitivity of the perovskite to water vapor, which can occur over a matter of hours or days. Different approaches to encapsulation and improved materials processing ameliorate these problems, but long-term field testing and accelerated life testing are necessary to assure the longtime reliability of the technology (e.g., commercial Si solar modules are guaranteed for lifetimes in excess of 20 years).

19.5 Efficiency Limits for Photovoltaic Converter

The record solar to electrical conversion efficiencies shown in Fig. 19.22 are all monotonically increasing with time for different technologies, albeit at different rates, and to date, less than 50%. Thermodynamics provides a guide to what the maximum conversion efficiency of a solar converter can approach. For example, the classical Carnot efficiency, $\eta_c = 1 - T_a/T_s$, representing a reversible engine working between the temperature of the Earth, T_a, and that of the sun, T_s, would predict efficiencies close to 95%. However, the Carnot efficiency assumes infinitesimally small amounts of work performed with no entropy production (inherent in the reversible assumption), which does not model a practical converter. de Vos has surveyed various thermodynamic engines for solar energy conversion [23], which have been reviewed by Green (Chap. 3, [2]). Considering the entropy production associated with blackbody radiation and absorption, a more realistic value closer to 85.4% is obtained.

It is clear that there is a substantial gap between the present operating limits of solar cells and their thermodynamic potential, which has driven considerable research on overcoming fundamental barriers to efficiency. In the following, we review the limits of efficiency including the constraints on current technology through an idealized analysis based on the concept of detailed balance, and how to circumvent the assumptions inherent in the derivation of a single gap absorber to reach the potential limits of efficiency.

19.5.1 Shockley-Queisser Limit

Shockley and Queisser's (SQ) analysis [24] of the limits of performance of photovoltaic devices, independent from their material parameters other than their energy gap, is the most well-cited work on this topic, although other such analyses appeared around the same time. The approach is based on the thermodynamic hypothesis of *detailed balance* and considers the only losses from the cell treated as an ideal blackbody absorber/emitter taking into account the chemical potential difference in the absorber due to absorption and external voltage. The idealized description assumes the following: (1) complete collection of all the photons incident on the absorber; (2) radiative recombination only; (3) one bandgap; (4) absorption across the bandgap in which one photon generates one electron-hole pair; (5) constant temperature in which the carrier temperature is equal to the lattice and ambient temperature; and (6) steady state, close to equilibrium.

The current density may be written as the sum of three terms, the first representing the incident photons absorbed above the bandgap of the semiconductor from direct blackbody radiation at the temperature of the sun given by Eq. (19.4), the second the diffuse blackbody radiation collected outside the incident cone of the direct radiation, and finally the third term the blackbody radiation from the solar cell (Eq. (19.4) modified by the quasi-Fermi energy splitting of the absorber equated to the external voltage)

$$J = qg\left[\left(fC\int_{E_G}^{\infty}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E}{kT_{sun}}\right)-1}+(1-fC)\int_{E_G}^{\infty}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E}{kT}\right)-1}\right)-\int_{E_G}^{\infty}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E-qV}{kT}\right)-1}\right] \tag{19.46}$$

with

$$g=\frac{2\pi}{h^3c^2}\quad f=\left(\frac{R_{sun}}{D_{sun}}\right)^2 \tag{19.47}$$

Here C is the concentration factor, E_g is the material bandgap, and V is the voltage across the cell. If a solar spectrum other than the ideal blackbody spectrum is used, then the first term is simply replaced by the integral of the photon flux above the bandgap.

In Eq. (19.46), the "dark" current discussed in the previous section is only due to blackbody radiation from the semiconductor absorber, which in effect is due to radiative recombination within the semiconductor generating photons above the bandgap. The power density delivered by the cell is the product of $J(V)V$, which has a maximum power point

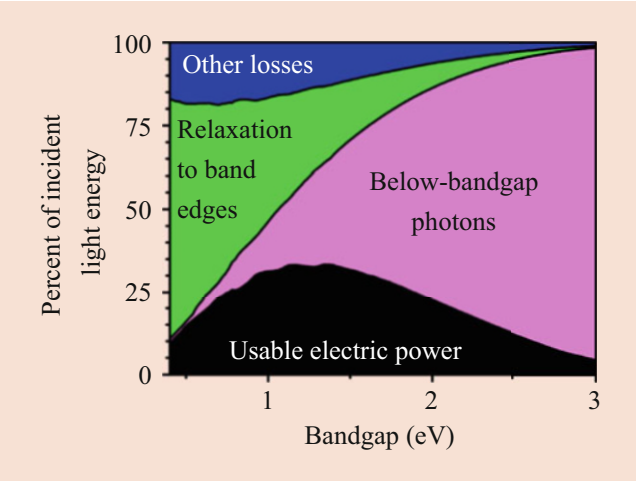

Fig. 19.24 The Shockley-Queisser efficiency limit (black curve) for a single gap absorber versus bandgap (AM1.5 solar spectrum). Also shown are the losses due to thermalization (green), transparency (pink), and entropy/heat loss (blue). (Source: Wikimedia Commons)

corresponding to the maximum conversion efficiency. The calculated results are shown in Fig. 19.24, where the black curve is the calculated efficiency versus bandgap for an AM1.5 terrestrial solar spectrum (hence the multiple maxima due to spectral features). The maximum efficiency without concentration is around 33.7% corresponding to maxima at 1.1 and 1.4 eV (conveniently close to Si and GaAs, respectively), while the effect of concentration is to increase the efficiency. The rest of Fig. 19.24 illustrates the principal losses compared to 100% efficiency. The main losses include loss of photons with energy below the bandgap (transparency) and loss of the excess energy of the photon above the bandgap (thermalization) in terms of energy relaxation of photoexcited carriers back to the band edges, with thermalization being the main loss for small bandgap materials and optical transparency the main loss for high bandgaps. Additionally there are other losses including unavoidable heat loss to the surroundings and irreversible entropy generation [25].

19.5.2 Overcoming the Shockley-Queisser Limit

The detailed balance efficiency versus bandgap shown in Fig. 19.24 has a number of assumptions built-in that may be circumvented in order to exceed the single gap SQ limit. Here we discuss some of those assumptions and strategies for avoiding them to overcome the single gap limitations.

Broadband Solar Spectrum: As discussed in Sect. 19.2.1, the solar spectrum is a broadband in nature as described by Planck's law, which leads to particular shape of the maximum

efficiency curve versus bandgap, representing a trade-off in losses between transparency and thermalization. If the input spectrum were monochromatic, for example, then the optimum bandgap would match the photon energy of such a source, and the efficiency would theoretically approach the thermodynamic limit since both transparency and thermalization would be eliminated. Transforming the solar spectrum to a narrower spectrum would therefore circumvent one of the assumptions in Eq. (19.46), and attempts at up/down conversion of portions of the solar spectrum through phosphors or two-photon absorption/emission have been pursued.

OneElectron-hole PairCreated Per Photon Absorbed: The assumption in Eq. (19.46) is that one EHP is excited per photon. However, if the excess energy of the electron or hole above their respective band edges is more than twice the bandgap, a second EHP may be created through the process of impact ionization, where the excess kinetic energy is transferred to creation of the second EHP. This process reduces the thermalization loss by converting excess photon energy into increased photocurrent. Kolodinski et al. considered carrier multiplication in the SQ limit of conventional Si solar cells [26]; however the effect was negligible due to restrictions on the threshold energy for impact ionization to occur due to momentum conservation in bulk crystals. In more recent years, strong multiplication effects have been measured in nanostructured systems such as quantum dots and nanowires in which momentum conservation is relaxed [27], discussed in more detail in Sect. 19.8.2. There the effect is referred to as multiexciton generation (MEG), as optical absorption occurs primarily through excitonic states in strongly confined systems like quantum dots and nanocrystals.

The Extracted Carrier Energies Correspond to the Band Edges: Ross and Nozik proposed the concept of hot carrier solar cells in the early 1980s [28], where electrons and holes are not collected at the band edges (and the voltage determined by the bandgap), but through energy selective contacts above and below the conduction and valence band edges, respectively. The operating voltage of the device would then be determined by energy separation of these energy selective contacts, while the photocurrent would be determined by the bandgap itself, thus circumventing the SQ limit. This concept requires that the absorber material has a low carrier energy loss rate to the lattice, so that the carriers can maintain sufficient average kinetic energy to be extracted through the energy selective contacts. Würfel and coworkers further considered the effect of impact ionization and carrier multiplication on the performance [29, 30]. Recent results are discussed in more detail later in Sect. 19.8.3.

Single Bandgap Absorber: The SQ model only considers a single bandgap material, but by the mid-1950s, it was already recognized that *multijunction* or *tandem* solar cells, discussed in more detail below, were capable of efficiencies above that of single gap devices. Tandem cells are most commonly fabricated as a stack of series connected junction cells, with the widest bandgap at the top, where it absorbs the blue portion of the solar spectrum, the next largest gap below, and so forth until the bottom cell which has the smallest bandgap. As shown in Fig. 19.22, III–V compound tandem cells demonstrate the highest efficiencies of any solar cell technology [31], with the record to date in excess of 47.1% in a six-junction metamorphic structure [32], compared to the single gap SQ limit of 33%.

19.6 Multijunction Solar Cells

Of the abovementioned approaches to circumvent the SQ limit, by far the most successful has been the demonstration and commercial development of multijunction or tandem solar cells. Such cells are the highest efficiency technology presently, particularly at high concentration. In tandem solar technology, multiple bandgap junction devices are connected together or simply grown sequentially on a substrate, where the multiple bandgaps reduce the thermalization loss and transparency issues of a single bandgap solar cell, as discussed in more detail below. The highest efficiency tandem devices are single crystal III–V materials grown epitaxially on top of one another, starting with the lowest bandgap material (which often is a Ge substrate which is lattice matched to GaAs) and ending with the highest bandgap, in terms of the direction of the incident radiation. In this way, the short wavelength light is absorbed in the top wide bandgap material, and the longer wavelength light is absorbed by subsequent layers. The cells are typically connected together in series with tunnel junctions, such that, overall, the current is the same through all the cells and the overall cell voltage is the sum of the voltages of the individual cells. The cost of the substrates and high-quality epitaxial growth (using, e.g., molecular beam epitaxy (MBE) or metal organic chemical vapor deposition (MOCVD)) makes the cost per cell quite high. The high cost of these devices is compensated for by using them in an optical concentrator (where the light intensity is 200× to 400× higher than typical sunlight), such that only very small areas are needed. The optical systems must track the sun, and these large systems are suited primarily for utility-scale applications. Three junction cells based on Ge/GaAs/GaInP or similar combinations have exceeded 40% efficiency as shown by the purple set of curves in Fig. 19.22, and the record as of the time of this writing is 47.1% from NREL in a six-junction structure, which is well in excess of the SQ limit for a single junction.

The detailed balance approach given by Eq. (19.46) can be generalized to consider multiple junctions, each with its own detailed balance equation, and with a modified spectrum according to the number of cells above or below (due to reabsorption of the emitted light) the particular junction in question. Consider an n-layer stack, in which cells are arranged in order of decreasing bandgap, with the highest bandgap closest to the top surface where radiation is incident. Consider the *i*th cell in the n-layer stack. The net absorption in this layer is due to absorption from incident light through upper layers plus re-emitted light from layers above and below. The current in the *i*th cell is then given by a generalization of the detailed balance equation for a single junction, Eq. (19.46), as.

$$J_i = qN = qg\left[\left(fC\int_{E_{G_i}}^{E_{G_{i+1}}}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E}{kT_{\mathrm{sun}}}\right)-1}+(1-fC)\int_{E_{G_i}}^{E_{G_{i+1}}}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E}{kT_{\mathrm{a}}}\right)-1}\right)-\int_{E_{G_i}}^{\infty}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E-qV_i}{kT_{\mathrm{a}}}\right)-1}\right] + \underbrace{qg\int_{E_{G_{i+1}}}^{\infty}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E-qV_{i-1}}{kT_{\mathrm{a}}}\right)-1}}_{\text{Reabsorbed photons emitted from cell above}} + \underbrace{qg\int_{E_{G_i}}^{\infty}\frac{E^2\mathrm{d}E}{\exp\left(\frac{E-qV_{i+1}}{kT_{\mathrm{a}}}\right)-1}}_{\text{Reabsorbed photons emitted from cell below}} \tag{19.48}$$

where the first two terms represent the light absorbed in the range of photon energies between the bandgap of the layer and the bandgap of the layer above due to both direct and diffuse light, the third term is the radiation emitted from this cell with V_i the voltage across the cell, while the last two terms represent absorption due to reabsorbed photons emitted from the cells above and below, respectively. Eq. (19.48) is then used for all the cells in the stack, in which the upper limits on the top cell go to infinity.

In the usual architecture, the cells are grown epitaxially on top of one another, which imposes stringent constraints in terms of lattice matching of the layers to minimize defect formation due to strain. The current then has to be the same in all the cells as they are series connected

$$J_1 = J_2 = \ldots J_n \tag{19.49}$$

Therefore, the voltage operating point of each of the cells described by Eq. (19.48) has to adjust such that the currents are the same, and the resulting operating voltage is the sum of the voltages of the individual cells when series connected.

The results of this calculation for maximum efficiency of different numbers of bandgaps for normal, low, and high concentration are shown in Fig. 19.25. As can be seen, concentration provides a significant improvement in performance for high number of junctions, which can be explained simplistically in terms of Eq. (19.3) for the open circuit voltage increase with photocurrent (proportional to concentration) and having junctions in series where the effect is additive, multiplying the concentration effect. For maximum concentration (set by étendue limits to 46,050X), one can approach the thermodynamic limit with an arbitrarily large number of junctions, where the thermodynamic limit for a solar energy converter is above 85%, as discussed in the preceding section.

As discussed earlier, commercial tandem cells are grown in series using epitaxial material growth technology, which is generally quite expensive compared to conventional Si solar cell manufacturing and has many material challenges to both optimize the bandgaps and have lattice-matched materials for low defect growth. Si-based tandems leverage the low cost of Si substrates in commercial technology today, with the efficiency advantages of a top cell grown on the underlying Si platform. Fig. 19.26 shows the calculated detailed balance efficiency versus bandgap for a two-terminal (2T), series constrained, top and bottom cell, which is peaked in a narrow bandgap range around 1.7 eV at 46%. A key challenge in tandems is that in series connected tandems, the maximum efficiency is achieved only for a narrow range of bandgaps as shown for a two-terminal structure, giving rise to the search for a 1.7 eV material that can be grown or deposited onto a silicon solar cell without an added substrate and yields stable, high performance. Realizing this bandgap with a material lattice matched to Si is quite challenging. What is also plotted in Fig. 19.26 is the efficiency versus bandgap when the 2T series constraint is relaxed. The dependence on bandgap is much weaker and shifted slightly higher to 1.9 eV, meaning that a range of bandgap options become available when current matching between the two cells is relaxed.

The main approaches to realizing 2J tandems in Si have been through III–V, II–VI, and perovskite top cells. The highest efficiencies have been reported by several groups for III–V cells bonded onto Si in a 4T configuration, with over 32% reported for 2J cells and 35.9% for 3J by EPFL/NREL [33]. However, the 4T approach generally requires a full III–V cell to be fabricated separately and bonded onto a Si substrate, which is most likely not cost competitive in terms

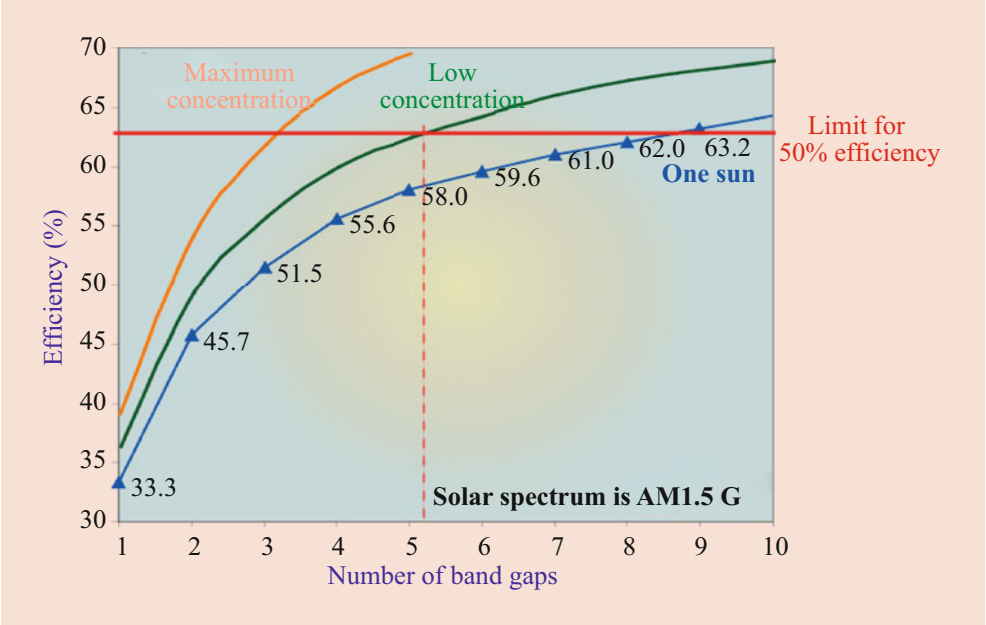

Fig. 19.25 Calculated detailed balance efficiency as a function of the bandgap number for a tandem cell, for three different concentrations of AM1.5 spectrum sunlight

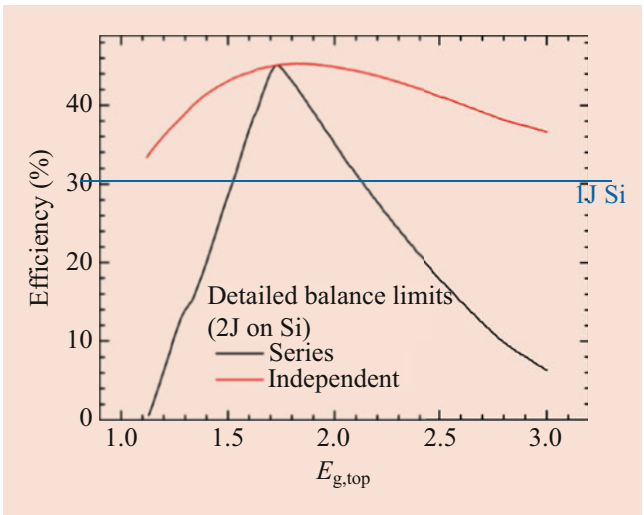

Fig. 19.26 Detailed balance efficiency versus bandgap of the top cell for a two-junction Si tandem

of current Si technology. II–VI materials are still in development for Si tandems, with basically only material growth demonstrations at present. The current highest efficiency in a monolithically grown series connected Si-based tandem is using a wider bandgap perovskite cell as the top cell [34]. The low temperature processing of the perovskite top cell is very compatible with integration with an already fabricated Si bottom cell. 2T perovskites on Si cells have recently exceeded 29% [35], the highest 2J performance reported to date for an integrated structure, as shown in Fig. 19.22 by the purple triangles. However, there remain many open questions about long-term stability of perovskites for solar applications, particularly with new higher bandgap materials.

From a stability, efficiency, and cost perspective, the direct growth of III–Vs on Si appears the most promising, with recent advances in the approaches and efficiencies of tandem structures. The key barrier to III–V/silicon solar cell is the lattice mismatch between silicon and most III–V materials. The importance and impact of III–V/Si integration means that many different approaches have been tried to overcome the lattice mismatch between Si and III–Vs. These include insertion of a layer that accommodates the strain [36, 37]; decoupling the III–V material from the Si substrate by limiting the direct contact between the two via techniques such as epitaxial lateral overgrowth [38–40] or nanostructures [41]; joining the III–V and Si by mechanical means such as bonding [42]; lattice-matched materials [43–47]; compositionally graded, metamorphic buffer layers; and the development of defect-tolerant materials [48].

GaP is the closest III–V material in terms of lattice constant for monolithic integration on Si; hence most approaches incorporate GaP, either for direct growth or as a grading layer for growth of other III–V materials. Grassman and coworkers have demonstrated 21.8% in a 2T tandem on Si using a GaP buffer and GaPAs grading layer to grow a GaAs top cell on Si [49, 50]. The University of Illinois and Arizona State University have collaborated on a graded junction cell on a GaP buffer, using graded GaAsP to grow a GaAsP top cell demonstrating 20% efficiency [51, 52]. Fraunhofer ISE has also used graded GaAsP growth to demonstrate a triple

junction cell with GaAs/GaInP top cells on Si exceeding 22% [53, 54]. Grading Si using a SiGe-based buffer as a template for further III–V devices has reached 20.6% [55]. An alternative option is to capitalize on defect and materials advances to develop a dilute nitride top solar cell [56]. Dilute nitrides are conventional III–V materials in which the introduction of a small amount of substitutional N (on the order of 1 to 2%) can lead to large changes in the bandgap and lattice constant, allowing for tunable materials to satisfy lattice and bandgap requirements in tandem cell applications. Dilute nitride-phosphides such as GaNPAs and GaInNP have been investigated for optoelectronic devices, including Si-integrated lasers and solar cells [57].

19.7 Nanotechnology-Based Approaches

Besides multijunction approaches, realization of many of the approaches listed for circumventing the Shockley-Queisser limit is difficult to realize in bulk semiconductor materials. For that reason, nanostructured materials have been an area of active investigation for so-called advanced concept or third-generation [2] photovoltaics. The advantages of nanostructured materials are in the ability to tune bandgaps through quantum confinement and surface effects, as well as modify the chemical and reactive properties of materials relative to their bulk forms. From the standpoint of optical properties, absorption is generally enhanced, and nanophotonic structures may be used to manage light in terms of light trapping and reflection losses. As discussed in connection with hot carrier solar cells, nanostructured materials may also have reduced energy loss rates, which help in terms of phenomena such as hot carrier extraction and carrier multiplication through impact ionization. The main detrimental effects are the increased surface to volume ratio, which may lead to increased recombination affecting both the short circuit current and the open circuit voltage as discussed in Sect. 19.3.1.

19.7.1 Nanomaterials

Nanostructure materials can be fabricated from the top down using nanoscale lithography such as deep UV, electron and ion-beam lithography, as well as direct manipulation of atoms on the surface using atomic force microscopy (AFM). At the same time, self-assembly of materials allows the growth from the bottom up of a variety of structures with atomic perfection. Some of the more interesting materials are summarized in the following. For an extensive review on the subject, see Chap. 2 of reference [58].

Layered Structures and 2D Materials: Already in the 1980s, epitaxial growth was exploited to realize nanostructure materials in one direction, the growth direction. The advent of molecular beam epitaxy (MBE) [59] and metal organic chemical vapor deposition (MOCVD) allowed atomic layer control of the growth of high-quality, lattice-matched heterojunctions. A *quantum well* (QW) corresponds to a layered structure of a narrow bandgap material sandwiched between two larger bandgap materials, which, as discussed in Sect. 19.3.4, can be type I or type II depending whether confinement exists for both electrons and holes (type I) or for just one (type II). A multi-quantum well (MQW) system is just a succession of QWs grown with sufficiently thick barrier material such that they are essentially isolated. If the barriers are sufficiently thin, then broadening of the QW states occurs and a superlattice (SL) is formed, with mini-bands. In all such materials, electronic confinement is only in one directly, and the motion in the plane is quasi-two-dimensional (2D), with a two-dimensional density of states.

In more recent years, true 2D materials have been synthesized and extensively characterized, beginning with work on *graphene* [60, 61], a 2D form of graphitic C, which forms a hexagonal honeycomb structure, and can be synthesized by exfoliation from graphite, chemical vapor deposition, as well vacuum graphitization of SiC. The electronic structure has a unique linear dispersion with no gap, where the conduction and valence bands meet at the so-called Dirac points, the discovery of which was awarded the 2010 Nobel Prize in physics. More recently, of 2D materials have been synthesized from transition metal dichalcogenide (TMD) monolayers, which are generally 2D semiconductors with bandgaps from 1 to 2 eV of the form MX_2, where X is a chalcogen atom and X is a transition metal [62]. Different 2D materials can be grown in layered structures called van der Waals heterostructures, which as the name suggests are bonded weakly in the vertical direction to form the equivalent of MQW and SL structures with unique optical and transport properties [63]. Because of their tunable bandgaps in the optimal range for solar energy conversion, there have been a number of demonstrations of photovoltaic effects, and proposals for energy converters based on such materials.

Nanowires and Nanotubes: These components are quasi-one-dimensional (1D) materials that are usually self-assembled, although they can be fabricated by top-down lithography as well. Carbon nanotubes (CNTs) are the most common nanotube structure, which are basically a rolled form of graphene, whose chirality (related to the direction along which the graphene sheet is rolled) determines whether they are metallic or semiconducting. Semiconductor nanowires (NWs) are solid crystalline, which may be grown using *vapor-phase synthesis*, in which nanowires self-assemble on from the gas phase onto a semiconductor substrate with a given crystallographic orientation. *Vapor-liquid-solid* (VLS) epitaxy is the most common method

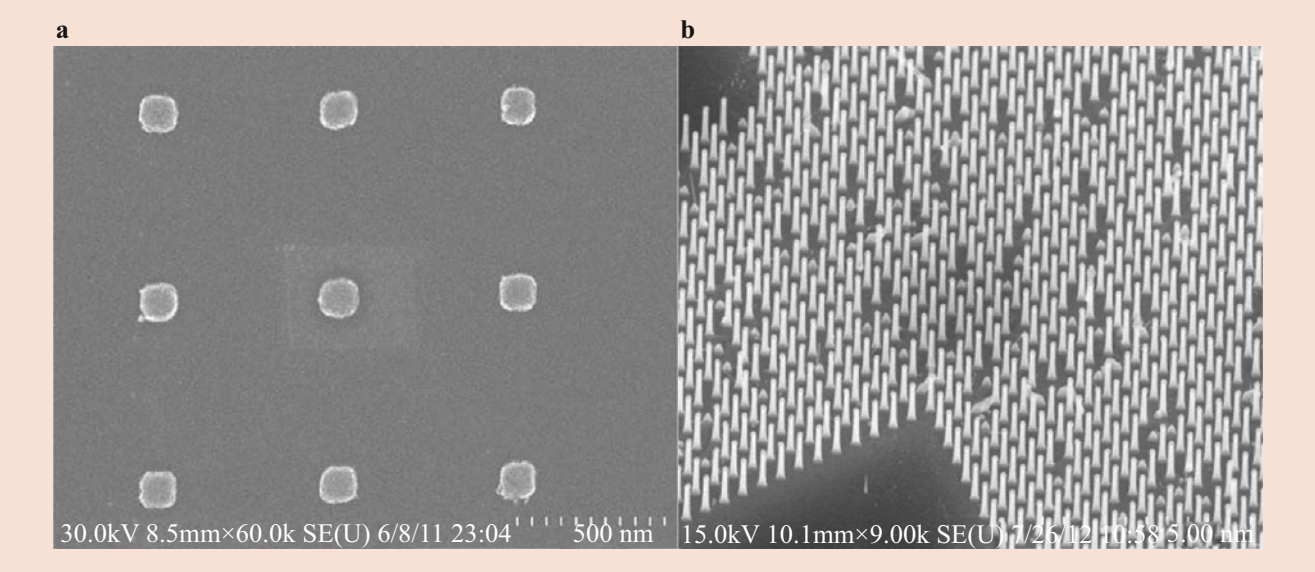

Fig. 19.27 Self-assembled growth of NWs using vapor-liquid-solid (VLS) epitaxy. (**a**) Scanning electron micrograph of Au seeds patterned with electron beam lithography. (**b**) Ge nanowires after growth on Si (111) [71]

of growth, in which metallic nanoparticles act as catalysts to nucleate the self-assembled growth of NWs, with the diameter of the NW directly related to the droplet size [64]. Fig. 19.27 shows a micrograph of Si NWs grown by the VLS method, where chemical vapor deposition (CVD) was used to generate the semiconductor precursors for VLS growth. The figure below also illustrates that the NWs may be deterministically placed using nanolithography techniques to pattern the catalyst.

Other methods may also be used for NW growth, however, including laser ablation and MBE. Growth of high-quality nanowires has been demonstrated in III–V (GaN, GaAs, GaP, InP, InAs) and II–VI (ZnS, ZnSe, CdS, CdSe) semiconductor NWs, as well as several different wide bandgap oxides (ZnO, MgO, SiO_2, CdO). Samuelsson and coworkers at Lund University have fabricated a variety of nanoscale electronic devices utilizing VLS-grown III–V semiconductor NWs as their active elements [65]. They have demonstrated that heterostructure nanowires of InAs and InP, as well as GaAs and InAs, can be realized that have very sharp heterointerfaces [66], both vertically and laterally (core-shell NWs, similar to core-shell nanoparticles; Fig. 19.28). Such heterostructure NWs have been used to fabricate nanoscale devices such as resonant tunneling diodes [67] and single [68] and multiply coupled [69, 70] quantum dots.

As discussed in more detail below, NWs can be used directly as the active absorber in solar cells (Sect. 19.7.4) and in terms of optical light management to increase absorption (Sect. 19.7.3).

Nanoparticles, Nanocrystals, and Quantum Dots: The names nanoparticles (NPs), nanocrystals (NCs), and quantum dots (QDs) are sometimes used interchangeably to denote either lithographically defined or self-assembled structures with characteristic dimensions on the order of 1–100 nm. If the NPs are single crystal structures, they are referred to as nanocrystals [72]. Nanoparticles can be metals, dielectrics, or semiconductors and are synthesized by a variety of techniques. Some mass-produced approaches include ball mill micro-machining, as well as pyrolysis and rf plasma techniques. High-quality NCs are synthesized through chemical solution methods, including sol-gel methods which result in colloidal solutions of nanoparticles. Self-assembled QDs of common III–V semiconductor materials (InAs, InGaAs, etc.) can form during epitaxial growth via the three-dimensional Stranski-Krastanov growth mode [73]. In this mode of growth, a thin layer of InAs is grown on top of a substrate of different lattice constant such as GaAs, where strain results in islanding of the epitaxial layer into 3D QDs, as shown by the micrograph in Fig. 19.28. Similar to NWs, QDs may become active components for realizing advanced concept solar cells discussed in the following sections as well as optical layers for light management beyond the texturing and antireflection coating approaches discussed in Sect. 19.3.2.

19.7.2 Dye-Sensitized and Quantum Dot Solar Cells

One of the first solar cell architectures that directly incorporated nanostructured materials as an active part of the absorber was the dye-sensitized solar cell (DSSC, or sometimes referred to as a Grätzel cell), which resembles an electro-

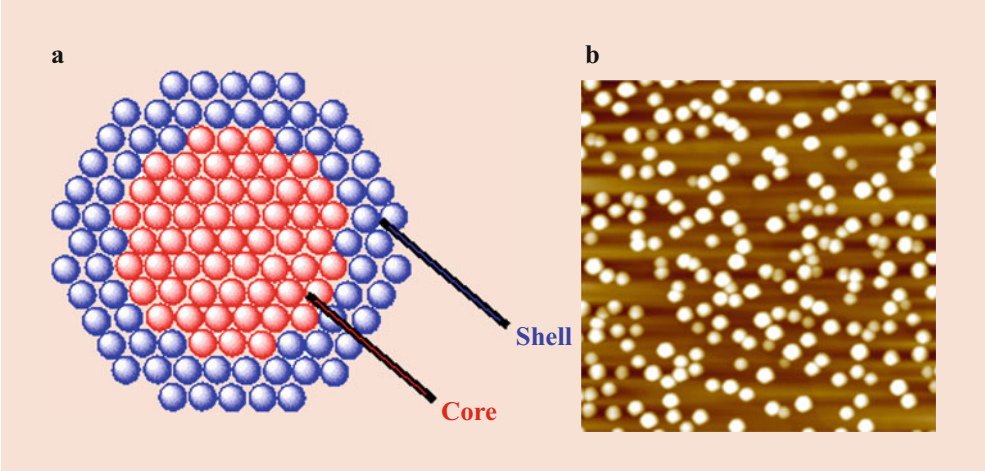

Fig. 19.28 (**a**) schematic of a core-shell nanoparticle (Wikimedia Commons). (**b**) micrograph of self-assembled InAs nanoparticles on a GaAs substrate [74]

chemical cell in design. The DSSC was first demonstrated by O'Regan and Grätzel in 1991 [75] and, as shown by the open red circles of Fig. 19.22, has reached efficiencies of over 11% with the conventional dye approach shown in Fig. 19.29. Conventional DSSCs have since been superceded by perovskite solar cells as discussed in Sect. 19.4.3, where the first high efficiency perovskite solar cells evolved from the DSSC architecture, and the highest efficiency perovskite cells still incorporate a nanostructured DSSC-like structure, albeit with the electrolyte replaced with a solid hole transport layer that is much more compatible with traditional thin film fabrication techniques.

The schematic of a conventional DSSC architecture is shown in Fig. 19.29. The absorber layer consists of nanoparticle or nanostructured TiO_2, which is a wide bandgap semiconductor with a bandgap of approximately 3.2 eV, coated with a dye such as ruthenium (Ru), whose HOMO-LUMO splitting is in the optimum range for the solar spectrum. The dye is usually spun on in liquid form to diffuse into and adhere to the TiO_2 nanostructure and is subsequently dried. The large surface to volume ratio of the nanostructured TiO_2 leads to an effectively large surface area, increasing light absorption. The whole structure is formed on a glass substrate as shown, coated with a TCO such as ITO or fluorine-doped tin oxide (FTO). When light is incident on the glass/TCO side, it is absorbed by the dye, and the excited e^- transfers from the excited LUMO level to the conduction band of the TiO_2 as shown. The electron diffuses through the TiO_2 matrix to the TCO and the external circuit. The positively charged hole left in the HOMO level reacts via a redox couple in the electrolyte, which is typically iodine based, consisting of I^- and I_3^- ions in solution. The dye is reduced by an electron being transferred to the dye through an oxidation process in the iodine, $3I^- = 2e^- + I_3^-$, where two holes in the dye are neutralized by converting three iodine ions into one I_3^- singly charged molecule, giving up two electrons to the dye. At

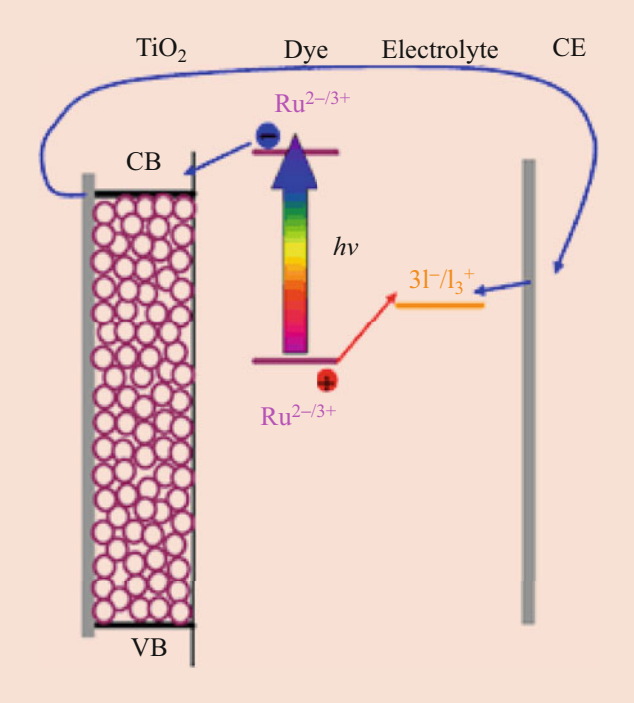

Fig. 19.29 Illustration of a dye-sensitized solar cell (DSSC) architecture. (Wikimedia Commons)

cathode, the positively charged ionic species, I_3^-,is reduced and converted back to $3I^-$ by the transfer of two electrons from the cathode, completing the circuit.

DSSCs have enjoyed some commercial success, particularly in niche applications such as building integrated PV, where different dyes corresponding to different colors provide some aesthetic benefits. Liquid electrolyte DSSCs suffer from stability issues as well as the complications of a panel structure involving liquid encapsulation. There are a variety of dyes, both natural and synthetic, that are suitable for DSSC

applications; however, they typically have a relatively narrow spectral absorption, which has led to the search for new dye materials such as inorganic NP-based dyes with broad absorption. Another problem arises due to recombination process occurring at the dye-TiO_2 interface, which lowers V_{oc}.

As discussed earlier in Sect. 19.4.3, a dramatic evolution of the DSSCs occurred with the development of the hybrid perovskite $CH_3NH_3PbI_3$ replacing traditional dyes, which could be introduced into the nanoporous TiO_2 matrix through low temperature processing. The liquid electrolyte was later replaced by a solid organic hole transport layer, which eliminated the issue mentioned above related to liquid-based cells, and a cell geometry more resembling that of a conventional thin film organic solar cell. More recently, the Cambridge group demonstrated that a planar hybrid perovskite thin film replacing the nanostructured TiO_2 could reach high efficiencies as well [22], which has increasingly become the dominant architecture, especially for tandem perovskite structures, although the mesoscopic approach continues to be investigated for high performance cells [76].

Quantum dot solar cells (QDSCs) have been of interest since the beginnings of the nanotechnology field [77]. As discussed in Sect. 19.8, QDSCs have many potential advantages in realizing advanced concept architectures in terms of multiexciton generation, hot carrier extraction, intermediate bands, and up-down conversion [78]. Like other nanomaterials, quantum confinement and surface effects allow tunable bandgaps for synthesizing ideal absorbers for single gap and multi-gap (tandem) cell applications. While MBE-grown QDs as described earlier have been used as absorbers in advanced concept architectures described later, colloidal quantum dots (CQDs) have been successful in realizing efficiency advances as shown in Fig. 19.22 by the open red diamonds.

There are several ways of incorporating CQDs into solar cell architectures. One is replacing the organic dyes in the DSSC structure above with semiconducting QDs such as InP, CdSe, CdS, and PbS [78]. More commonly, they are dispersed in an electron or hole conducting polymer forming, or in a ligand network ink, forming an organic solar cell architecture as discussed in Sect. 19.4.3. With the latter approach, the Toronto group in collaboration with KAUST demonstrated an 11.6% efficient PbS CQD-based device [79]. More recently, QDSCs based on inorganic perovskite CQDs ($CsPbI_3$) [80] (NREL) and hybrid perovskite CQDs of $FAPbI_3$ (where FA is formamidinium) (University of Queensland) [81] reached efficiencies of 13.4% and 16.6%, respectively. Of particular note is that the stability of these CQD-based perovskite materials appears superior to the bulk hybrid perovskites discussed earlier. While these recent perovskite-based QDSC results are quite promising, there are still many obstacles to overcome in terms of cost and stability which are active areas of research presently [82].

19.7.3 Light Management in Photovoltaics

As discussed in Sects. 19.2.2 and 19.3.2, maximizing solar light absorption in the semiconductor is critical in obtaining good short circuit current, which generally means getting photons into the semiconductor (no reflection from the front), and absorbing the photons before they can escape from the back or front of the cell. The necessary path length for absorption is directly related to the inverse of the absorption coefficient, $\alpha(h\upsilon)$, which is a strong function of wavelength, being small for photons just at the bandgap, and increasing strongly for shorter wavelengths. In terms of the path length, the fraction, f, of photons absorbed is given by

$$f = [1 - R(\lambda)]\left(1 - e^{-\alpha(\lambda)l}\right) \tag{19.50}$$

where R is the reflection coefficient from the front surface and l is average path length of photons in the absorber. Clearly one wants to minimize reflectance, while at the same time increasing the path length or correspondingly the absorption coefficient, which are the main objectives of light management.

Figure 19.30 illustrates the classical "ray optics" trajectory of light incident on a generic absorber, which has a textured surface which refracts light away from normal incidence, and a back-side reflector, which is in general textured as well to randomize the direction of the light. Due to internal reflection considerations, on the front surface, the ray is reflected and executes a number of bounces between the front and back surface before eventually exiting the front surface again at a small angle relative to the normal. For an absorber of width W, if there was no texturing on the front, and no reflection from the back, the path length is simply $l = W$. Adding an ideal back reflecting and assuming zero reflection when incident on the front surface leads to $l = 2\ W$.

Yablonovitch [8] used statistical arguments assuming ideal diffusive scattering from the front and back surfaces and classical ray optics, to derive the so-called classical light trapping limit for the enhancement of the path length in an absorber such as in Fig. 19.30

$$\langle l \rangle = 4n_s^2 W \tag{19.51}$$

where n_s is the index of refraction of the absorber. Taking Si as an example, with $n_s \approx 3.8$ for long wavelengths, a maximum path length enhancement of 58 is predicted. The implication is that one could reduce the thickness of the Si wafer from a typical value close to 200 μm to just a few microns, which would lead to substantial savings in terms of material costs (if one could process such thin Si), and actually lead to a boost in the cell voltage somewhat analogous to the effect of concentration.

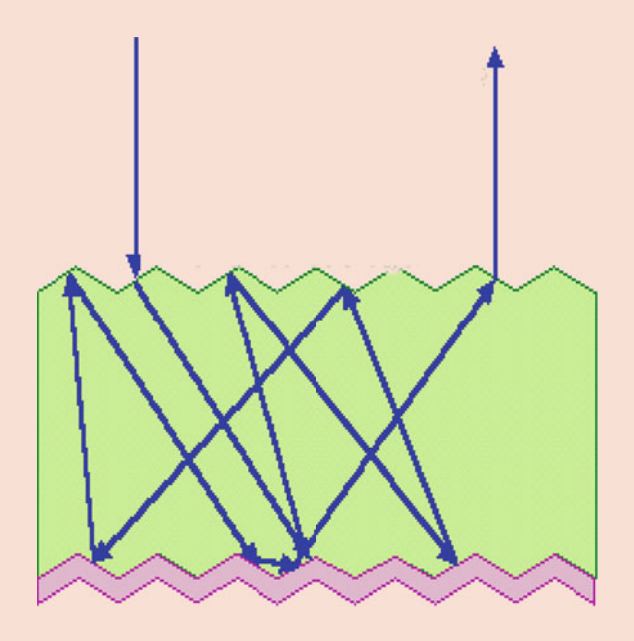

Fig. 19.30 Illustration of the classical path of light in a general semiconductor absorber structure including texturing of the front, the back, and a back reflector. (With permission from PVEducation.org)

Nanostructured materials offer the potential to go beyond the classical light trapping limit given by Eq. (19.51) [83], with characteristic dimensions corresponding to the regime of diffraction-limited optics. In recent years, there has been considerable interest in periodic arrays of optical scatterers forming *photonic bandgap* materials [84, 85], which are analogues to the band structure in semiconductor materials, in which gaps are opened up in the spectrum due to Bragg scattering. Such modification of the optical dispersion leads to passbands and stopbands for the propagation of electromagnetic radiation at certain frequencies. Such arrays can then be used to reflect or selectively enhance absorption, allowing the classical light trapping limit to be superceded, at least for certain bands of frequencies.

A common way to realize photonic bandgap structures is to grow or fabricate periodic arrays of NWs or nanopillars, as shown on the left side of Fig. 19.31. There, particular nanopillars were fabricated top-down using *nanosphere lithography*, in which silica nanoparticles are deposited on the surface of Si in a close packed hexagonal structure, followed by reactive ion etching through the nanospheres to form a periodic array [86]. The right side of Fig. 19.31 shows the measured reflectance (dashed curves), comparing the reflectance from different height nanopillars compared to bare Si. The solid curves correspond to full-wave finite difference time domain (FDTD) solutions of Maxwell's equations, where the ratio of the incident to reflected waves determines the reflectance. As can be seen, the nanopillars significantly decrease the reflectance due to light trapping, and that this reflectance is well described by the full-wave electromagnetic solutions to Maxwell's equations (as opposed to ray optics). The sharp features in the numerical simulations are due to the sharp features assumed in simulation, whereas experimentally, the nanopillars are somewhat tapered and the edges at the top and bottom are smoothed out. Atwater's group studied different NW arrays including both periodic and randomly spaced arrays and showed that the absorption properties of the arrays were evidence exceeding the classical light trapping limit over a limited band of optical frequencies [87].

Besides photonic bandgap structures, nanoplasmonic structures are also of interest in terms of enhanced light trapping. Plasmonic structures may correspond to metals adjacent to a dielectric, metal strips, and finally metallic nanoparticles on a surface or interface. Metal nanoparticles are similar to the semiconductor ones discussed in the Sect. 19.7.1 in terms of synthesis, where typically Au or Ag are used due to their low loss. Strong interaction between the incident electromagnetic waves and the collective charge oscillations of the metal structures results in the formation of hybrid surface plasmon polariton (SPP) modes. Such coupling is strongest close to the plasma frequency of the metal, and the SPP modes strongly favor propagation along the surface, which increases the effective path length manyfold, hence increasing absorption. Plasmonic structures may be incorporated at the front or back surface as well as within the absorber itself, and have been investigated in Si, III–V, and organic solar cells, where in particular they are used to try and improve the red response of cells, where absorption is usually weakest. For Si solar cells, for example, path length enhancements of seven to eight times were reported in Si cells [88], while plasmonic nanoparticle arrays of Au NPs on GaAs cells showed increase in short circuit current of 8% [89].

19.7.4 Nanowire Solar Cells

As discussed in the previous section, NW arrays have demonstrated good light management properties in terms of photonic bandgap properties, with the potential to exceed the classical light trapping limit. Semiconductor NWs may also act as the active optical absorber in photovoltaic applications, in which the effective absorption per volume of material is greatly enhanced compared to the bulk due to the nanophotonic enhancements in array structures. NWs also have the advantage of having good quasi-1D transport properties along the axis of the NW, allowing for separation and collection of photoexcited EHPs. III–V NWs are routinely grown on Si substrates, allowing for the possibility of Si-based tandems discussed in Sect. 19.6. In terms of lattice matching constraints and critical thickness limitations in

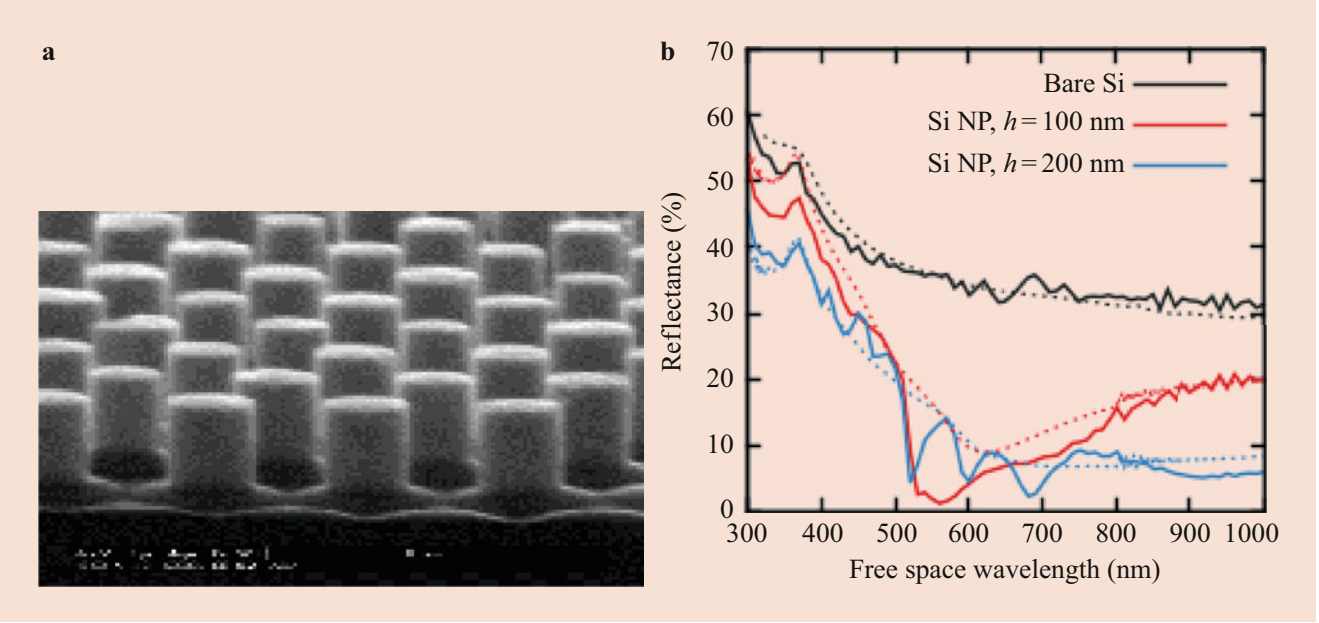

Fig. 19.31 (**a**) Micrograph of nanopillars fabricated using nanosphere lithography. (**b**) Measured (dashed) and simulated reflectance from a regular hexagonal array of Si nanopillars with period, $p = 600$ nm, for cylinder heights of a 100 (red) and 200 nm (blue) [86]

epitaxially grown layered structures, the finite lateral extent of NWs allows the strain to be accommodated in the lateral direction, allowing much more flexibility in the heterogeneous growth of different lattice constant materials. The ability to grow both vertical and lateral (core-shell) structures allows for the design of material systems to be used to realize advanced concept photovoltaics that cannot be realized with bulk materials. The main disadvantage of NWs (and all nanostructured systems) is that the large surface to volume ratio means that surface recombination effects are enhanced, which is detrimental to solar cell performance as discussed in Sect. 19.3. Surface passivation strategies are therefore critical. In the case of NWs, an effective strategy is growth of a core-shell structure with a large bandgap material as the outer layer, which reduces recombination [90].

There have been a number of studies of optoelectronic devices based on NWs including solar cells, starting in the mid-2000s [91–94]. The best performance in NW solar cells has been demonstrated in III–V compound semiconductors like GaAs, due to the high absorption associated with a direct bandgap material, and good transport properties. As mentioned above, one of the advantages of NW-based systems is that III–V materials may be grown on Si substrates, providing another approach for Si-based tandem solar cells. A schematic of an InGaAs NW array solar cell architecture is shown in the upper panel of Fig. 19.32. The NWs are core-shell structures, with InGaAs cores, and InP cladding layers, grown on Si (111) substrates. The (111) orientation is usually necessary to grow vertical NWs. This radial core-shell design has been used by the Technical University of Munich group for optoelectronic applications such as NW light-emitting diodes (LEDs) and lasers. [95]. As shown in the bottom panel of Fig. 19.32, regular arrays of NWs with well-defined periodicity are grown using nanolithographic techniques, in this case nanoimprint lithography, which is a low-cost method for nanofabrication. The main difficulty in such NW solar cell approaches is in making both p and n contacts. While the Si substrate serves as one contact, the top must be contacted separately as shown, which must be isolated from the substrate to avoid leakage.

Besides Si-based tandem solar cells, there is considerable interest in Si-based optoelectronics, integrating III–V-based photonic circuits with Si microelectronics. Chuang et al. [97] demonstrated the first NW GaAs LED and GaAs NW avalanche photodetectors (APD) grown on Si substrates using relatively low temperature processes compatible with CMOS technology. They later demonstrated the first InGaAs/GaAs core-shell NW laser grown on silicon [98].

For NW solar cells, one may either use lateral core-shell junctions or vertical junctions grown vertically along the axis of the NW. Colombo et al. reported a single GaAs core-shell NW p-i-n solar cell [99, 100] with an efficiency of 4.5% and a V_{oc} for GaAs cells of almost 1 V, which is comparable to that of high performance GaAs bulk solar cells. Radial GaAs junction arrays were reported by Mariani et al. [101] with efficiencies of 2.54%. In the past 5 years, remarkable improvement in the performance of NW solar cells has been reported. Axial InP p-i-n junction arrays were reported by Borgström et al. [102] with 13.8% efficiency in 2013. Sol

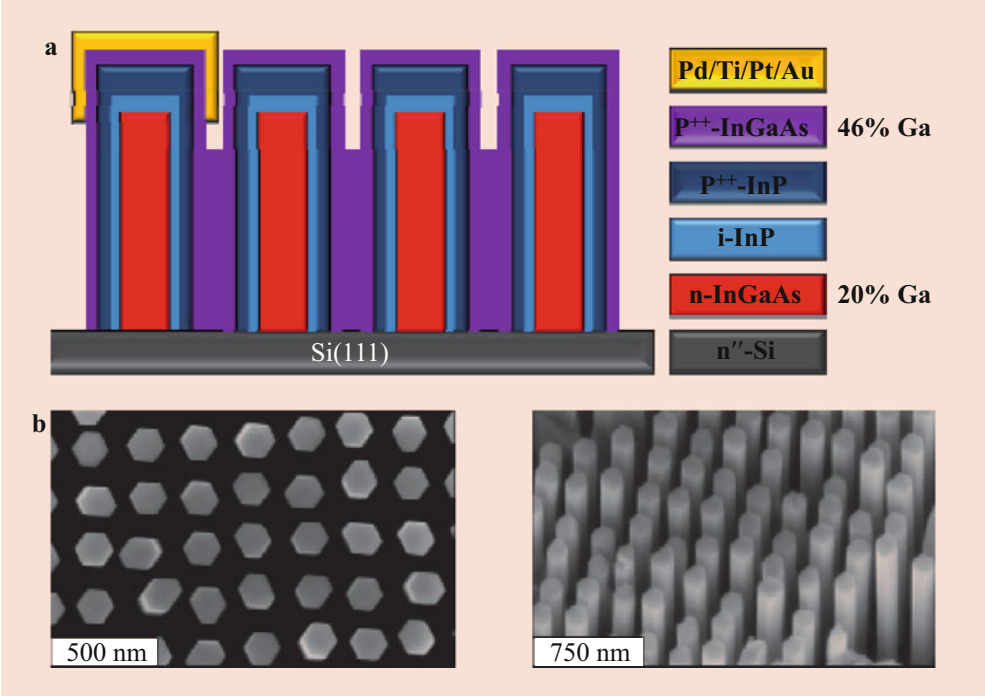

Fig. 19.32 (**a**) InGaAs core-shell nanowire solar cell structure. (**b**) SEM picture of arrays of NWs defined by nanoimprint lithography [96]

Voltaics and Lund University reported GaAs VLS-grown nanowire solar cells with independently tested efficiencies of 15.3% in 2016 [103]. In the same year, Eindhoven University reported a 17.8% InP vertical junction nanowire solar cell formed by etching and passivation [104]. The improvement in NW solar cell technology has occurred quite rapidly, from a few percent in 2009 to over 17% in 2017, similar to that of perovskite solar cells, although not represented on the NREL efficiency charts.

19.8 Advanced Concept Photovoltaics

Advanced concept is a term sometimes used to describe novel approaches to exceeding the Shockley-Queisser (QS) limit beyond the demonstrated approach of multijunction solar cells, based on circumventing the implicit assumptions in QS discussed in Sect. 19.5.2. Below we briefly review three such concepts, intermediate band, multiexciton generation, and hot carrier devices. There are also other approaches not discussed here, including up-down conversion using phosphors and nanoparticles to narrow the effective spectrum, as well as hybrid photovoltaic-thermal approaches, such as thermophotovoltaics, or spectral splitting approaches to use both photovoltaics and concentrating solar thermal for electrical energy production. Green's book on third-generation photovoltaics provides an excellent overview of these various approaches [2].

19.8.1 Intermediate Bands

Finally, rather than fabricating multiple junctions, another proposed approach to circumvent the SQ single bandgap assumption is to introduce multiple energy levels within the same material. Luque and Martı [105, 106] first proposed the concept of an *intermediate band* (IB) solar cell, although the same basic concepts were already investigated earlier in connection with MQW solar cells [77, 107, 108]. It consists of an intermediate band between the conduction and valence band of a bulk-like material. The most widely investigated approach is illustrated in Fig. 19.33, where the intermediate band arises from the introduction of either quantum wells or quantum dots into a wider bandgap material. Quantum wells have quantized levels as shown, which broaden in a MWQ or SL structure. However, there remains a continuum of states in the directions parallel to the growth direction, which is a disadvantage in realizing a separate intermediate band. Quantum dots on the other hand have true discrete density of states, which broaden into an intermediate band when grown as a SL. Besides IB QW and QD structures, bulk IB materials may be synthesized, for example, in alloy structures [109], where a narrow band exists between the conduction and valence bands.

Figure 19.33 illustrates the processes and energy separations in the IB concept. Here E_c and E_v represent the CB and VB edges of the higher bandgap material with bandgap E_G. The center of the IB is an energy E_{IV} above the VB, and E_{IC} below the CB. As shown, the IB allows sub-bandgap photons

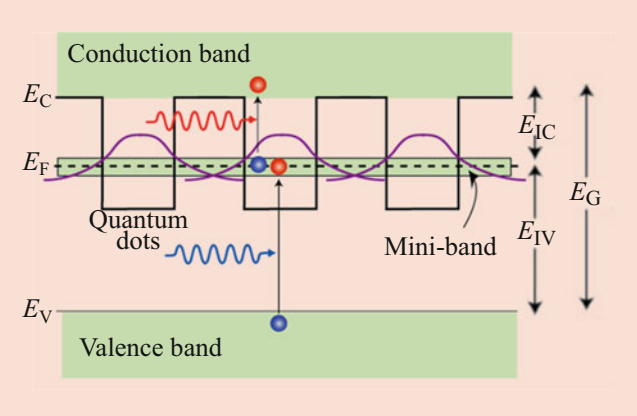

Fig. 19.33 Illustration of an intermediate band solar cell architecture based on quantum dot (or quantum wells) levels introduced within a wider bandgap host semiconductor [110]

to be absorbed, promoting electrons from the VB to the IB and promoting electrons in the IB to the CB. The third process is the direct band to band absorption from VB to CB. In order for the IB concept to provide an efficiency increase of the SQ limit, there must be a separate quasi-Fermi energy associated with the IB band which is separate from that of holes in the VB and electrons in the CB. For example, if the Fermi level of the IB is above the IB and close to the CB (the usual case under strong photoexcitation), then the IB states are all filled, and not transitions can occur to the IB. Hence, ideally, it should be half occupied. Likewise, if the IB and CB quasi-Fermi energies are common, then cell will be effectively a cell with a bandgap E_{IV}, with a drop in V_{oc}. Thus, having multiple quasi-Fermi energies is a necessary for efficiency operation.

Detailed balance may again be used to calculate the maximum conversion efficiency as a function of E_G and E_{IC} (E_{IV} being simply E_G-E_{IC} in this three-level approach). For any particular value of E_{IC}, there exists an optimum E_G for maximum efficiency. Luque and Martí used detailed balance to calculate the maximum efficiency versus E_{IC}, where the optimum combination corresponds to $E_G = 1.95$ eV and $E_{IC} = 0.71$ eV, corresponding to an efficiency of greater than 60% under concentration, clearly well above the SQ single gap limit.

There have been a number of experimental reports that demonstrate the presence of the three individual processes, in a number of different technologies including solar cells, quantum dot lasers, and quantum cascade lasers [111–115]. However, demonstration of independent quasi-Fermi energies necessary for IB cell performance is difficult. Marti et al. have demonstrated the ability to collect carriers at high energy using two low-energy photons [116], which is a necessary process for IB operation. In addition, early results from Nelson et al. in QW solar cells are explained [117] by a different Fermi level inside a QW than in the barrier. Thus there is the suggestion that multiple quasi-Fermi levels can exist in multilevel structures, although the demonstration of a high performance IB cell that convincingly exceeds the SQ limit effect remains elusive.

An extensive review of the state of the art of IB solar cell technology is given by Okada et al. [118], which the interested reader is referred to for more detail. A well-studied system is that of self-assembled multiple layers of InGaAs QDs grown on GaAs as discussed in Sect. 19.7.1 via Stranski-Krastanov strained growth mode. Although the combination of bandgaps and intermediate-level energies is nonideal from the detailed balance calculations mentioned above, single crystal defect-free structures may be grown, where the QDs tend to self-align during between subsequent layers, so that large numbers (10s of layers) may be grown. The main challenge in realizing a viable IB solar cell technology is demonstrating a significant increase in short circuit current due to the sub-bandgap absorption of photons while not degrading the open circuit voltage, which has been hard to simultaneously achieve if the occupancy of the IB level is tied to that of the CB. While this has been demonstrated to some extent in GaAs cells, typically the baseline GaAs cells for comparison have inferior V_{oc} (0.7–0.9 V) compared to the voltages of record GaAs cells which exceed 1.1 V [119]. Various schemes have been introduced such as doping the QDs, strain compensation, and other approaches, to both improve the optical efficiency and minimize recombination. For example, Bailey et al. have demonstrated GaAs-based IB cells with voltages over 1.0 V [114], with improvement in the short circuit current, although the efficiency was still less than the baseline cell.

19.8.2 Multiple Exciton Generation (MEG)

An energetic electron or hole in a semiconductor with a kinetic energy greater than the bandgap may lose its kinetic energy creating one or more EHPs depending on the energy. This process is generally called impact ionization, since promoting an electron from the VB to CB is equivalent to bond breaking. This may occur through acceleration of a charge carrier to the threshold energy for this process under high electric fields, or it may occur for photoexcited electrons whose excess energies are high enough to create a second EHP. Figure 19.34 illustrates the creation of multiple electron-hole pairs for different photon energies, assuming that electrons near the top of the VB are excited into the CB with an excess energy equal to the difference of the photon energy and the bandgap. As shown, there are different thresholds reached in energy when the photon energy in this picture is $h\nu = 2E_g$, $3E_g$, $4E_g$, etc., resulting in 2 EHPs, 3 EHPs, etc. When present in a solar cell, the quantum efficiency can

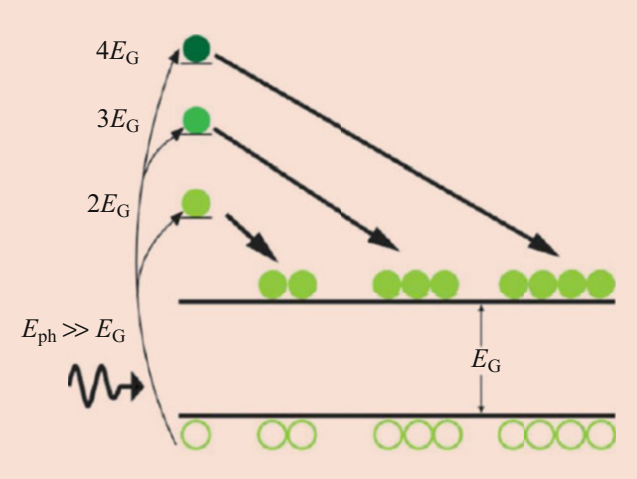

Fig. 19.34 The multiple carrier generation process for photon energies in excess of one, two, three, and four times the bandgap

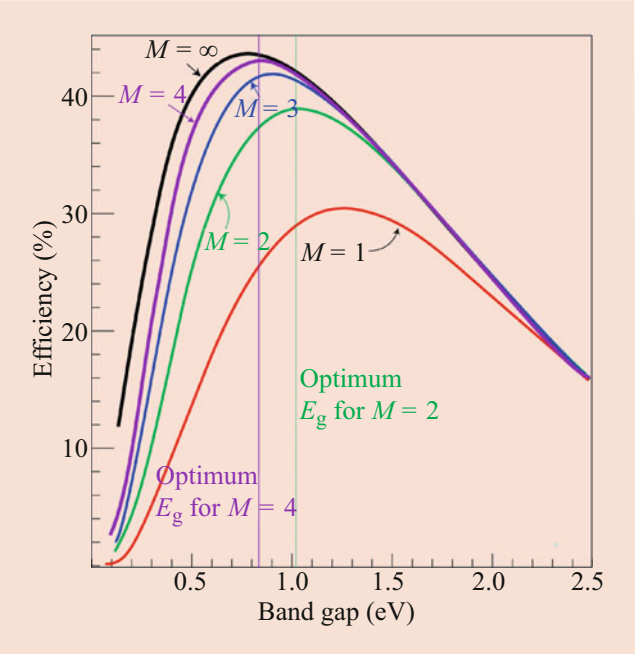

Fig. 19.35 Calculated detailed balance efficiency as a function of bandgap for the AM0 blackbody spectrum with consideration of increasingly higher order multiplication factors

now be greater than 100%, breaking the assumption of 1 EHP per photon, increasing the photocurrent, and allowing the SQ limit to be overcome.

Creation of multiple electron-hole pairs by energetic photons was already known for Ge in the 1960s. Kolodinski et al. measured the quantum efficiency in bulk silicon solar cells as a function of photon energy, where they showed greater than 100% QE occurring above 3 eV [26]. Such a high photon energy is beyond the useful range for the solar spectrum, due to the fact that the threshold for impact ionization in bulk crystals must simultaneously satisfy both energy and crystal momentum conservation, which shifts the threshold up by a factor of 1.5 using simple effective mass considerations with parabolic bands.

On the other hand, due to quantum confinement in nanomaterials, conservation of crystal momentum is relaxed, in particular for QDs. Experimentally using ultrafast absorption and other spectroscopies, threshold energies for carrier multiplication were found to be close to twice the fundamental gap in PbSe and PbS CQDs with quantum efficiencies in excess of 300% [120, 121]. The optically excited states of QDs are strongly excitonic in nature due to the strong confinement, hence the term *multiple exciton generation*, or MEG for short. Experiment [122] and theoretical calculations [123] suggest that MEG occurs over very short time scales and may be regarded as a coherent effect, rather than as two successive scattering processes, although there is still not agreement on this interpretation. MEG has now been demonstrated in a variety of nanomaterials, including CQDs of PbSe, PbS, InAs [124], PbTe [125], Si [126], and CdSe [127].

The effect of MEG on the detailed balance efficiency is easily incorporated into Eq. (19.46) [128]. The incident photon flux includes both the direct and diffused terms, which in the SQ analysis is equated to the photocurrent assuming 1 EHP per photon, which in the presence of MEG is weighted inside the energy integrals of the first two terms by the quantum yield (QY) as a function of photon energy, $Q(E)$, which is the number of EHPs produced per incident photon. For the ideal case, carrier multiplication is assumed to jump abruptly with each multiple of the threshold exceeding, represented mathematically by the staircase function

$$Q(E) = \sum_{m=1}^{M} m\Theta\left(E - mE_g\right) \tag{19.52}$$

where Θ is the unit step function, m is the number of electron-hole pairs generated per photon, E_g is the threshold energy (ideally the bandgap energy), and M is the maximum number of EHPs per incident photon. Additionally, it is usual to weight the voltage term, qV, by $Q(E)$ in the third integration to account for the inverse process to MEG (Auger recombination in the bulk), i.e., multi-electron recombination [2]. Assuming the blackbody spectrum form with a unity concentration factor in Eq. (19.46), the calculated detailed balance efficiency versus bandgap with different values of M in Eq. (19.52) is shown in Fig. 19.35. The result using the AM1.5 spectrum gives a similar and somewhat higher efficiency but less smooth as was the case in Fig. 19.24 due to spectral features.

The case of $M = 1$ is just the SQ limit for the blackbody spectrum. Already for $M = 2$, there is a sizable increase in maximum efficiency, which approaches 44% for the limit of

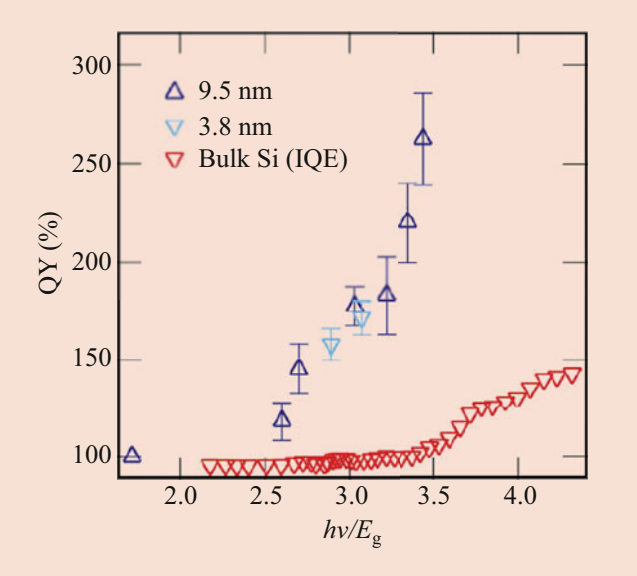

Fig. 19.36 Measured quantum yield versus photon energy (normalized by the bandgap) for bulk Si and two different diameters of nanoparticles. (With permission from [127])

M going to infinity. The optimum bandgap decreases with increasing multiplication factor M, as shown, going from 0.76 eV for large values to 1.05 for $M = 2$ [129], very close to that of Si.

The ideal quantum efficiency given in Eq. (19.52) is never in practice observed, as in experimental data shown in Fig. 19.36. The idea case assumes the existence of multiple separate, noninteracting MEG processes for excitation of 2 EHPs, 3 EHPs, etc. Also, the assumption that all excess energy of the photon is given to electrons in the CB is only true near the band edge for a high ratio of hole to electron effective masses. In the realistic case of photon energies exceeding twice the bandgap, the density of states of holes and electrons coupled by a high-energy photon is roughly equal, leading to a smearing out of the threshold energy for the onset of MEG.

Ultrafast spectroscopy has been primarily used to measure MEG by monitoring the transient state filling on a picosecond time scale at the bottom of the conduction band for different pulse excitation energies, which provides a measure of the QY in terms of the number of EHPs produced per incident photon. Fig. 19.36 plots experimental QY data for Si NPs measured spectroscopically by NREL [126] in comparison to the experimental internal quantum efficiency data of bulk Si solar cells [130]. As mentioned earlier, the threshold for turn-on (QY > 100%) for bulk Si does not occur until relatively high energy due to energy and momentum conservation constraints, while for Si NPs, the turn-on is much closer to twice the bandgap (including quantum confinement and excitonic effects in NPs). The NP data shows more of a linear slope past threshold rather than an abrupt turn-on, characteristic of most experiments. As mentioned above, the slope is related to the partitioning of the excess energy between electrons and holes, as well as the efficiency of the multi-excitation effect relative to competing energy relaxation effects due to phonons and other processes. While most evidence for MEG comes from ultrafast optical measurements in NPs, recently the internal quantum efficiency of PbSe quantum dot solar cells was reported by the NREL group in which for short wavelength photons above the threshold for MEG, quantum efficiencies greater than 100% were measured [131], which is promising for realizing MEG effects in real devices.

Besides MEG in NPs, other nanostructures have exhibited carrier multiplication effects. Evidence for MEG in CNTs was reported by Gabor et al. in CNT photodiodes [132]. MEG in multiexciton in PbSe nanowire/nanorod structures was demonstrated by Cunningham et al. where the performance of PbSe nanorods was significantly improved compared to PbSe NPs in terms of both the QY threshold and the slope after threshold (steeper) [133]. MEG in NWs would have potential advantages in terms of the NW solar cells discussed in Sect. 19.7.4, as efficient carrier collection may occur along the axis wire for vertical structures or transverse in core-shell structures, in contrast to NP-based structures which require some extraction mechanism such as tunneling for carrier collection.

As mentioned earlier, the efficiency of the MEG process depends on a competition between carrier multiplication processes like impact ionization and inelastic energy loss mechanisms such as electron-phonon scattering, which relax the excess energy of the electrons and holes back to the band edges (thermalization). Such energy relaxation processes are also important for hot carrier solar cells, discussed in the next section. In semiconductors, electrons lose (or gain) energy through acoustic and optical phonon emission (absorption). Due to the relatively large energy associated with optical phonon emission, on the order of 20–50 meV per event, optical phonon energy loss usually dominates, particularly in polar III–V and II–VI materials where the Fröhlich interaction (polar optical scattering) for zone center optical phonons is strong.

Nanostructures such as in QWs, NWs, and NPs have been experimentally observed to have reduced energy relaxation rates by a number of researchers discussed in more detail in the next section, for example, by Pelouch et al. [134]. In reduced dimensionality nanostructures, energy relaxation requires *intersubband* scattering in order for electrons and holes to reach their lowest energy states in the CB and VB, respectively, i.e., scattering between the quantized states associated with the spatial confinement in one or more directions. Due to this requirement, the optical emission rate may

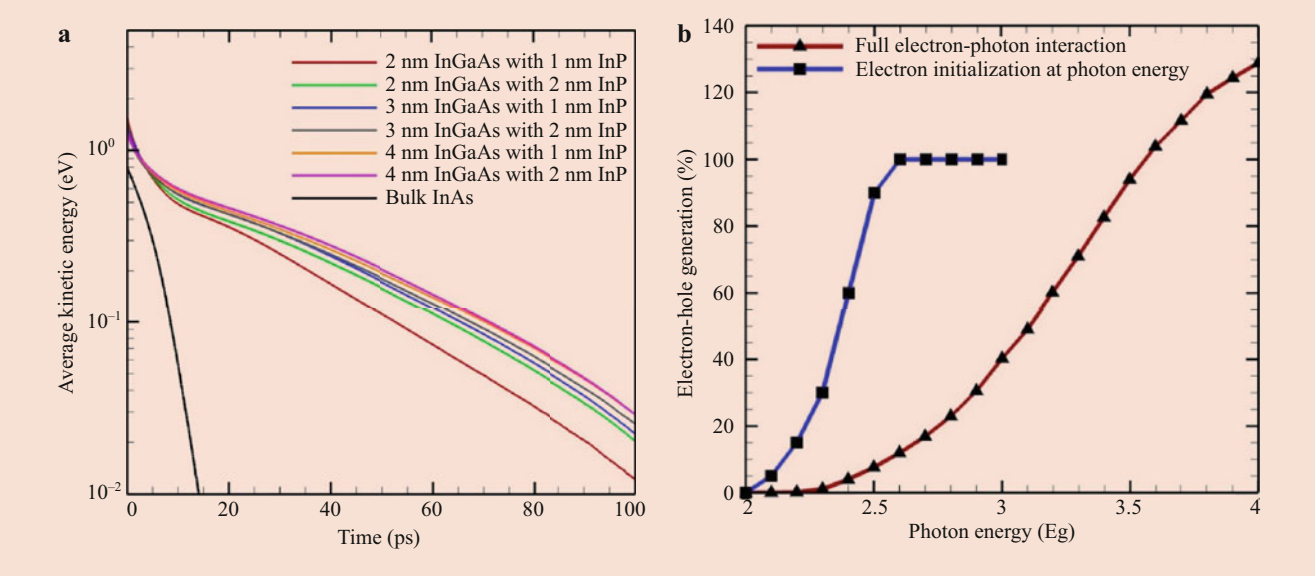

Fig. 19.37 (**a**) Full band Monte Carlo simulation of the average kinetic energy versus time for carriers excited in a short time pulse at an energy $2E_g$ above the CB edge (bulk) and lowest confined state (NWs) for different diameter NWs. (**b**) Simulated quantum yield (relative to the initial population) versus excitation energy for a 2 nm InGaAs NW and 1 nm InP cladding [135]

be suppressed due to so-called "phonon bottleneck" effects, when the subband spacing is such that there is no final state to scatter to. In 2D materials like QWs, there is a continuum of states associated with the free transverse motion which usually provides a channel for scattering. However, in 1D (NWs) and 0D (NPs, QDs), such effects become more important due to the spike-like density of states (DOS).

The left panel of Fig. 19.37 shows the simulated energy versus time of a short time pulse of photoexcited electrons in bulk InGaAs compared with narrow core-shell InGaAs/InP nanowires of various core and shell thicknesses using full band ensemble Monte Carlo simulation, a particle-based technique for simulating nonequilibrium carrier dynamics [135]. As shown, the energy loss rate, here limited mainly by polar optical phonon scattering, is significantly slower in the nanowire structures compared to the bulk. Such results are consistent with slow energy relaxation observed in semiconductor NWs. Optical studies in InP NWs using transient Raleigh scattering [136] and steady-state photoluminescence [137] showed energy relaxation times of several hundred ps and high carrier temperatures under steady-state excitation.

The right panel of Fig. 19.37 shows the simulated carrier multiplication versus photon energy based again on full band NW Monte Carlo simulation, including the calculated QY due to impact excitation rate in NW systems [135]. The blue curve corresponds to the simple assumption of all the excess photon energy going to the electrons, whereas the red curve is a more realistic calculation in which the dipole matrix element for direct band to band absorption is used to generate the electron and hole injected distributions, where the excess energy is more evenly split between the two systems. As can be seen, while the simple model leads to a more ideal (i.e., Eq. (19.52)) step-like QY, the full calculation of the optical absorption leads to a higher threshold and lower slope after threshold.

19.8.3 Hot Carrier Solar Cells

The final advanced solar cell concept discussed in this chapter is related to circumventing the SQ assumption that the carriers are collected at energies corresponding to the band edges, which are the main source of thermalization loss discussed in Sect. 19.5. The idea is to extract photoexcited carriers at energies well above the band edges before they lose energy to phonons as discussed in the previous section. Figure 19.38 illustrates the concept of a *hot carrier solar cell* proposed by Ross and Nozik in the 1980s [28]. The structure consists of an ideal absorber with a low energy loss rate for the photoexcited electrons and holes. *Energy selective contacts* extract electrons only on the left in a narrow energy window, and holes to the right as shown. Realization of such contacts is challenging; one of the main approaches is implementation of a resonant tunneling structure, such as a double barrier heterostructure, or tunneling through an artificial impurity such as a QD in a wide bandgap material [138]. The contacts themselves should be at temperature of the surround ambient as discussed by Würfel et al. [30], requiring that the absorber must be spatially separated from the cold metallic contacts; otherwise there will be strong energy

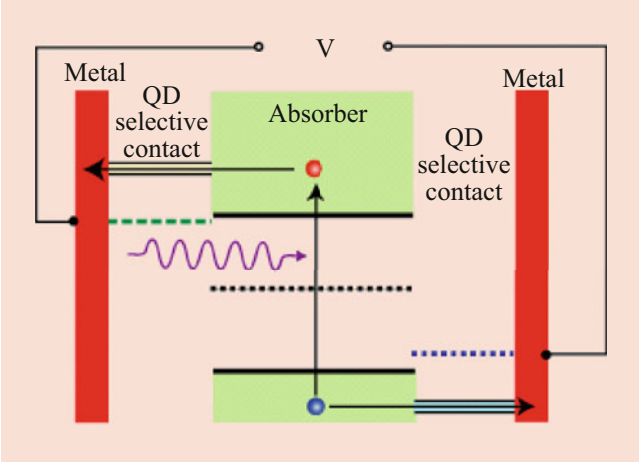

Fig. 19.38 Hot carrier solar cell architecture consisting of an ideal absorber with energy selective contacts [110]

loss mechanism due to cold contact electrons interacting with carriers in the absorber layer.

While the carriers in a hot carrier device ideally do not lose energy through phonon scattering processes, they do exchange energy among themselves through electron-electron, electron-hole, and hole-hole scattering. This can occur through two-particle scattering or scattering between charge carriers and collective excitations such as plasmons. Such scattering drives the distribution function of the carriers toward the equilibrium distribution represented by the Fermi-Dirac (FD) (or for nondegenerate carriers, Maxwell-Boltzmann, MB) distribution, however at an effective temperature, T_H, much greater than the lattice temperature, T_L.

Ensemble Monte Carlo (EMC) simulation has been used to simulate this nonequilibrium evolution of the carrier distribution [135], as shown in Fig. 19.39. The EMC simulations are for a quasi-2D system (10 nm GaAs/AlGaAs quantum well), which show the evolution of the electron distribution from a highly nonequilibrium distribution shortly after the pulse to a heated FD distribution. Scattering due to polar optical phonons, intervalley deformation potential, and carrier-carrier scattering (electron-electron, hole-hole, electron-hole) are included. Immediately after the optical pulse, the electron distribution is an athermal Gaussian-shaped distribution at the excess carrier energy. Even at these short times, an optical phonon *sideband* or *replica* is observed below the peak due to the effectiveness of polar optical phonon scattering. As time progresses, a series of phonon replicas appear showing that the initial cooling occurs through a cascade of optical phonon emission events. During this time, the distribution broadens due to electron-electron scattering, and eventually the phonon replicas vanish and are replaced by a what appears to be a heated FD/MB distribution, whose temperature continues to decrease with increasing time due to phonon emission.

Ross and Nozik considered the theoretical performance of hot carrier solar cells [28], based on the detailed balance approach discussed in Sect. 19.5. Within this approach, the electrical power delivered from the cell, P_{out}, may be written.

$$P_{out} = \left(I_{ph}/q\right) \Delta\propto_H T_a/T_H + \left(I_{ph}/q\right) \varepsilon_{ext} \left(1 - T_a/T_H\right) \tag{19.53}$$

where I_{ph} is the photocurrent corresponding to photons above the bandgap of the absorber, $\Delta\mu_H$ is the quasi-Fermi-level splitting in the absorber, T_a and T_H are the ambient and hot carrier temperature in the absorber (assuming a heated FD/MB distribution as discussed earlier), respectively, and ε_{ext} is the separation of the selective energy contacts or, more precisely, the Fermi energy separation of the metal contacts to the electrons and holes. In the limit that the ambient and hot carrier temperatures are the same, this just reverts to the usual SQ model where the voltage out is the quasi-Fermi energy separation. For high carrier temperatures, the first term is small, and the output voltage is determined by ε_{ext}, while the photocurrent corresponds to the gap of the absorber, which then favors small gaps. There is a limit on ε_{ext} set by the total energy available in the solar spectrum, so that assuming no energy loss and small bandgaps, the theoretical detailed balance conversion efficiency approaches the maximum thermodynamic conversion efficiency of 85.4% [139]. Würfel and coworkers later considered the effect of impact ionization on the ultimate efficiency of this concept [140, 141].

For the hot carrier solar cell to exceed the SQ limit, it's necessary that the energy loss rate in the absorber be very low such that a high carrier temperature may be maintained, as evidenced by Eq. (19.53). This is very challenging, since the energy rate due to optical phonons in the bulk and in quantum wells is subpicosecond. As seen in Fig. 19.39, even at very short times, polar optical phonon emission is already cooling the initial high energy distribution of carriers. As discussed in Sect. 19.8.2, the energy loss rate in NWs is reduced several times compared to bulk, although this rate is still too fast reaching high carrier temperatures under steady-state conditions. In QDs, the energy loss rate is further reduced, due to phonon bottleneck effects. As mentioned in the previous section, pump and probe as well as *cw* experiments in QWs have demonstrated greatly reduced cooling rates, and high carrier temperatures for high excited carrier densities, despite the fast polar optical phonon energy relaxation rate. Attempts have been made to utlize this in a hot carrier solar cell architectures, where researchers have demonstrated hot carrier transfer from quantum well absorbers to contacts [142], and photovoltaic conversion efficiencies above 10% [143].

One proposed explanation for strong hot carrier effects in nanostructure system is in terms of nonequilibrium optical phonons (hot phonons) [144, 145]. In nanostructures in con-

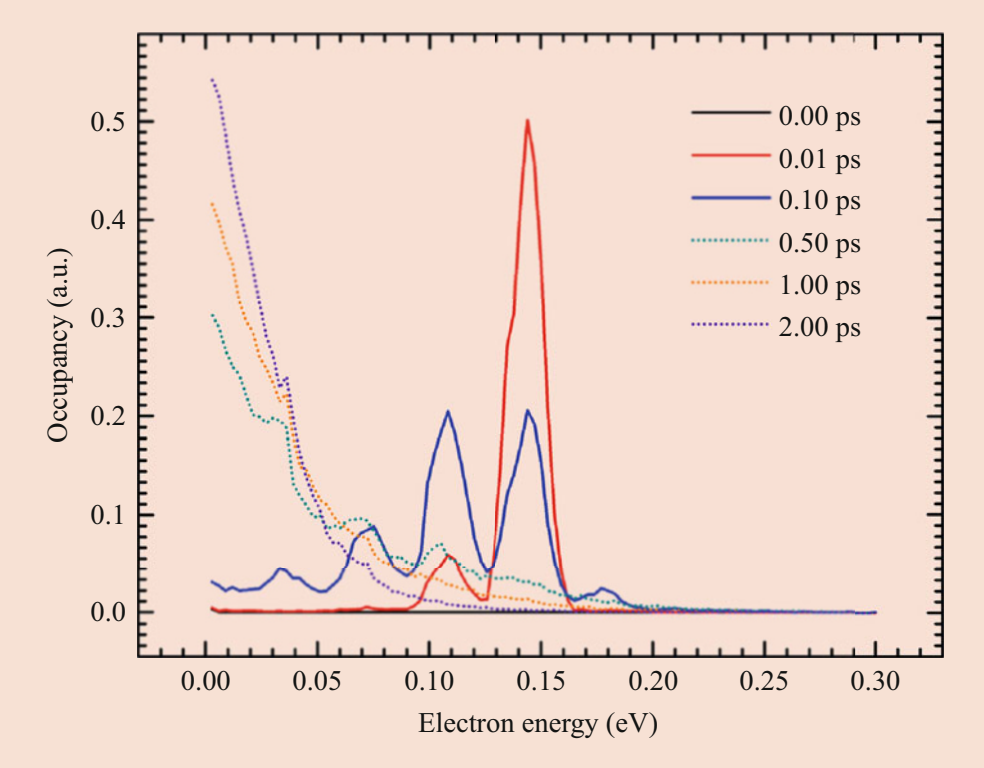

Fig. 19.39 EMC simulation of the time evolution of the electron distribution in the conduction band of a 10 nm GaAs quantum well at 10 K for carriers injected at 150 meV above the band edge, with an injected carrier density of $5 \times 10^{11}/\text{cm}^2$ [135]

trast to bulk systems, the excitation of EHPs occurs in a small volume spatially, and hence energy relaxation and phonon emission also occur in the same small volume. In particular, optical phonons have a very small group velocity, essentially zero at the zone center, and so remain in the excitation volume until they decay into acoustic modes through anharmonic three and four phonon processes, which propagate away from the excitation volume at essentially the sound velocity of the crystal. The nonequilibrium population of optical phonons increases the probability of phonon absorption, it transfers the energy lost back into the electron-hole system, and the excess kinetic energy of the EHP is retained in the coupled charge carrier/optical phonon system, essentially until the hot phonons decay into acoustic modes.

Time-resolved Raman scattering has been used in the past to measure nonequilibrium phonon effects during ultrafast photoexcitation and to directly measure the anharmonic phonon decay time through the time dependence of the anti-Stokes line (which is proportional to N_q, the phonon population at the relevant phonon wave vector). Measurement has been reported for a variety of III–V compound bulk and quantum well materials [146–149], where typical anharmonic decay times are in the 1–10 ps time scale. The UNSW group has argued that nonequilibrium "hot" phonons may play a critical role in reducing carrier energy loss in hot carrier solar cells, allowing for high electron/hole temperatures in the absorber. Engineering materials as absorbers with long phonon decays (phononics), both in the bulk and in nanostructured structures, are currently being investigated [150, 151].

Ensemble Monte Carlo (EMC) simulation as described in Sect. 19.8.2 has been used to simulate ultrafast carrier dynamics and nonequilibrium phonons in quantum well materials [152, 153], where hot phonon effects have been shown to lead to substantial reduction in carrier cooling. Figure 19.40 shows the simulated effect of phonon lifetime on carrier relaxation using EMC simulation, similar to earlier work on this topic [135, 144, 154]. In these simulations, electrons are injected via a 200-fs-wide 2 eV laser pulse within a 10 nm GaAs/AlAs QW. The injected carrier density is $5 \times 10^{11}/\text{cm}^2$ in all cases and the lattice temperature is 5 K. In Fig. 19.40, the simulated carrier temperature versus function of time is plotted, assuming different anharmonic phonon decay times, ranging from 0 (i.e., no hot phonons) to 100 ps.

Without hot phonons, the electrons cool rapidly and decay to the lattice temperature within ~5 ps. As the phonon lifetime is increased, the decay slows and starts to be governed by the anharmonic decay time rather than the electron-phonon emission rate. The effect is strongly density dependent, similar to experiment, since a higher injected density leads to a higher nonequilibrium phonon population, which increases the strength of the hot phonon effect. Hence, finding absorber

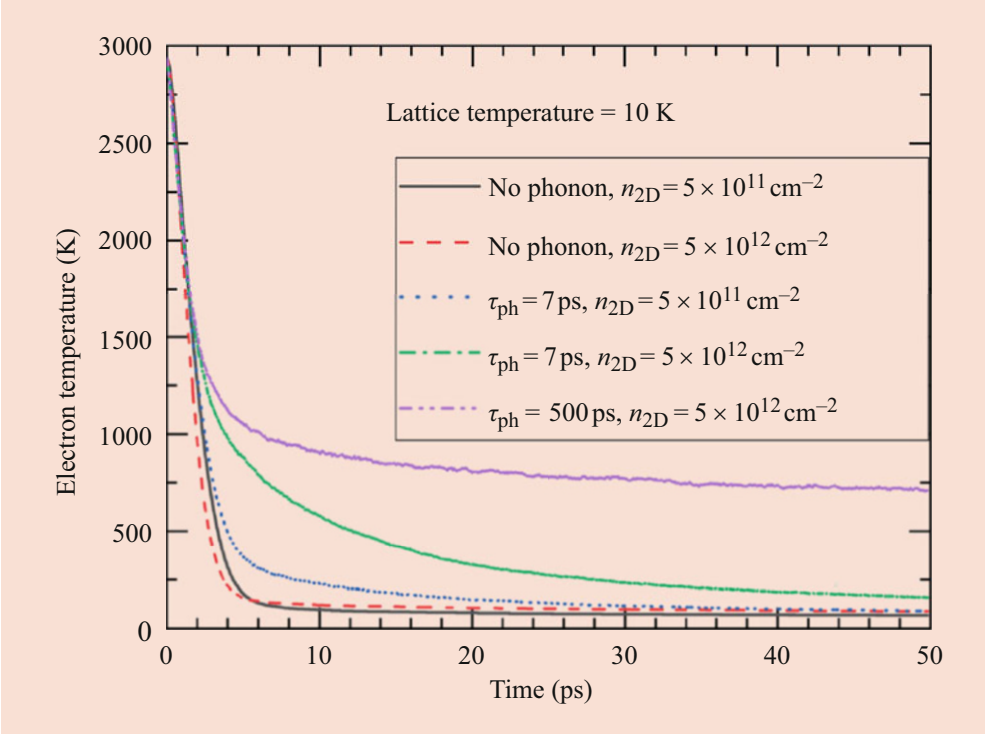

Fig. 19.40 EMC simulation of the electron temperature versus time in a 10 nm GaAs/AlAs QW for different phonon anharmonic decay times

materials with long phonon lifetimes is a possible approach to realizing hot carrier solar cell performance.

19.9 Summary

In this review chapter, we have discussed the state of the art with respect to photovoltaic device technology. We started with an overview of the fundamentals of solar cell device operation, and the nature of the solar energy spectrum and its absorption by the device. We then went into detail into the basics of solar cell operation, and what limits the main figures of merit, the open circuit voltage, short circuit current, and fill factor, where a particular emphasis was given on the role the minority carrier recombination plays. Methods of reducing such effects through passivation and carrier selective structures such as heterostructures were also introduced. We then provided an overview of the main technologies and their reported efficiencies starting with Si wafer-based technology and GaAs, then thin film technology, and organic solar cells, ending with recent developments of perovskite-based solar cells which are a hybrid of organic and inorganic cell architectures.

We then provided a synopsis of the limits of solar cell performance, and the use of detailed balance to derive the Shockley-Queisser limit for single junction cells. Methods of circumventing this single gap limit were discussed, which set the stage for discussing multijunction or tandem solar cells which currently hold the record for highest conversion efficiency in any solar technology, greater than 46%. We then discussed how nanotechnology may play a role in realizing other ways of circumventing the SQ limit in terms of advanced concept architectures. Nanotechnology is playing an increasing role in improving existing devices, as well as new device architectures seeking to improve efficiency while seeking lower cost. We discussed how, for example, nanostructures are playing an increasing role in improving light management in solar cells to improve light collection and allow thinner materials to be used reducing cost. Nanostructured materials play a central role in device architectures such as the dye-sensitized solar cell, which in turn became the basis for perovskite solar cells, which have rapidly overtaken thin film technology in terms of efficiency and approach that of crystalline Si solar cells. Nanowire solar cells have also shown tremendous improvement in recent years, with efficiencies over 15%. Research continues on realizing advanced concept solar cell structures such as multiexciton generation and hot carrier solar cells, and recent results show continued improvement in the design and architectures of such systems.

Abstract

The basic principle of operation of an x-ray detector is described through the Shockley-Ramo theorem, and the ionization energy, i.e., electron and hole pair creation energy, is introduced and used in formulating the responsivity of the detector. Typical detector materials and structures are also described. The spectroscopic detector operation is explained and its resolution is discussed. One of the most extensive modern applications of semiconductor detectors is in medical x-ray imaging. Flat panel x-ray imagers (FPXIs) are described in detail due to their extensive use in imaging. In direct conversion (DC) FPXIs, the absorbed x-ray photons are directly converted to charges in the pixel's photoconductor. The applied field then drifts them to the collecting electrodes of the pixel. These FPXIs use either a thin-film transistor (TFT) active matrix array (AMA) on a glass substrate, based on a-Si:H technology or, in a smaller area, CMOS (complementary metal oxide semiconductor), CCD (charge-coupled device), or ASIC (application-specific integrated circuit) silicon chips as the sensor to read the image. The image is a charge distribution on the pixels of the TFT-AMA/CMOS. The TFT-AMA and CMOS are currently the most popular with larger size detectors based on the TFT-AMA sensor. A semiconductor, such as a-Se, HgI_2, and CdZnTe, is used with these readout technologies as the photoconductive medium. The current competition between TFT-AMA and CMOS sensors discussed and the advantages and disadvantages of various semiconductors are highlighted. Present DC FPXI principles are reviewed, important physical phenomena are underlined, and the sensitivity, responsivity, linearity, signal-to-noise ratio, noise sources, and resolution, in terms of modulation transfer function, detective quantum efficiency, and lag and ghosting properties of FPXIs, are examined and explained with examples and extensive references where details can be found.

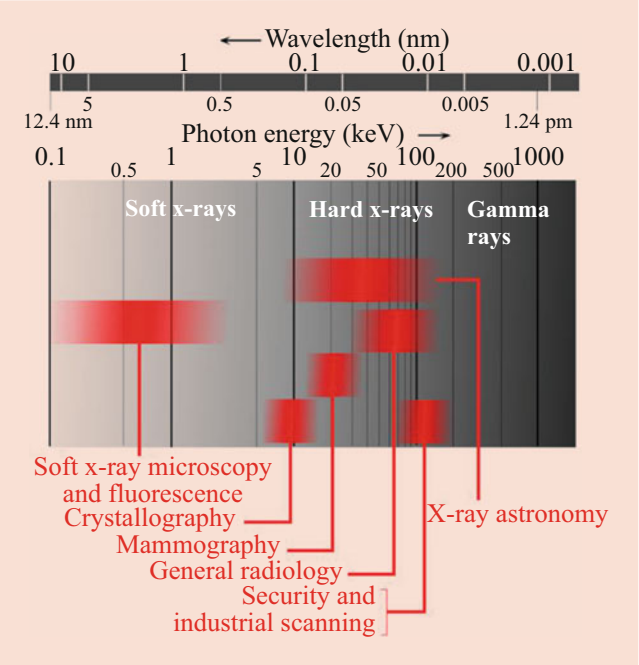

Fig. 20.1 The x-ray spectrum and applications over various spectral regions

hard x-rays, as shown in Fig. 20.1. Various modalities of medical x-ray imaging cover photon energies from roughly 10 keV up to 150 keV, whereas crystallography typically uses x-ray photons of energy roughly around 10 keV, and security scanning such as those at airports use hard x-rays, typically 80–160 keV. Soft x-ray microscopy and fluorescence spectroscopy cover approximately the range 0.1–3 keV and involve the imaging and compositional analysis of microstructures, including biological specimens. The whole x-ray range from 0.1 to 150 keV has a multitude of applications that require various specialized detectors.

Semiconductor x-ray detectors are among the most important class of detectors for detecting and measuring this type of radiation. These semiconductor detectors do more than just detecting and measuring radiation because, in the form of arrays, they can be used as imaging detectors and capture x-ray images, one of the most important applications of semiconductor detectors. Figure 20.2 shows a simplified functional classification of semiconductor x-ray detectors, which involves the measurement of dose, x-ray energy spectrum, and x-ray imaging in the form of arrays. The latter class of imaging detectors is probably the most important application that has experienced unmatched growth in the last two decades, which will be described in detail in Sect. 20.3 and thereafter.

The measurement of dose using a semiconductor detector is a well-established practice, and there are several semiconductor materials that are currently used for this purpose as summarized in Table 20.1. The measurement of the x-ray spectrum is more complicated because the detector must be able to measure the energy of the absorbed x-ray photon and needs to have external electronics to discriminate between different amounts of charge generated inside the semiconductor by different energy individual x-ray photons.

Consider a high resistivity semiconductor that is electroded and biased as shown in Fig. 20.3a. The electrodes do not inject carriers but allow excess carriers in the sample to leave and become collected by the battery so the dark current is negligible. The field F in the sample is uniform and $F = V/L$. This situation is almost identical to the intrinsic region of a reverse biased *pin* photodiode as depicted in Fig. 20.3b in which the p^+ and n^+ doped layers are very thin, the intrinsic (i-) layer is wide, and the detector is reverse biased. We are interested in the external current $i_{ph}(t)$ and the charge collected Q_c (the integration of $i_{ph}(t)$) when an x-ray photon is absorbed in the detector. When a single x-ray photon is absorbed at a position x from the left electrode as in Fig. 20.3a, it instantly creates N electron and hole pairs (EHPs) by the ionization of the medium. Consider initially only one pair of electron and hole. The electron and the hole drift in opposite directions with respective drift velocities $v_e = \mu_e F$ and $v_h = \mu_h F$, where μ_e and μ_h are the electron and hole drift mobilities, respectively. The transit time of a carrier is the time it takes for a carrier to drift from its generation point to the collecting electrode. The electron and hole transit times t_e and t_h, respectively, are marked on the t vs x diagram in Fig. 20.3c where

$$t_e = \frac{L - x}{v_e} \quad \text{and} \quad t_h = \frac{x}{v_h} \tag{20.1}$$

The external photocurrent $i_e(t)$ due to the drifting of the electron is given by the Shockley-Ramo theorem [1, 2], i.e.

$$i_e(t) = \frac{ev_e}{L}; \quad t < t_e \tag{20.2}$$

The simplest derivation of Eq. (20.2) for the present geometry involves equating the work done in moving the electron a distance dx ($= v_e\, dt$) in time dt to the energy delivered by the battery over the same time dt, which is $i_e\, V\, dt$ and taking the field $F = V/L$. Note, however, that strictly the field cannot be totally nonuniform because the injected charges modify the field at the electrodes. It is this change in the field, however small, at the electrode that actually draws carriers and results in an external current.

This current continues to flow while the electron is drifting, which is for a duration t_e, at the end of which the electron reaches the positive terminal of the battery. Thus, although the electron has been photogenerated almost instantaneously, the external photocurrent is *not* infinitesimally short and has a time spread of t_e as shown in Fig. 20.3d, i.e., it is a "pulse."

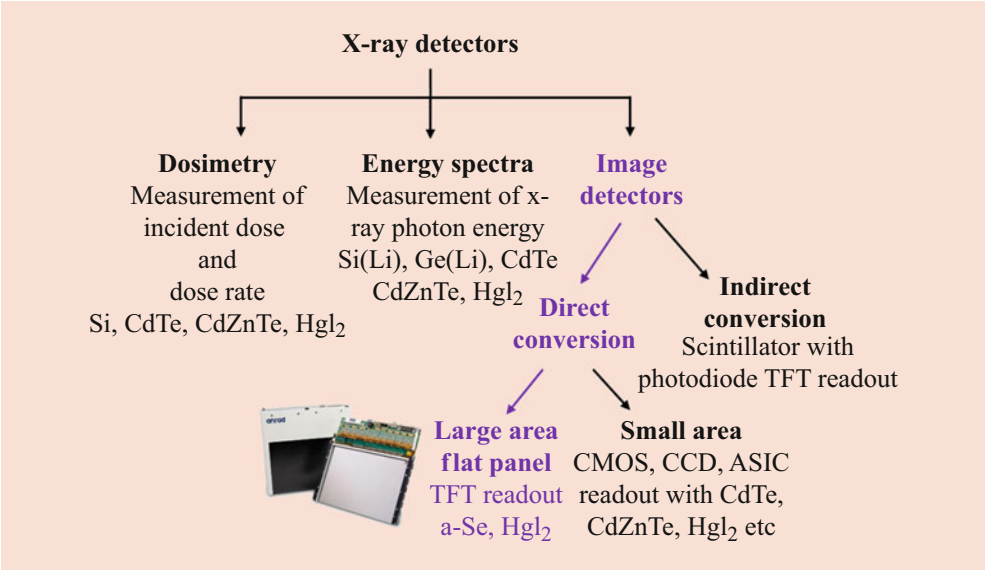

Fig. 20.2 A simplified classification of x-ray detectors. The highlighted branch is the emphasis in this chapter

Table 20.1 Selected examples of *single-crystal* semiconductors for use in x-ray detectors for the measurement of dose or energy spectra

Semiconductor (Z)	Detector type	Density (g cm^{-3})	E_g (eV)	W_i (eV)	F_N	Comments
Si (14)	*pn*, *pin*, or Schottky junction	2.33	1.12	3.62 (300 K) 3.77 (77 K)	0.08–0.13	Reverse biased to widen the depletion region. Can be used at room temperature. Used in various semiconductor detector probes in dosimetry
Si(Li) (14)	*pin*-like with an "intrinsic"-like region					Li doped Si *pn* junction behaves like *pin*. Operation needs cooling (e.g., liquid nitrogen) to prevent Li drift. Various commercial products
Ge Ge (Li) (32)	*pin*-like, metal/HPGe/metal	5.33	0.72	2.96	0.06–0.11	77 K values. Must be cooled. Can measure 0.3 keV to 3 MeV. Commercial spectroscopic detectors with high resolution
CdTe (48/52)	Schottky, *pin*, and photoconductive	5.85	1.44	4.43	0.06–0.09	Commercial room temperature spectroscopic detectors. $\mu_e\tau_e \approx 10^{-3}$ cm^2/V, $\mu_h\tau_h \approx 10^{-4}$ cm^2/V
CdZnTe (48/30/52)	Schottky and Photonductive	5.8	1.57	4.64	0.10	Commercial room temperature spectroscopic detectors. $\mu_e\tau_e \approx 3 \times 10^{-2}$ cm^2/V, $\mu_h\tau_h \approx 10^{-5}$ cm^2/V
HgI_2 (80/53)	Metal/HgI_2/metal	6.4	2.15	4.2	0.12	Small size detector. Room temperature spectroscopy. $\mu_e\tau_e \approx 3 \times 10^{-4}$ cm^2/V, $\mu_h\tau_h \approx 10^{-5}$ cm^2/V

E_g is the bandgap and W_i is the ionization energy. If the detector type is not fully known, metal/semiconductor/metal is shown. HPGe is high purity Ge. Data are typical values quoted in the literature as in [9, 25]. (F_N is difficult to measure and also has an energy and temperature dependence so the values are only estimates)

Similar arguments can also be applied to the drifting hole, shown in Fig. 20.3a–d, which generates a hole photocurrent $i_h(t)$ in the external circuit given by

$$i_h(t) = \frac{ev_h}{L}; \quad t < t_h \tag{20.3}$$

The total current in the external circuit is the instantaneous photocurrent, $i_{ph}(t)$, and is the sum of $i_e(t)$ and $i_h(t)$ as shown in Fig. 20.3e. If we integrate the external photocurrent $i_{ph}(t)$, as in Fig. 20.3f, to evaluate the collected charge $Q_c(1)$, due to the generation of one EHP at x, this would be

$$Q_c(1) = \int_0^{t_e} i_e(t)\,dt + \int_0^{t_h} i_h(t)\,dt = e \tag{20.4}$$

Thus, one e of charge is collected in the external circuit per EHP generated in the semiconductor, even though both the electron and hole drift inside the medium. Notice that

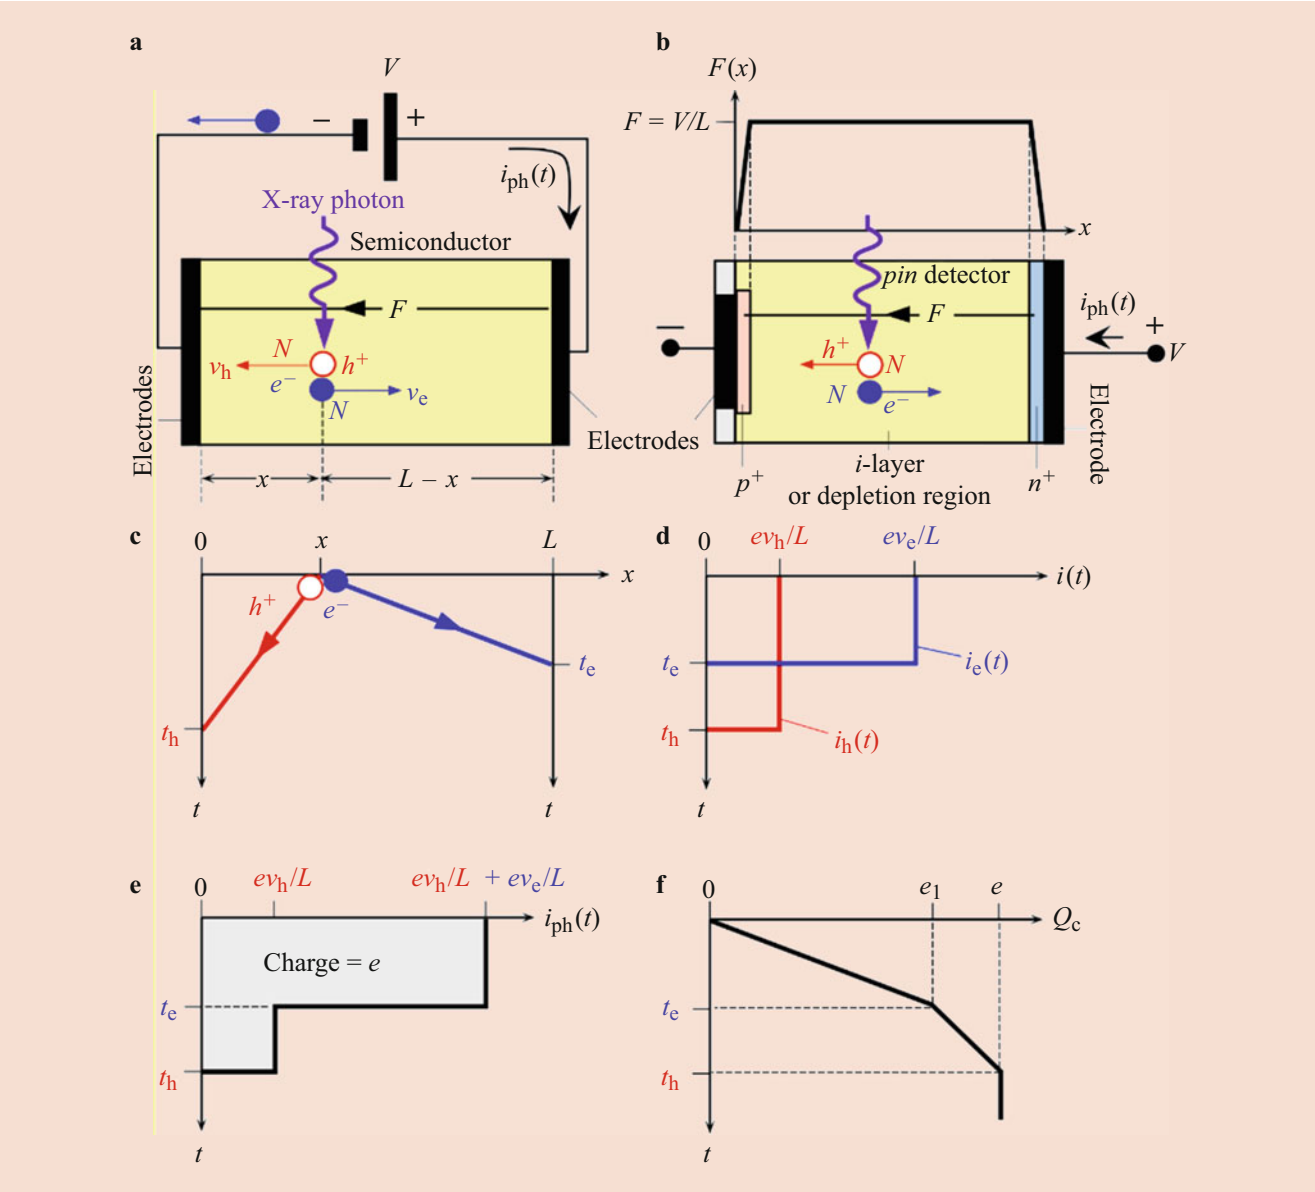

Fig. 20.3 (**a**) An electron and hole pair (EHP) is generated at position x. (**b**) The same photogeneration in an ideal reverse biased *pin* detector in which the n^+ and p^+ sides do not inject carriers; they effectively serve as noninjecting contacts. (**c**) The electron and the hole drift in opposite directions with drift velocities v_e and v_h, respectively. The electron arrives at time $t_e = (L–x)/v_e$ and the hole arrives at time $t_h = x/v_h$. (**d**) As the electron and hole drift, each generates an external photocurrent shown as $i_e(t)$ and $i_h(t)$. (**e**) The total photocurrent is the sum of the hole and electron photocurrents. (**f**) The instantaneous collected charge as a function of time. Eventually at time $t = t_h$, $Q_c = e$

when the electron reaches the positive electrode, the collected charge is $e_1 < e$ because we still have the drifting hole left, which must reach the negative electrode to yield a total collected charge of e. With N EHPs generated at x, the collected charge Q_c is then simply eN. In the presence of trapping, not all the x-ray ionized charge $Q_i = eN$ is collected and $Q_c < Q_i$. This is accounted by introducing a charge collection efficiency as described in Sect. 20.4.1.

Since N EHPs per absorbed x-ray photon result in a collected charge of $Q_c = Q_i = eN$, the only issue becomes relating Q_i (or N) to the energy of the absorbed x-ray photon and hence to the absorbed dose, which can be related to the incident dose. Suppose that an amount of energy $E_{absorbed}$ is absorbed from an incident monochromatic x-ray radiation. This may correspond to one x-ray photon or many. The conversion of this absorbed energy to electrical charges is gauged by a quantity known as the ionization energy W_i or the electron and hole pair (EHP) creation energy. (Also written as $W_\pm$ and W_{EHP}.) The absorbed x-ray photon first knocks out a projectile primary electron from an inner K or L shell. The latter primary electron interacts with the medium along its track and ionizes the medium to generate EHPs. Suppose that

N of these EHPs can escape from the track and then drift to the collection electrodes without experiencing any trapping or recombination, that is, there is no loss of carriers during bulk transport. These N electrons and N holes correspond to a charge of Q_i in the external circuit. The definition of W_i is the average energy absorbed from the radiation in creating one EHP

$$W_i = \frac{E_{absorbed}}{N} = \frac{E_{absorbed}}{Q_i/e} \tag{20.5}$$

The reciprocal of W_i is a measure of the x-ray photogeneration efficiency. The usefulness of W_i lies in the fact that this quantity for most semiconductors is a material constant that is related to the bandgap (E_g) and practically independent of the photon energy (over typical x-ray energies). Thus, once it is measured and known, the conversion efficiency from x-rays to charges is then a known quantity, and therefore the dose measurement becomes straightforward. The energy of the photon can also be inferred from Q_i, but one has to avoid photon pileup to ensure the measured Q_i corresponds to a single absorbed photon, in which case Q_i represents the energy of the x-ray photon as explained in Sect. 20.2.

The ionization energy W_i of various semiconductors has been studied as a function of photon energy and the applied field, and in nearly all crystalline semiconductors, W_i depends on the bandgap E_g through a relationship of the form

$$W_i = cE_g + W_{phonon} \tag{20.6}$$

where c and W_{phonon} are constants, as reviewed in [3]. Shockley's early semiquantitative arguments made $c = 2.2$ and W_{phonon} equal to the product of the average number of optical phonons and the average optical phonon energy involved in the ionization process per EHP [4]. The Klein relationship [5] makes $c = 2.8$ and casts Eq. (20.6) into $W_i = 2.8E_g + W_{phonon}$ where W_{phonon} is on the order of 0.1–0.5 eV, which supports the empirical rule that $W_i \approx 3E_g$ [6]. Table 20.1 also lists W_i values for a number of crystalline semiconductors where it can be seen that the Klein rule holds well for Si, only approximately for Ge, CdTe, and CZT, but not for HgI_2 (see [3]).

It should be apparent from the discussion above that the EHP creation in Fig. 20.3a, b should occur in the region of the semiconductor where there is a strong field to separate and drift the carriers to the collection electrodes and the sample geometry must allow the absorption of the incident radiation. Detectors based on the *pn* junction or a Schottky junction are reverse biased to ensure the depletion layer width should be as wide as possible because the electric field is actually within the depletion region. The reverse bias is normally such that it almost depletes the whole semiconductor by widening the depletion region. Recall that the depletion region is in the semiconductor side for a Schottky junction and on the n-side in a p^+ n junction. The field in the depletion region is not constant, and hence *pin* devices are preferred not only because of their wider i-layer, or depletion layer width, but due to a relatively uniform and large field one can achieve in this layer. The i-region of a perfect ideal *pin* detector would be intrinsic, but generally there is always some doping in this region so it is a depletion region rather than a true i-region, and with reverse bias, the depletion region stretches fully between the p^+ and n^+ thin layers. The result is that the electric field is not exactly constant but has a gradient that represents the ionized dopants in the region, that is, if ρ_I is the net space charge density due to ionized dopants, $dF/dx = \rho_I/\varepsilon_o\varepsilon_r$.

Lithium doped Si detectors, Si(Li) (pronounced "silly"), are among various commercial detectors used in x-ray detection and spectrometers. Li is an interstitial donor in Si so a *pn* junction made by doping a p-Si crystal with Li would result in a *pn* junction. The Li atoms become Li^+ and can be drifted by an applied field deep into the p-side. The p-side has ionized acceptors (e.g., B^-), but in the region of acceptors and Li^+ ions, there is no net space charge, and the device resembles a *pin* detector. Once formed by drifting the Li^+ ions, the Si(Li) detector has to be operated at low temperatures. A Si detector without Li doping can be operated at room temperature.

A few selected compound semiconductors such as CdTe, CdZnTe ($Cd_{0.92}Zn_{0.08}Te$ – $Cd_{0.9}Zn_{0.1}Te$), and HgI_2 are already used as x-ray and γ-ray spectroscopic detectors. They do not need cooling and can be used at room temperature, which is a distinct advantage. Their properties have been extensively reviewed in literatures [7–15] and in recent books [16, 17] and chapter [18]. Smaller bandgap semiconductors such as Ge have a higher intrinsic concentration and thus a higher dark current, which adds noise to the signal. Both Ge and Ge(Li) are operated at low temperatures, e.g., 77 K, to keep the dark current small and avoid Li drift instability in Ge(Li) detectors. Table 20.1 summarizes the properties, including W_i, of a few selected single-crystal semiconductors for use in x-ray radiation detection and/or spectroscopy. It can be seen that the compound semiconductors CdTe and CdZnTe and HgI_2 can be operated at room temperature. Operation at lower temperatures improves the performance. There are many experimental semiconductors that are not listed, which have good commercial potential. For example, GaAs *pin* x-ray detectors for spectroscopy have been demonstrated [19]. GaAs arrays have been also demonstrated for x-ray spectroscopy with high resolution [20]. SiC is another possible x-ray detector material that has favorable properties for x-ray spectrum measurements and can be used in harsh environments [21, 22]. Owens and Peacock provide a comprehensive review and several tables of properties for a large number of potential x-ray detector materials, though their emphasis is on spectroscopic detector application [7]. A recent extensive review of semiconductors for x-ray detec-

tor applications, including tables of properties, growth and characterization, and detector principles, can be found in Owens' recent books [16, 17] and chapter in [18].

The advantage of using a reverse biased *pin* detectors is that under reverse bias, the p^+-layer and n^+-layer do not inject carriers into the *i*-layer and the only current in the dark is due to thermally generated EHPs in the *i*-layer. Any carrier injection from the p^+-layer and n^+-layer into the *i*-layer is due to diffusion of minority carriers (e.g., minority carrier electrons in the p^+-layer diffusing into the *i*-layer) which is small as the gradient is very small [23]. The contact behavior of the electrodes to the n^+-layer and p^+-layer is assumed to be ohmic so they do not limit the current flow in either direction. Reverse biased *pn* junction behaves similarly in that there is no carrier injection in the dark into the depletion region and again the dark current is due to the thermal generation of EHPs in the depletion region. The reverse current in the Schottky junction is the emission of carriers from the metal over the Schottky barrier height (Φ_B) into the semiconductor, e.g., electrons from the metal into the conduction band for a metal/*n*-type Schottky junction. The reverse biased Schottky, *pn*, or *pin* junctions enable noninjecting contacts to be made to a semiconductor and thereby reduce the dark current. It is also possible to employ back-to-back Schottky junctions so that under bias one junction is always reverse biased to limit the current. These metal-semiconductor-metal Schottky junction detectors operate as photoconductive detectors. If a semiconductor has a sufficiently high resistivity, the detector resistance may be sufficiently high for it to be usable as an x-ray detector, i.e., the dark current may be sufficiently small. In such cases, the semiconductor need not have noninjecting contacts. The importance of contacts to semiconductors has been well-recognized in photodetector work and discussed in the literature, e.g., [16, 17, 24].

The discussion above has ignored two important factors that are needed to relate the actual collected charge Q_c to the incident radiation dose (not absorbed dose) or incident exposure. First is that not all incident x-ray photons will be absorbed, only a fraction determined by the quantum efficiency of the detector as described in Sect. 20.4.1. Second, not all carriers can drift and reach the collection electrode. Some carriers become trapped or recombined. The collected charge is then less than Q_i, i.e., $Q_c < Q_i$. This is represented by a factor called the charge collection efficiency and is also described in Sect. 20.4.1 The responsivity, i.e., the sensitivity, and the signal-to-noise performance of an x-ray detector are covered in Sect. 20.4.2 inasmuch as the concepts applied to the pixel of an imaging detector also apply to discrete x-ray detector devices, if one excludes the readout related pixel and peripheral electronics. Pixelated detectors such as detector arrays are discussed in Sects. 20.3 and 20.7. The response of a pixelated detector, the so-called small pixel effect, is described in Sect. 20.7 where the differences between the effects of carriers moving toward and away from the pixels are highlighted. Pixelated detectors provide unique advantages by favoring one type of carrier (that moving toward the pixels) over the other, which is also covered in Sect. 20.7. Section 20.2 describes the use of crystalline semiconductors in spectroscopic detectors where the detection system can measure the energy of the absorbed photon.

20.2 X-Ray Spectroscopic Detectors

Photon energy spectroscopy is probably the most important application of crystalline semiconductor detectors mentioned above, especially for x-rays and γ-rays. The basic principle of photon energy spectrum measurements using a semiconductor detector is illustrated in Fig. 20.4. The technique is called pulse height spectroscopy. The basic principles of x-ray spectrum measurements with semiconductor detectors are widely described in radiation detection textbooks such as in references [25–28].

Consider a stream of monoenergetic photons from a radioactive source in which the photon energy is E_{ph}. Photons are sufficiently separated so that one photon at a time is absorbed as in Fig. 20.4. When one of these photons is absorbed, an amount of charge Q_i is generated through the conversion in Eq. (20.5). In the absence of trapping, the external preamplifier in Fig. 20.4 will register a collected charge $Q_c = Q_i$. If the conversion process were identical for each absorbed photon, then there would be no fluctuations in Q_c, and we can infer the exact E_{ph} from Q_c, but the conversion process has its statistics. Put differently, W_i is an average quantity in Eq. (20.5) and has a probability distribution. We can use a pulse shaper after the preamplifier in Fig. 20.4 so that a pulse is generated and the height of the pulse represents Q_c. We can then connect a multichannel analyzer to the pulse shaper output to bin different amounts of charge collected into channels and hence draw a histogram in which the number of occurrences (counts) is plotted against Q_c (the channel number). We can suitably calibrate the measurement system for a known photon energy so that we can convert the Q_c to photon energy E and plot the number of occurrences (counts) against the photon energy E as in Fig. 20.4, which is called a pulse height spectrum. In the ideal case, we would find a Gaussian distribution which has a mean that corresponds to E_{ph}, but the distribution has a finite width ΔE, which is measured as full width between half maximum (FWHM). There are two fundamental reasons for the observed ΔE that are directly related to the semiconductor material.

The conversion process of an absorbed photon to Q_i/e number of carriers has fluctuations; it is also known as x-ray photogeneration variance. It is not simply E_{ph}/W_i but fluctuates about this mean value. If the conversion (the ionization of the medium by the primary electron) was a string

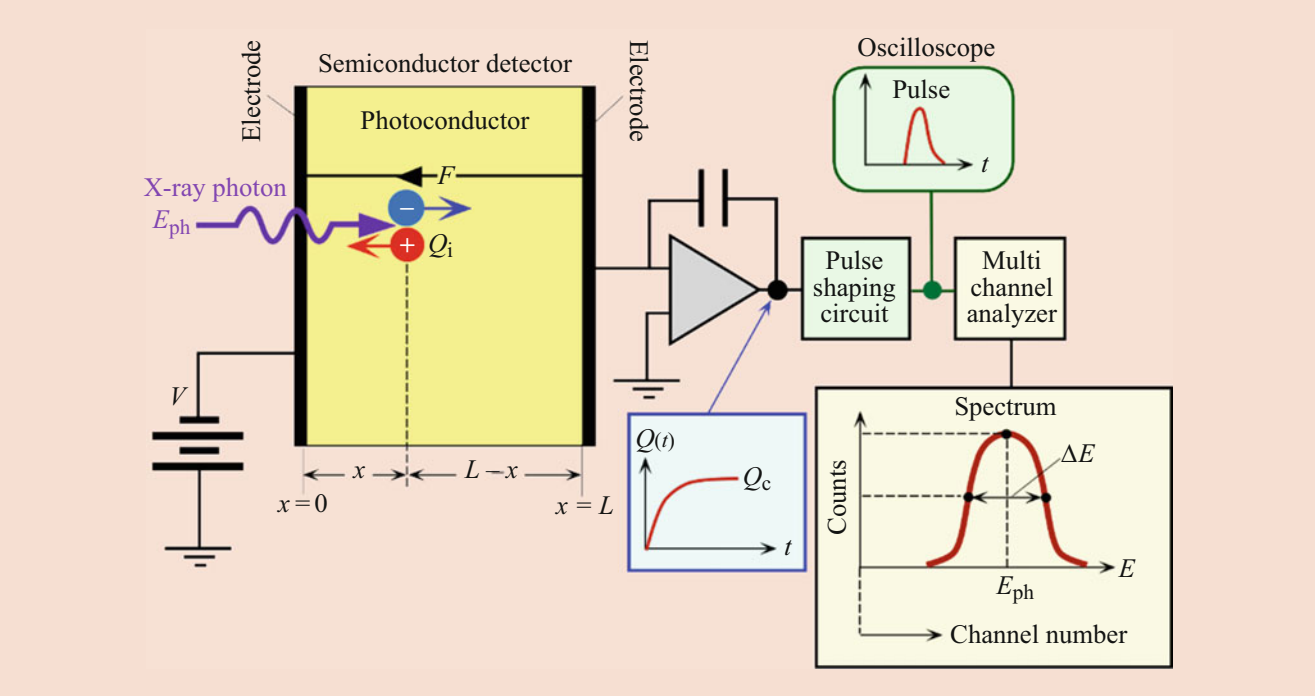

Fig. 20.4 The basic principle of photon energy spectrum measurements using a semiconductor detector. The technique is called "pulse height spectroscopy"

of independent events, the conversion statistics would be a Poisson distribution so that the variance of the conversion process would be Q_i/e and the root-mean-square variation would be $\sqrt{Q_i/e}$. However, in semiconductors, the statistics is modified by a Fano factor F_N [29], discussed in [30], so the variance of conversion is not Q_i/e but $F_N Q_i/e$. If $\Delta E_{conversion}$ is the FWHM in the pulse height spectrum in Fig. 20.4 from the statistics of the conversion process alone, then this would be

$$\Delta E_{conversion} = 2.355\sqrt{F_N E_{ph} W_i} \tag{20.7}$$

The Fano factors for many semiconductors are typically less than 1 and are listed in Table 20.1. $F_N < 1$ is accounted by the fact that EHP creation events in the primary track cannot be totally independent and must be correlated through energy conservation so that the spread in the collected number of carriers is less than that expected from Poisson statistics. A reliable experimental measurement of F_N requires that the photogenerated carriers suffer no trapping (all are collected) and the electronic noise in the measurement circuit is suppressed. F_N is usually inferred from an energy spectrum peak, i.e., ΔE in Fig. 20.4. F_N has been also reported to have an energy and temperature dependence [17].

The second important broadening mechanism is the effect of charge trapping during the drift of the carriers toward their collection electrodes. Those trapped changes are not fully collected as explained in Sect. 20.1 so the measured charge is less than Q_i. The collection efficiency η_{CC} due to charge generation as a point x in the sample is given by the Hecht collection efficiency [31] as

$$\eta_{CC} = \frac{Q_c}{Q_i} = \frac{\mu_e \tau_e F}{L}\left[1 - \exp\left(-\frac{L-x}{\mu_e \tau_e F}\right)\right] + \frac{\mu_h \tau_h F}{L}\left[1 - \exp\left(-\frac{x}{\mu_h \tau_h F}\right)\right] \tag{20.8}$$

where x is the point of generation of charge Q_i (from conversion) (Fig. 20.4); τ_e and τ_h are electron and hole lifetimes, respectively; μ_e and μ_h are electron and hole drift mobilities, respectively; and $\mu_e \tau_e F$ and $\mu_h \tau_h F$ are electron and hole schubwegs, respectively. The carrier schubweg represents the mean distance a carrier drifts before it is trapped or disappears by recombination. There are two intermingled fluctuations in Eq. (20.8): First is that not every photon is absorbed at x so there will be fluctuations in x and hence in Q_c. The absorption probability of a photon along the sample follows an exponential distribution exp $(-\alpha x)$ where α is the linear attenuation coefficient of the medium. Second, charge trapping during drift is a stochastic process, and there will be fluctuations in η_{CC} even if each photon was absorbed exactly at x. The analytical treatment for relating the fluctuations in η_{CC} to a corresponding spectral broadening, i.e., ΔE_{CC}, is not straightforward and may be found in references [32–34]. Semiempirical expressions have

also been suggested that relate ΔE_{CC} to the mean photon energy E_{ph} through a power law dependence [11].

The third contribution arises from the noise associated with the leakage current of the detector and the noise due to the electronic chain, starting with the preamplifier, to the final output. All these noise sources are lumped into a single quantity called the electronic noise and result in a FWHM broadening of $\Delta E_{electronic}$.

The overall width ΔE that is observed is then due to these three processes and can be written as

$$\Delta E^2 = \Delta E^2_{conversion} + \Delta E^2_{CC} + \Delta E^2_{electronic} \tag{20.9}$$

The semiconductor material of choice determines the first two and the electronics the last factor. Owens has reviewed the present semiconductors for radiation detection and spectroscopy and has provided a useful empirical relationship for calculating ΔE [9, 11, 17]; Equation (78) in Chap. 8 in [17] is an empirical relationship for ΔE that used three fit parameters (including the Fano factor) and has the electronic noise $\Delta E_{electronic}$ as input.

The resolution of a spectrometric detector is nominally quoted in terms of the FWHM width ΔE at the photon energy E_{ph}, as shown in Fig. 20.4. Obviously, the smaller is ΔE, the better is the resolution of the detector in discriminating different energy photons. High purity Ge detectors operated at low temperatures have especially high spectral resolution. For example, if the electronic noise can be reduced by special techniques, then a resolution of 345 eV at 59.5 keV or 0.57% is achievable at 100 K [35], though typical quoted values in various tables have been 670 eV at 77 K [17]. Typically, the energy resolution with compound semiconductor detectors at room temperature is approximately 2% or more, but less at low temperatures as discussed in reference [11]. Tables 4, 3, and 9.5 in references [9, 11, 17], respectively, provide the best values that are observed for a range of semiconductors at energies 5.9 keV and 59.5 keV.

20.3 Flat Panel X-Ray Image Detectors

This section and the remainder of the chapter describe the properties and the performance of direct conversion x-ray image detectors utilizing the x-ray photoconductivity of semiconductors. The emphasis is on large area x-ray image detectors that can be used in various x-ray imaging modalities. The last few decades have seen a nearly full transformation of x-ray imaging to modern digital imaging. The hardware for digital x-ray imaging needs a suitable x-ray detector that is capable of capturing and providing the image as an electrical signal [36–38]. The requirements on the detector technology have become more and more demanding as medical x-ray imaging today is not only about projection imaging but involves real-time imaging (fluoroscopy) and tomosynthesis, among other imaging enhancements such as dual energy imaging, photon counting, etc., each of which has its own demands on the detector technology [39–46]. The focus of this chapter is on semiconductor-based direct conversion flat panel x-ray imagers (FPXI), in which a semiconductor acts as a photoconductor and converts the absorbed x-ray photons to collectable charges [47]. A comprehensive and detailed review of flat panel image detectors, both direct and indirect, has been given by Rowlands and Yorkston [48]. Outside medical imaging, direct conversion imagers have shown potential for a number of applications from materials science (crystallography) to nondestructive testing and inspection [49–51].

In one of the most common types of FPXI, the basic readout of the signal is based on an active matrix array (AMA). AMA is a two-dimensional large array of pixels as shown in Fig. 20.5. An AMA is essentially a two-dimensional array of pixels in which each pixel has a thin-film transistor (TFT) that can be externally addressed. Each pixel is configured identically with the TFT gate G_i connected to a particular address line i and the source S_j to a particular data line j. The AMA has $M \times N$ number of gate and data lines, where M and N can be several thousand. The product $M \times N$ determines how many pixels will constitute the image. The intrinsic readout resolution of the detector is determined by the pixel pitch, which is typically 50–100 μm. The TFT array is laid out on a suitable flat rectangular glass substrate and is purchased by the detector manufacturing company as a component onto which the semiconducting photoconductor is coated. The TFT-AMA substrate makes use of the well-established hydrogenated amorphous silicon (a-Si:H) technology for displays.

The AMA substrate is vacuum coated with a photoconductive layer, such as stabilized amorphous selenium (a-Se), as shown in Fig. 20.6. The top surface is then contacted with a suitable electrode to apply a bias voltage, which establishes a field in the photoconductor. Upon the absorption of x-ray photons in the pixel, electrons and holes are generated, and these carriers drift and give rise to an x-ray photocurrent. Each pixel also has a charge storage capacitor C_{ij} as shown in Figs. 20.5 and 20.6. The x-ray photocurrent in the pixel photoconductor accumulates charges on this storage capacitor, and the total charge accumulated Q_{ij} is the signal on the pixel (i,j). Thus, C_{ij} integrates the x-ray photocurrent in the pixel. Although Figs. 20.5 and 20.6 specifically show a-Se, other semiconductors have also been tried. For example, HgI_2 has been coated by screen printing on a TFT AMA to fabricate a FPXI with good performance [53].

The a-Si:H TFT switch shown in Figs. 20.5 and 20.6, when switched on, allows the charge Q_{ij} on C_{ij} to be read out into the external circuit, which has a charge amplifier to amplify the signal toward digitization. Once the gate G_i of

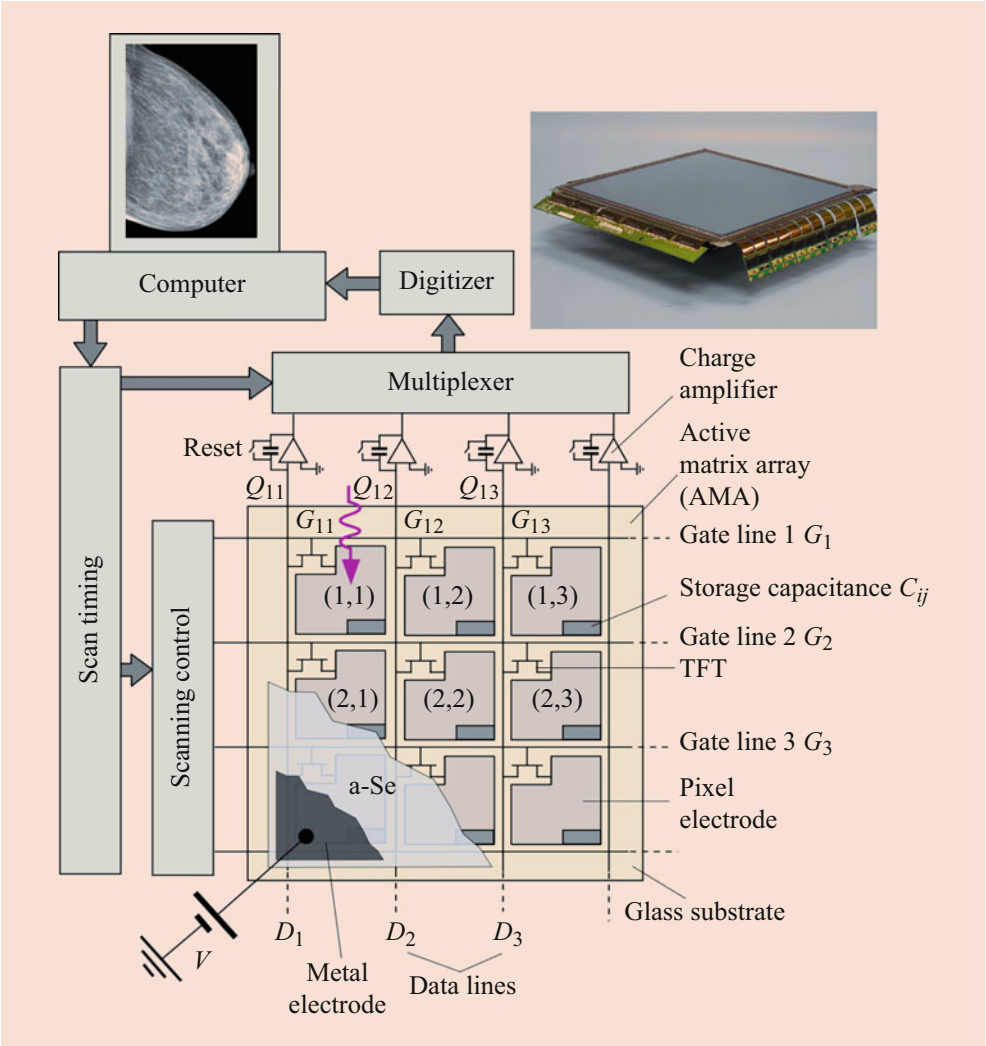

Fig. 20.5 The structure of a typical direct conversion active matrix array-based flat panel x-ray imagers. (Adapted from Kasap et al. [52])

the TFT_{ij} is activated, the TFT_{ij} switches on, and the collected charge on C_{ij} is readout as GQ_{ij} where G is the amplifier gain. The amount of charge Q_{ij} that is generated depends on the incident radiation X_{ij} on that particular pixel (i,j) because the electron and hole pairs generated in the photoconductor is proportional to the total absorbed radiation energy. Clearly, we can represent the x-ray image in terms of the charges Q_{ij} residing on the pixel storage capacitors of the FPXI. Historically, the first demonstrations of a-Se-based FPXIs were reported by Rowlands and coworkers [54–59] and by Lee, Cheung, and Jeromin [60–62] in the mid-1990s. Since those first demonstrations, much research has been done in characterizing and understanding the performance and imaging properties of these a-Se-based FPXIs, for example, as reported in references [63–65]. In hindsight, it should have been obvious that once the TFT-AMA technology was developed for the flat panel display industry, the development of FPXIs would ensue [66].

In the case of small area detectors shown in Fig. 20.2, the basic readout technology is CMOS, CCD, or, alternatively, a particular ASIC (application-specific integrated circuit) pixelated readout chip, with CMOS normally having a larger area among these. Other readout technologies have been also used. In direct conversion, usually an x-ray photoconductor such as CdZnTe crystals are indium bump-bonded (equivalent to "cold welding") to electrodes on a CMOS so that the x-ray generated charges can be fed into the CMOS (see for example [67, 68]). CdZnTe crystals have also been bonded to ASIC readout chips and CCDs again using indium bumps to produce high-resolution detectors for slot scanning x-ray imaging [69, 70]. Direct coating of the CMOS with a photoconductor has also been tried, for example, a-Se directly evaporated onto a defined area of the CMOS [71]. The CMOS chips are then tiled to assemble a full-size mammographic x-ray imager. In recent years, advances have been made in increasing the effective imaging area of

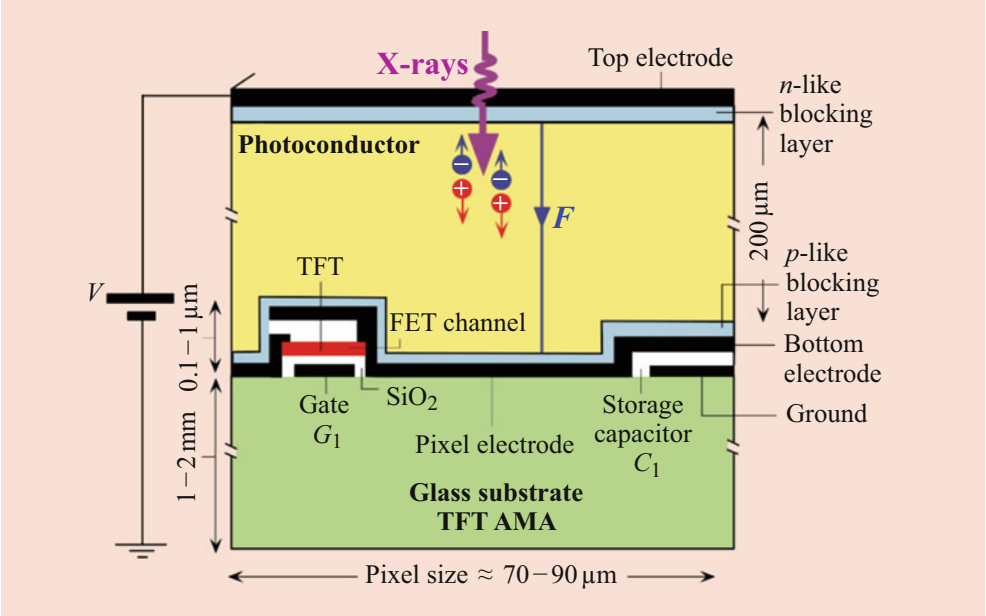

Fig. 20.6 A typical pixel structure of an a-Se direct conversion FPXI

wafer-size CMOS chips through stitching and tiling [72]. In another application, polycrystalline layer of HgI_2 was grown directly on a CMOS chip (10 cm × 10 cm) to construct an x-ray imager [73]. There are several distinct advantages to using crystalline photoconductors on CMOS readout chips. First is that the pixel size can be made very small and the whole operation can be very fast compared to TFTs arrays. The second is that most CMOS imaging chips have on-pixel MOS transistors and achieve on-pixel amplification to improve the DQE. Presently, the largest area commercial CMOS single sensors are about 11 cm × 14 cm and use indirect conversion as described in [74]. Manufacturers such as Dexela and Teledyne DALSA also offer CMOS tiled detectors for specific x-ray imaging applications that include not only medical imaging but also industrial imaging (e.g., nondestructive testing).

As can be seen from Fig. 20.5, the electrode in the pixel does not cover the whole pixel area. It gives the impression that not all the incident x-rays are utilized, that is, the regions outside the collection electrode form "dead zones" that are not involved in the conversion of the absorbed x-rays to the pixel signal charge. The fill factor (FF) of a FPXI quantifies what percentage area of the pixel is actually utilized in capturing the incident radiation and converting it to a signal. FF is the fraction of a pixel that is sensitive to the incident radiation. The apparent geometric FF for the TFT-AMAs used in direct conversion FPXIs depends on the AMA design and the application. Typically FF values are in the range 75–85%. The effective FF, what one observes in imaging characteristics, however, is higher, nearly 100% inasmuch as the field in the dead zone bends toward the pixel electrode and enables x-ray generated charges above the dead zone to be collected [63].

Figure 20.6 shows a schematic cross section of a single pixel with its TFT, storage capacitor, and photoconductive layer. Figure 20.7, on the other hand, shows a simplified equivalent circuit of a pixel. In current commercial FPXIs, the semiconductor of choice for the photoconductive layer is stabilized a-Se. Stabilized means that a-Se has been alloyed with 0.2–0.5% As so as to prevent the crystallization of pure a-Se and then doped with Cl in the ppm amounts to control the charge transport (see [75] and recent review in [76]). The actual photoconductive layer is not a simple single layer but rather a multilayer structure. The pixel detector structure in Fig. 20.6 has thin blocking layers between the photoconductor and the electrodes to prevent charge injection from the contacts to reduce the dark current. The x-ray absorption, the charge generation, and the drift of electrons and holes occur in the thick so-called *i*-like layer in which both electrons and holes are mobile with long carrier ranges. The *i*-layer has electron and hole schubwegs $\mu\tau F > L$, the thickness of the photoconductor, so that hardly any charges are lost. This a-Se *i*-layer in mammographic detectors is about 200 μm thick and absorbs nearly all the incident radiation. There is a thin *n*-like layer between the positive electrode and the *i*-layer. This layer traps holes but allows electrons to drift, i.e., $\mu_e\tau_e F > L > \mu_h\tau_h F$. The *n*-layer has a high percentage of As for stabilization and has been doped with an alkaline dopant. Trapped holes in the *n*-layer modify the electric field profile and reduce the field right at the electrode, which reduces the rate of hole injection and hence the dark current [77]. The thin *p*-layer between the *i*-layer and the negative electrode is

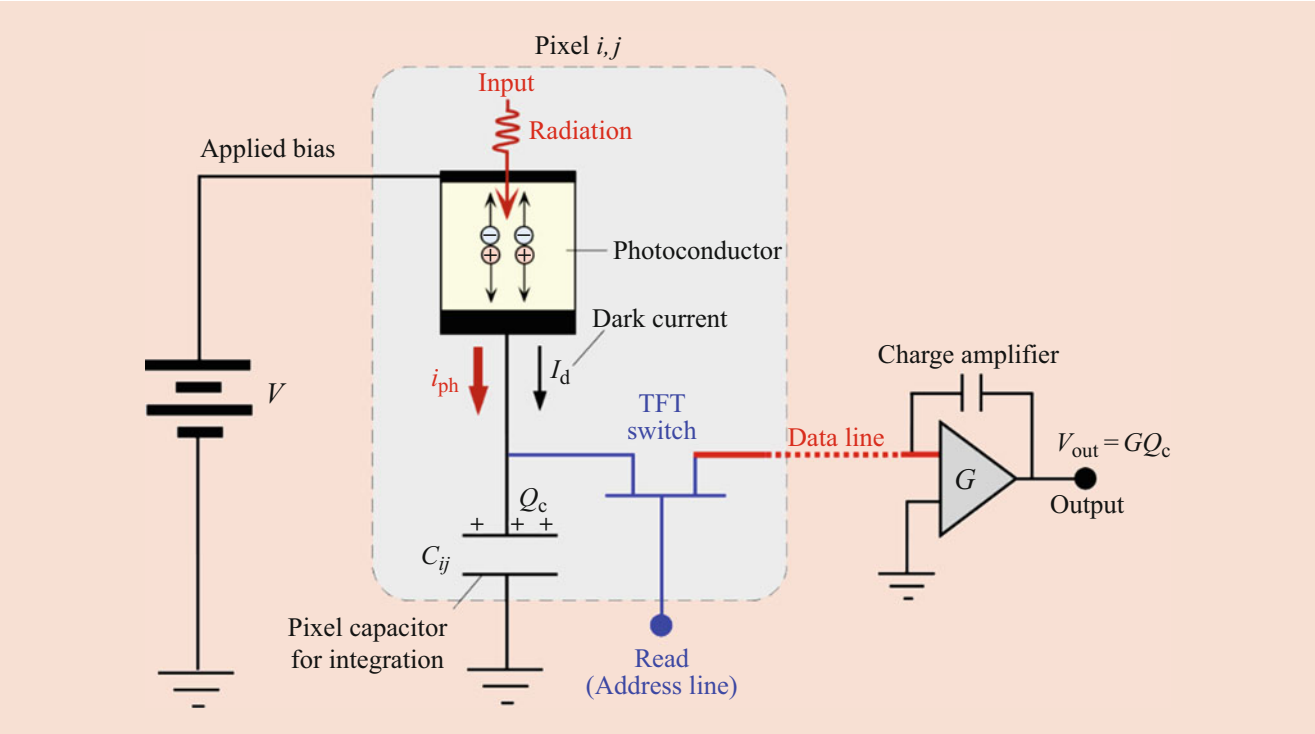

Fig. 20.7 A simplified equivalent circuit of a pixel

an amorphous As_2Se_3 film, which allows hole transport but traps electrons. Trapped electrons in the *p*-layer reduce the field at the negative electrode and hence the rate of injection of electrons from the contact. The *p-i-n* structure was the key to the success of the a-Se-based FPXI because it allowed the dark current to be extinguished to an innocuous level [78–80]. It is important to emphasize that the terminology of *n*-, *i*-, and *p*-layers does not follow the conventional definitions in crystalline semiconductor theory based on electron and hole concentrations or the position of the Fermi level. The terminology in the amorphous semiconductor field is based on the relative magnitudes of the electron and hole ranges, i.e., the $\mu\tau$ values: $\mu_e\tau_e \gg \mu_h\tau_h$ for *n*-type, $\mu_h\tau_h > \mu_e\tau_e$ for *p*-type, and $\mu_e\tau_e \approx \mu_h\tau_h$ for *i*-type.

The imaging properties of a-Se-based FPXIs for various medical imaging modalities have been well-examined and analyzed (see for example [65, 81–89]). There have been a number of other photoconductors, such as polycrystalline layers of TlBr [90, 91], PbI_2 [92–95], HgI_2 [53, 96–108], CdTe [109], CdZnTe [110, 111], PbO [112–116], and various perovskite methylammonium lead halides (MA Pb-halides) [117–121] that have been investigated to replace a-Se. Some of these, in particular HgI_2 and some of the MA Pb-halide perovskites [122, 123], have shown much potential for use in commercial FPXI applications. HgI_2 can be prepared by evaporation or by screen printing, both of which are suitable for large area detector applications. MA Pb-halide perovskites, in polycrystalline form, can be easily and cheaply prepared in large areas from solution (in contrast to vacuum deposition) and have already shown very good performance in photovoltaics and photodetector applications [124]. Their use in x-ray detector applications seems a natural research and development path for this class of materials that can easily absorb x-rays. The basic underlying problem with most of these semiconductors is that either they exhibit an unacceptably large dark current under high fields needed to extract all x-ray generated charges or they do not possess sufficient charge collection efficiency because they need to be operated at a low field to prevent a large dark current [52]. Notice that the electron and hole $\mu\tau$ products for the polycrystalline CdZnTe layers in Table 20.2 are much less than those for the single crystal in Table 20.1. The $\mu\tau$ products have been observed to decrease with the polycrystallinity of the layers, e.g., $\mu_e\tau_e$ in polycrystalline HgI_2 layers decreases with decreasing grain size [104]. In some cases, there are technological problems in manufacturing a homogeneous layer over a large area. Table 20.2 provides a summary of the properties of current photoconductive layers that either are used or have potential for use in large area FPXIs. Material issues related to compound semiconductors for FPXI applications have been reviewed in [52, 125, 126]. The most developed at present is stabilized a-Se with several commercial companies manufacturing and marketing flat panel x-ray image detectors, especially for mammography

20.4 Signal and Noise

20.4.1 Responsivity

Consider a photoconductive detector that is irradiated for a certain duration with an amount of radiation X, which may be measured in grays (Gy) in air or in roentgen. As shown in Fig. 20.7, we can integrate the x-ray generated photocurrent $i_{ph}(t)$ on the pixel capacitance and hence find the collected charge $Q_c = \int i_{ph}(t)\, dt$. The x-ray sensitivity is defined as charge collected per unit incident radiation, $S_x = Q_c/X$. The sensitivity depends on four factors as highlighted in Fig. 20.8, which will be discussed below. Let α be the linear attenuation coefficient of the semiconductor medium and L be the photoconductor thickness. The dependence of α on the photon energy for a few selected semiconductors is shown in Fig. 20.9. Then, the quantum efficiency η_Q in the medical detector field is defined as the fraction of x-ray photons that are attenuated inside the medium as illustrated in Fig. 20.10 (top image) and is given by

$$\eta_Q = 1 - \exp(-\alpha L) \tag{20.10}$$

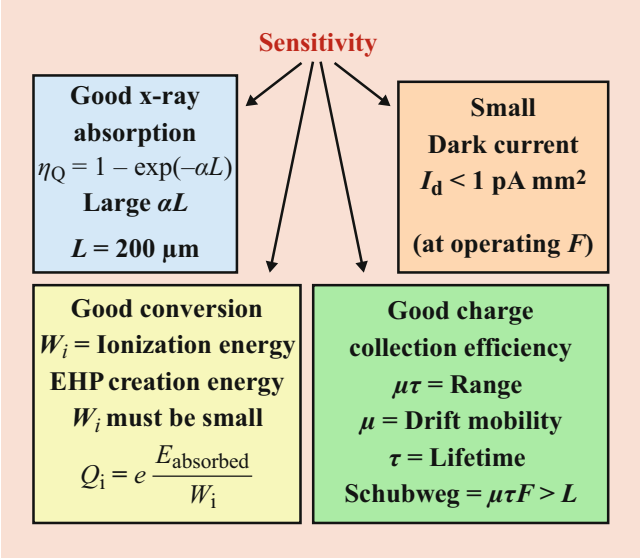

Fig. 20.8 The x-ray sensitivity and the signal-to-noise ratio depend on four factors

The reciprocal of α is the attenuation depth δ ($= 1/\alpha$). It is the depth from the detector surface within which 63% of the incident photons have been attenuated (absorbed or scattered), i.e., $\eta_Q = 0.63$. At a distance of 2δ, i.e., $L = 2\delta$, 86% of the radiation is attenuated. α depends on the x-ray

photon energy and also on the atomic number and density of the medium. The current a-Se mammographic detectors have $L = 200$ μm, so that, as apparent from Fig. 20.9 (or Table 20.2), $\delta \approx 50$ μm at 20 keV, which means that nearly all the incident radiation is attenuated in the photoconductor. At a photon energy of 60 keV, a-Se has $\delta \approx 1000$ μm, which is one of its drawbacks because to attenuate 86% of the radiation we would need a layer that is 2 mm in thickness. To maintain an operating field of 10 V/μm, we would need to apply 20 kV, which has its own practical problems such as eliminating corona discharges. Fluoroscopic a-Se detectors actually use a layer of thickness 1 mm since peak of the x-ray spectrum is at 70 kVp and the average photon energy is roughly 40 keV. From Fig. 20.9, it should be apparent that semiconductors with heavy elements such as CdZnTe, PbO, PbI_2, and HgI_2 have a distinct quantum efficiency advantage over a-Se in the general radiology range (40–100 keV). Perovskites contain lead halides and also exhibit strong x-ray absorption.

Consider a monoenergetic x-ray beam as the input to the detector. Suppose that Φ_0 is the incident photon fluence defined as the number of incident photons per unit area and per unit roentgen of exposure at a given photon energy. $\Phi_0(E)$ is the incident photons per unit area and per unit exposure. The photon fluence $\Phi(x)$ in the semiconductor will decay exponentially with distance, following a $\Phi(x) = \Phi_0 \exp(-\alpha x)$ behavior as shown in Fig. 20.10. In a small interval x to $x + dx$, $\alpha\Phi\, dx$ photons are attenuated, which can be integrated from $x = 0$ to $x = L$ to find the fraction η_Q of the incident photons that are attenuated as in Eq. (20.10). If α_{en} is the energy absorption coefficient of the medium, then the energy absorbed from an attenuated photon of energy E is $(\alpha_{en}/\alpha)E$. If A is the detector area that receives the radiation, then the energy absorbed from attenuated photons is the product of $A\Phi_0$, η_Q, and $(\alpha_{en}/\alpha)E$, which means the total energy absorbed is

$$E_{\text{absorbed}} = A\Phi_o \left[\frac{\alpha_{en}(E)}{\alpha(E)}\right] E\left\{1 - \exp\left[-\alpha(E)L\right]\right\} \quad (20.11)$$

If the input radiation is a spectrum from E_1 and E_2, then Φ_0 needs to be replaced by $\Phi_0(E)\, dE$, which is now defined as the number of photons per unit area per unit exposure in the photon energy interval E to $E + dE$, and then the whole expression on the left in Eq. (20.11) needs to be integrated with respect to E from E_1 and E_2 over the spectrum.

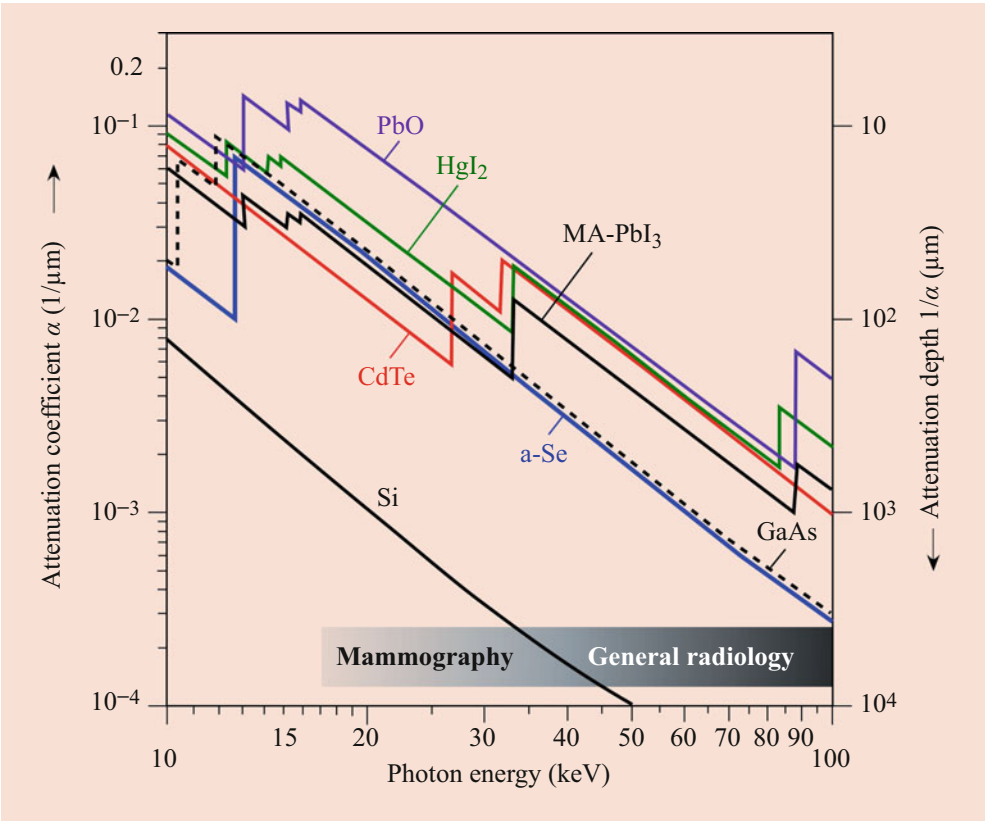

Fig. 20.9 X-ray attenuation coefficient α and attenuation depth $1/\alpha$ for selected semiconductors as a function of photon energy. (The densities of PbI_2, HgI_2, and PbO were assumed to be the same as those for the corresponding single-crystal values, which may not generally be the case inasmuch as the deposited layers would be polycrystalline and likely to have voids)

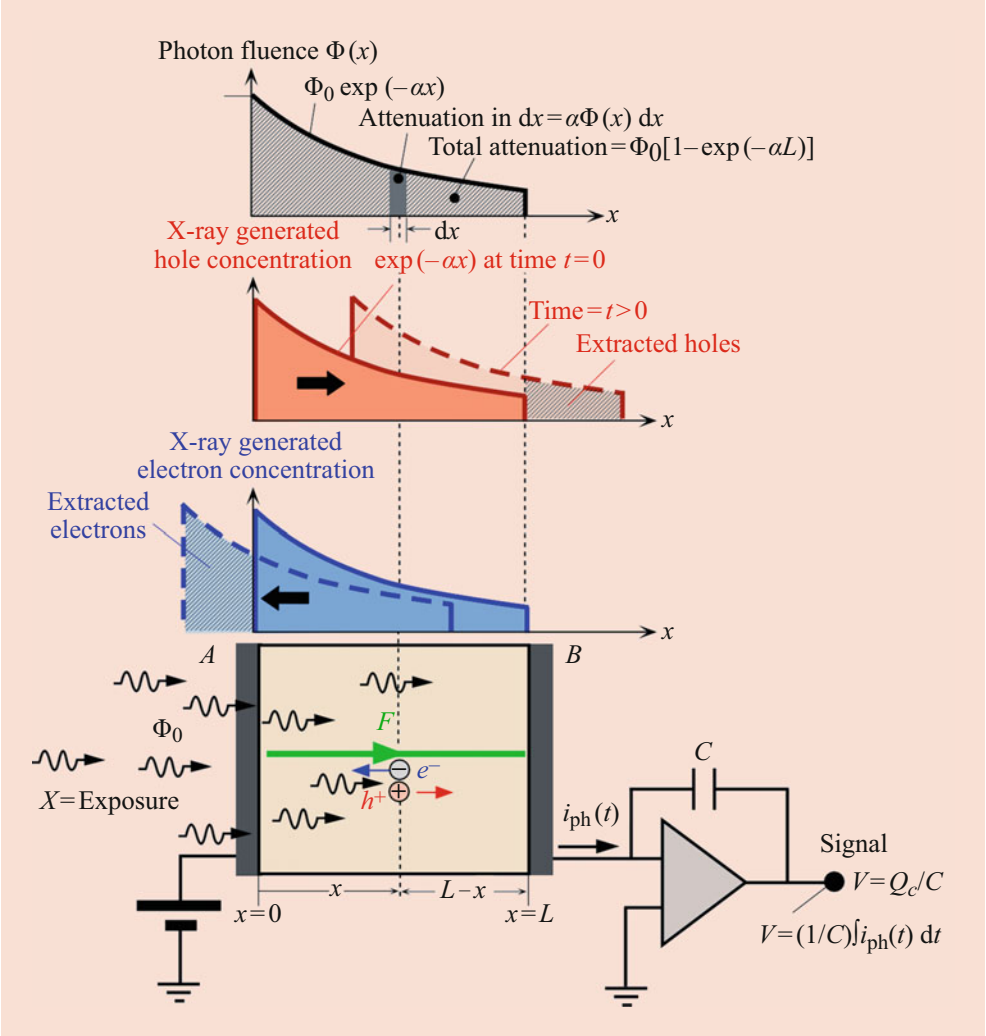

Fig. 20.10 The principle of operation of an integrating x-ray detector. The photon fluence through the sample, hole, and electron profiles at photogeneration ($t = 0$) and at a later time (before collection) and the detector with an electron and hole created at a position x. The signal is the external photocurrent $i_{ph}(t)$ integrated to deliver a charge Q_c which appears as a voltage $V = Q_c/C$

As introduced in Sect. 20.1, the conversion efficiency of the deposited energy $E_{absorbed}$ in Eq. (20.11) to electrical charges is gauged by the EHP creation energy W_i in Eq. (20.5). The charge generated is $Q_i = eN$. If all these N electrons and N holes drift to the collection electrodes (Fig. 20.7) without being trapped or recombined and become collected, then the charge collected in the external circuit by the integration of the photocurrent is Q_i. Thus

$$Q_i = eN = e\frac{E_{absorbed}}{W_i} \tag{20.12}$$

Clearly W_i represents the first step conversion efficiency; some W_i values are listed in Tables 20.1 and 20.2.

As mentioned in Sect. 20.1, the Klein relationship for crystalline semiconductors predicts $W_i = 2.8E_g + W_{phonon}$, where W_{phonon} is on the order of 0.1–0.5 eV. Que. and Rowlands argued that in amorphous semiconductors, one has to relax the **k** vector conservation rule and proposed that $c = 2.2$ in Eq. (20.6) [129]. Crystalline Si has a bandgap of 1.1 eV and a W_i of 3.61 eV [130] which agrees well with the Klein rule since $2.8E_g + 0.5$ eV is 3.58 eV. a-Si:H has a bandgap of 1.7 eV and a W_i that is 3.4–4.4 eV [131], which is much closer to Que and Rowlands rule than the Klein rule. a-Se is an exception to both rules because its W_i is significantly larger than $2.2E_g$ or $2.8E_g$ and depends on the electric field as indicated in Table 20.2 as well as the photon energy [132]. In a recent study, W_i for a-Se was examined up to very large fields (e.g., 80 V μm^{-1}) and found to saturate at about 8–9 eV. A useful empirical relationship for a-Se over typical x-ray diagnostic energies, for fields up to about 30 V μm^{-1} and at room temperature, is $W_i \approx W_{i\infty} + B/F$ where $W_{i\infty} = 6$ eV and $B = 440$ eV/F, where the field is in V/μm [133]. The field and temperature dependence of W_i can be

explained by using Langevin recombination of diffusion and drifting ionized electrons and holes in the primary electron track [134, 135]. (See reviews in [76, 136].)

The electrons and holes photogenerated by the absorbed radiation follow the exponential decay of the photon fluence as shown in Fig. 20.10. For simplicity, assume that the incident x-ray radiation is a very short pulse. The electrons and holes initially have exponential distributions of $n(x,t)$ and $p(x,t)$, and then the latter drift with $p(x,t)$ toward the negative electrode and $n(x,t)$ toward the positive electrode as shown in Fig. 20.10. In the absence of any trapping or recombination in the bulk, the collected charge Q_c would be the same as Q_i. However, we need to consider carriers lost during the drift of N electrons and N holes that are distributed exponentially as in Fig. 20.10 so that Q_c becomes

$$Q_c = Q_i \eta_{CC} = Q_i \eta_{CC}\,(\Delta, x_h, x_e) \tag{20.13}$$

where η_{CC} is a Hecht-type collection efficiency and a function of the ratio $\delta/L = \Delta$ and x_e and x_h are, respectively, the electron and hole schubwegs per unit length, $\mu_e \tau_e F/L$ and $\mu_h \tau_h F/L$

$$\eta_{CC} = \eta_{CCh} + \eta_{CCe} = x_h \left[1 + \frac{\left(e^{-1/x_h} - e^{-1/\Delta}\right)}{(\Delta/x_h - 1)\left(1 - e^{-1/\Delta}\right)}\right] + x_e \left[1 - \frac{\left(1_e - e^{-1/\Delta - 1/x_e}\right)}{(\Delta/x_e + 1)\left(1 - e^{-1/\Delta}\right)}\right] \tag{20.14}$$

where the collection efficiencies of holes and electrons have been separated into η_{CCh} and η_{CCe}. The radiation receiving electrode is assumed to be positive [33, 137–141]. In this simple model of the detector, the output Q_c is proportional to Q_i and hence to the incident radiation X, which means that we can use linear system concepts to extend the above model for a delta pulse input to any shape of x-ray excitation. While Eq. (20.12) strictly applies under small signal conditions, that is, the perturbation of the field by the injected charge is negligible, the equation shows much resilience even under strong injection, and errors are not as large as one may anticipate [142]. Further, Eq. (20.14) assumes that the semiconductor properties are homogenous, that is, the carrier ranges (mobility × lifetime product) do not vary across the sample. It is possible to continue to use Eq. (20.14) in cases where the carrier ranges are not uniform in the sample by suitably defining effective carrier ranges as discussed in [143].

The charge collection efficiency for a given photoconductor depends on x_e and x_h and hence on the applied field. For x-ray photon absorption very near the radiation receiving electrode, $\Delta << 1$, η_{CC} passes over to the classical Hecht collection efficiency [31] for the carrier that has to traverse the whole photoconductor thickness (holes for positive bias on the radiation receiving electrode). It should be emphasized that the analytical expressions for η_{CC} usually assume small signals and hence neglect the space charge perturbation, which can affect η_{CC} [144, 145]. Figure 20.11 is a plot of the collection efficiency of holes and electrons, that is, η_{CCh} and η_{CCe}, respectively, as a function of $\mu\tau F/L$ for each carrier for

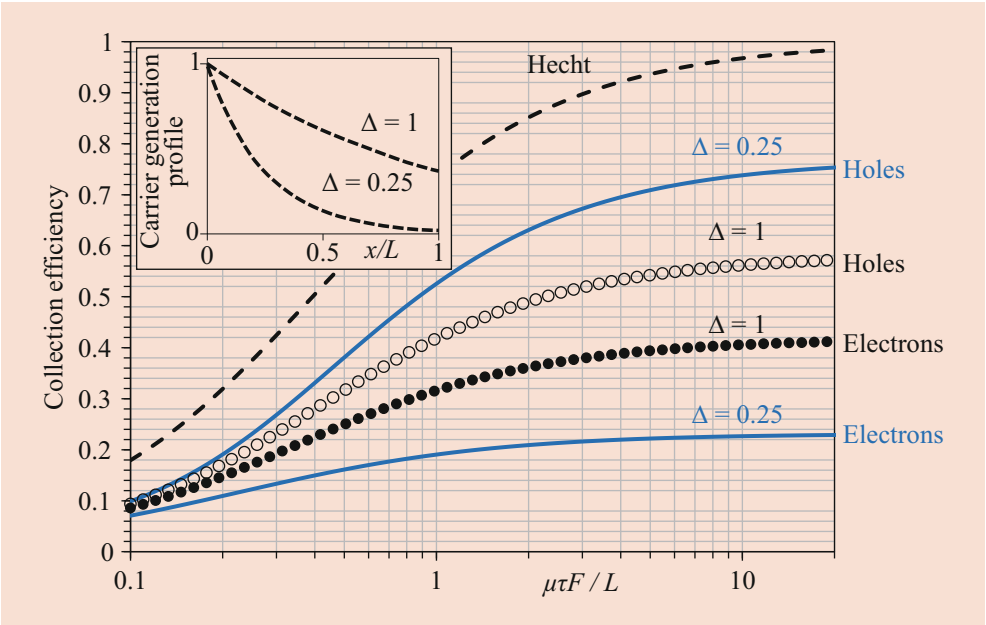

Fig. 20.11 Collection efficiency vs normalized schubweg ($\mu\tau F/L$) for electrons and holes with two different photogeneration profiles, $\Delta = 1$ and $\Delta = 0.25$

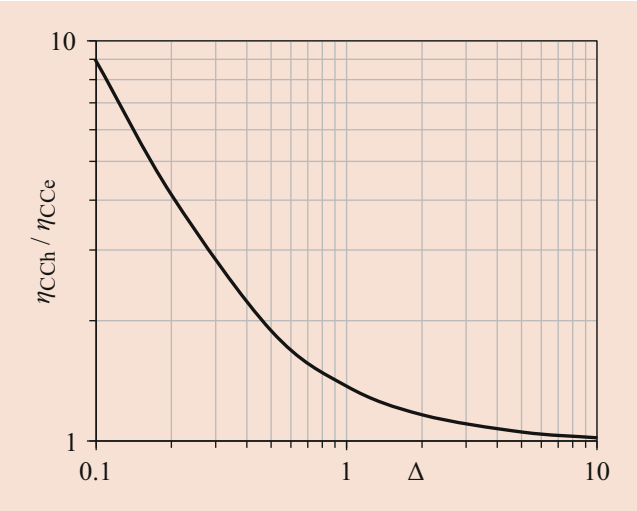

Fig. 20.12 Ratio of hole charge collection efficiency to electron collection efficiency (η_{CCh}/η_{CCe}) vs Δ ($= \delta/L$)

two different x-ray attenuation profiles, $\Delta = 1/\alpha L = 1$ and $\Delta = 0.25$. Notice that holes make a bigger contribution to the collected charge Q_c than electrons and their contribution increases as Δ becomes smaller, eventually reaching the Hecht curve. Most semiconductors have asymmetric $\mu\tau$ products as apparent in Table 20.2 with one type of carrier being favored over the other. It is therefore important to ensure that the carrier with the longer range is drifted toward the bottom electrode. Figure 20.12 highlights how, under positive bias, with decreasing x-ray attenuation depth (decreasing Δ), the collected charge Q_c is more and more dominated by the collection of holes.

20.4.2 Signal and Linearity

The signal from a single pixel in the x-ray image detector in Fig. 20.7 is given by Eq. (20.13), in which Q_i depends on the absorbed energy in Eq. (20.11) so that at a photon energy E the signal is

$$Q_c = \eta_{CC} Q_i = e\eta_{CC}\left[\frac{(\alpha_{en}/\alpha)\,E}{W_i}\right](A\Phi_0)\,\eta_Q \qquad (20.15)$$

and is proportional to the incident fluence Φ_0. Increasing the photon fluence Φ_0 increases the signal Q_c in a linear fashion. Equation (20.15) needs to be integrated over the energy spectrum of the input radiation for a polyenergetic spectrum. Q_c in Eq. (20.15) is per unit exposure such as 1 R or 1 mR and hence needs to be scaled for any arbitrary exposure X

$$Q_c = e\eta_{CC}\eta_Q \frac{(\alpha_{en}/\alpha)\,E}{W_i} A\Phi_0 X \qquad (20.16)$$

It is important to emphasize that the highly desirable linear relationship between Q_c and X is lost under high exposure rates (large signals) or for semiconductors with less than ideal carrier ranges, e.g., $\mu\tau F$ is comparable to L. Under high doses delivered to the sample, x-ray generated electrons and holes create a bulk space charge, distorting the field; they can recombine with each other, become trapped, and recombine with oppositely charged trapped carriers, and there may be x-ray-induced defects created that can trap carriers. Space charge due to trapped carriers needs to be considered as well. All these factors were needed to explain the deviation of an a-Se detector response from the linear behavior under very large doses operating at 2 MeV radiation [146]. Correct approach, beyond the scope of this chapter, to modeling large signals is to solve the continuity equation, trapping and recombination rate equations with trap filling as well as new trap generation, and the Poisson equation. Generally, only numerical solutions can be obtained as described in [146]. The main result is that η_{CC} becomes dependent on the rate of charge generation or rate of dose delivery and the actual Q_c vs X behavior falls below the small signal linear behavior.

The derivation of Eq. (20.16) assumes that the accumulation of charge Q_c and hence the buildup of voltage (Q_c /C_{ij}) on the pixel capacitor do not significantly modify the voltage across the photoconductor, which would modify the field F and hence the sensitivity of the pixel; the responsivity would be poorer at smaller fields. In nearly all cases, Q_c /C_{ij} << V, the applied voltage.

Equation (20.16) is the pixel response to an incident exposure of X (in roentgen) at the pixel. It is no different from the response of any photoconductive x-ray detector used in the integrating mode. For monoenergetic radiation, the fluence Φ_0 as photons cm^{-2} R^{-1} can be obtained from [147]:

$$\Phi_0 = \frac{5.45 \times 10^{13}}{(\alpha_{en,air}/\rho_{air})\,E} \qquad (20.17)$$

where $\alpha_{en,air}$ is the energy absorption coefficient of air, ρ_{air} is the density of air, and E is the photon energy in eV. Alternatively, Φ_0 in photons mm^{-2} per mR is given by Boone [148] over the photon energy range 1–150 keV as

$$\Phi_0 = \left[a' + b'\sqrt{E}\ln E + \frac{c'}{E^2}\right]^{-1} \qquad (20.18)$$

where E is the photon energy in keV and $a' = -5.0233 \times 10^{-6}$, $b' = 1.8106 \times 10^{-7}$, and $c' = 0.0088387$. The conversion from exposure in roentgen to dose in air in Grays is straightforward.

20.4.3 Noise Sources in the Detector

The evaluation of signal-to-noise ratio (SNR) involves considering various noise sources that corrupt the signal in Eq. (20.16) on the pixel capacitor C_{ij} in Fig. 20.7. Since charge signal on C_{ij} has to be read out, it is not possible to exclude the noise from the readout and peripheral electronics, including the quantization noise in converting the analog signal to a digital form. (The analog-to-digital converter has to be at least 14 bits to cover dynamic range of the pixel signal.) If the readout of a pixel occurs at every Δt seconds, then during Δt, the pixel capacitor C_{ij} accumulates charges from the dark current I_d shown in Fig. 20.7. Although the dc value of this charge in the dark can be subtracted from the total charge read, its fluctuations represent noise and corrupt the signal. These charge fluctuations are expressed as root-mean-square (RMS) number of electrons, often abbreviated to rmse. Further, the read and reset operations of the TFT also result in charge fluctuations on C_{ij}. As we move from the TFT, along the data line to the charge amplifier in Fig. 20.7, more noise is added. A proper evaluation of the detector noise involves several factors from the photoconductor to the charge amplifiers in Fig. 20.7, starting with the incoming radiation. The detailed analyses can be found in references [48, 149], whereas the treatise below is a descriptive semi-quantitative approach in considering only the most important contributions.

The quantum noise in the incident radiation is due the Poisson statistics of photons. If Φ_0 photons are incident, then the RMS noise is ${\Phi_0}^{1/2}$ and since the signal is proportional to Φ_0, SNR $= \Phi_0/{\Phi_0}^{1/2} = {\Phi_0}^{1/2}$, which improves with higher exposure, i.e., it is worse at lower exposures. The quantum efficiency η_Q in Eq. (20.6) is an average value for the attenuated photons based on the fact that the probability of absorption along the detector length is an exponential distribution of the form $\exp(-\alpha x)$. Therefore, η_Q has a variance given by $\eta_Q(1-\eta_Q)$ which vanishes for full absorption, hence the need to absorb as much of the incident photons as possible. It is a maximum at $\eta_Q = 0.5$.

Consider the absorption of a single photon that deposits an energy $E_d = (\alpha_{en}/\alpha)E$. Assume $\eta_Q = 1$. The conversion process of this absorbed photon to charge carriers also has fluctuations as explained in Sect. 20.1. It is not simply E_d/W_i but fluctuates about this mean value. The variance of this conversion is $F_N(E_d/W_i)$, where F_N is the Fano factor. The corresponding RMS fluctuations in the converted charge is $\Phi_0(F_N E_d/W_i)^{1/2}$. However there is also the conversion of photon noise in the input radiation to carriers, i.e., $(\Phi_0)^{1/2}(E_d/W_i)$; thus, the conversion noise $N_{conversion}$ in rmse for converting Φ_0 photons is given by

$$N^2_{conversion} = \Phi_0^2\left(\frac{F_N E_d}{W_i}\right) + \Phi_0\left(\frac{E_d}{W_i}\right)^2 \qquad (20.19)$$

The Fano factor for many semiconductors is typically less than 1 (e.g., $F_N \approx 0.1$ for Si). a-Se is an exception to this observation. There are no systematic and replicated experimental studies on F_N, but inferences from pulse height spectrum measurements and simulations indicate that F_N is not less than unity and is likely to be more [132, 150]. The free EHP creation process in a-Se involves two intermingled independent processes: first, the generation of electrons and holes in the primary electron track and, second, the diffusion and drift of these electrons and holes in the track in which they experience Langevin recombination. Those electrons and holes that escape recombination and hence the track constitute the observed W_i [135]. Both of these process have a variance that leads to an overall effective Fano factor that is likely to be greater than unity. In addition, the presence of K-fluorescence escape and reabsorption complicates not only W_i but also the statistics in Eq. (20.19), which adds variance to the converted charge statistics due to x-ray photons around the K-edge. The fluctuations in the number of collected charges per incident x-ray photon from a-Se have been measured and show higher fluctuations (more noise) around the K-edge (12.7 keV) which highlights the K-edge fluoroluminescence escape and reabsorption effects [151].

The charge collection efficiency, as represented by η_{CC}, is an average value for the collected charge Q_c. As explained in Sect. 20.2, charge trapping is a stochastic process, which means that η_{CC} has to be viewed as a mean value and the charge collection process possessing a certain variance [33, 34]. Provided that the collection efficiency is high, the variance in the latter can generally be neglected compared to other fluctuations.

The shot noise of the dark current through the photoconductor causes fluctuations of the charge accumulated on the pixel capacitor C_{ij}. Suppose that the capacitor is read every Δt seconds (frame time) so that the dark current integration time is Δt. The mean value of the number of accumulated charges is $I_d \Delta t/e$. Shot noise follows Poisson statistics so that the RMS noise N_d in the number of carriers collected on C_{ij} is

$$N_d = \sqrt{I_d \Delta t/e} \qquad (20.20)$$

Most analyses of photoconductor noise in the imager pixel consider only the shot noise in Eq. (20.20), due to the fact that usually not much information is available on the excess noise behavior of the photoconductor under consideration. Excess noise is a form of noise that is in excess of shot and thermal noise. All semiconductors would exhibit excess noise if measured down to sufficiently low frequencies. There are several forms of excess noise as reviewed in detail in [152–156], but the most important three sources for x-ray photoconductors are generation-recombination (GR) noise, flicker noise, and contact noise. The first two fluctuations

are in the conductance of the medium. Contact noise is due to fluctuations of carrier injection from the contact or variations in the current due to phenomena at the surface or near the contact surface (e.g., in the depletion region). If the dark current is a leakage current over the device surface, it can easily exhibit flicker noise in which the noise depends on the surface conductance.

The quantity of interest in describing noise is its spectral noise power density S_i, the square of the current fluctuations in a small frequency interval Δf averaged many times per unit frequency, i.e., $<i^2>/\Delta f$. GR noise follows a Lorentzian spectrum, whereas for flicker and contact/surface noise, the spectra are approximately $1/f$ type, but they have different dependences on the dc current and detector geometry. Table 20.2 summarizes the main features of the three types of excess noise considered.

The GR noise invariably involves a single defect level in the bandgap that aids recombination and generation, which results in the fluctuations in the number of carriers N and hence in the conductance. It can also be caused by the fluctuations in the rate of trapping and detrapping of carriers through a set of traps at a well-defined discrete energy level. In the latter case, a straightforward expression is provided by Copeland for a discrete level of traps in an extrinsic semiconductor [157, 158]. S_i depends on $I_d{}^2$ and has a $1/f^2$ roll-off at high frequencies and a flat spectrum at low frequencies, i.e., a Lorentzian spectrum. It scales inversely with the active volume of the device. It is quite often observed in intrinsic semiconductor crystals with defects, for example, Ge [159], Si [160], $Al_xGa_{1-x}As$ [161], etc.

Both flicker and contact noise can be represented by an equation of the form

$$S_i = \frac{C_n I_d^b}{f^\alpha} \tag{20.21}$$

where C_n is a device-specific constant and different for flicker and contact noise and α and b are constants that characterize the nature of observed noise, with $\alpha = 1$ being "pure $1/f$ noise." One of the differentiating features between flicker and contact noise sources is in the dc current dependence. Normally, $b = 2$ for flicker noise since it is fluctuations in the conductance of the medium, whereas $b < 2$, often $b = 1$, for contact noise. Further, in flicker noise, the constant C_n is inversely proportional to the total number of carriers and is usually written as $C_n = \alpha_H/N$, where α_H is called the Hooge parameter, a characteristic parameter that gauges the relative measure of fluctuations in the medium. On the other hand, for contact noise, C_n depends on the surface area involved between the metal and the semiconductor.

In the case of contact noise, usually some kind of carrier emission over a barrier height Φ_B is involved as in a Schottky junction. Small variations in Φ_B at the metal-semiconductor interface can easily lead to a $1/f$ type noise with $\alpha \approx 1$ and $b \approx 1$ [162]. $1/f$ noise can also arise from a distribution of surface traps at the contact or near the surface. One of the examples directly related to x-ray detector materials is the excess noise in CdZnTe single crystals with different contacts [163]. This noise has been found to exhibit $1/f$ type excess noise behavior, and its magnitude has been correlated with the surface conditions of the crystal and the metallization used for the contact. In the case of ohmic contacts, as in In-CdZnTe, in which the current is limited by the bulk material, the excess noise has a GR origin.

Flicker and contact noise are the most dominant excess noise sources in x-ray photoconductors used in both small and large area detectors. Table 20.3 provides a summary of the three excess noise sources that usually contribute to the photoconductor noise with examples on a few semiconductors.

The effect of $1/f$ noise in integrating detector performance has been described in [171, 172], and a proper analysis requires establishing a low cutoff frequency f_0 for the low-frequency fluctuations. Its exact value is not too critical since the dependence of RMS of the fluctuations on f_0 is a $(\ln f_0)^{1/2}$ behavior, i.e., a very slow change with f_0. In general, flicker noise contribution with background subtraction can be written as

$$N_{\text{flicker}} = (1/e)\,\kappa C_n^{1/2} I_d \Delta t \tag{20.22}$$

in which κ is a numerical constant that depends on a number of factors such as f_0 and the sampling scheme. If double sampling and subtraction are used, such that the period before exposure, during exposure, and after exposure are sampled, and each has a duration Δt, then $\kappa = (8 \ln(2))^{1/2} = 2.35$, and there are other sampling possibilities [172]. The importance of C_n cannot be underestimated, and there are sampling sequences that can lower the overall SNR. The RMS fluctuations from shot and $1/f$ noise are typically less than 100 rmse if the dark current is sufficiently suppressed, probably of the order of 50 electrons.

There are several noise sources associated with the particular readout technology used, e.g., TFT vs CMOS or passive pixel vs active pixel. The active pixel sensor (APS) has additional transistors in the pixel to introduce gain. For the TFT technology, these have been reviewed by Yorkston and Rowlands [48]. We consider only the significant sources. There is a so-called *reset* noise or *kTC* noise from the TFT and the capacitor C_{ij} circuit because when the TFT is addressed, it transfers the charge and discharges C_{ij}, but thermal fluctuations across the TFT channel resistance lead to an amount of random charge with a variance (kTC_{ij}/e) to be left on the pixel capacitor. Strictly, C_{ij} should be replaced with an effective capacitance C_{in} that includes C_{ij} and the input capacitance of the TFT. If C_{ij} is 1 pF, this switching noise

Table 20.3 Summary of excess noise sources in semiconductors suitable for x-ray detection

Noise	Fluctuation source	Typical spectral power spectrum	Typical selected examples
Generation-recombination (GR)	Conductance	$S_i \propto \left(\frac{I_N^2}{V}\right) \frac{\tau}{[1+(2\pi f\tau)^2]}$	S_i for a given set of traps or a recombination center at a single energy level. τ is the characteristic time associated with the GR process Pure crystals with discrete defects, e.g., Ge [159], Si [160], epitaxial $Al_xGa_{1-x}As$ [161]
Flicker or 1/*f*	Conductance	$S_i \propto \frac{I_d^2}{Nf^\alpha}$	Ge [164], CdTe [165], PbI_2 [166], CdZnTe, GaAs [167], InSb [168], a-Se [169], a-Si:H [170]
Contact	Injection from contact	$S_i \propto \frac{I_d}{f^\alpha}$	Metal/semiconductor contacts, e.g., metal/Si [162], metal/CdZnTe [163]

N is the total number of free carriers involved in the conduction and *V* is the volume of the sample

corresponds to charge fluctuations of $(kTC_{in})^{1/2}$ or to about 400 rmse. The TFT switch is operated twice, reset and read, so we should multiply by $\sqrt{2}$ to get $(2kTC_{in})^{1/2}$ or about 560 electrons [48]. This noise is part of the TFT operation and arises from the channel resistance of the TFT.

Beyond the pixel and the TFT, there are two more important noise contributions, associated with the charge amplifiers and the data lines. These noise sources are lumped into a single quantity called the data line noise and quoted as a number of electrons referred to the input of the charge amplifier. In TFT arrays, this is roughly 800–2000 electrons and is a function of the lumped data line capacitance, data line resistance, and readout speed. In general, the data line noise dominates all other noise sources in passive pixel TFT arrays. This large noise can be reduced by using a source follower or an amplifier at the pixel level, which makes the pixel an active pixel, rather than passive with just a TFT switch. Active pixel architectures in which the pixel has an embedded amplifying transistor have attracted much interest due to their improved overall SNR in which readout noise per pixel can reach sub-500 electrons for a-Si:H TFTs and less, below 200, for CMOS detectors. a-Si:H-based TFT arrays with on-pixel amplification have been studied and show improved SNR with respect to passive pixel sensor (PPS, with only a TFT switch) [173–175]. Although the electronic noise from the data line and charge amplifier can be significantly reduced, the 1/*f* noise in the a-Si:H channel of the amplifying TFT begins to dominate. Therefore, solutions based on replacing a-Si:H TFTs with poly-Si (polycrystalline silicon) have been explored, and these show potential to realize a reduction in the overall pixel noise, for example, down to around 600 electrons or less [176]. Amorphous In-Ga-Zn-O (IGZO) TFTs arrays have been also demonstrated with lower noise than a-Si:H TFTs and with higher TFT gain because of the higher carrier mobility in a-IGZO than in a-Si:H [177]. However, IGZO TFTs tend to be more susceptible to x-ray radiation damage and are not commonly employed as yet in APS designs although PPS designs have started to see commercial use. It is important to mention that nearly all sensitive CMOS imaging chips already have on-pixel amplification, which means that coating these with a suitable photoconductor can lead to high DQE imagers even though there is the cost of stitching and tiling them. As mentioned above, CMOS imagers also have smaller pixel size as a distinct advantage.

The quantum noise-limited SNR decreases with increasing dose. On the other hand, the electronic noise is usually independent of the incident radiation dose. Therefore, the detector could be quantum noise-limited if the incident dose is sufficiently high to overcome the effect of the electronic noise. When the incident dose is reduced down to very low levels, the detector performance is mainly controlled by the electronic noise. Therefore, the schemes for the reduction of electronic noise become essential for low-dose imaging applications.

20.5 Image Resolution

Resolution or resolving power is the ability to record separate images of small objects that are placed very closely together. The resolution is normally examined in the spatial frequency (*f*) domain. Spatial frequency is similar to temporal frequency except that distance (usually in mm) is used instead of time. In the spatial frequency domain (mm^{-1}), smaller objects correspond to higher frequencies, and larger objects correspond to lower frequencies in the image. The spatial resolution of an imaging device or a system can be described in terms of the modulation transfer function (MTF) which is the relative response of the system as a function of spatial frequency. The x-ray image is two-dimensional, and thus, a two-dimensional MTF(f_x , f_y) is required, which is the two-dimensional Fourier transform of the point spread function (PSF). This is the response of an imaging system to a point input (infinitesimally thin spatial pulse). For a rotationally symmetric system, MTF is also rotationally symmetric and can be expressed in terms of single radial frequency *f*, which is the Fourier transform of the line spread function (LSF). When an imaging system is stimulated with a signal in the form of a line, the LSF is constructed by evaluating the system response perpendicular to the line. The size of the picture element, the *pixel*, in an image sets a limit on what can theoretically be resolved in that image. While images

with small pixels have the *potential* to deliver high spatial resolution, many other factors also affect spatial resolution, and in many cases, it is not the pixel size that is the limiting factor in spatial resolution.

The effect of a digital detector on its image has been described as a two-step process: (i) integration of interacting input quanta in each element to produce a pre-sampling detector signal and (ii) sampling of the pre-sampling detector signal. In the spatial frequency domain, these two processes are described in terms of (i) pre-sampling MTF and (ii) aliasing as determined by the sampling spacing. Therefore, the shape of pre-sampling MTF contains all the information on signal blurring of the detector. The MTF of an imaging system can be described as a cascade of several stages where the overall MTF is simply the product of the MTF of all the individual stages. The pre-sampling MTF of an image detector can be expressed as

$$\mathrm{MTF}(f) = \mathrm{MTF_m}(f) \times \mathrm{MTF_{tr}}(f) \times \mathrm{MTF_a}(f), \qquad (20.23)$$

where $\mathrm{MTF_m} = p_{\mathrm{pe}}\mathrm{MTF_{pe}} + p_{\mathrm{k}}\mathrm{MTF_k} + p_{\mathrm{c}}\mathrm{MTF_c}$ is the weighted MTF including the MTFs due to the range of the primary photoelectron, K-fluorescence reabsorption, and Compton scattering [178], $\mathrm{MTF_{pe}}$ is due to the range of the primary photoelectron, $\mathrm{MTF_k}$ is due to the K-fluorescence reabsorption, $\mathrm{MTF_c}$ is due to Compton scattering, $\mathrm{MTF_{tr}}$ is due to the charge carrier trapping, and p_{pe}, p_{k}, and p_{c} are the relative probabilities of the released charge carriers being from the photoelectric primary electron interaction, K-fluorescent x-ray reabsorption, and Compton scattered photon, respectively. $\mathrm{MTF_a}$ is the modulation transfer function associated with the aperture function of the pixel electrodes. $\mathrm{MTF_a}$ arises due to averaging the signal over a pixel area and describes how spatial frequencies are passed through the detector elements. If the aperture is a square with a dimension a, then

$$\mathrm{MTF_a}(f) = |\mathrm{sinc}(af)| = \left|\frac{\sin(\pi af)}{\pi af}\right| \qquad (20.24)$$

The spatial resolution in direct conversion FPXIs is usually high and closer to the aperture function, as compared to phosphor-based FPXI [36]. The signal blurs due to the range of primary photoelectron, and Compton scattered photons are insignificant for diagnostic x-rays (up to 100 keV) [178, 179]. Therefore, the charge carrier trapping and the reabsorption of K-fluorescent x-ray photons are the two dominant mechanisms responsible for the loss of resolution [180, 181] in direct conversion FPXI. Some of the K-fluorescent x-ray photons may be reabsorbed at different points within the detector volume from the primary x-ray photon interaction point. This generates additional EHPs and creates a lateral spreading of signal. The loss of resolution due to fluorescence reabsorption is maximum (although not very substantial) just above the K-edge of the photoconductor. This effect can be ignored when (i) the incident x-ray photon energy is lower than the K-edge of the photoconductor or (ii) the mean energy of the x-ray beam and the K-edge occurs at widely different energies [180]. Que. and Rowlands [178] described a numerical method to calculate the $\mathrm{MTF_k}$ by considering the PSF of the detector and subsequent two-dimensional (2D) Fourier transform of the PSF. Later, a simplified and convenient semi-analytical model to calculate $\mathrm{MTF_k}$ by determining the LSF and a subsequent 1D Fourier transform was developed and applied to a-Se and HgI_2 detectors [182]. The charge carrier trapping has a significant effect on the resolution of these direct conversion x-ray image detectors, which is discussed below.

The direct conversion FPXI geometry consists of a photoconductor layer sandwiched between two electrodes; the electrode at one side is a continuous metal plate and the electrode on the other side of the photoconductor is segmented into an array of individual square pixels of size $a \times a$ as shown in Fig. 20.13a. The *geometric* pixel aperture width in a flat panel detector is smaller than the pixel pitch (center-to-center spacing between two pixels). However, it is shown that the effective fill factor (the effective fraction of pixel area used for image charge collection) of a photoconductive flat panel detector is close to unity [183, 184]. Therefore, the *effective* pixel aperture width a is virtually identical to the pixel pitch. Some of the x-ray generated carriers become captured by deep traps in the bulk of the material during their drift across the photoconductor. Suppose that a carrier is trapped in the photoconductor above a particular (central) pixel electrode of a pixelated image sensor. This trapped carrier induces charges not only on the central pixel electrode but also on neighboring pixel electrodes as shown in Fig. 20.13b and consequently there is a lateral spread of information and hence a loss of image resolution.

Straightforward analytical expressions for the MTF due to distributed carrier trapping in the bulk of the photoconductor have been described in [185], where the effect of charge carrier trapping on the resolution of a direct conversion FPXI has been examined as a function of charge carrier ranges. Trapping of the carriers that move toward the pixel electrodes degrades the MTF performance, whereas trapping of the other type of carrier that moves away from the pixels improves the sharpness of the x-ray image.

The a-Se-based x-ray detectors use thin blocking layers between the bulk layer (nearly intrinsic) and the metal contacts (Figs. 20.6 and 20.13) in order to minimize the dark current at the operating electric field. The operating electric field refers to the applied field that ensures the x-ray generated charges are mostly collected. The thicknesses of these blocking layers are few microns (usually 4–8 μm), whereas the total photoconductor thickness is at least few

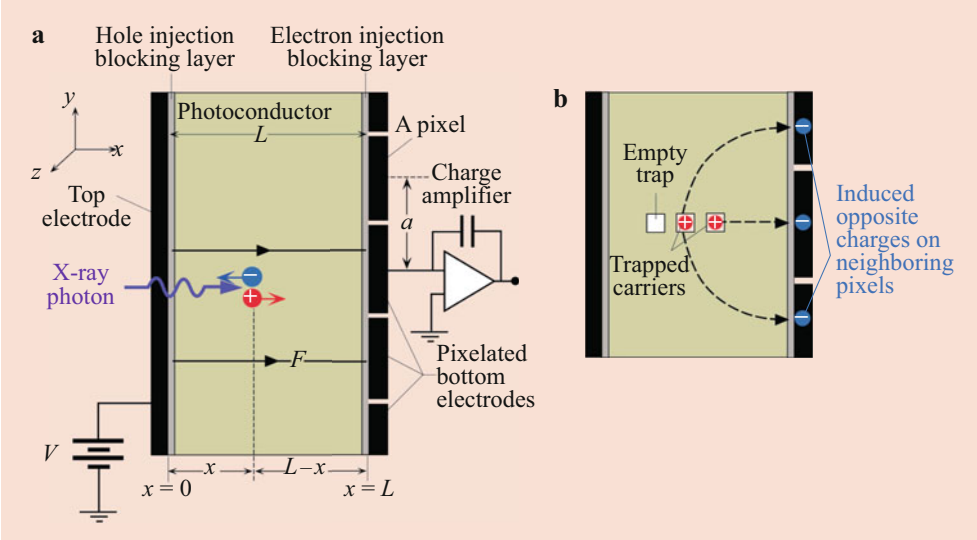

Fig. 20.13 (**a**) A cross section of a direct conversion pixelated x-ray image detector. (**b**) Trapped carriers in the photoconductor induce charges not only on the central pixel electrode but also on neighboring pixel electrodes, spreading the information and hence reducing spatial resolution

hundred microns. The amount of trapping/defect states in the blocking layer is much larger than the bulk photoconductor layer. Therefore, one can expect much more trapped carriers in the blocking layers than in the bulk photoconductor layer. If charge carrier trapping occurs right at the interface between the photoconductor and blocking layer only, then its corresponding MTF can be calculated by a simple analytical expression [181, 186].

Figure 20.14 shows the measured MTF for various flat panel x-ray image detectors for mammographic applications. The thicknesses of a-Se, HgI_2, and CsI (indirect conversion) layers are 200, 127, and 150 μm, respectively. The measured MTF data for a-Se detector are extracted from [187]. The plotted values for HgI_2 and CsI:Tl are based on published MTF results of [53, 188], normalized to correspond to the 85 μm pixel aperture. The MTF of a direct conversion detector (e.g., a-Se and HgI_2) is close to a sinc function (i.e., MTF_a). The charge carrier trapping and the reabsorption of *K*-fluorescent x-ray photons are the two dominant mechanisms responsible for this little difference. The state-of-the-art MTF of the indirect conversion detectors (CsI detectors) is still much worse than that of direct conversion detectors. The omnidirectional propagation of x-ray generated optical photons (i.e., optical scattering) in the CsI layer is the dominant cause of loss of resolution in indirect conversion detectors.

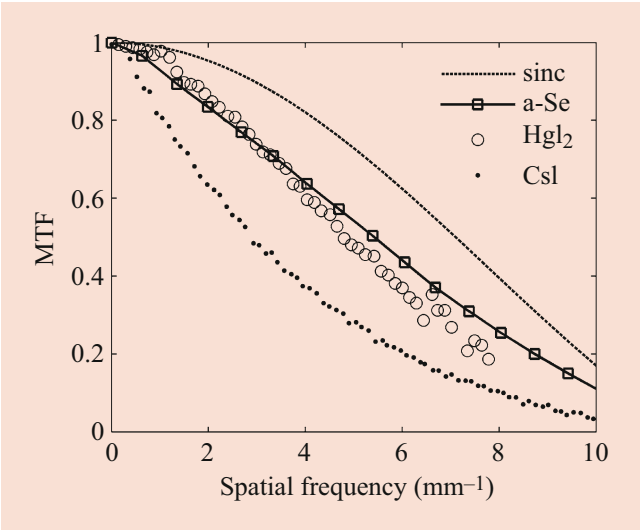

Fig. 20.14 Measured MTF for various flat panel x-ray image detectors. The dashed line is MTF_a based on 85 μm aperture size. The measured MTF on a-Se, HgI_2, and CsI detectors are adapted from [53, 187, 188], respectively

20.6 Detective Quantum Efficiency (DQE)

Detective quantum efficiency (DQE) measures the ability of the detector to transfer signal relative to noise from its input to its output. The random nature of image quanta gives rise to random fluctuations in image signals contributing to image formation and hence creates random noises. Images are partially degraded by various sources of statistical fluctuations, which arise along the imaging chain. The relative increase in image noise through an imaging system as a function of spatial frequency f is expressed quantitatively by DQE(f) which represents the signal-to-noise transfer efficiency at different frequencies of information in an image. The DQE(f) is defined as

$$\mathrm{DQE}(f) = \frac{\mathrm{SNR}^2_{\mathrm{out}}(f)}{\mathrm{SNR}^2_{\mathrm{in}}(f)}, \tag{20.25}$$

where $\mathrm{SNR}_{\mathrm{in}}$ and $\mathrm{SNR}_{\mathrm{out}}$ are the signal-to-noise ratio at the input and output stages of an image detector, respectively, and DQE(f) is unity for an ideal detector.

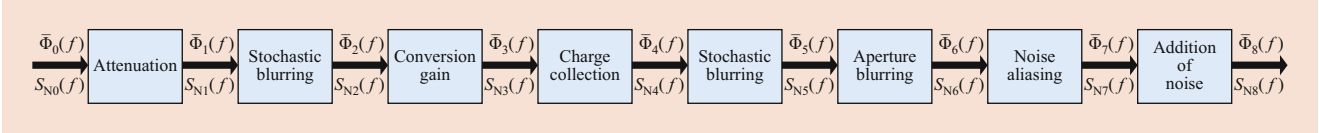

Fig. 20.15 The block diagram shows the propagation of signal and NPS through the eight stages of a direct conversion x-ray imaging detector

The SNR(f) is a function of the MTF and the noise power spectrum (NPS). The extent of noise in an image is quantified by its variance, but it does not quantify the noise *texture* (the way the noise looks). To get the noise texture, we need to find the frequency dependence of the noise variance, which is quantified by NPS(f). Indeed, the integral of the NPS over all frequencies equals the variance σ^2. The scattering of image quanta gives rise to image blurring which is quantified by MTF(f) as described above. The MTF(f) describes how well an imaging system *processes signal*, and the NPS(f) describes how well an imaging system *processes noise* in the image. The noise in the number of x-ray quanta incident on the detector follows a Poisson process and is uncorrelated. If the Φ_0 is the average number of x-ray photon incident on the detector, then its variance is $\sigma^2 = \Phi_0$ and thus the input NPS(f), $S_{N0} = \sigma^2 = \Phi_0$. The input $\text{SNR}^2 = \Phi_0$ (see Sect. 20.4.3). Therefore, the DQE(f) can be written as

$$\text{DQE}(f) = \frac{K[\text{MTF}(f)]^2}{\text{NPS}(f)\Phi_0}, \tag{20.26}$$

where K is a constant that converts units. For simplicity, we are often interested in measuring DQE ($f = 0$) of an imaging detector since it represents signal quality degradation due to the signal and noise transfer characteristics of the system without considering signal spreading. In that case

$$\text{DQE}(f) = \frac{\text{DQE}(0)[\text{MTF}(f)]^2}{\text{NPS}_0(f)}, \tag{20.27}$$

where $\text{NPS}_0(f)$ is the noise power spectrum of the system normalized to unity as f approaches 0.

The DQE can be conveniently calculated by developing an appropriate cascaded linear system model [189, 190]. In the cascaded linear system model, an imaging system is described as cascades of simple and independent elementary stages. The effect of charge carrier trapping on the DQE(f) has been analyzed in [191, 192]. Zhao et al. [193] have studied the effects of K-fluorescence on DQE(f) by developing a cascaded linear system model with a combination of series and parallel processes [194]. Recently, a cascaded linear system model for calculating the DQE(f) of a direct conversion x-ray detector has been developed that incorporates the effects of both charge carrier trapping and the reabsorption of K-fluorescent x-rays [182]. In the latter work, the authors have examined various effects on DQE(f) and also verified their model by fitting with the experimental results on a-Se and HgI_2 detectors. The K-fluorescence phenomenon has a significant effect on DQE(f) performance if the average incident x-ray photon energy is relatively close to the K-edge of the detector material [182]. If the average incident x-ray photon energy is far from the K-edge of the detector material, one can use a relatively simpler model for calculating DQE(f) as described in [179].

The linear system model for the calculation of DQE(f) of a photoconductive detector consists of eight stages: (1) x-ray attenuation, (2) scattering of x-ray photons before EHP creation, (3) generation of charge carriers (conversion gain), (4) charge collection, (5) blurring due to charge carrier trapping, (6) aperture blurring, (7) noise aliasing, and (8) addition of electronic noise. The flowchart shown in Fig. 20.15 illustrates these eight separate stages and the signal and noise in different stages. Each of these stages can be categorized as one of the following five processes: (i) stochastic gain, (ii) stochastic blurring, (iii) deterministic blurring, (iv) aliasing, and (v) addition. The first, third, and fourth stages in Fig. 20.15 are considered as the stochastic gain stage. The stochastic gain enhances the noise associated with the quanta in two ways: first, the quantum noise is itself amplified, and second, noise associated with the stochastic nature of the amplifying mechanism is introduced into the output. The second and fifth stages are the stochastic blurring stages. Stochastic blurring is caused by random scattering of quanta in a distribution. That is, each quantum is randomly relocated to a new location with a certain probability. The integration of signal onto individual pixels in a digital detector is the deterministic blurring stage (sixth stage). The details of the signal and noise propagation through various stages are described in [179]. This cascaded linear system model has been applied to a number of different photoconductive detectors [180, 195, 196].

High conversion gain and high charge collection efficiency are required to improve the DQE performance of an x-ray image detector. The conversion gain Eq. (20.12) depends on W_i, which is a material property of the photoconductor. The charge collection efficiency can be improved by increasing F and improving the $\mu\tau$ products of the carriers. However, increasing F also increases the dark current dramatically, and thus, there is a practical limitation on F. DQE improves dramatically by reducing electronic noise (Sect. 20.4.3) in low-dose imaging applications [191].

20.7 Pixelated Detectors and Small Pixel Effect

The basic structure of a pixelated detector is shown in Fig. 20.13a where, as apparent, the rear electrode is pixelated with a pixel size of a. *Small pixel effect* is the phenomenon in semiconductor pixelated detectors in which the collected charge mainly depends on the motion of the charge carriers that move toward the pixel electrodes. Stated differently, the motion of charge carriers close to the pixel electrodes (near-field region) can produce almost full signal (collected charge) strength in the external circuit, and the motion of charge carriers outside this region induces very little signal. The reason is that the induced charge on a particular pixel electrode by a moving charge is very small when the charge is far away (the distance to the pixel is much greater than the pixel dimension) due to charge sharing among many pixel electrodes and increases rapidly when the charge is in the vicinity of this pixel. As a result, the change in induced charges in pixel electrodes due to the carrier motion through the near-field region is much higher than their motion in the outside of the near-field region (this change in induced charge produces electric current in the external circuit, and the integration of this current is the collected charge).

The Shockley-Ramo theorem [1, 2, 197] provides a convenient way to calculate the induced current flowing through an electrode of multielectrode detectors (e.g., pixelated image detector) due to the motion of charge carriers in the detector. The shape of the weighting potential across the photoconductor thickness determines the relative contribution of the induced signal strength for carrier movement across different segments of the photoconductor thickness. Analytical expression for the weighting potential of pixelated detectors having a square pixel can be found in [198] where the effects of small pixels on x-ray sensitivity of pixelated detectors have been considered. Figure 20.16a, b shows the individual carrier contributions to the normalized sensitivity (S_t and S_b) versus normalized pixel width (a/L) for various levels of trapping ($x_t = \mu_t \tau_t F/L$ and $x_b = \mu_b \tau_b F/L$). The subscripts t and b represent the carrier type that drifts toward the top and bottom electrodes, respectively. The quantum efficiency (Eq. 20.10) is $\eta_Q = 0.90$ and thus $\Delta = 0.4343$. The normalized sensitivity is the product of the charge collection efficiency and the quantum efficiency. That means, the normalized sensitivity represents the charge collection and absorption-limited detector sensitivity. S_t and S_b are the individual carrier contributions to the normalized sensitivity due to the carrier drifts toward the top and the bottom electrodes, respectively, and the resultant total sensitivity is simply $S_t + S_b$. The maximum total normalized sensitivity is equal to the quantum efficiency when both carrier lifetimes are infinity. S_t decreases with decreasing normalized pixel width. A very small fraction of carriers moves through the near-field region for the carriers that move toward the top electrode. Therefore, the induced signals due to the carrier drift toward the top electrode decrease with decreasing normalized pixel width and so does S_t. The sensitivity obviously decreases with increasing amounts of trapping as evident in Fig. 20.16a. Without carrier trapping and for small pixels, all the carriers that drift toward the bottom electrode pass through the near-field region. Therefore, the relative fraction of the total normalized sensitivity, S_b, contributed by the charges that drift toward the bottom electrode increases with decreasing pixel width, and the other type of carrier contribution becomes less important. Notice that S_b increases with decreasing pixel width for weak trapping but it decreases with decreasing pixel width under heavy trapping. The carrier generation profile is exponential across the photoconductor thickness. Most of the carriers become trapped before reaching the near-field region under heavy trapping for very small pixel detectors. Thus, S_b for very small pixel detectors is also small under heavy trapping. The extent of near-field region decreases with decreasing normalized pixel width. Therefore, this effect is more pronounced in detectors with pixel dimensions that are small compared with the detector thickness.

Since the charge collection efficiency of pixelated detectors mainly depends on the transport properties (mobility and lifetime) of the charges that move toward the pixel electrodes, the effects of poor transport properties of other type of carriers can be eliminated by having smaller pixels. Some of the potential photoconductors (e.g., a-Se, CdZnTe and HgI_2) for x-ray image detectors have asymmetric transport properties (mobility-lifetime products) for electrons and holes. Therefore, the charge collection efficiency of pixelated detectors can be improved by ensuring that the carrier (electron or hole) with the higher mobility-lifetime product is drifted toward the pixel electrodes.

20.8 Image Lag and Ghosting

The detectors should be free of image lag and ghosting effects. When the photoconductor is exposed to x-rays, a transient photocurrent starts to flow that reaches almost a steady value at the carrier transit time [199]. Ideally, the current should be present as long as the detector is subjected to x-ray exposure, and once the radiation is stopped, it should diminish to zero. In reality, some of the drifting carriers are trapped at various levels of defect states within the bandgap of the photoconductor layer, and these trapped carriers are released later. The release time from a trap depends on the energy depth of the trap from the transport band edge and hence can lead to significant lag [200]. As a result, in some detectors, a transient decaying current can be detected for several hundreds or thousands of seconds after the cessation

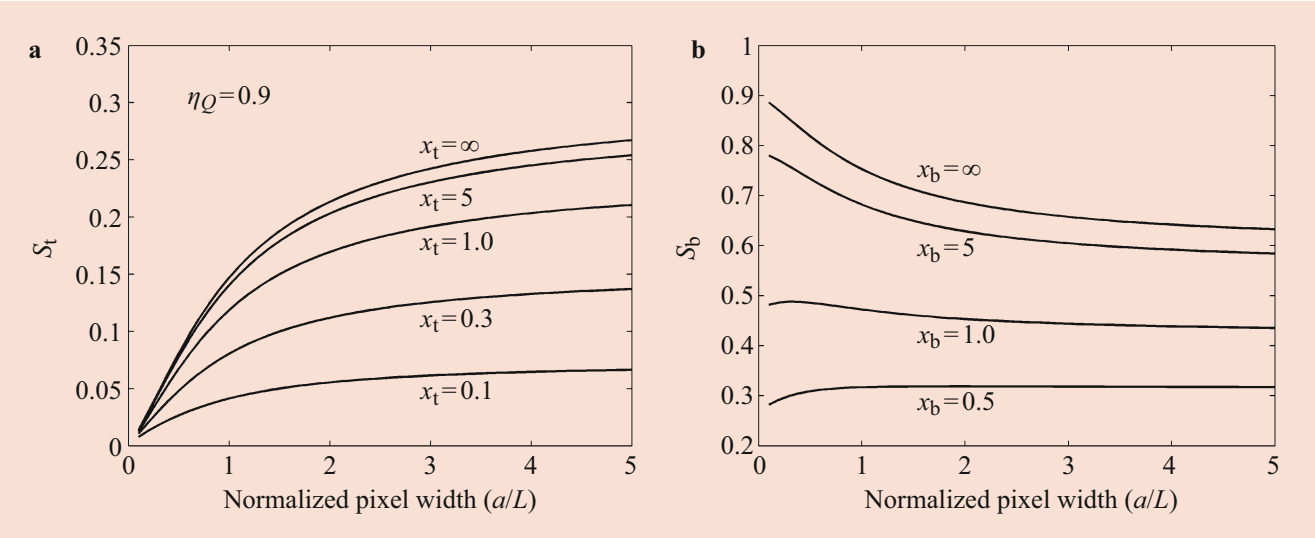

Fig. 20.16 (**a**) Normalized sensitivity due to transport of the carriers that drift toward the top electrode, S_t, versus normalized pixel width for various levels of carrier trapping. (**b**) Normalized sensitivity due to transport of the carriers that drift toward the bottom electrode, S_b, versus normalized pixel width for various levels of carrier trapping. The normalized absorption depth is $\Delta = 0.4343$. Normalized pixel width is a/L

of the excitation. This is known as the residual current or the lag signal and has been modeled for a-Se detectors in [199]. For most applications, this is an undesirable phenomenon because when part of the current from a previous exposure combines with the next one, the resulting image can be inaccurate, particularly when images are acquired in a fast sequence, e.g., in fluoroscopy. The image lag signal has been measured in most of the potential photoconductive detectors. The amount of image lag signal in a-Se detectors has been found to be negligible, whereas it is quite significant in some of other polycrystalline detectors [201].

The x-ray exposure can change the x-ray sensitivity of the exposed area and thus lead to a shadow impression of a previously acquired image which becomes visible in subsequent uniform exposure, which leads to what is called "ghosting" [202]. Ghosting can severely affect the diagnostic value of x-ray images. The causes of change in x-ray sensitivity and resolution and their recovery mechanisms in a-Se detectors have been systematically investigated in the last decade [203, 204]. Although the relative amounts of changes in sensitivity and resolution, arising from repeated exposure in commercial a-Se detectors, are below the tolerance level, they are due to the following probable mechanisms: (i) recombination of drifting carriers with oppositely charged trapped carriers [200], (ii) creation of x-ray-induced metastable trap centers [205, 206], and/or (iii) reduction of the free carrier generation due to space charge (i.e., due to a nonuniform electric field) [200, 204]. It is expected that the ghosting phenomenon may also be present in other photoconductive (e.g., HgI_2, CZT, PbO, and PbI_2) detectors, although a very limited number of reports are available in literatures [207, 208].

Ackowledgment The authors thank the Natural Sciences and Engineering Research Council (NSERC) for the financial support for their x-ray detector work. One of the authors (SK) thanks Analogic Canada (formerly Anrad Corporation) for the continued support of his x-ray photoconductor research.

Safa Kasap is a Distinguished Professor of Optoelectronic Materials and Devices at the University of Saskatchewan in Canada. His research area is on photoconductive detectors. He is the Editor-in-Chief of Springer's *Journal of Materials Science: Materials in Electronics* and a Fellow of IEEE, APS, OSA, and the Royal Society of Canada. He is the author of two textbooks: *Principles of Electronic Materials and Devices* (4Ed) and *Optoelectronics and Photonics: Principles and Practices* (2Ed).

Zahangir Kabir is a Professor in the Electrical and Computer Engineering Department at Concordia University, Montreal, Canada. His research interests include charge carrier transport mechanisms and phenomena in semiconductor materials and devices with applications to optical and x-ray detectors, field effect transistors, lasers, graphene, CNTs, and solar cells. He has authored and co-authored more than 50 refereed journal papers.

Photodetectors Based on Emerging Materials

21

Jiantong Li and Mikael Östling

Contents

21.1 Background of Graphene-Based Photodetectors 778

21.2 Performance Metrics of Photodetectors 778
21.2.1 Responsivity (R_{ph}) 778
21.2.2 Quantum Efficiency 779
21.2.3 Noise Equivalent Power (NEP) 779
21.2.4 Detectivity (D^*) 779
21.2.5 Linear Dynamic Range (LDR) 779
21.2.6 Response Speed 779
21.2.7 Photoconductive Gain (G_{ph}) 779

21.3 Physical Mechanisms for Photodetection 780
21.3.1 Photovoltaic Effect 780
21.3.2 Photothermoelectric Effect 780
21.3.3 Bolometric Effect 781
21.3.4 Plasma-Wave-Assisted Mechanism 781
21.3.5 Photogating Effect 781

21.4 Practical Realization of Graphene Photodetectors 781
21.4.1 Metal-Graphene-Metal (MGM) Photodetectors (PV and PTE Effects) 781
21.4.2 Graphene-Based Bolometers 782
21.4.3 Plasmonics-Enhanced Graphene Photodetectors 783

Abstract

Photodetectors that convert light into electrical signals have become an indispensable element for a large number of technologies to enable extensive applications, ranging from optical communications to advanced imaging and motion detection, to automotive industry particularly including self-driving cars, and to astronomy and space exploration under harsh environment. The present photodetector market is predominated by silicon (CMOS-based) photodetectors. With the continuous growth of application areas, highly desired are photodetectors of higher performance in terms of speed, efficiency, detectable wavelength range, and integrability with semiconductor technology. These necessitate the development of new photodetectors based on special materials, rather than the conventional silicon single crystals, as building blocks for various advanced photodetection platforms. To this end, we summarize in this chapter the recent status of advanced photodetectors based on the emerging material, graphene. Our discussion includes the performance metrics, working mechanisms, practical implementation, as well as opportunities and challenges, for graphene-based photodetectors.

21.1 Background of Graphene-Based Photodetectors

Photodetection is becoming more and more important in a wide range of applications, including the ubiquitous visible light cameras and video imaging, medical X-ray and near-infrared (NIR) imaging, night-vision and shortwave infrared (SWIR) surveillance, motion detection, machine vision, gas sensing, optical communications, and so on [1–3]. It primarily makes use of semiconductors to transduce photons of different energies (determined by the bandgap of the semiconductors) into electrical signals for subsequent signal processing and applications. Up to date, the predominant materials for photodetectors in modern electronics and optoelectronics are still crystalline silicon, thanks to the high performance, low cost, manufacturing maturity, and high-level integration with CMOS electronics [4]. Over the past decade, amazing progress has been made in implementing a wide variety of optical and electro-optical devices in silicon, including laser sources, modulators, detectors, waveguides, and filters [5]. With the integration of CMOS technology, large-scale arrays of photodiodes and phototransistors have been developed for fabricating multifunctional image sensors. The applicability is, however, strongly limited by the property of silicon. For example, for applications in the infrared (IR) spectrum which is below the energy bandgap of silicon, photodetectors based on non-silicon materials become necessary. With the rapid development of emerging applications, such as self-driving cars, authentication systems, augmented and virtual reality, and point-of-need health care [3], a new and important demand has arrived for advanced photodetectors based on special materials that possess ultrafast conversion, high-frequency communications, significantly wider detectable spectrum, and readily tunable bandgaps.

During the past decade, graphene and other 2D materials have received great interest in a large variety of research fields. These materials possess a combination of many exceptional properties, such as adjustable energy bandgap, direct bandgap of many monolayer 2D materials, easy stacking of different 2D materials for vertical heterojunctions by van der Waals force, scalable synthesis process and compatibility with traditional microfabrication technique, as well as being ultrathin and flexible. All these properties make them potentially extremely interesting in photodetector applications [4, 6]. Among them, graphene is the most famous and appealing material for the development of photodetectors. First, its zero bandgap enables charge carrier generation by light absorption over a very wide energy spectrum, ranging from ultraviolet (UV) to visible to IR to terahertz (THz) spectral regimes with a constant absorbance of ~2.3% per layer [7]. Second, its high carrier mobility allows to convert rapidly photons or plasmons to electrical currents or voltages [8, 9]. Third, the chemically passivated graphene surface greatly diminishes the influence of substrates and offers opportunities for integrated photonic devices on arbitrary substrates. Last, the strong quantum confinement resulting from the ultrathin 2D structure leads to many intriguing physical properties distinct from that of bulk materials [10]. For example, as a 2D material, its conductance is very sensitive to electrostatic perturbation by photogenerated carriers close to the surface [1], which is a desired property for high-gain photodetection.

Therefore, graphene can provide advanced or complementary techniques to silicon-based photodetectors. This chapter overviews the recent research progress of graphene-based photodetectors. We first summarize the performance metrics and basic physical mechanisms of photodetectors, then introduce the latest experimental realization of various photodetectors based on graphene, and finally discuss about the current challenges and outlook the future research directions.

21.2 Performance Metrics of Photodetectors

Typical figures of merit (FOMs) used to evaluate the performance of a photodetector include responsivity, detectivity, quantum efficiency, noise equivalent power (NEP), and response speed [1, 10]. Below is the introduction of these key metrics.

21.2.1 Responsivity (R_{ph})

Responsivity indicates the electrical output of a photodetector responding to an optical signal and is one of the most important characteristics for a photodetector. It is defined as the ratio of the photocurrent I_{ph} to the incident light power P_{in}, as

$$R_{ph} = I_{ph}/P_{in}; \tag{21.1}$$

or as the ratio of photovoltage V_{pc} to P_{in} as

$$R_{ph} = V_{pc}/P_{in}. \tag{21.2}$$

R_{ph} is often given in units of A/W. For a typical single-layer graphene (SLG) photodetector, responsivity is at the level of a few mA/W [10]. Also, responsivity is proportional to external quantum efficiency (EQE, the conversion rate from photons to electrons/holes) as

$$R_{ph} = \mathrm{EQE} \times \lambda q/hc, \tag{21.3}$$

where λ is the incident light wavelength, q is the absolute value of electron charges, h is the Planck constant, and

c is the light speed, and hence, the responsivity depends on the wavelength. For broadband photodetection, constant responsivity across a large spectral range is preferred, while single-color detectors need a sharp peak in a narrow range. In practice, power independent responsivity is also desirable in systems that respond linearly to optical input [10].

21.2.2 Quantum Efficiency

The external quantum efficiency (EQE) is the ratio between the number of electron-hole (e-h) pairs per second collected to produce the photocurrent I_{ph} and the number of incident photons per second, as

$$\mathrm{EQE} = \left(I_{ph}/q\right) / \left(P_{in}/E_{ph}\right), \tag{21.4}$$

where E_{ph} is the incident photo energy. Similarly, internal quantum efficiency (IQE) is the ratio between the e-h number and the number of absorbed photons, as

$$\mathrm{IQE} = \left(I_{ph}/q\right) / \left(A_{abs}P_{in}/E_{ph}\right), \tag{21.5}$$

where A_{abs} is the absorbed fraction.

21.2.3 Noise Equivalent Power (NEP)

The noise equivalent power (NEP) is the minimum measurable power [11] or the signal power for a given bandwidth when the signal-to-noise ratio is unity [1]. It is calculated as

$$\mathrm{NEP} = P_{in}/\sqrt{B} = i_n/R_{ph}, \tag{21.6}$$

where B is frequency bandwidth of the photodetector and i_n is the noise current. NEP is thereby in units of W $\mathrm{Hz}^{-1/2}$.

21.2.4 Detectivity (D^*)

The specific detectivity is another typical FOM used to characterize photodetector performance. It is the minimum detectable level of light and is calculated as

$$D^* = \sqrt{A \cdot B}/\mathrm{NEP} = \sqrt{A \cdot B}\, R_{ph}/i_n, \tag{21.7}$$

where A is the area of the photosensitive region. D^* is in units of Jones with 1 Jones = 1 cm $\mathrm{Hz}^{1/2}$ W^{-1}, in recognition of the work of R. C. Jones on sensitivity of radiation sensors [1].

21.2.5 Linear Dynamic Range (LDR)

The linear dynamic range (LDR) is the illumination intensity range within which the current response of a photodetector scales linearly with the light intensity [12] and is given by

$$\mathrm{LDR} = 20 \log \left(J_{ph}/J_d\right), \tag{21.8}$$

where J_{ph} is the photocurrent density measured at a light intensity of 1 $\mathrm{mW/cm}^2$ and J_d is the dark current density. In practice, a large LDR is desired so that a photodetector can detect both high- and low-intensity lights.

21.2.6 Response Speed

Response speed characterizes the capability of a photodetector to detect a signal at a certain rate [10]. In the frequency domain, speed is defined by the frequency at which responsivity is reduced to 50% of its maximum value. In the time domain, response time is used to characterize the response speed and defined as the time required for a transient output signal to reach 0.707 of its steady-state change upon a sudden change of the incident light. For some systems, the response time may be asymmetric between light switch ON and OFF. Then the response speed is characterized by the rise and fall times at 10% and 90% of the maximum photocurrent, respectively [12]. Fast operation (up to tens of GHz) is extremely important for telecommunication and interconnection, but for other applications such as sensing and imaging, only moderate speed (a few kHz) is required [10].

21.2.7 Photoconductive Gain (G_{ph})

Photodetectors are commonly benchmarked by their photoconductive gain , the number of carriers detected for each single incident photon. It can be quantified by the ratio of the lifetime (τ_{trap}) of the trapped carriers to the drift transit time ($\tau_{transit}$), as

$$G_{ph} = \frac{\tau_{trap}}{\tau_{transit}}, \text{ with } \tau_{transit} = L^2/\mu V_{bias} \tag{21.9}$$

where L is the source-drain separation distance (channel length), μ is the carrier mobility, and V_{bias} is the bias voltage.

It is worth mentioning that in many cases, trade-offs have to be made between different FOMs [10]. For instance, responsivity can be effectively increased through integration with extra light absorbers, but often the response speed is sacrificed. More relevant discussion is included in the following sections.

21.3 Physical Mechanisms for Photodetection

Several different mechanisms have been realized in graphene and 2D materials-based photodetection and other optoelectronic applications, including the photovoltaic effect, the photo-thermoelectric effect, the bolometric effect, the photogating effect, and the plasma-wave-assisted mechanism, as summarized in Fig. 21.1 and detailed below.

21.3.1 Photovoltaic Effect

Photovoltaic (PV) current is generated through separating photon-induced electron-hole (e-h) pairs either by built-in electric fields at a p-n junction or a metal-semiconductor Schottky junction [13, 14] (Fig. 21.1a) or by the external electric field under an applied bias voltage. As graphene is a semimetal, external electric field is not favored due to the very high dark current and power consumption. The built-in field can be created by several techniques, including local chemical doping [15], splitting gates [13, 16], or inherent work function difference between graphene and a contacting metal [17]. In a splitting gate structure, the doping can be tuned to be either p- or n-type, depending on the applied gate voltages. In graphene-metal junctions, the doping is fixed, typically as p-type for metals that have higher work function than graphene (4.45 eV). The electric field is the only factor to determine the photocurrent. Thus, photocurrents switch sign when going from p-n junction to n-p junction or from p-p^+ junction to p^+-p junction [1].

A special phenomenon for graphene is the carrier multiplication (Auger-type) impact ionization [10] where the strong carrier-carrier scattering, owing to the zero bandgap, leads to the conversion of one high-energy electron-hole pair into multiple electron-hole pairs of lower energy [18–20], which potentially enhances the overall photodetection efficiency. This process fundamentally differs from the impact ionization in traditional semiconductors where a sufficiently large electric field increases the kinetic energy of a carrier which then loses energy to create other low-energy carriers, resulting in avalanche breakdown [10].

21.3.2 Photothermoelectric Effect

The photothermoelectric (PTE) effect refers to the conversion of light-induced temperature gradient to an electric voltage. Due to the large thermal conductivity of graphene, the PTE effect generated by lattice heating is not significant. In contrast, significant photovoltage can be produced by photogenerated hot electrons. Due to the strong electron-electron interactions, photo-excited electron-hole pairs lead to ultrafast (~10–50 fs) heating of the carriers in graphene [21–23]. Because of the large optical phonon energy in graphene (~200 meV), the carriers can remain at a temperature much higher than the lattice temperature for a few picoseconds. The final thermal equilibration between the hot electrons and the lattice needs a nanosecond timescale due to the slower scattering between charge carriers and acoustic phonons [24, 25]. As a result, the temperature difference between hot carriers (e.g., in two graphene regions with different doping, Fig. 21.1b) can produce a photovoltage, $V_{PTE} = (S_1 - S_2)\Delta T_e$, where $S_{1,2}$ (in V K^{-1}) is the thermoelectric power (Seebeck coefficient) in the two different graphene regions and ΔT_e is the electron temperature difference between the regions. Photoresponse generated by hot carriers rather than lattice heat-

ing can achieve wide bandwidths, like in the case of PV photodetectors. The PTE effect typically dominates in graphene p-n junctions [16, 26] or in suspended graphene [27].

21.3.3 Bolometric Effect

The bolometric effect refers to the change in the transport conductance caused by light heating (Fig. 21.1c). Because this photodetection relies on light-induced conductance change, instead of direct photocurrent generation, it requires an externally applied bias and can operate on homogeneous graphene (no p-n junction is needed). The conductance change may result from the temperature-dependent carrier mobility and/or the change of carrier density.

21.3.4 Plasma-Wave-Assisted Mechanism

In a field-effect transistor (FET), when exposed to an oscillating radiation field (Fig. 21.1d), a finite dc voltage may be generated. Based on this rectification, Dyakonov and Shur [28, 29] proposed a photodetection scheme. The 2D electron gas hosted in an FET can act as a cavity for plasma waves (collective density oscillations) [1]. For weakly damped plasma waves (the transport time of a plasma wave from the source to the drain is shorter than the momentum relaxation time), their constructive interference can be used to detect the radiation with a resonantly enhanced response. This is the so-called resonant regime of plasma-wave photodetection and can produce a signal 5–20 times stronger than the broadband nonresonant signal in the case of overdamped plasma waves (plasma waves launched at the source decay before reaching the drain) [29]. Dyakonov and Shur [29] showed that even if the incoming field is ac, the photovoltage response of a 2D electron system in a FET still contains a dc component, which provides rectification of the signal. This is particularly useful for the detection of THz radiation. Detection of THz radiation in graphene FETs has been theoretically discussed [30] and experimentally demonstrated [31, 32].

21.3.5 Photogating Effect

The photogating effect is based on light-induced modification of the graphene carrier density and hence its conductance [1]. Typically, one type of photogenerated carrier is captured by the trap centers or transferred from external source, both of which result in change of carrier density. Therefore, the photoconductive gain, G_{ph}, can be strongly enhanced by using a high-mobility conductor, such as graphene, and by a long lifetime. Also responsivity based on the photogating effect can be very large, up to millions of A/W because photo-induced carriers can move several times through the channel before recombination, providing a significant optical gain [10]. In contrast, responsivity in the PTE and bolometric regimes is limited to less than a few mA/W. However, longer photocarrier lifetime reduces the operation speed. And the photoconductive detectors may exhibit high dark current, which influences the noise equivalent power and detectivity.

21.4 Practical Realization of Graphene Photodetectors

In practice, a large variety of graphene photodetectors have been developed based on different mechanisms, heterogeneous junctions with other materials, and advanced architectures. This section summarizes the representative implementations of these photodetectors.

21.4.1 Metal-Graphene-Metal (MGM) Photodetectors (PV and PTE Effects)

The MGM photodetectors (Fig. 21.2) were the first and simplest class of graphene-based photodetectors to be investigated. In early reports [9, 33–35], photocurrent was generated through the PV effects by local illumination of one of the metal/graphene interfaces of a back-gated graphene FET. The field arising from charge transfer from the contact metal to graphene [36, 37] can thus be adjusted by choosing the proper metal [34, 38]. Besides the PV effect, the PTE effect may also dominate the photoresponse in the vicinity of p-n junctions or interfaces of SLG and bilayer graphene (BLG) [26, 27, 39]. The PTE effect can be distinguished from the PV effect according to the sign of the photocurrent. Different from the PV current, the PTE current reverses the direction in bipolar p-n junctions and also unipolar p^+-p or n-n^- junctions [26], due to the change of transconductance upon transport between different doping region transports. The relative contributions of the PTE and PV effects to the photocurrent can be controlled through adjusting the wavelength. At longer wavelengths, the PV effects become pronounced.

Because the photocurrent is only generated in the vicinity of metal/graphene interface region, interdigitated finger structures (Fig. 21.2b) with asymmetric electrode metals are often used to increase the effective photodetection area [9] and suppress the dark current. Thanks to the high carrier mobility and short carrier lifetime in graphene, MGM photodetectors can operate at high data rates. In single metal-graphene junctions, it has been demonstrated that photoresponse does not degrade at a modulation frequency of 40 GHz [8] and all-optical measurement gave an intrinsic bandwidth of 262 GHz. It is worthy of mentioning that

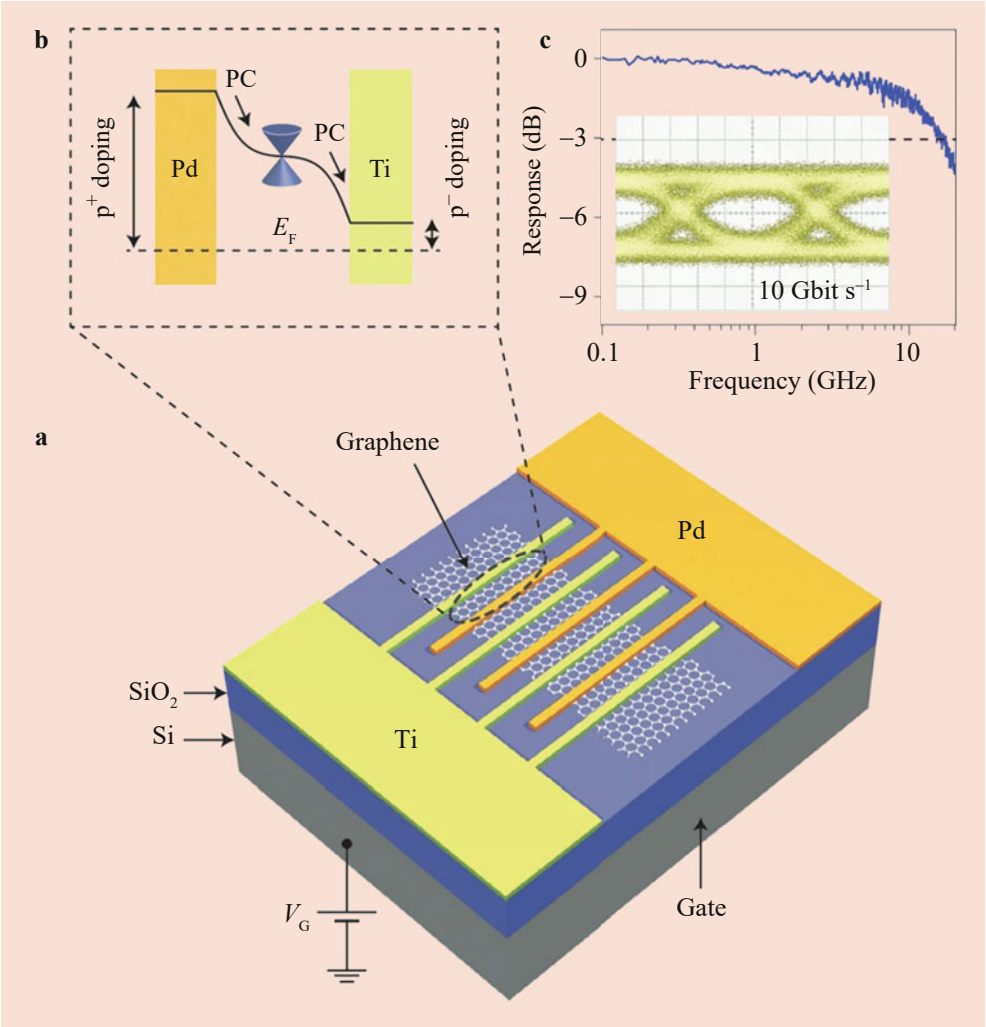

Fig. 21.2 A typical metal-graphene-metal photodetector with asymmetric contacts: (**a**) Three-dimensional schematic. (**b**) Energy band and profile, where the arrows and Dirac cone indicate the electron flow and the charge neutrality point, respectively. PC stands for photocurrent. (**c**) High-frequency response. both PV and PTE effects are compatible with the high bandwidths owing to the decoupling of electron and lattice temperature [1].

21.4.2 Graphene-Based Bolometers

Bolometric responses have been observed at room temperature when SLG is biased [17, 40]. The dominant factor for the conductance change (either photo-induced excess carriers or temperature-dependent mobility) can be controlled through adjusting Fermi level (E_F) of graphene [17]. However, the weak temperature dependence of the electrical resistance in graphene [41] makes it difficult to extract the temperature difference through electrical transport measurements, resulting in a small responsivity at the level of 0.2 mA/W [17]. To solve this problem, several strategies have been demonstrated, such as introducing disorder [42], patterning nanostructures [43], and opening a bandgap in bilayer graphene [40]. As shown in Fig. 21.3a, an extra optically transparent top gate was applied to a dual-gated bilayer graphene device (Fig. 21.3a) to open a bandgap at the Dirac point [44, 45] and obtain electron temperature (T_e)-dependent resistance [44] to generate bolometric photoresponse [40]. The devices attain a high voltage of 2×10^5 V W^{-1} and a very low NEP of 33 fW Hz$^{-1/2}$ at 5 K as compared with commercial silicon bolometers (200–2000 fW Hz$^{-1/2}$). Their intrinsic speed exceeds 1 GHz at 10 K, three to four orders of magnitudes higher than commercial silicon bolometers and superconducting transition-edge sensors at similar temperatures. In addition, a graphene-superconductor tunnel junction bolometer (Fig. 21.3b) has also been demonstrated at radio-frequency regions [46], which should also apply for optical detection [1].

(**b**) Device structure of an SLG-aluminum tunnel junction bolometer [46]. (Reproduced with permission from [1] Copyright (2014) Springer Nature)

21.4.3 Plasmonics-Enhanced Graphene Photodetectors

The excitation of surface plasmons is an effective method to increase the photoresponse of graphene photodetectors. Localized plasmons in metal nanostructures were first used along with graphene to obtain surface-enhanced carrier density (Fig. 21.4a, b) [48] and Raman scattering [50] and to enhance strong fields in subnanometer gaps [51]. The introduction of plasmonic nanostructures near the contacts [49] of graphene-based photodetectors (Fig. 21.4c–e) has also been demonstrated to significantly improve the device performance (Fig. 21.4e). In addition, nanostructures with geometries resonant at desired wavelengths offer opportunities for selective amplification, potentially allowing light filtering and detection, as well as polarization determination in a single device [52]. As compared with traditional devices, the plasmonic structures greatly improve the frequency performance because their contribution to the capacitance (fractions of femtofarads) is negligible, whereas they can significantly reduce the contact resistance.

Besides, field enhancement by plasmons can also improve photodetection performance due to the intrinsic collective charge oscillations of the 2D electron liquid inside graphene (Fig. 21.4f, g). The high carrier mobility and 2D character of graphene greatly enhance its light absorption [53], which provides an ideal solution to make use of graphene as both photodetector and plasmonic enhancers. As is shown in Fig. 21.4e, graphene nanoribbon arrays on SiO_2 with different widths have been demonstrated as room-temperature tunable IR photodetectors with a performance improvement by 1500% [47].

21.4.4 Detectors Based on Photogating

A gain mechanism that provides multiple electrical carriers per single incident photon is crucial for photon detection at very low intensities, even approaching the single-photon level [1]. This can be achieved by effectively absorbing light with appropriate sensitizing centers and then transferring the carriers into the conductor (photogating effect, Fig. 21.5a) [54, 55]. It often results in a shift in the typical resistance versus gate-voltage curve, as shown in Fig. 21.5b. Graphene is excellent for room-temperature high-gain photodetection because of its high mobility (thus short carrier transit time) and its strong conductance dependence on the electrostatic perturbation by photogenerated carriers close to the surface. As a good example, colloidal quantum dots, such as PbS [54] (Fig. 21.5), CdS, or ZnO [56], are widely used to sensitize graphene. They have strong light absorption and bandgap tunability and can cover the absorption range from ultraviolet to SWIR [57]. Graphene decorated with PbS quantum dots can exhibit a high gain of 10^8 corresponding to $R_{ph} \sim 10^7$ A/W (at room temperature) for low light intensities

$\sim 10^{-14}$ W [54]. Given the high QE (>25%), specific detectivity of 7×10^{13} Jones, video imaging speed ~30–60 Hz, and low NEP $\sim 10^{-17}$ W (at the noise floor of 0.1 Ω $Hz^{-1/2}$), this hybrid system is a promising platform for visible and SWIR applications [1].

21.5 Graphene-Based Heterostructures for Photodetectors

Although graphene-based optoelectronic devices are being extensively studied and some have already reached a competitiveness level comparable to conventional semiconductor devices [1, 58], several intrinsic drawbacks of graphene still limit the applicability, including low light absorbance (only 2.3%) of SLG and short light-matter interaction length causing ineffective light harvesting, ultrashort lifetime of excitons in pure graphene leading to fast carrier recombination, and low sensitivity of graphene-based detectors. To essentially address these drawbacks, various graphene-based heterostructures have been developed for photodetector applications to improve the performance [1, 12]. Here, we summarize these heterogeneous structures with different materials.

21.5.1 Graphene/Silicon

Graphene/silicon Schottky junctions are among the most studied devices for graphene heterojunction photodetectors where silicon absorbs light and graphene acts as an optically transparent charge carrier collector. The zero-gap and semimetallic properties of graphene are very promising for the wideband photodetection from microwave to UV regimes. The heterojunctions significantly increase the speed of carrier separation due to the built-in electric field, while the photocarrier lifetime is not reduced evidently under 1550 nm illumination [61]. As a result, an IQE of 10% was obtained for graphene/Si junctions in contrast to an IQE ~1% in regular Schottky junctions. The device performance can be further improved through introducing metal nanoparticles (such as Pt nanoparticles) [62] or an extra MoO_3 layer [63] for surface doping. To reduce the leakage current in the graphene/Si Schottky junctions, a thin interface layer of SiO_2 can be employed [64]. In particular, through the scanning photocurrent measurement technique, Riazimehr et al. [59] find that higher photocurrent (corresponding to a responsivity about 0.3 A/W) is generated in the graphene/SiO_2/Si region as compared to the graphene/Si region (responsivity about 50 mA/W) at reverse biases above a threshold voltage (Fig. 21.6a, b). This behavior is independent of excitation

laser power and could be ascribed to the formation of an inversion layer in the Si layer under the graphene/SiO_2 junction. Furthermore, when the graphene/SiO_2/Si region is patterned in interdigitated structure (Fig. 21.6c) [60], a high EQE of >80% is achieved for wavelengths ranging from 380 to 930 nm with the maximum EQE of 98% at 850 nm, where the responsivity also peaks to 635 mA/W (Fig. 21.6d).

The performance improvement can also rely on porous Si and Si NWs. As shown in Fig. 21.7a–c, the graphene/porous Si Schottky diodes have achieved an excellent performance of responsivity up to about 0.3 A/W, as well as 60% EQE and 3 μs response time [65]. Alternatively, the NIR photodetectors based on a graphene/silicon nanowire array decorated with Au nanoparticles (Fig. 21.7d) [66] exhibit high performance of 10^6 light-to-dark current ratio (Fig. 21.7e) and high response speed (rise/fall time of 73/96 μs, Fig. 21.7f), possibly resulting from the enhanced optical absorption due to the strong optical trapping effect of silicon nanowire arrays and the surface plasmon coupling by Au nanoparticles.

21.5.2 Graphene/III–V Semiconductors

Heterojunctions between graphene and III–V semiconductors have also been used for photodetectors. GaN and GaAs are direct bandgap semiconductors with excellent optical/-electrical properties for various photodetection applications. Graphene/GaN Schottky diode [69] has shown high light-to-dark current ratio (10^5) under UV illumination. In addition, graphene/GaN nanowire array (Fig. 21.8a–c [67]) shows extremely high responsivity of 25 A/W at 357 nm, validating the promising application of graphene/GaN junctions in the UV region. On the other hand, graphene/GaAs Schottky

junctions are promising for NIR light detection [68]. As shown in Fig. 21.8d–f, graphene/GaAs nanocone arrays exhibit reproducible photodetector performance of 10^4 light-to-dark current ratio, 1.73 mA/W responsivity, and fast response speed with rise/fall times of 72/122 μs. Recently [70], using a thin layer of AlO_x as a surface protective layer to suppress carrier recombination and a barrier to reduce dark current, the performance of graphene/GaAs NIR photodetectors can be further improved, with the responsivity increased to 5 mA/W and rise/fall times decreased to 320/380 ns.

21.5.3 Graphene/Organic Semiconductors

Thanks to their simple solution processability at low temperatures [71], flexibility, low cost, and lightweight, organic semiconductors have attracted great interest in forming heterojunctions with graphene for photodetector applications. As shown in Fig. 21.9, a graphene/pentacene heterostructure can be fabricated on flexible substrates to serve as a multifunctional photodetection with nonvolatile memory function for storing optical signals [72]. The device exhibits excel-

lent performance at 400–800 nm with maximum responsivity and specific detectivity of 700 A/W and of 10^{13} Jones (Fig. 21.9c), respectively. It can also retain the photocurrent for a long time exceeding 10^4 s (Fig. 21.9d). The photocurrent remains invariant for more than 200 cycles and increases with the illumination power (Fig. 21.9e).

In addition, monolayer organic C8-BTBT crystals can also be integrated on graphene by van der Waals epitaxy [73] to obtain high-performance photodetectors with the responsivity larger than 10^4 A/W. By using multilayer C8-BTBT, the responsivity can be further increased to 4.76×10^5 A/W. The excellent performance may be attributed to the ultrahigh photoconductive gain and the high interfacial charge transfer efficiency due to the high quality of C8-BTBT layer and graphene/C8-BTBT interface [12]. However, the multilayer photodetection has much longer response time (~830 ms) than the monolayer device (~25 ms), probably due to the interlayer hopping of trapped carriers within the C8-BTBT crystals.

21.5.4 Graphene/Perovskites

Organic-inorganic halide perovskite materials are widely used in solar energy applications and recently have been envisioned as excellent candidate for next-generation photodetector materials because of their high adsorption coefficient, tunable bandgap, small exciton binding energy, long carrier diffusion length, ambipolar charge transport, and high carrier mobility [12]. It has been demonstrated that graphene/perovskites, such as graphene/$CH_3NH_3PbI_3$ ($MAPbI_3$) hybrid, can achieve a responsivity of several hundreds of A/W at a response time shorter than 1 s [74, 75] (Fig. 21.10). The enhanced performance is mainly ascribed to the electron transfer from graphene to perovskite layer to fill its empty states in the valence band and hence reduce the photocarrier recombination. Furthermore, photodetectors based on vapor deposited ultra-flat $MAPbI_3$ films on graphene obtain an even higher responsivity of 1.73×10^7 A/W and specific detectivity of 2×10^{15} Jones [76]. In particular, when a thin layer of P3HT has been inserted between $MAPbI_{3-x}Cl_x$ perovskite and graphene as a hole-transport layer [77], the carrier diffusion length is significantly increased, resulting in more efficient transfer of photogenerated holes to graphene and electrons to perovskite layer. Remarkably, a record value of 4.3×10^9 A/W has been obtained for the P3HT-enhanced photodetectors.

21.5.5 Graphene/Other 2D Materials

Besides graphene, black phosphorus (BP) and transition metal dichalcogenides (TMDCs) are also popular 2D layered materials for optoelectronic applications [6]. BP is a direct bandgap semiconductor whose bandgap can tuned from 0.3 to 1.9 eV by reducing the number of layers [78]. It excels in photodetection due to the easy excitation by absorption of visible and NIR lights [79]. Its anisotropic crystal structure and hence anisotropic electrical and optical properties lead to promising polarization-dependent light detection. Similarly, TMDCs, such as MoS_2, $MoSe_2$, WS_2, and WSe_2, also show tunable bandgaps ranging from an indirect bandgap of ~1.1 eV in bulk crystal to a direct energy gap of ~1.9 eV in monolayer crystal [80, 81]. For example, TMDCs could be used to manufacture photodetectors with high on/off ratio, which is superior to zero-bandgap graphene. Recently, several III–VI group layered (transition metal monochalcogenide) materials have also been demonstrated as promising photoresponse materials, such as GaS, GaSe, and InSe [6]. They also exhibit good tunability in bandgaps through adjusting the layer number. In addition to 2D semiconducting materials, 2D insulating materials also play an important role in photodetection. For example, hexagonal boron nitride (h-BN) are usually used as appealing barrier layer to restrain the dark current, due to its good chemical stability and thermal conductivity [82].

Although a large variety of individual 2D materials have demonstrated promising photodetection applications, the more attractive property of 2D materials for photodetectors relies on their van der Waals interaction between neighboring layers without dangling bonds, which enables the integration of multiple 2D materials to form heterostructures and obtain fundamentally different properties [12]. In a common geometry, 2D layered semiconductors and graphene act as the light absorber and the electrodes, respectively, to form planar metal-semiconductor-metal phototransistors. Different from metal electrodes, the Schottky barrier between the graphene electrode and the 2D semiconductors can be tuned by adjusting the Fermi level of graphene, making it possible to obtain ideal Ohmic contact between the two 2D materials. Also, the photoresponse characteristics of the heterostructures can be adjusted by electrostatic gating or optical input control [12]. Up to now, heterostructures between TMDC, BP, and III–VI 2D semiconductors have all be developed for photodetectors, as introduced below.

Various high-performance photodetectors based on graphene/TMDC heterostructures have been demonstrated with the TMDC being MoS_2, $MoTe_2$, WS_2, WSe_2, and so on. Remarkably, a high responsivity of up to 10^{10} A/W has been achieved in phototransistors based on heterostructures between mechanically exfoliated graphene and MoS_2 [85]. The high responsivity relies on the local trapping of photogenerated holes in MoS_2 and the gate electric field-enhanced electron transfer to graphene. The trapped holes can even act as local gates to generate significant photogating effect on graphene through capacitive coupling. Meanwhile,

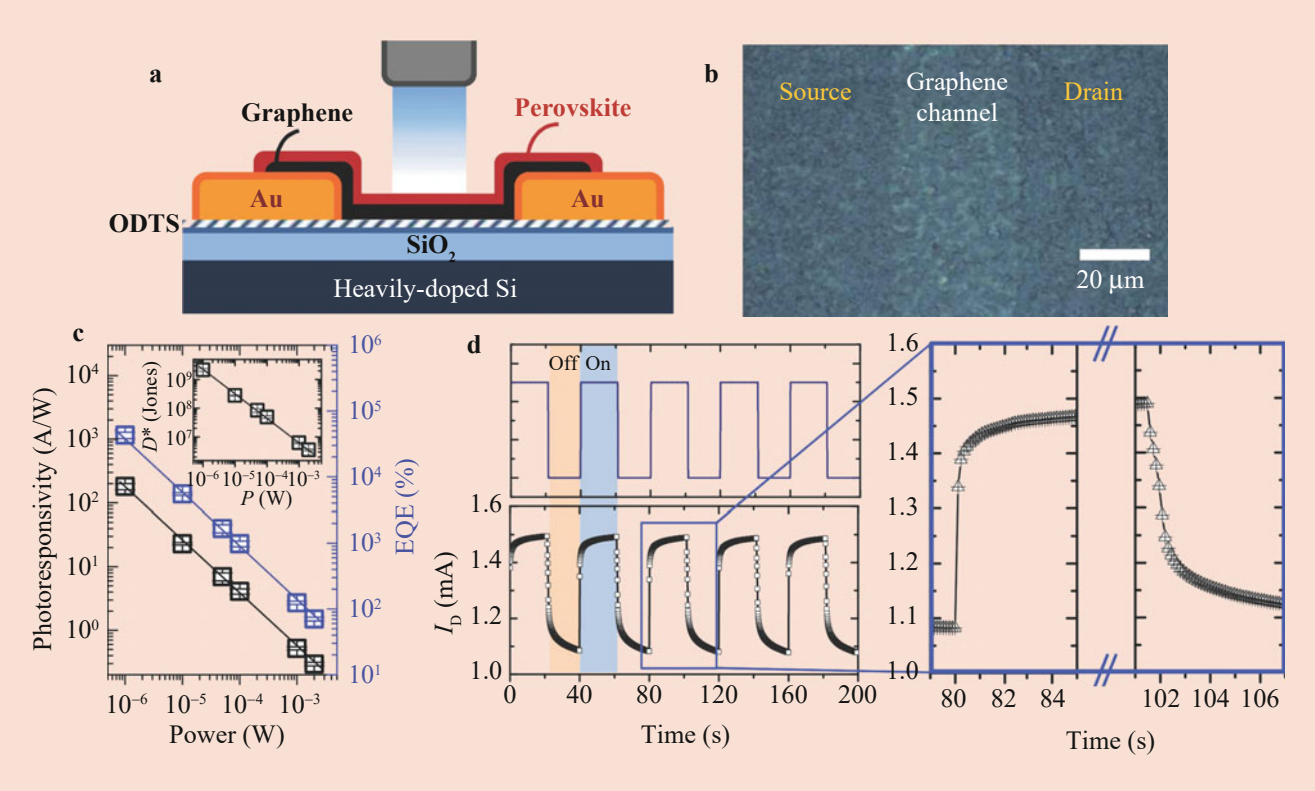

Fig. 21.10 Photodetectors based on graphene/perovskite heterostructures. (**a**) Schematic of the hybrid photodetector. (**b**) Optical micrograph of the $CH_3NH_3PbI_3$-graphene photodetector. (**c**) Responsivity, EQE, and specific detectivity (inset) under different illumination powers. however, the trapped holes have long lifetime that evidently increase the response time of the photodetectors. In contrast, a graphene/WSe_2/graphene heterostructure [83] with a trilayer WSe_2 (2.2 nm thick) sandwiched between two graphene electrodes (Fig. 21.11a–c) exhibits fast response of around 5.5 ps and high internal quantum efficiency (70%). In another study, it is found that a graphene/WS_2/graphene heterostructure phototransistor shows abnormal dependence of the responsivity on incident light power [86]. The responsivity increases with the increasing optical power at a gate voltage of 0 V (off state), whereas it decreases at the gate voltage of 30 V (on state). The mechanism could be at on state; the photogating effect increases the Fermi level and reduces the contact resistance, so that the Fermi level of graphene is weakly influenced by illumination, thereby causing different power dependence of responsivity. Interestingly, a unique MoS_2/graphene/WSe_2 heterostructure-based photodetector (Fig. 21.11d–f) indicates the broadband response in the range from 400 to 2400 nm [84], with high responsivity and detectivity, respectively, of 10^4 A/W and 10^{15} Jones in the visible range, but decreasing to 0.1 A/W and 10^9 Jones at 2400 nm IR wavelength. The possible reason for the performance dependence on the incident light wavelengths is that short-wavelength light can be absorbed by all the three materials (WSe_2, graphene, and MoS_2) in the heterostructures, while long-wavelength light can only be absorbed by graphene which results in low photocurrents.

Recently, BP and III–VI 2D materials have also been integrated with graphene to fabricate wideband 2D heterostructure photodetectors. Highly efficient photodetectors operating at NIR wavelengths have been fabricated based on the graphene/BP heterostructures (Fig. 21.12) [87]. Thanks to the large photon absorption over a broadband wavelength range of the BP flakes, the graphene-BP heterostructure device exhibits a broadband photodetection from the visible to IR wavelengths and moreover shows a high responsivity up to ~3.3 × 10^3 A/W at 1550 nm, which is more than 3000 times higher than those of previously reported photodetectors operating at the same wavelength. All the devices with different BP thickness exhibit qualitatively similar behaviors, while thicker BP flakes give rise to higher photoresponse (Fig. 21.12d). The devices can be stable for at least 60 days when operating at ambient conditions (Fig. 21.12e). They also show a high photoconductive gain (1.13 × 10^9), an ultrafast charge transfer (41 fs, Fig. 21.12f), a polarization-

dependent photocurrent response, and a long-term stability at 1550 nm [87]. In another study, by using the broadband transparency of graphene and the favorable band lineup of graphene with InSe, wideband photodetectors with spectral response extending from NIR to visible spectrum have been fabricated based on planar graphene/n-InSe/graphene van der Waals heterostructures. The devices exhibit high responsivity of up to 10^5 A/W at wavelength of 633 nm and fast rise/fall times of 1/10 ms [88]. The high responsivity appears in the vertically stacked InSe and graphene layers with an optical window created by overlapping the two graphene electrodes, thus enabling sensitive photodetection.

21.6 Integrated Graphene Photodetectors

The low absorption of monolayer graphene (only ~ 2.3% of incident light) severely limits the overall responsivity of conventional graphene photodetectors to a typical value of a few mA/W. Highly desired are techniques that can effectively improve the optical absorption and responsivity. It has been discussed in Sect. 21.5 that integration of graphene photodetectors with light absorbers (such as quantum dots and perovskite) can improve the responsivity through the photogating effect. But typically these techniques result in lower operating speed [54, 74]. In this section, we discuss about the techniques of integrating graphene photodetectors with optical cavity and waveguides to improve the device performance.

21.6.1 Integration with Optical Cavity

It has been demonstrated as an effective way to significantly improve light absorption through embedding graphene into optical or photonic crystal cavities (PCC) [10]. Typically, optical cavities comprise arranged mirrors (either Bragg mirrors or metallic reflectors) [89, 91] with the gap equal to a quarter of the resonant wavelength so as to trap the electric field inside the cavities. When graphene integrates with an optical cavity, light may pass through it for several times which significantly increases the light absorption. Furchi et al. [89] integrated a metal/graphene/metal detector with a Bragg mirror-based microcavity (Fig. 21.13a, b) to reach a light absorption of 60% (about 26-fold enhanced) and a responsivity of 21 mA/W. However, it is worthy of mentioning that the sharp resonant peak of an optical cavity often reduces the operating bandwidth of photodetectors, because the Bragg mirror-induced optical confinement is only in the vertical direction [10]. In contrast, PCC permits very high-quality factor due to the three-dimensional optical confinement. Dmitri et al. [90] have demonstrated a proof-of-concept device (Fig. 21.13c, d) of a high-quality hBN/graphene/hBN heterostructure bolometer placed onto a suspended silicon PCC and integrated with a Johnson noise readout. The device operates at telecom wavelengths and exhibits an enhanced bolometric response at charge neutrality with a NEP about 10 pW $Hz^{-1/2}$ and a record fast thermal relaxation time <35 ps (Fig. 21.13e, f).

21.6.2 Integration with Waveguides

In addition, due to their very low losses and high optical mode confinement, silicon waveguides have enabled a large variety of new applications, including nano-optomechanics, biosensing, nonlinear optics, and very long-wavelength integrated photonics [96]. It has also allowed hybrid integration of new materials into the silicon system for extended functionality, for example, integrating organic materials to increase optical nonlinearities and bonding III–V materials to create on-chip light sources. Integration of graphene photodetectors with low-loss optical waveguides can also greatly enhance the light absorption. The waveguides confine and guide the evanescent mode of optical electric field which propagates parallel to graphene channels. Therefore, light interacts with graphene throughout its travel in the waveguide so as to maximize the optical absorption [10]. It has been demonstrated the light absorption of a graphene-integrated silicon waveguide based on a Mach-Zender interferometer [97] can be increased up to 50% and 90% in 15-μm- and 50-μm-long graphene samples, respectively. The responsivity is also increased to 0.05 A/W and 0.1 A/W for 24-μm- [98] and 50-μm [99]-long silicon waveguides, respectively. In particular, a high responsivity of 0.13 A/W is obtained (Fig. 21.14a) when a graphene/silicon heterostructure is naturally integrated with silicon waveguide on SOI substrate [92]. Also, a compact photodetector [95] is realized through embedding graphene *inside the slot layer* of high-*k* (Al_2O_3)

slot waveguides (Fig. 21.14). Due to the high mode concentration in the slot region, this structure leads to a high light-graphene interaction and hence a responsivity of 3.6 mA/W for a 40-μm-long graphene detector. Making use of the avalanche multiplication at high reverse biases of an integrated graphene/silicon Schottky photodetector (Fig. 21.14b, c), a high responsivity up to 0.37 A/W is achieved for 1.5 μm incident light [93]. A recent study [94] also demonstrated that graphene photodetectors integrated on silicon nitride waveguides (Fig. 21.14d–f) with interdigitated metal contacts (to reduce the channel spacing down to ~200 nm) exhibit a high responsivity of 2.36 A/W and bandwidth of 33 GHz at 1550 nm.

21.7 Graphene Photodetectors with Special Geometry or Architectures

Recently, it has been demonstrated that special geometry and architectures have potential to lead to new mechanism and functionalities of graphene-based photodetectors.

Despite the diversity of mechanisms in graphene-based photodetectors, such as PV and PTE effects, all of these photocurrents are prominent at high charge densities but are suppressed at the charge neutrality point (CNP). A recent research [100] has discovered a new photocurrent phenomenon in graphene that appears exclusively when the Fermi level is at the Dirac point and vanishes at high charge densities. For intrinsic graphene with special geometrical patterns, such as those in Fig. 21.15, the photocurrents emerge at free graphene edges (in area far away from the contacts) exclusively at the CNP where the Fermi level matches the Dirac point. At high charge densities where the Fermi level leaves away from the Dirac point, conventional photocurrents appear only near the graphene/metal contacts. The new mechanism originates in the asymmetry of electron-hole velocities in graphene [101]. Electrons and holes have an intrinsic velocity difference, and upon being excited by photons, they will diffuse at different speeds, separate, and produce a local electric field. Since the diffusion has no directional preference, the local electric fields are circularly symmetric around the excitation point and cancel each other out, resulting in zero total electric field in the electrical circuit. However, when light is shone on the edge of the graphene, the diffusion is no longer circularly symmetric, and this gives rise to a residual electric field to produce photocurrent in the circuit. Therefore, graphene with well-designed edges can serve as a photocurrent source [101]. As the CNP photocurrents are carried at the group velocity of unthermalized electrons, they should exhibit an ultrafast response time, possibly leading to ballistic photodetectors. Hence, the new mechanism is promising for ultrahigh-speed and ultra-broadband optoelectronics [100].

The attractive properties of graphene and 2D materials for photodetectors are not restricted to their unique electrical and optical properties, but also include their mechanical strength and flexibility and great compatibility with various substrates. For example, making use of heterostructure of single-layer graphene and MoS_2, Domenico et al. [103] developed flexible photodetectors on plastic substrates for visible wavelengths. The devices are gated by polymer electrolyte with external responsivity up to ~45.5 A/W (at least two orders of magnitude higher than that of conventional semiconductor membranes), photoconductive gain ~4 × 10^5, operation voltage <1 V, and optical transparency >82%. In addition, Wonho et al. [102] even integrate an array of graphene/-MoS_2 heterostructures on 3D substrates with complex and mechanically assembled 3D systems (Fig. 21.16). The 3D photodetectors exhibit a maximum responsivity of 38 A/W and rise and decay time of 290 ± 130 ms and 420 ± 210 ms, respectively. In particular, the overall photodetectors are optically transparent (~ 87% transmittance at 550 nm) which enables 3D systems to simultaneously detect the position, direction, intensity, and angular divergence properties of incident light. To realize the same functionality in 2D layouts, significantly more components are needed [102].

21.8 Conclusions and Outlook

The performance of representative graphene-based photodetectors is summarized in Table 21.1.

From Table 21.1, one may readily find that graphene-based photodetectors are being developed with intensive efforts from extensive research fields. So far, the focus is still on the performance improvement through integration with various materials, components, and systems. For many types of detectors, their performance has already surpassed the existing technologies, such as high responsivity (up to ~10^{10} A/W), wideband detection (UV-THz), and ultrafast response speed (down to ps). This can also be clearly seen in Fig. 21.17 which indicates a systematic comparison of performance metrics between standard and graphene (or 2D materials-)-based photodetector technologies [4]. Undoubtedly, graphene-based photodetectors have great potential to complement to or even replace the present silicon photodetectors in many applications. However, it should be mentioned that most techniques still make trade-off between different performance metrics. For example, heterostructures typically give rise to high responsivity, while the response speed is sacrificed. Integration with optical cavity increases the light absorption but significantly limits the operating bandwidth. So highly desired are comprehensive technologies that may integrate multiple complementary materials (especially new 2D materials) and components (especially optical cavity and waveguides)

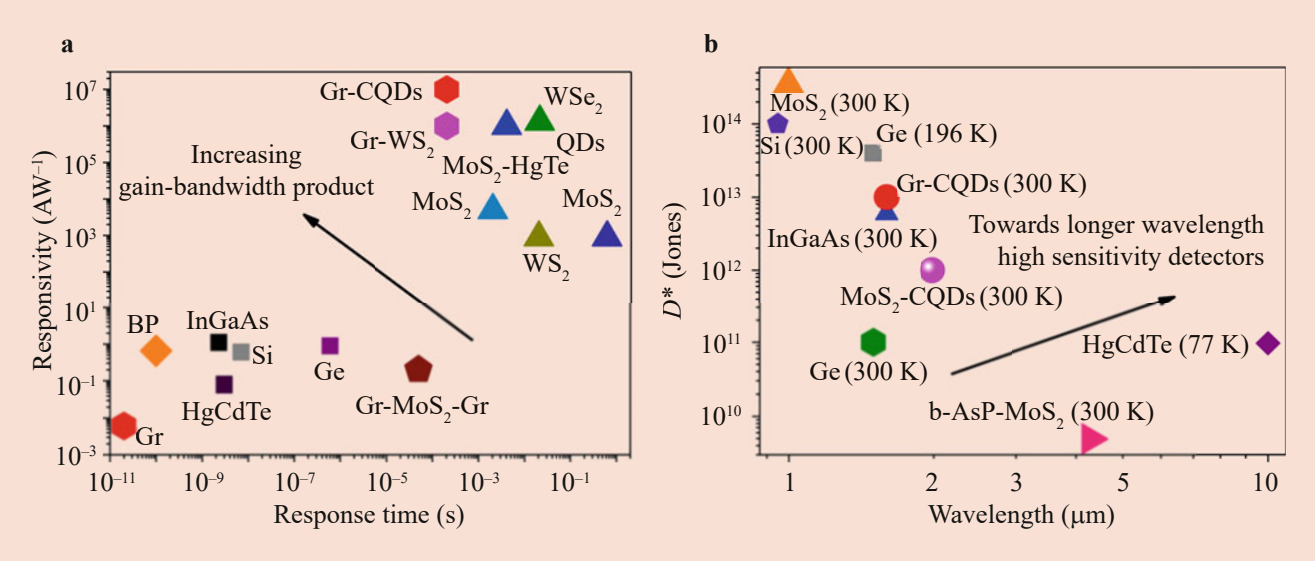

Fig. 21.17 Overview of performance metrics of standard and 2D-based photodetector technologies. (**a**) Responsivity against time response for various photodetector technologies. The top left region corresponds to high-gain bandwidth product detectors and should be the ultimate performance target of future photodetectors. (**b**) Plot of the specific detectivity D^* against absorption onset (bandgap) for various photodetector technologies. "Gr" means graphene. with graphene to achieve thorough improvement of various performance metrics. Moreover, the exploration of new mechanisms, such as the geometry-dependent photoresponse in graphene [100], may offer opportunities to provide innovative solutions for groundbreaking performance to essentially eliminate the present dilemma in making trade-off among different performance metrics.

Besides the competitive photodetection performance, graphene-based photodetectors excel in compatible form factor with the standard silicon technology and ideal adaptability to a large variety of substrates, either rigid or flexible, single crystalline or amorphous, and planar or 3D curved. This greatly simplifies the integration and offers opportunities to develop multifunctional photodetectors to enable engineering unique system-level function through simple integration of devices on desired substrates. A good example is shown in [102]. Therefore, one may expect more advanced photodetecting systems based on graphene photodetectors can be developed in the near future to provide both high performance and multifunctionalities.

Finally, it is worthy of emphasizing that the most attractive points of graphene and other 2D materials for photodetector applications do rely not only on their outstanding photonic performance but also on their unique combination of many other properties. It is important to make use of the latter to develop in the future advanced photodetectors that integrate multiple functionalities and merits. For example, most 2D materials are compatible with liquid solution processes, which offer opportunities to develop solution-processed or solution-printed photodetectors based on 2D materials [3, 104] for both performance- and cost-competitive technology [4]. On the other hand, distinguishingly different sensors can be produced even when graphene is placed in the same device structure. For instance, a suspended graphene with simply contacted source and drain contacts can be both a good photodetector with increased responsivity [27] and an excellent pressure sensor with orders of magnitudes higher sensitivity than conventional pressure sensors [105]. Consequently, it is becoming a new trend to develop multifunctional graphene sensors which after integrating with decoupling techniques can detect both light illuminance and other environmental signs, so as to provide a compact solution to comprehensive systems (e.g., environmental monitoring, energy management, health care, feedback control of machines) where various types of sensors are normally needed [72, 106]. A final observation is that most of the above detector types, how promising they may all be, depend on reliable, reproducible, and cost-effective fabrication technologies which, at the moment, still are to be shown for large-scale production.

Abstract

The frequency band of the electromagnetic spectrum between microwaves and infrared is nowadays defined as the Terahertz band (1 THz corresponds to 10^{12} Hz). The development of specific applications for this area requires the use of devices able to operate (for instance, as emitters, detectors, amplifiers, etc.) in this domain of extremely high frequencies. For this purpose, it is necessary to cleverly combine favourable materials and charge transport properties with specific physical mechanisms and appropriate device topologies in order to reach electrical operation in conditions that, with respect to standard electronics, can be considered as extreme. Alternative strategies (not treated in this chapter) involve either the use of optical devices or a combination of electrical and optical systems. Here, we present an overview of the main electronic devices used for applications in the Terahertz frequency domain subdivided into two-terminal devices (such as Gunn, Schottky and resonant-tunnelling diodes) and three-terminal devices (such as field-effect, heterojunction bipolar and complementary metal oxide semiconductor transistors). A section devoted to non-conventional devices exploiting ballistic transport concludes the survey.

Keywords

Terahertz (THz) · Gunn diode · Schottky-barrier diode (SBD) · Resonant-tunnelling diode (RTD) · Field-effect transistor (FET) · Heterojunction bipolar transistor (HBT) · Complementary metal oxide semiconductor transistor (CMOS) · Ballistic rectifier (BR)

22.1 Introduction

When analysing the electromagnetic spectrum, the adjacent frequency band between microwaves and infrared is nowadays described as Terahertz (THz) band where 1 THz corresponds to 10^{12} Hz. Since the transitions between frequency bands are smooth, the low- and high-frequency limits of the THz band are not precisely defined. However, one commonly accepted determination considers that this band extends from 0.1 THz (i.e. 100 GHz) to 10 THz. It is also useful to convert these frequency limits into wavelengths using the relation

$$\lambda = c/f \tag{22.1}$$

where $c = 299,792,458$ m/s is the light speed in vacuum and f the frequency, or into wavenumbers ν using the relation

$$\nu = 1/\lambda. \tag{22.2}$$

The energy E can be derived from

$$E = hf, \tag{22.3}$$

where $h = 6.63 \times 10^{-34}$ Js $= 4.1 \times 10^{-15}$ eV s is the Planck's constant. The energy can be also converted into temperature T as

$$T = E/k_B, \tag{22.4}$$

where $k_B = 1.38 \times 10^{-23}$ J/K is the Boltzmann's constant. The THz band in terms of these different physical quantities is indicated in Fig. 22.1 by the coloured region.

To better understand the physical properties of the THz waves, it is useful to remember that a frequency of 1 THz corresponds to a wavelength in vacuum $\lambda = 0.3$ mm (submillimetre waves), to a wavenumber $\nu = 33.3$ cm^{-1} to an energy $E = 4.14$ meV and to a temperature $T = 48$ K. The characteristic photon energy of the THz radiation is much smaller than the band gap energy of common semiconductors as well as smaller than the ionisation energy of most atoms and molecules. For this reason it can be considered a non-ionising radiation.

The region of the spectrum between 20 μm and the millimetre region has been indicated for a long time as the "far-

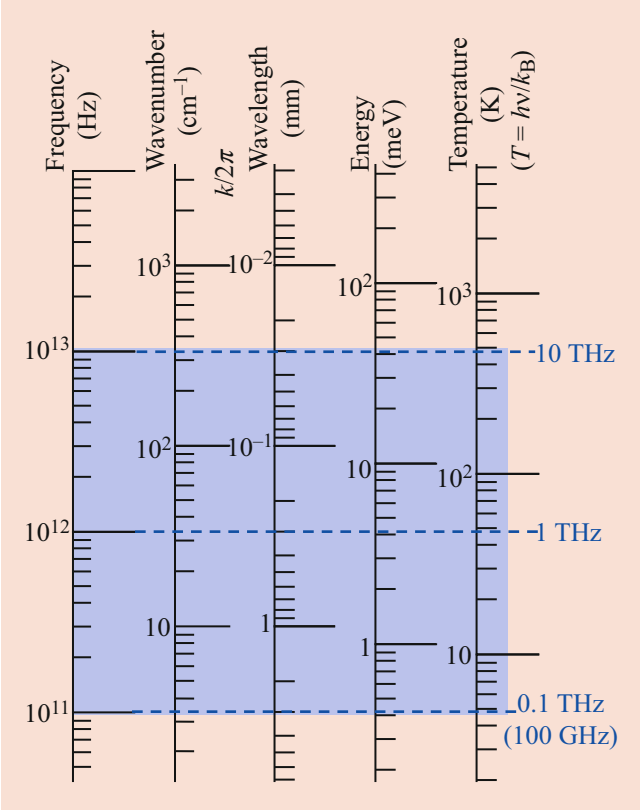

Fig. 22.1 Terahertz portion of the electromagnetic spectrum in terms of frequency, wavenumber, wavelength, energy and temperature

infrared" (FIR) region. Later it was proposed to indicate this portion as the "submillimetre", even if a cutoff at 1 mm was not entirely satisfying. In 1978, it was suggested to use an accurate, but rather long, title "short millimetre and submillimetre-wavelength range" (SMSMR), but this name did not become very popular. More recently the term Terahertz became to be used especially in association with the experimental technique called THz time-domain spectroscopy (TDS) [1, 2] but is now accepted and used in most of publications and specialised journals. A comprehensive historical description of the progressive development of THz science can be found in Ref. [3].

For many years the lack of efficient, reliable, low-cost and room-temperature emitters and detectors has limited the practical applications of THz devices and systems. However there has been recently significant progress in the development of continuous-wave and pulsed emitters that, coupled to lab-developed or commercially available detectors, has opened the way to the use of THz devices and systems in several domains. Nowadays the scientific literature on this domain is very large, and many review articles and books devoted to this topics can be found [4–14].

Historically it was in the 1970s that scientists realised that the THz portion of the electromagnetic spectrum offers unique opportunities in astronomical research [15, 16]. However the presence of vibrational and rotational levels of water vapour represents a major problem for research in this spectral region due to the very high absorption of the Earth's atmosphere [17]. As a consequence THz astronomy has been limited to research in the upper atmosphere, to high-altitude observatories and balloon flights.

In parallel to spatial telecommunications the need for larger bandwidths in standard telecommunications has become one of the strongest driving forces for THz applications. This is due, on one hand, to the need of cramming as many telecommunication channels as possible into single high-frequency carriers and, on the other hand, to the need of speeding up multimedia services and broadband interactive communications. Up to now, this demand has been satisfied by means of advanced modulation schemes and signal-processing technologies at microwave frequencies. However, it is now evident that only an increase of the carrier frequencies will provide the spectral resources needed to satisfy this growing need of ultrafast wireless communications. The huge bandwidth associated with the THz band (most of which has not been allocated for specific uses yet) represents a very promising opportunity for increasing the data rates further beyond 10 Gb/s. Even if THz communications has not entered the market yet and is in its early stage of development, many publications have clearly shown its potential in this field [18–25].

In the last decades another emerging application is that of biophysical and biomedical imaging due to the ability of THz radiation to penetrate deep into many organic materials without causing any damage associated with ionising radiation such as X-rays and also due to the possibility to simultaneously acquire both image and spectral information. For the above reasons it can be used for spectroscopic identification of biological signals, 2D and 3D imaging (including cancer detection [26]), pattern formation and recognition and THz tomography [27, 28]. Additionally, to enhance the efficiency of imaging systems, THz absorbers can be introduced into detectors. Due to the lack of naturally occurring dielectrics, artificially engineered resonant materials called metamaterials can be used [29]. Biological applications are also based on the specific spectroscopic fingerprints of biological matter (DNA, RNA, proteins, lipids, etc.) in the THz frequency domain involving vibrations of a substantial fraction of the atoms forming the molecule and motion associated with intermolecular hydrogen bond vibrations. These fingerprints provide information on the conformational state of the molecule but also on the effects of its environment such as the intensive absorption lines of water and other surrounding molecules [27, 30]. The bound water which influences the biological function represents also a strong absorbing medium for THz waves.

Besides biological matter, many other molecules have rotational and vibrational transitions in the THz range giving access to the spectroscopic analysis of a large variety of materials in security as well as various other areas such as air pollution, climate research, industrial process control, agriculture, food industry, workplace safety and many others [31–34]. Since most plastics, textiles and paper exhibit small absorption of THz waves, it becomes possible to detect chemical, biological, radiological and nuclear defence (the so-called CBRN) agents, explosives or illegal drugs [35]. While passive detection systems operate at frequencies where the background emissivity and reflectivity are rather different from those of the object of interest so that image contrast can be improved, active systems eliminate the background and can better detect and identify the objects at the cost of an increase in system complexity.

It is also worthwhile to mention the growing field of light-matter interaction which concentrates on physical phenomena at very high THz intensities. These intensities can be generated by optically pumped molecular lasers, free-electron lasers and femtosecond lasers. The physical phenomena in this domain include tunnelling processes in high-frequency fields, nonlinear absorption of radiation, nonlinear optics in the classical sense, hot electron dynamics, Bloch oscillations, ponderomotive action of the radiation field on a free electron gas, photoelectric and optoelectronic effects, and THz spin-dependent phenomena [36].

In the following sections we will systematically describe the basic principles and the main characteristics of the most used electronic devices forming the building blocks for the

design and development of THz detectors and emitters: first two-terminal devices (Gunn diodes, Schottky diodes, resonant-tunnelling diodes), then three-terminal devices (field-effect transistors, bipolar transistors, metal oxide semiconductor transistors) and finally ballistic devices. Other extensive reviews can be found elsewhere [37, 38].

We emphasise that the present chapter is intentionally restricted to an overview of electronic devices: the reader should be aware that there exists a whole domain of science and technology devoted to THz detection and emission using optical devices (such as quantum-cascade lasers or p-Ge lasers) and systems [3, 9, 39, 40].

22.2 Gunn Diodes

Gunn diodes are two-terminal semiconductor devices exhibiting negative differential conductance (NDC) at high electric fields that can be used to build free-running oscillators. Gunn oscillators have been found in many applications such as instrumentation, RADAR, imaging systems, weapons and communication systems. State-of-the-art Gunn oscillators operate at more than 300 GHz.

Gunn diodes, also called transferred electron devices (TEDs), were first demonstrated oscillating at 4.5 GHz on a 25 μm n-doped GaAs slab by J. B. Gunn in 1963 [41]. One year later, Kromer linked Gunn's experimental results with Ridley and Hilsum's theoretical studies [42–44] and concluded that the oscillations observed by Gunn resulted from the so-called transferred electron mechanism. The transferred electron mechanism appears in some semiconductor materials such as GaAs and InP that have lower Γ valley and higher L and/or X valleys (also called satellite valleys) in their conduction bands, as shown in Fig. 22.2a [45]. Under low electric fields (Ohmic regime), majority electrons stay in the Γ valley and travel at a speed proportional to the electric field. However, as the electric field increases and exceeds a critical value E_{th} (also called threshold electric field), that is approximately 3.2 kV/cm for GaAs, some electrons get "hotter" and start transferring to the higher L valley where electrons become heavier and slower because of the greater effective mass. Thus, the average speed of electrons decreases as the electric field is increased. This phenomenon is reflected in the current-voltage (electric field) characteristics (Fig. 22.2b) that shows negative differential conductance (NDC), i.e. a negative slope, above the threshold electric field.

Using NDC, one can apply Kurokawa's methods to design oscillators [46]. In fact, Gunn diodes may operate in different modes, and each mode has different limits on the oscillation frequencies and DC-RF conversion efficiencies. We will briefly describe the mechanism of the wide-used fundamental transit-time mode of oscillation in the next section. Information on other modes of oscillation can be found elsewhere [45, 47, 48].

22.2.1 Transit-Time Mode Gunn Oscillations

We assume that a piece of n-doped bulk GaAs sample has a length L and a doping level N (Fig. 22.3a). When an external bias V is applied to the sample between the anode and cathode, an electric field E is induced within the sample. The anode and the cathode are Ohmic and typically have a very high doping level N_0 ($N \ll N_0$) as shown in Fig. 22.3f. The electric field E_0 and drift velocity v_0 are at their lowest in the Ohmic contact regions (Fig. 22.3c, i). Ignoring the potential drop in the Ohmic contact regions, the electric field within the active region is $E{=}V/L$. For $E{=}E_1{<}E_{th}$ (Fig. 22.3b, c), the electron drift velocity v_1 (Fig. 22.3i) is proportional to the electric field E_1. If the applied electric field is greater than the threshold field, e.g. $E = E_2 > E_{th}$ (Fig. 22.3b, d), a small fluctuation of the electron concentration ΔN (Fig. 22.3g) can occur, typically arising from a nucleation event such as non-uniform doping or intrinsic noise. The result is a localized increase of the electric field, ΔE, or an electric field domain (Fig. 22.3d). As can be seen in Fig. 22.3b, the increase in electric field leads to a reduction in drift velocity of Δv as shown in Fig. 22.3j. The total current through the sample drops as well. At the same time, the electric field outside the domain drops because the total applied voltage between the anode and cathode is fixed.

If the applied electric field remains unchanged at the leading edge of the domain, electrons within the domain travel more slowly than the electrons ahead and outside of the domain. The faster electrons are accelerated at a lower electric field; thus the depletion region associated with the domain widens (Fig. 22.3h). On the other hand, at the trailing edge of the domain, electrons that are behind and outside the domain travel faster than the electrons within the domain; therefore more electrons accumulate behind the domain (Fig. 22.3h). As a consequence, the high field domain keeps growing while moving towards the anode and the space charge dipole also keeps developing. Meanwhile, both the electric field outside the domain and the electron drift velocity within domain keep reducing (Fig. 22.3k).

After a short while, when the domain velocity is equal to the electron drift velocity outside the domain, then the domain stops growing but travels to the anode at a constant speed, v_{domain}, until it disappears at the anode where the electric field is minimal. Meanwhile, the electric field within the sample is restored to its original magnitude, E_2, and a new domain starts nucleating near the cathode end of the sample, so that the process repeats. This periodic cycle of domain formation, transport and disappearance leads to the coherent current oscillation that was observed by Gunn.

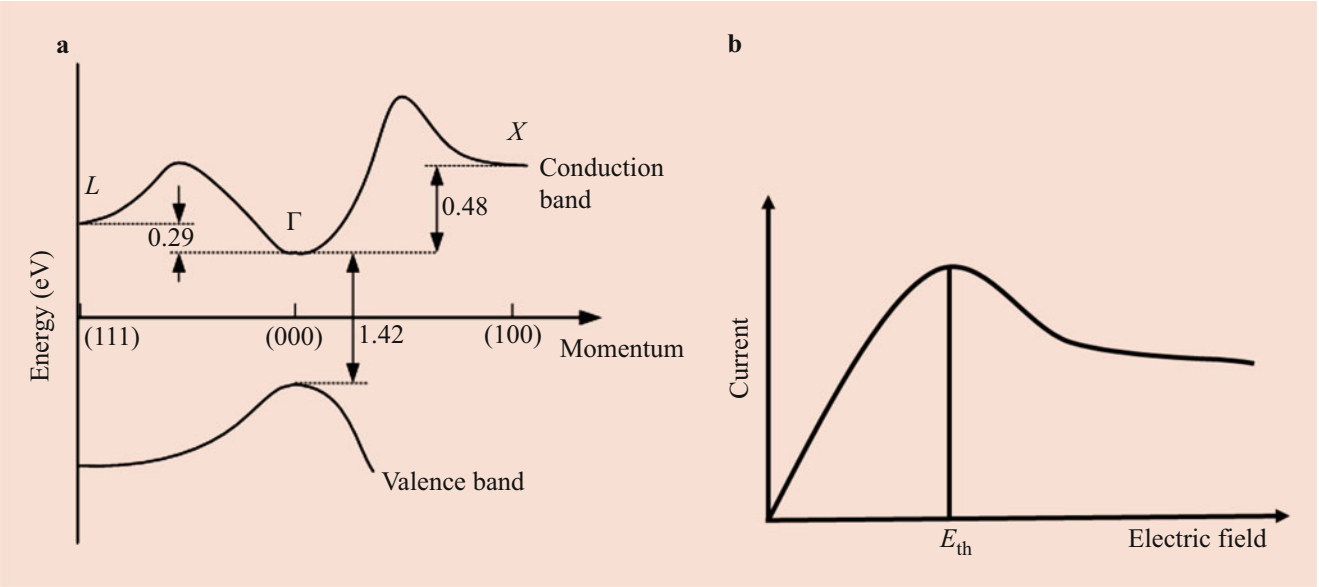

Fig. 22.2 (**a**) Simplified energy band structure of GaAs showing the band gap and the energy separations between the different valleys and (**b**) current versus electric field characteristics of the bulk material showing the threshold field E_{th} above which negative differential conductance appears

The oscillation frequency is approximately determined by the transit-time of the domain or the ratio of the domain velocity to the distance, L, that the domain travels. It is given by

$$f = \frac{v_{\text{domain}}}{L} \tag{22.5}$$

where the average domain velocity is equal to the average electron drift velocity v_{ave} which can be approximated using a numerical method as follows

$$v_{\text{ave}} = \frac{\mu_0 E + v_s (E/E_{\text{th}})^4}{1 + (E/E_{\text{th}})^4} \tag{22.6}$$

where μ_0 is the electron mobility at low electric field and v_s is the electron saturation velocity. To achieve higher oscillation frequency, one can either increase domain velocity by employing materials with high average drift velocity or reducing domain travel distance using advanced fabrication technologies.

22.2.2 Materials for Gunn Diodes

The general requirements of semiconductor materials for Gunn diodes are the following ones [45]:

- the band gap ΔE_g must be greater than the intervalley band difference ΔE between the minimum of the central valley and the minimum of higher satellite valleys so that avalanche breakdown will not occur before the onset of NDC;
- the intervalley band discontinuity ΔE must be several times greater than the thermal energy kT (approximately 0.027 eV at room temperature) so that the electron intervalley transfer is not due to the heating effect;
- the electron effective mass in the higher satellite valley must be larger than that in the central valley so that the electron mobility in the satellite valley is lower than that in the central valley.

The most commonly exploited materials for Gunn devices are n-GaAs and n-InP which were initially reported by Gunn. Since then, many other semiconductor materials have also been explored. These include n-Ge, n-CdTe, n-InSb, GaSb, ternary compounds $GaAs_xP_{1-x}$ ($x < 0.5$), $In_xGa_{1-x}Sb$, $In_xGa_{1-x}As$ and even the quaternary compound $Ga_{0.13}In_{0.87}Ga_{0.37}P_{0.63}$ [45]. However, those materials have yet to find commercial applications owing to poor material quality, high cost or difficulty of fabrication. Recently, there has been an increasing interest on GaN because of its promising thermal and power handling capabilities. Several reports based on numerical simulations show GaN has great potential in terms of oscillation frequency and radio-frequency power. However, experimental results are not yet available due to the poor quality of materials in terms of crystal defects, impurities, dislocations, etc. [49–51].

22.2.3 Realisations of Gunn Oscillators

Conventionally, Gunn diodes are made in a vertical format, as shown in Fig. 22.4a, which means the direction of current

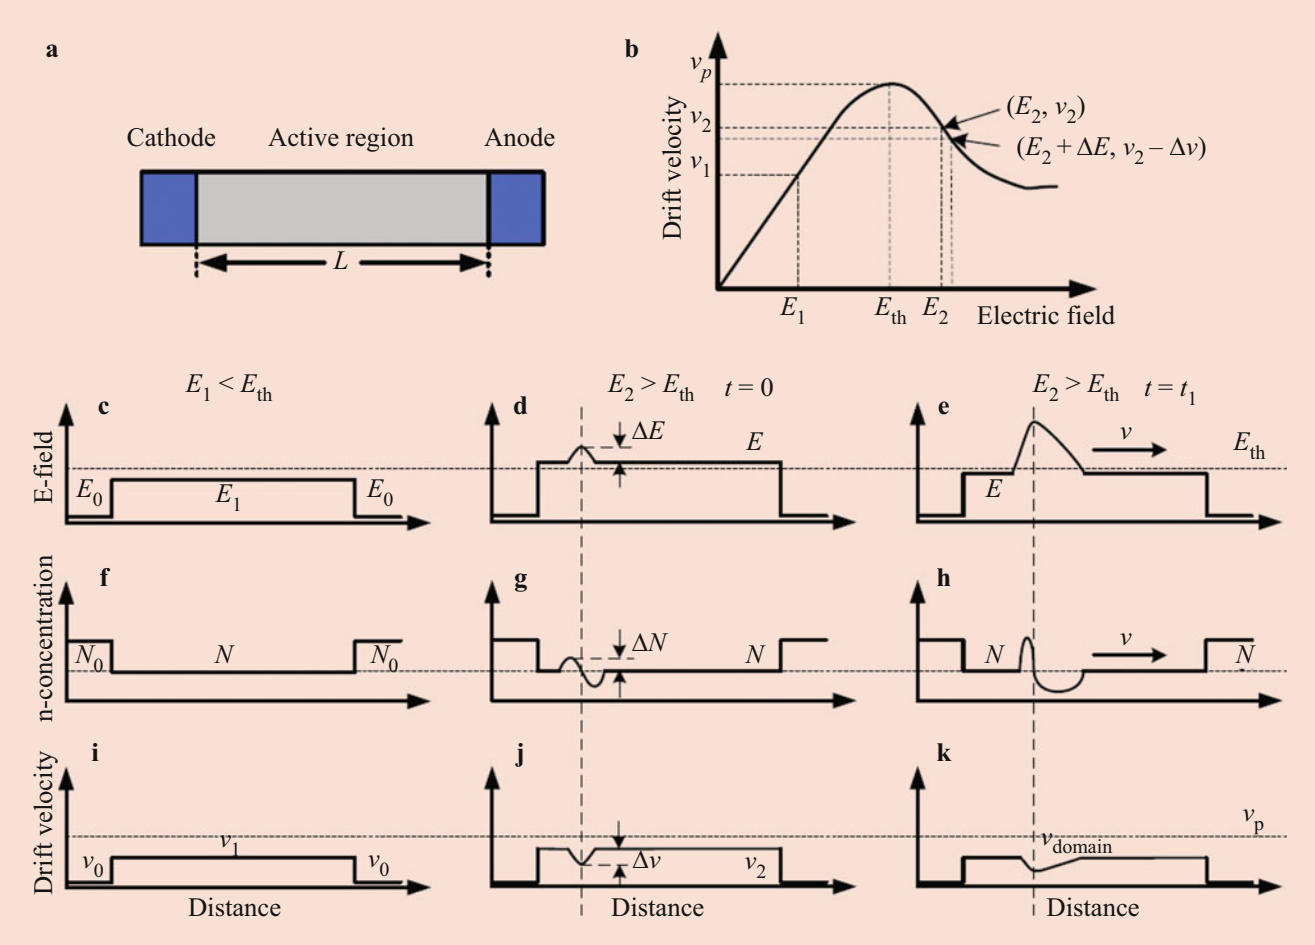

Fig. 22.3 (**a**) Scheme of a simple Gunn diode of length *L*. (**b**) Drift velocity versus electric field of the bulk material. (**c**, **d**) and (**e**) Illustration of the evolution of the electric field profile inside the diode for the formation of Gunn domain under transit-time mode of oscillation. (**f**, **g**) and (**h**) The same for the electrons concentration. (**i**, **j**) and (**k**) The same for the drift velocity [45]

flow is perpendicular to epitaxial layers of the device. To realise a Gunn oscillator, a vertical Gunn diode is embedded in a metallic waveguide cavity with a disc resonator, a radial line bias-tee, a sliding backshort and a heat sink as illustrated in Fig. 22.4b [45]. The disc resonator sitting on the top of the Gunn diode determines the output oscillation frequency. The radial line bias-tee allows DC bias to be applied on to the diode but prevents radio-frequency signals from leaking through. The heat sink beneath the Gunn diode helps dissipate heat generated as high current passes through the Gunn diode. The backshort serves as a tuner that improves circuit matching or frequency tuning by being manually moved forwards or backwards. The radio-frequency power is extracted from the rectangular waveguide. Gunn oscillators of this type are characterised by low phase noise, high-frequency stability and moderate power level. The highest oscillation from InP Gunn diodes is 160 GHz for its fundamental mode and 420 GHz from its third harmonics [53]. Although relatively high power is possible, the waveguide-based Gunn oscillators suffer from limited frequency tunability, lack of integration with integrated circuits, high cost of construction, difficulty of handling the thin and fragile diodes and poor reproducibility.

Forster et al. developed monolithic vertical Gunn diodes as shown in Fig. 22.4c [52,54]. Such Gunn devices are compatible with Monolithic Microwave Integrated Circuit (MMIC) process and have the potential for mass production. However, like conventional Gunn diodes, the oscillation frequency of these devices is still limited by the thickness of the mesa, and so far only 37.5 GHz has been demonstrated.

Alternatively, Gunn diodes can be configured in a planar form which has current flowing parallel to the epitaxial layers as shown in Fig. 22.4d. Compared with monolithic vertical Gunn devices, planar Gunn diodes have the advantages of lithographically controlled anode-cathode separation, and therefore the oscillation frequency of the device can be carefully controlled. Initial planar Gunn diodes only had a thin layer of n-doped material on the top of a substrate, and devices could operate at less than tens of gigahertz [57,58].

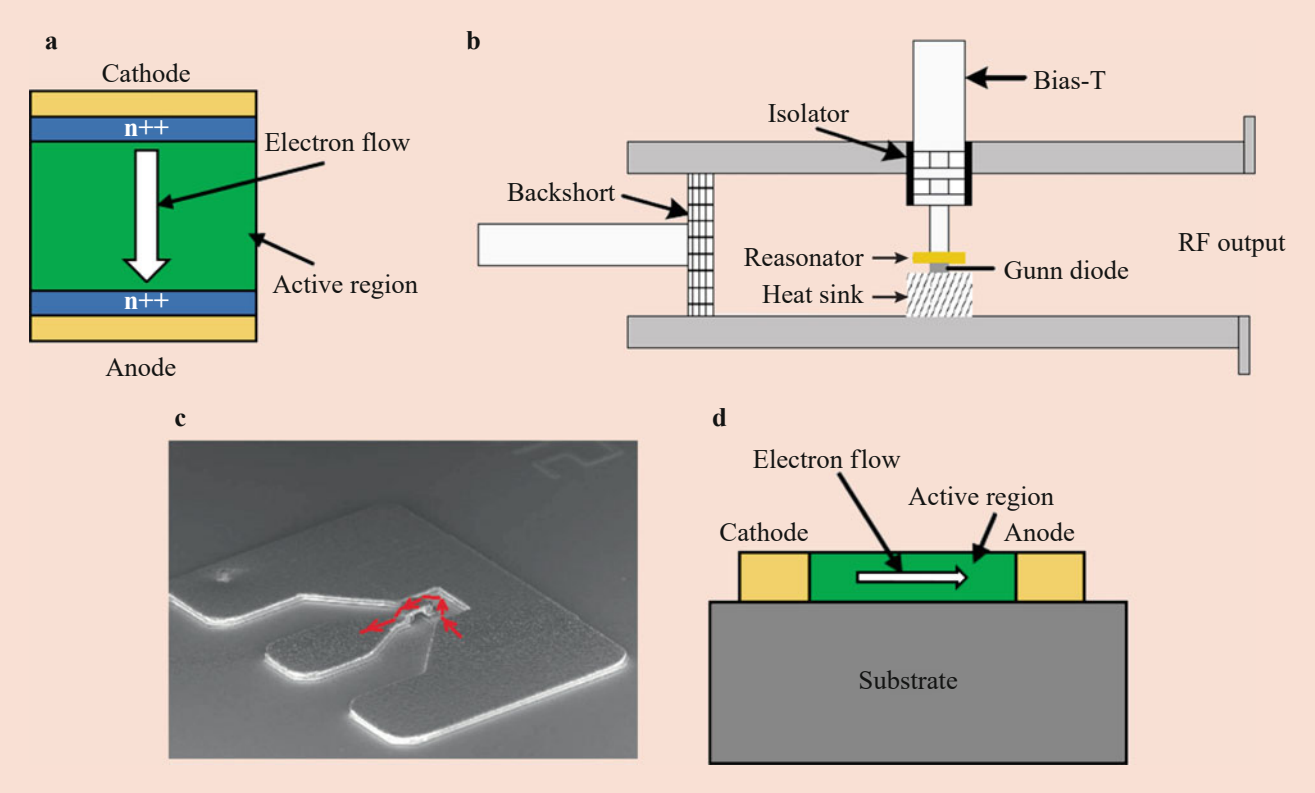

Fig. 22.4 Illustration of various configurations of Gunn diodes and oscillators. (**a**) Conventional discrete vertical Gunn diode and (**b**) its oscillator configured in rectangular waveguide cavity; (**c**) monolithic vertical Gunn diode [52] and (**d**) a planar Gunn diode

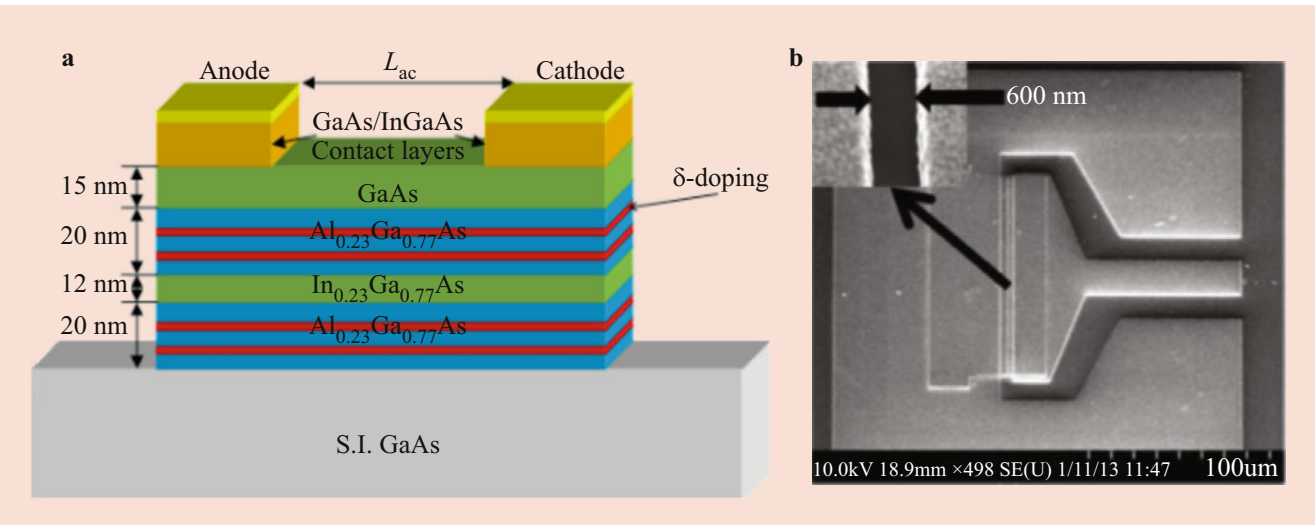

Fig. 22.5 Planar Gunn devices operating at frequencies greater than 100 GHz. (**a**) Schematic view of GaAs-based HEMT-like epitaxial layers [55], and (**b**) sub-micrometre planar Gunn diode oscillating at 307 GHz. (Reproduced from A. Khalid et al., *Journal of Applied Physics* **115**(11), 114502 (2014) [56], with the permission of AIP Publishing)

Recent developments of HEMT-like planar Gunn diodes, as shown in Fig. 22.5a, have significantly improved the fundamental oscillation frequency beyond 100 GHz [55, 59, 60]. The HEMT-like structure enables better electron confinement in the channel and higher drift velocity. With the advance of nanofabrication technology, planar Gunn diodes could generate oscillation beyond 300 GHz (Fig. 22.5b) [56].

22.2.4 Perspectives

Gunn diodes in planar configuration exhibit promising frequency performances which are highly desirable for future wireless and mobile communications, RADAR, imaging and other fields. There is still potential to improve the performances, such as frequency and power beyond 0.5 mW at 100 GHz [45] and 30 μW at 300 GHz [56]. Future research activities in this topic should include:

- improving oscillation frequency using materials with higher electron drift velocity, e.g. InAs or 2D materials, developing novel structures and decreasing channel length [61–64];
- enhancing output power by deploying multiple channels [45, 65], composite contact design [66] or materials with high bandgap, e.g. GaN [65];
- exploring new features and applications, for example, self-mixing effect and injection locking as detectors [67].

22.3 Schottky Diodes

Despite the continuous effort to develop new technologies to fill in the THz gap [4, 68–72], the Schottky-barrier diode (SBD) still offers unequalled performances at room temperature. It is used in the front-ends of heterodyne THz systems (Fig. 22.6) as ultra-wide bandwidth, stable, compact, tunable, spectrally pure and powerful emitter and/or to detect variation in sub-millimetre and THz radiation related to the physical temperature of optical blackbodies at a magnitude below 0.1 K and with a high resolving power up to 10^6. In addition to a proven operability for laboratory spectroscopy [73], SBDs have a historical background in practical implementation in many systems for signal generation or rectification. For instance, they have been successfully used in high-altitude balloons, airplanes or space-born telescopes for atmospheric science radiometry [74–77], in ground- and space-based astronomy and planetary science [78, 79]. These implementations have led to a growing demand of Schottky technology up to and above THz frequencies for a larger range of applications that span from biology and medicine [80], active imaging [81], telecommunication systems [24], astrophysics [82] to planetary science on our planet and the Solar System [83–85]. This plethora of applications makes it necessary to understand the operation of Schottky-based systems at their limits in order to reach the best performances. In the first part of this section, we address the basic principle of operation of the Schottky contact under zero DC bias and its frequency and temperature limitations related to material parameters. In the second part, we review the high-frequency limitations due to the parasitic elements located in the diode vicinity, and we discuss the associated effort in fabrication development (as illustrated in Fig. 22.7). Then, we extend the discussion to some of the configurations proposed to excite and balance the THz Schottky junctions in order to reach state-of-the-art performance. Finally, we review some of the future challenges in the main driving applications.

22.3.1 Terahertz Schottky Junction

The Schottky contact is formed by a metal to semiconductor contact. At room temperature, the current transport process is dominated by majority carriers through a thermionic emission over the barrier created by the unequal work functions of the two materials. The energy band structure of the junction is illustrated in Fig. 22.8, where E_F, *CB* and *VB* are the Fermi level, the conduction band and the valence band, respectively. As soon as the metal and the semiconductor are in contact, some of the free electrons in the semiconductor accumulate on the surface of the metal. The semiconductor is immediately depleted of electrons under the anode (the depletion region), and an electric field, which opposes further movement of electrons, is built between the anode and the semiconductor. As a result, a difference of potential is established between the semiconductor and the anode, that is, the built-in voltage V_{bi}.

The magnitude of the band bending V_{bi} and contact resistance depends on the semiconductor dielectric constant ε_{epi}, its epilayer doping density N and the Schottky barrier value $\varphi_B = \varphi_M - \chi_S$, where φ_M is the work function of the metal and χ_S the electron affinity of the semiconductor. The metal-semiconductor interface and the opposite boundary of the depleted area act like two capacitor plates in dynamic equilibrium, whereas the depletion region acts as a dielectric. By applying a bias voltage V to the junction, it is possible to influence the depletion width as

$$W(V) = [(2\varepsilon_{epi}/qN)(V_{bi} - V)]^{\gamma} \tag{22.7}$$

where q is the electron charge and γ the doping profile index, which depends on the junction geometry and the doping profile.

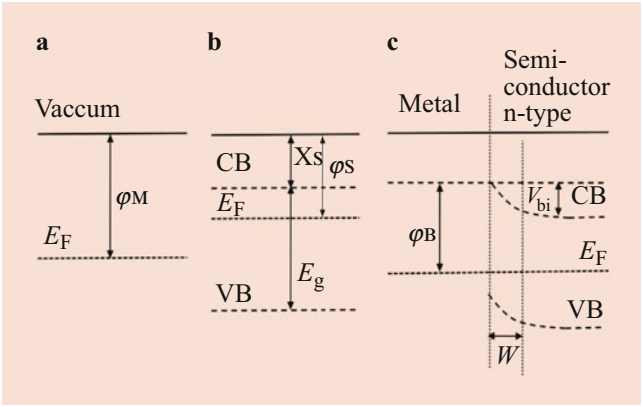

Fig. 22.8 (**a**) Energy band from metal, (**b**) semi-conductor and (**c**) metal/semi-conductor contact at thermic equilibrium

If we excite the junction with a large signal, the dopants electrons are emitted, pushed away and the depletion becomes wider in the reverse voltage region and narrower in the forward voltage region. The junction capacitance is calculated from the partial derivative of charge with junction voltage as

$$C_j(V) = A\gamma_c\varepsilon_{epi}/W(V) \tag{22.8}$$

where A is the anode area and γ_c a correction factor discussed in the next paragraph. The current-voltage relationship has been described in Ref. [87] by analogy with the drift-diffusion model of a $p-n$ junction as

$$I(V) = I_{sat}\exp\left(\frac{qV}{\eta k_B T} - 1\right) \tag{22.9}$$

with

$$I_{sat} = A^{**}T^2 W\exp\left(\frac{-\varphi_B q}{k_B T}\right) \tag{22.10}$$

where η is the ideality factor in order to compensate the non-ideal behaviour (with $\eta \geq 1$), k_B the Boltzmann constant, T the working temperature, I_{sat} the saturation current (ideally expressed as a function of temperature [88]) and A^{**} the modified Richardson constant [89]. These two non-linear regimes co-exist and are referred to as varactor and varistor modes. The excitation of the former or latter mode depends on the DC bias voltage value and polarity applied to the junction under operation. In the varactor case, the non-linearity of the capacitance dominates and favours high power handling capacities and harmonic generation with 100% theoretical efficiency at the junction level. The THz frequency limitation is driven by circuit and chain configuration [90, 91], breakdown voltage levels [90] or power handling limits [91]. In the varistor case, the non-linearity of the conductance is stronger in the vicinity of flat band. The varistor mode is preferably excited for mixing operation, and used in multiplier operation only when DC circuitry cannot be implemented. In this

case, the multiplier theoretical efficiency is reduced down to $1/m^2$, where m is the multiplying factor. The barrier cutoff frequency is defined as

$$f_c = \frac{1}{2\pi Z_s C_{tot}} \tag{22.11}$$

where C_{tot} is the capacitance of the depletion region under the Schottky contact and Z_s is, to a first approximation, the resistance of the undepleted semiconductor. This resistance extends to the Ohmic contact of the diode and is expressed for a circular anode as

$$Z_s = \frac{\rho_{epi} t_e \gamma_c}{R_o} \tag{22.12}$$

where t_e is the epilayer thickness, ρ_{epi} is the epilayer resistivity, R_o is the anode radius and γ_c is a correction factor between 0 and 1. As a result, the cutoff frequency varies linearly with the $\sqrt{N}\mu$ product, where μ is the electron mobility. The expression is extended below and above plasma frequency with different values depending on semi-conductor material, *i.e.* larger on n-type GaAs than on n-type Si Schottky contact [92]. These elementary considerations are used in order to optimize the anode size either analytically [93] or using Monte Carlo simulations [94]. GaAs THz mixers and multipliers typically feature sub-micron anodes diameters, 50–250 nm epilayer thickness and doping concentrations ranging from 10^{16} to 10^{18} cm^{-3}. For varactor operation at a given frequency, the anode size will be larger, the epilayer thickness thicker and the doping lower than for varistor operation. In addition, the temperature of operation is an important parameter in the functioning of the junction at THz frequencies. On one hand, the ever-increasing availabilities of driver emitters is pushing the power handling of multipliers, increasing the thermal stress and self-heating effect at the anode level, which can degrade the multiplier efficiency. To compensate this effect, Schottky junctions have been fabricated on semi-conductor materials such as silicon carbide (SiC) [95], gallium nitrite (GaN) [96, 97] and diamond, since they offer larger breakdown voltage and better thermal conductivity than GaAs. Other implemented solutions for a better thermal handling in multipliers consist in increasing the size and number of anodes, the substrate thickness and/or in transferring the substrate of THz GaAs planar Schottky onto quartz [98] or diamond [99]. On the other hand, cryogenic temperatures of operation are often implemented [100] when power is scarce, when the transmission line is lossy and most-of-all in order to minimize THz mixer and multipliers intrinsic and extrinsic noises. Under cryogenic operation, the conduction is no longer dominated by thermionic emission but by quantum tunnelling [101]. As the junction temperature drops, the ideality factor increases, and the junction knee moves to higher voltages. This effect can be compensated by modelling the multiplier or mixer efficiency at a maximum cryogenic temperature, by trading the series resistance with doping density [102] or by using semi-conductor material with high mobility and low-temperature electron freeze-out (typically 40 K for GaAs). Other materials are considered for they have higher electron mobility, implying that the knee of the I/V characteristics occurs at a lower voltage, such as InSb [103], offering a greater tradeoff between temperature of operation and local oscillator power requirement.

22.3.2 Parasitics of Terahertz Schottky Planar Diode

The size of the anode is quickly decreasing with increasing frequency. Indeed, an appropriate combination value of junction capacitance and series resistance implies sub-micron anode dimensions in the THz frequency range. For these dimensions, the efficiency of multipliers and mixers is strongly affected by the parasitic and fringing edge effects at the close vicinity of the junction. Therefore, the definition of the diode geometry and its integrated matching circuitry becomes a crucial part of the research development process [104]. The first millimetre wave and THz Schottky contacts were fabricated with a metal tip (whisker) inserted in a honey-comb structure. The latter structure presents a very little parasitic capacitance. Whisker mixers quasi-optically pumped with CO_2 lasers still keep the state-of-the-art performance around 2 THz [105] and up to 5 THz [106] and have flown in satellites [75]. Nevertheless, the whisker-mounted diode suffers from reliable repeatability. Thus, planar technology was pushed forward in order to keep the high capacity of the whiskered structure, while adding the robustness necessary for spatial qualification levels to the micronic structure [77, 86,90]. The first planar discrete diode flip-chip mounted onto a larger substrate [107] offered the possibility of using a different substrate material, such as quartz [108] or SiN [77,90], to reduce the line dielectric constant. However, this operation provides few microns positioning uncertainty between the diode chip and the matching network circuit, which is enough to affect the performance in terms of bandwidth. Therefore, at 600 GHz and up to 2.5 THz, GaAs monolithic fully integrated circuit technology [109] has been developed on micron-thick and high resistivity GaAs membranes. This way, one can limit substrate mode effects and control accurately both the parasitics and transmission line impedances (Fig. 22.9).

The planar diode discrete or integrated MMIC Schottky device is fabricated on a high-conductivity n-type GaAs substrate supporting a very pure, high conductivity n-buffer layer. This layer assures a low series resistance, and prevents the substrate impurities from diffusing into the epitaxial layer during the fabrication process. A very thin *n*-epitaxial layer is grown on top of the buffer. The contact of the metal anode to

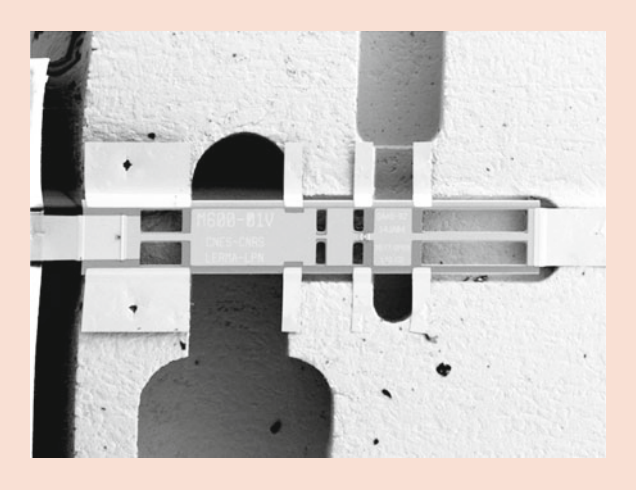

Fig. 22.9 MMIC integrated Schottky circuit configuration in split-block channels described in [110]

the epitaxial layer forms the rectifying junction, commonly made of gold-germanium, gold-platinum or gold-titanium for GaAs diodes. Finally, an Ohmic contact is formed by a metal layer on the substrate, which forms the cathode pad. The anode is defined on the top surface and is isolated by an oxide (SiO_2) layer. Different manufacturing processes based on similar fabrication steps prefer either contact lithography [109] combined (or not) with a more precise but expensive electron-beam system [107, 111, 112].

Figure 22.10 illustrates the SBD cross section and its parasitic lumped components identified in a planar SBD. The total parasitic capacitances C_{Tot} is noted:

$$C_{\text{Tot}} = C_{\text{j}}(V) + C_{\text{f}} + C_{\text{p}} + C_{\text{pp}} + C_{\text{gap}} \tag{22.13}$$

where C_{f} is the capacitance between anode finger and n^+-GaAs, and the sum of C_{p}, C_{pp} and C_{gap} is the total pad-to-pad capacitance $C_{\text{p,sum}}$. The quantity $C_{\text{j}}(V)$ is defined in Eq. (22.8) and depends on the correction factor γ_{c}, which is affected by the edge effect due to the small area of the anode. For a circular shape anode γ_{c} is given by [92]

$$\gamma_{\text{c}} = 1 + 4b_1 \frac{W(V)}{R_{\text{o}}} + 3b_2 . W^2(V) R_{\text{o}}^2 \tag{22.14}$$

where b_1 and b_2 are numerical value of, respectively, 0.36 and 0.34. For square shape anodes, γ_{c} becomes [113]

$$\gamma_{\text{c}} = 1 + 4b_1 \left[\frac{(L + l)W}{Ll} \right] \tag{22.15}$$

where L and l are the anode side dimensions. The model has been extended to the case of general shape and considering surface effects in Ref. [114]. For the anti-parallels pair structure described in the next paragraph, we note that $C_{\text{p,sum}}$ parasitic capacitance is short-circuited in the even-harmonic equivalent circuit. This is compensated by a supplementary mutual inductance between fingers that shall be minimized to avoid a resonance effect on the mixer conversion loss. In addition, the series impedance can be written as a sum of different impedances and resistances [104]

$$Z_{\text{s}} = R_{\text{s,epi}} + R_{\text{sheet}} + Z_{\text{spread}} + Z_{\text{skin}} + R_{\text{ohmic}} \tag{22.16}$$

where $R_{\text{s,epi}}$ stands for the resistance created by current flow through the un-depleted epitaxial layer, R_{sheet} corresponds to the current flow through the substrate depending on the plasma resonance correction factor [115], Z_{spread} stands for the bulk spreading impedance caused by expansion of the current after the small anode area and Z_{skin} is the skin effect impedance. The control of the 3D parasitics and its modelling [104] is crucial for operation optimisation at THz frequencies and can be accurately controlled and optimized with planar technology. Measurements lead to the extraction of the lumped elements [116]. Other structures have been fabricated to reduce the contribution of the spreading resistance, such as vertical diodes [117] or structures where the membrane is locally removed by back-side photolithography [118]. From the metal contact point of view, carbon nanotubes Schottky contacts could offer an alternative to their solid-state counterparts because of the nm diameter scale junction areas, high electron mobilities and low estimated capacitances [119].

22.3.3 Terahertz Schottky Multipliers and Mixers

The performance of the multipliers and mixers is evaluated on the basis of three indicators: the power efficiency in the case of multiplier, the conversion losses and noise temperature for a mixer. Altogether the Schottky contact quality, the balance and geometry of the circuit as well as its propagating lines dimensions have to be optimised with great care in the THz range. At these frequencies, the line loss starts to be significant enough to overcome the signal couplings, and the available local oscillator power is scarce. The current state-of-the-art THz circuit configurations introduced in the previous paragraph feature either planar SBD flip-chip mounted onto a thin substrate or integrated Schottky MMIC [109] that are inserted in a narrow channel. The signals are transposed from a TE_{01} mode in the waveguide input port to a quasi-TEM mode and progressively matched to the diode cell on each of the frequency bands (RF, LO and IF for a mixer and first and n^{th} harmonic for a multiplier). In addition, the arrangement of the diode in two or three terminal port structures [120, 121] illustrated in Fig. 22.8 favours even or odd mode harmonic generation or mixing, but also signal balancing including AM signal noise rejection and signal

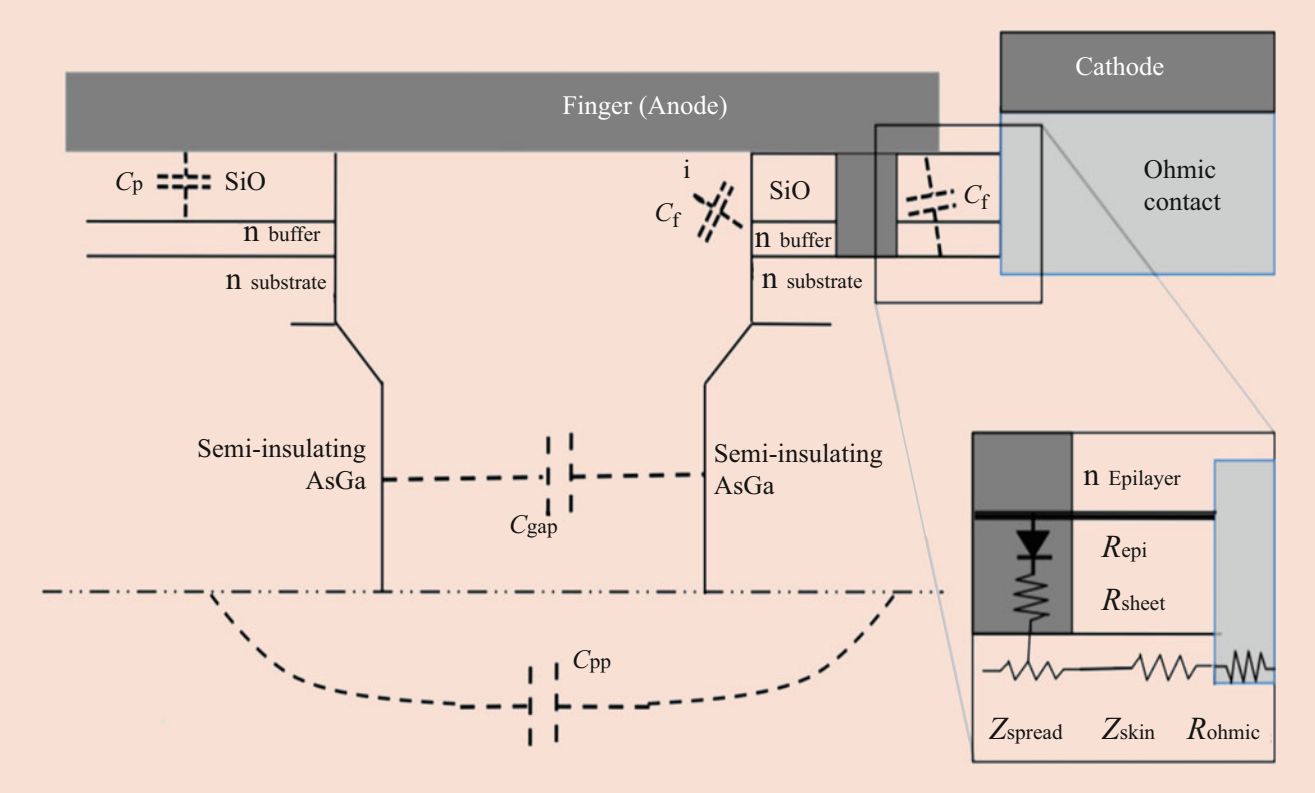

Fig. 22.10 Schottky-barrier diode (SBD) electrical model and its parasitic lumped components

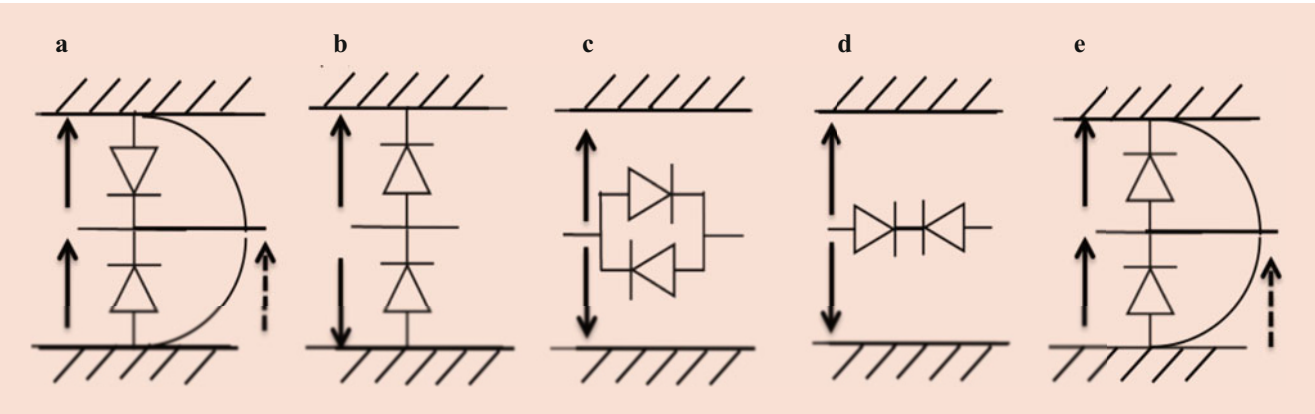

Fig. 22.11 Two and three terminal circuit configuration in split-bloc channels. The arrows represent the primary mode excited (TE_{01} mode in the waveguide input port) and quasi-TEM mode in the transmission lines. Configurations a, b, c, d, e and corresponding references are detailed in Table 22.1.

isolation in order to leverage emitter stability, interference and spurious signals.

In a mixer, a minimum of two balanced anodes guarantee minimum noise contribution, but the number of anodes can increase for multiplier operation in order to improve power handling capabilities. In both cases, the characteristic discrepancies of the diodes can have a significant impact on the total conductance and could be compensated by independent DC biasing. The DC bias of the diode is additionally necessary in varactor frequency multipliers where high power efficiency is required or in mixers to compensate from the low power availabilities of local oscillator emitters at THz frequencies. The implementation of DC biased circuitry at high frequency is particularly delicate, as it can lead to a breaking of the symmetry involved in the balance of the devices, produce cross-mode coupling and also in a non-negligible way pick up external spurious during operation.

Table 22.1 Selection of different implemented configuration

Configuration	*a*	*b*	*c*	*d*	*e*
Doubler	[91, 122]		[120]		
Tripler		[123]	[124, 125]	[126, 127]	
Mixer		[121, 128]	[86, 110, 121]		[129]

Figure 22.11 and Table 22.1 give a selection of different implemented configurations. Configuration *a* favours a very high third harmonic isolation in [122] for doublers. In [91] it is enhanced with a two-port parallel arrangement at each diode level in order to improve the power handling capabilities. Configurations *b* and *c* allow trapping the second harmonic in the diode loop. They are widely implemented in subharmonic mixing to reduce the LO frequency of operation down to half of the RF signal frequency. Configuration *b* is implemented in open-loop configuration triplers [123,124] or balanced subharmonic mixers [128]. However, configuration *c* strengthens the confinement and balance of the second harmonic signal, and provides wider channel dimensions not affordable by open-loop configuration, and thus introduces a larger range of low loss transmission lines for matching the input and output signals securing best mixer performances at 600 GHz [110] up to 1.2 THz [128] or varistor tripler [125]. A variation of configuration *c* with a split central line gives access to the even harmonics for doubler [120] or subharmonic mixing. It is also proposed for low noise and wide instantaneous IF bandwidth fundamental balanced mixers (FBM) predicting good noise temperature performance and more than 4 times typical RF and IF instantaneous bandwidths [130] or for frequency tripling over 50% relative bandwidth at 300–520 GHz in Ref. [130]. The DC bias circuit can be achieved in configuration *c* where the diode cell has to be revisited at a lower level to allow a DC path while keeping an anti-parallel arrangement at RF, LO and IF frequencies necessary for subharmonic operation [86]. The fabrication methods rely on fabrication accuracy supplementary insulator layer underneath the bridge in order to avoid DC contact from n^{++} layer to gold. A single DC path feeding the two anodes has been demonstrated in Ref. [86] at 1.2 THz (Fig. 22.6). Independent DC-paths for the diodes of an anti-parallel pair mixer have been proposed in Refs. [130]. Both solutions feature a multilayer process that leads to a high fabrication effort and rely on the quality of the insulators and pinhole density level. Another design of a subharmonic mixer based on a splitted microstrip transmission line (or slotlines) consists in applying the bias through the IF port avoiding multilayer process [131]. Finally, configuration *d* is an anti-series configuration, which epilayer has to be optimized for odd harmonic generation [126, 127] and configuration *e* is a balanced configuration used in fundamental mixing [129]. FBMs can theoretically reach better noise performance than SHMs [132].

22.3.4 Driving Application of THz Schottky Diodes

Both Schottky-based detectors and emitters have a long history of practical implementation in laboratory-, ground- or space-based systems. We will now review the main driving applications. These applications are actively shaping the technological development of Schottky-based THz multipliers and mixers. In THz astronomy the interest lies in both interstellar medium and planetary atmospheres, since they are incredibly rich in molecular species with spectral rotational and vibrational signatures that lie in the 1–10 THz frequency range. The Heterodyne Instrument for the Far-Infrared (HIFI), launched on the Herschel Space Observatory, has provided an unprecedented view of the Universe up to 1.9 THz [79]. Important discoveries, especially the abundance and structure of singly ionized carbon, have now been documented. However, many important molecule lines are beyond this frequency range [129]. For instance, the OH line located around 2.5 THz is a fundamental tracer of the interstellar chemistry of azote and oxygen and can be used for the study of diffuse clouds. Relatively close to this frequency the HD line is expected at 2.675 THz. This molecular line stands as the important tracer of the cosmological H/D ratio, the formation of the first generation of stars and of the evolution of the giant planets. Moreover, the HD line would provide planetary scientists critical information on the evolution of the atmosphere of rocky planets and moons. For all the reasons above, heterodyne receivers are most suitable for molecular detection in this THz frequency range as they offer high spectral resolution along an instantaneous bandwidth of few GHz. The mixer of choice is often based on superconductor technology, such as the Hot Electron Bolometer (HEB) mixer. HEBs work above superconductor-insulator-superconductor (SIS) mixer operating frequencies from 500 GHz to 5 THz with noise temperature around 800–1000 K, which is about 10–20 times the quantum limit. HEB and SIS detectors require 4 K or below for operation relying of costly cryocoolers or liquid helium cryostats. Commonly, they are actively coupled to room temperature solid-state technology LO system, *i.e.* the herein discussed Schottky-based multiplier emitters . These emitters offer the best output power with wide frequency band tuning and unequaled spectral purity. Their phase noise comes from the synthesizer's degrading naturally as a function of the order of multiplication. Recently, sustained effort has been done on building heterodyne receiver arrays below the THz frequencies, and many of them have been deployed on ground-based telescope at high altitude [133]. While the Schottky-based multiplier emitters also appear to be the best

option for developing a portable 2–3 THz receiver array [134], there is still a great effort to be done on improving their efficiency and their coupling to the detector detector and largely increase the power handling of multipliers to making state-of-the-art emitter and lower frequency driver stages reaching above 1 mW of continuous wave (CW) power at 1 and 1.5 THz [91, 135]. In THz radiometry, composition and wind measurements with a broad temporal and spatial coverage are critical for our understanding of the dynamics and coupling processes in the thermosphere/ionosphere system. They can be investigated by measuring dynamical variables such as neutral wind speeds, temperature and atomic oxygen density above approximately 100 km. The 2.06 THz emission is a promising line for remote sounding of thermospheric winds. The strong interest in this line is pushing towards the development of Schottky-based mixers for room or passively cooled temperatures (150–300 K) [118] that can fit in a 6U CubeSat for spaceflight or ultra-compact global radiometer system [136]. A larger user range of applications is being developed going from biology and medicine [80], active imaging [81] and telecommunication systems [24, 137], which are focusing on the implementation of adaptation of the systems to their particular use and environment. Regarding telecommunications, the trend in electronics consumer market is to transfer ever-increasing amount of information wirelessly to conceive standards able to accommodate data rates of hundreds of Gb/s and even Tb/s. Despite fibre optic extension, millimetre-wave backhaul (BH) market will still connect more than 50% of mobile sites with point-to-point (P2P) and point-to-multipoint (PMP) links for front- and back-hauling for dense urban scenarios. In this particular context, high-sensitivity sub-THz receivers preserve the amplitude and phase information of the incoming radiation to minimize the signal-to-noise-and-distortion-ratio (SNDR) characteristics, with best instantaneous IF BW [24, 137]. The next generation of Schottky-based solid-state instruments will have to keep their inherent performance in terms of spectral resolution, while achieving high portability related to their operative environment. They will open the path to new portable THz instruments with a flexible observation tradeoff between sensitivity, mapping speed and spatial coverage that could be adapted to in situ spectroscopic measurements and portable telecom systems.

22.3.5 Perspectives

The application mentioned above will benefit greatly from the potential improvement margin in sensitivity or continuous power generation performances of the SBD at THz frequency. This optimisation focuses on several aspects at different levels starting from the junction material, parasitics, frequency cutoff, and power handling (see Sects. 22.3.1 and 22.3.2), its implementation in an embedded RF circuit (see Sect. 22.3.3) and finally its use at system level (see Sect. 22.3.4).

22.4 Resonant Tunnelling Diodes

Resonant-tunnelling diodes (RTDs) have re-emerged in the recent years after almost two decades of oblivion as a viable active device for THz frequencies. Meanwhile, the fundamental operating frequencies of RTD oscillators have almost reached 2 THz, RTD oscillators work at room temperature, can have tiny dimensions and provide an output power close to mW level. They can also be used as detectors. Combination of all these salient features in one device suggests RTDs as a promising enabling technology for THz applications. This section will review the basic principles of operation of RTDs and RTD oscillators, the present status of the RTD sub-THz and THz radiation emitters and detectors, and it will outline several possible applications for RTDs.

22.4.1 Resonant Tunnelling

The resonant-tunnelling phenomenon is essentially a quantum-mechanical analogue to the transmission of light through a Fabry-Pérot resonator known for more than a century in optics. Resonant tunnelling has been described in a classical book on quantum mechanics already 70 years ago [138]. Due to resonant tunnelling, the double barriers become highly transparent for electrons, which are in resonance with one of the quantum well (QW) states between the single barriers [138] as described in

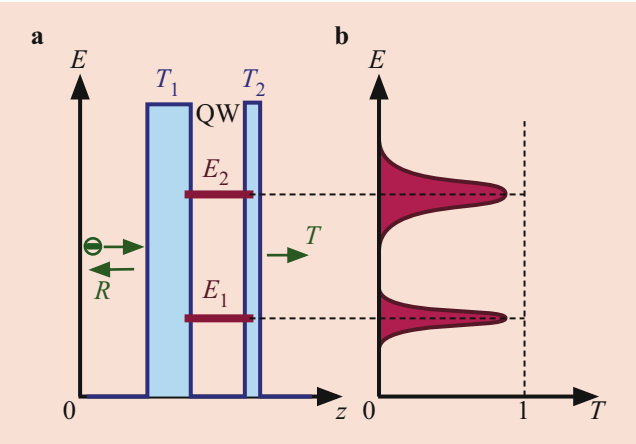

Fig. 22.12 (**a**) Tunnel double barrier consisting of two barriers with low tunnel coefficients ($T_i \ll 1$) and a QW with resonant states (E_i) between them. (**b**) The total tunnel coefficient of the double barriers (T) exhibits a series of resonant-transmission peaks, when the energy of the incident electron coincides with one of the resonant states in the QW. R indicates the reflection coefficient associated with carriers reflected by the barriers

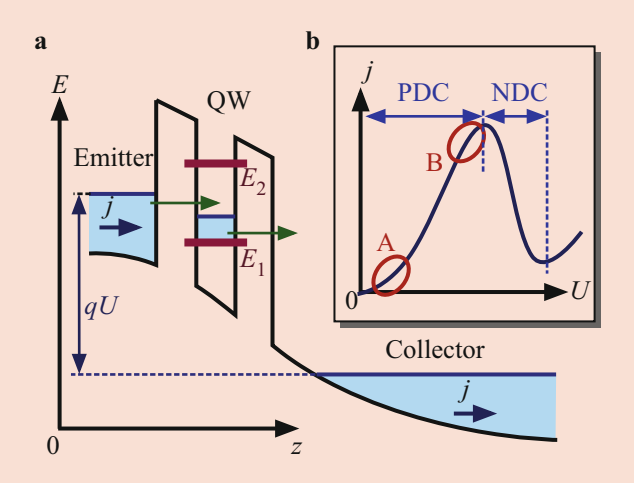

Fig. 22.13 (**a**) Band diagram of a semiconductor heterostructure RTD, where a double tunnel barrier is sandwiched between n-doped emitter and collector. The QW contains two energy levels (E_1 and E_2). A voltage difference U is applied between the emitter and collector contacts. (**b**) N-shaped RTD I-V curve with an NDC region. The region of the onset of the resonant tunnelling (**a**) and the positive-differential-conductance (PDC) region (**b**), where the current is starting to switch off, exhibit highly nonlinear I-V curve, which could be used in THz detectors

Fig. 22.12. If the barriers are symmetric, then the resonant-tunnelling transmission becomes as high as 1, i.e. the barriers become ideally transparent. The phenomenon could be used to construct tunnel devices with particular properties. Of special interest and importance are resonant-tunnelling diodes (RTDs) with an N-shaped I-V curve and a negative-differential-conductance (NDC) region; see Fig. 22.13. The RTDs are usually based on semiconductor heterostructures, where two (or sometimes more) tunnel barriers are sandwiched between highly doped contact regions. The electrons are resonantly tunnelling through the barriers from the emitter to the collector. With increase of the applied bias (U), at some point, the QW resonant state (2D subband in the QW) shifts below the conduction-band bottom in the emitter and, consequently, the resonant current due to elastic tunnelling through the QW states becomes impossible. This leads to a decrease in the RTD current (j) and appearance of an NDC region. This NDC region makes the RTD an active device, i.e. the RTD exhibits gain in this region of applied bias. The mechanism of NDC in RTDs with two and more barriers and even resonant-tunnelling transistors have been predicted and described more than half a century ago [139]. However, practically realisable RTDs have been described a decade later and experimentally demonstrated shortly afterwards [140].

An instructive analysis of coherent resonant tunnelling in RTDs (as outlined above) could be found in Ref. [141]. An alternative point of view (sequential-tunnelling model [142]) suggests that electrons can tunnel through the barrier in two steps: they tunnel into the QW first, then they loose their coherence due to a scattering event, and afterwards, as a second step, they tunnel further to the collector. Surprisingly, the RTD I-V curves turn out to be the same in both approaches [143], thus reproducing the NDC region equally well. By contrast, shot noise suppression below a value of 0.5 was found to discriminate resonant tunnelling from sequential tunnelling, where maximum suppression cannot achieve values below 0.5 [144].

Coulomb interaction has an ubiquitous effect on the DC and AC RTD characteristics. It leads to an increase in NDC, i.e. to a steeper decrease of the current in the NDC region. In high-quality RTDs, it can even transform an N-shaped I-V curve into a Z-shaped one with a hysteresis region [145,146].

22.4.2 RTD Oscillators

An RTD oscillator consists of a passive resonator (it could be a simple resonant LC circuit) connected to an RTD operating in the NDC regime. The NDC can compensate for the losses in the resonator thus bringing the resonator into oscillations. The high-frequency properties of RTDs enable operation of such oscillators even at THz frequencies, which are record-high for electronic devices.

The fundamental oscillation frequencies of RTD oscillators have been increasing very rapidly during the 1980s with a frequency of approximately 0.7 THz reported in 1991 [147]. The sub-THz oscillators at that time have been based on hollow-waveguide resonators with a whisker-contacted RTD mounted inside the waveguide. Fabrication of such oscillators was a challenging task, and higher operating frequencies could not be achieved in the subsequent almost 20 years; therefore the development and research on RTD oscillators has almost stopped at that time.

A breakthrough has been achieved around 2010, when two groups have demonstrated THz RTD oscillators at ≈1 THz [148] and ≈1.1 THz [149]. The oscillators were based on resonant slot antennas integrated with RTDs. This concept of RTD oscillators was demonstrated for the first time earlier in 1997 at 650 GHz [150]. Meanwhile, the frequency of almost 2 THz has been achieved with such RTD oscillators [151]. On-chip slot-antenna oscillators are usually mounted on a hemispherical Si-lens [148, 151], since antenna radiation is predominantly emitted into the substrate. The Si-lens makes such oscillator relatively bulky ($\sim$cm^3). On the contrary, slot-antenna oscillators on a membrane could be integrated with additional planar horn antennas, which leads to a very compact ($\sim$mm^2) THz emitter [149]; see Fig. 22.14.

In recent years, few other types of sub-THz and THz RTD oscillators have also been reported, e.g. RTD oscillators integrated with on-chip patch antenna at 0.5 THz [152]. It has also been shown that microstrip travelling-wave RTD oscillators should be operating at THz frequencies [153].

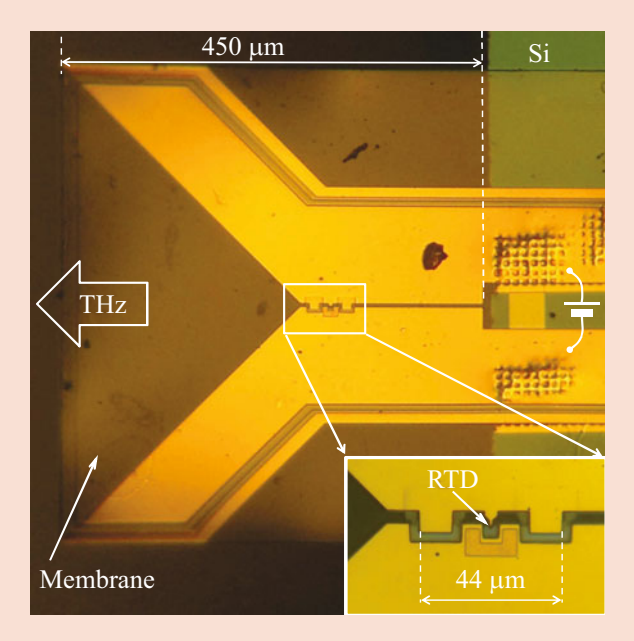

Fig. 22.14 Membrane slot-antenna THz RTD oscillator with an additional Vivaldi antenna. (Reprinted from [149], with the permission of AIP Publishing)

Such oscillators are similar to metal-metal THz quantum cascade lasers (QCLs), where the cascade is replaced by its single period, i.e. an RTD . Contrary to THz QCLs which require cryogenic cooling, microstrip RTDs and all other types of RTD oscillators are room-temperature devices.

GaAs RTDs with AlAs or AlGaAs barriers were usually used in the past [154–156], since it is a lattice-matched material system. Later on, InGaAs RTDs with AlAs barriers and InGaAs/InAs QW started to be used [150]. AlAs barriers are strained in this case, but they are higher (≈1.2 eV) than those in GaAs/AlAs RTDs, that allows one to suppress "valley" current and the peak-to-valley current ratio could be as high as ≈50 at room temperature in this material system [157]. In such RTD with very thin barriers (≈1 nm), a current density of ≈30 mA/μm^2 has been achieved [151], thus leading to high NDC and high gain. This material system is predominantly used nowadays [148, 149, 151, 158–160].

Antimonide RTDs have been studied as well in the last decades due to their type-II band offsets at the InAs/AlSb heterojunction and particularly low-resistance Ohmic contacts to InAs. For example, InAs/AlSb RTDs have been used in oscillators working at ≈0.7 THz [147]. GaN/AlN RTDs start to show promise in recent years; however their current density and the conductance of the Ohmic contacts are an order of magnitude lower than those in InGaAs/AlAs RTDs [161]. Another intriguing material system is based on graphene layers separated by a few-monolayer-thick boron-nitride barrier. NDC in such structures has been demonstrated recently [162].

22.4.3 Frequency Limitations of RTDs

Two obvious time constants could be identified in RTDs. One is the tunnelling time through a single barrier; it is extremely short [163] and not relevant for frequency limitations of RTDs. The second one is the tunnel lifetime (τ) of the quasi-bound (resonant) states in the RTD QW. τ can become arbitrary long, and when we reduce the tunnel transparency of the barriers, it might potentially limit the operating frequencies of RTDs [164].

However, the dynamics of RTDs is quite involved [160, 165–167]. It is determined by the QW-charge relaxation processes, which could be described in the linear response approximation by a relaxation time constant ($\tau_{\rm rel}$). If the Coulomb interaction effects are neglected, then $\tau_{\rm rel} = \tau$, but Coulomb interaction modifies $\tau_{\rm rel}$ considerably. In general, $\tau_{\rm rel}$ depends on the thicknesses of the RTD layers (RTD geometry), material parameters, doping profile and the operating regime of RTD. Particularly, $\tau_{\rm rel} < \tau$ and could be even $\tau_{\rm rel} \ll \tau$ in the positive-differential-conductance (PDC) region of the RTD I-V curve. On the contrary, $\tau_{\rm rel} > \tau$ and could be $\tau_{\rm rel} \gg \tau$ in the NDC region. These effects have been confirmed experimentally [168].

Another important consequence of the Coulomb interaction is the displacement currents, which provide a mechanism of current flow through the RTD barriers at high frequencies ($\tau_{\rm rel}\omega \gg 1$, ω is the angular frequency) [160, 165, 167]. Particularly, the real tunnel current can be flowing through the emitter RTD barrier, but the displacement current mechanism provides the current flow through the collector barrier. The mechanism leads to persistence of NDC to the frequencies, which are far beyond the inverse relaxation-time limit, i.e. when $\tau_{\rm rel}\omega \gg 1$. The high-frequency NDC is particularly large in RTDs with heavily doped collectors; see Fig. 22.15a. These effects have been demonstrated directly experimentally [168]. Further on, it was experimentally demonstrated that RTD oscillators can also work at frequencies far beyond or at least close to the inverse relaxation-time and tunnel-lifetime limits [149, 169, 170]. The frequencies covered in these experiments are up to 1.1 THz, but the analysis of the experimental data indicates that these are ubiquitous effects, which should extend to the higher frequencies as well.

Both the relaxation-time and displacement-current effects could be included into a general, but rather simple 4-element RLCR equivalent circuit of RTDs [160, 165, 167]; see Fig. 22.15b. The circuit corresponds to the following equation for the RTD admittance (Y_{RTD}):

$$Y_{\rm RTD}(\omega) = i\omega C_{\rm ec} + G^{\infty} + \frac{G^0 - G^{\infty}}{1 + i\omega\tau_{\rm rel}}, \qquad (22.17)$$

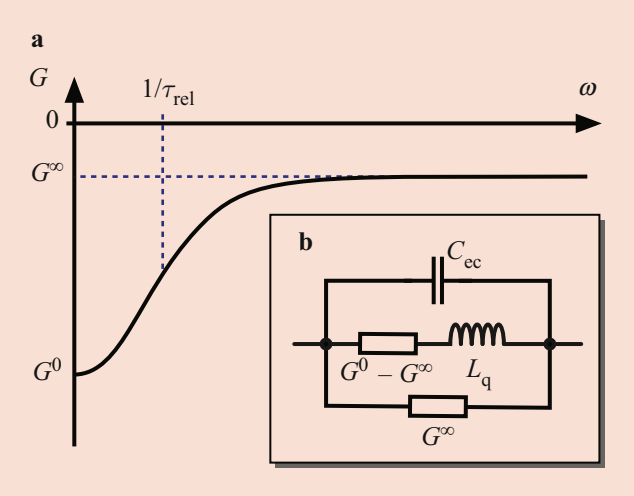

Fig. 22.15 (**a**) A sketch of the frequency dependence of the RTD conductance in the NDC region of a double-barrier RTD with a heavily doped collector. The DC RTD conductance (G^0) rolls off at the frequency of $1/\tau_{rel}$ and saturates at the level G^∞ with the further increase of frequency. (**b**) A general AC equivalent circuit of a double-barrier RTD

where C_{ec} is the geometrical emitter-collector RTD capacitance, L_q is a "quantum" inductance, equal to $\tau_{rel}/(G^0 - G^\infty)$. The circuit describes well the experimental data on RTDs and RTDs oscillators mentioned above [149, 160, 168–170].

Although the above inherent limitations of RTDs could be overcome by a proper design of RTD layers, the limitations due to parasitics will remain, and they are still limiting the operating frequencies of RTDs and RTD oscillators. The main parasitic contribution is coming from the RTD contact resistance, although other contributions are also important, especially at THz frequencies, e.g. the spreading resistance of the doped semiconductor layers, inductive contribution of an air bridge, Ohmic losses in the metal layers of the antenna and resonator, etc. [159, 160].

Nonlinearity of RTD I-V curve (Fig. 22.13b) can be used for THz radiation detection, the RTD acting as a passive device in this case. Additionally, it can be used to probe the inherent frequency limitations of RTDs. Such measurements have demonstrated a huge potential of RTDs: the nonlinear RTD response has been measured up to 3.9 THz already several decades ago [171, 172].

22.4.4 Applications of RTDs

RTDs are not used in practice yet. However, they do show great promise for practical applications in the last decade. RTD oscillators are evolving into a viable and enabling technology for THz and sub-THz emitters: they are quite simple devices [159, 160] of sub-mm dimensions [149], operating at room temperature and providing an output power close to a mW level while their power consumption is quite low (dc-to-THz conversion efficiency is at the level of few percent); they cover the frequencies from zero to 2 THz [151]. Combination of all these properties in RTD oscillators is unique for THz emitters.

The oscillator linewidth is an important parameter for practical applications. A free-running RTD oscillator has the linewidth in the range of ≈10 MHz [169], although with a phase-lock-loop stabilisation, it could be reduced to ≈1 Hz [173]. Another important parameter is the frequency tunability. Due to variation of the RTD capacitance with bias, RTD oscillators are tunable in a narrow frequency range of ≈1–2% [159, 160]. The tuning range can be increased to ≈10–20% by building an additional varactor into an RTD oscillator. Integrating several such oscillators in one chip, one can extend the tuning range even further, e.g. up to ≈40% [174].

Meanwhile, THz systems based on RTD oscillators have been also demonstrated experimentally. For example, imaging system and high-resolution spectrometer with RTD oscillators have been demonstrated at ≈300 GHz. High-data-rate wireless transmission has been also reported: single-channel 34 Gbit/s transmission at 500 GHz and two-channel 2×28 Gbit/s transmission [175] relying on frequency (500 GHz and 800 GHz) and on polarisation (2 orthogonal linear polarisations) division multiplexing.

SBD have been used as detectors in the above data-transmission experiments. However, nonlinear RTD detectors could be used instead: wireless system at ≈300 GHz based on RTDs as oscillators and detectors with the data-transmission rate of 9 Gbit/s has been reported recently [176].

22.4.5 Perspectives

RTD oscillators and detectors already have characteristics appropriate for some applications. However, the study of RTDs shows that there is much room for further development. Particularly, much higher output power and operating frequencies should be achievable with RTD oscillators, while much higher sensitivity should be within the reach of THz RTD detectors; thus RTDs evolve into an enabling technology for real-world THz applications.

22.5 Field-Effect Transistors

Even if the initial theoretical idea of Lillienfeld of building a transistor "for controlling electric currents" [177] was based on the unipolar field-effect concept, the field-effect transistor (FET) was not fabricated until 1952 by George

Clement Dacey and Ian Ross, at Bell Labs (in that case a JFET [178], with a PN junction as gate contact), some years after the bipolar junction transistor. The high input impedance of FETs (nowadays using gate electrodes based on metal oxide semiconductor junctions or Schottky contacts) makes them the privileged choice not only for digital circuits (based on Silicon) but also for high power systems (based on wide bandgap semiconductors such as gallium nitride or silicon carbide) and high frequency and low noise applications (based on III-V semiconductors), which will be our focus.

From one hand, in recent years the operation frequency of last generation FETs, called high electron mobility transistors (HEMTs) or Heterojunction FETs (HFETs), has well entered into the THz range. These transistors are based on different types of heterojunctions made with high mobility III-V semiconductors (mainly InP HEMTs with InGaAs/InAs composite channel) and with gate lengths shorter than 50 nm. After the first THz transistor fabricated at Northrop Grumman in 2007 [179], the THz HEMTs technology has also been developed at Fraunhofer [180], and more recently at Fujitsu [181] and it is now allowing the development of terahertz monolithic integrated circuits (TMICs) [182], for example, low noise amplifiers above 600 GHz [183], 850 GHz front ends for transmitter and receivers [184], the first circuit able to amplify signals above 1 THz [185].

On the other hand, MOSFETs based on III-V compounds are also envisaged as alternates to the Si CMOS technology for digital circuits in order to become the key for continuing Moore's law [186].

These important milestones have been reached by means of important technological efforts and by applying the traditional scaling rules, but also by focusing on the reduction of the parasitic effects (mainly the cross-talk contributions of the contact accesses to the gate-source capacitance C_{gs} and gate-drain capacitance C_{gd}), since the intrinsic limit of the cutoff frequencies of 100 nm-gate HEMTs is already within the THz range, as indicated by Monte Carlo simulations [187]. Indeed, the physical modelling of HEMTs has allowed the advance of the technology by avoiding the expensive trial and error approach when testing new architectures (as double gate transistors [188]), novel materials [189] or noise performances [190].

22.5.1 Frequency Limitations of FETs

Apart from the "classical" operation as amplifiers and digital switches, since recently, FETs are also being exploited as THz detectors at frequencies well above their typical cutoff frequencies f_T and f_{MAX}. In fact, by definition, these cutoff frequencies indicate the limit of operation of transistors as amplifiers (used as a 2-ports circuit) under different loads. f_T is related to the cutoff of the power gain with short-circuited output, and f_{MAX} to the cutoff of the maximum available gain, thus providing the maximum frequency of oscillation of a circuit using a transistor embedded into an optimum external passive feedback network.

In the last generation of THz FETs, the values of f_T and f_{MAX} are not only limited by the intrinsic gate capacitances but also by parasitic effects (mainly contact resistances and pad capacitances). On the other hand, when using FETs as THz detectors , the operating conditions are completely different (as well explained in Ref. [191]) with respect to their operation as amplifiers or oscillators, since they act as a one-port circuit, with just one AC input (RF or THz). Therefore, two possible approaches can be taken, whether superimposing an AC signal to the DC bias (i) at the drain (drain coupling conditions, DCC), or (ii) at the gate (gate coupling conditions, GCC), with source grounded in both cases.

Under DCC the gate contact is not used as an input port, but just to bias the devices. The output signal is commonly the DC drain voltage, measured in an open circuit, as shown in the large signal equivalent circuit of Fig. 22.16. The key point of that circuit is the nonlinear dependence of the drain current I_{D0} vs. drain voltage (i.e. the DC $I_D - V_{DS}$ curves), which provides a non-zero V_{out} when an AC signal is applied to the drain contact.

While in two-port configuration, the frequency limit of FETs is given by the total gate capacitance (the sum of C_{gs} and C_{gd}), when used as one-port detectors, the cutoff frequency is higher, since only one of the capacitances, C_{gs} or C_{gd}, is effective. Under DCC operation C_{gd} is the key, since the gate is AC grounded, so that C_{gs} is short-circuited and the influence of the gate resistance is null. Conversely, only C_{gs} is of importance for determining the limit frequency for signal detection in GCC. Interestingly, RF detection in GCC can only be performed above a certain frequency, when gate and drain can be considered as an AC short circuited (i.e. $1/(\omega C_{gd}) \rightarrow 0$), since an output signal can only be obtained when an AC drain voltage is applied.

The initial demonstrations of THz detection by means of FETs were made using commercial GaAs HEMTs fabricated by Fujitsu [192–194], and laboratory prototypes of HEMTs on different material systems: GaAs [195], GaN [193] and InP [196], but also with Si MOSFETs [197], all of them fabricated following the "classic" design rules for optimising their operation as amplifiers. The theoretical background for the THz detection was based on the plasma wave theory by Dyakonov–Shur [198, 199], so that FETs used for THz detection have been imprecisely labelled as "plasma-wave detectors ". Even if such theory has been the engine for the

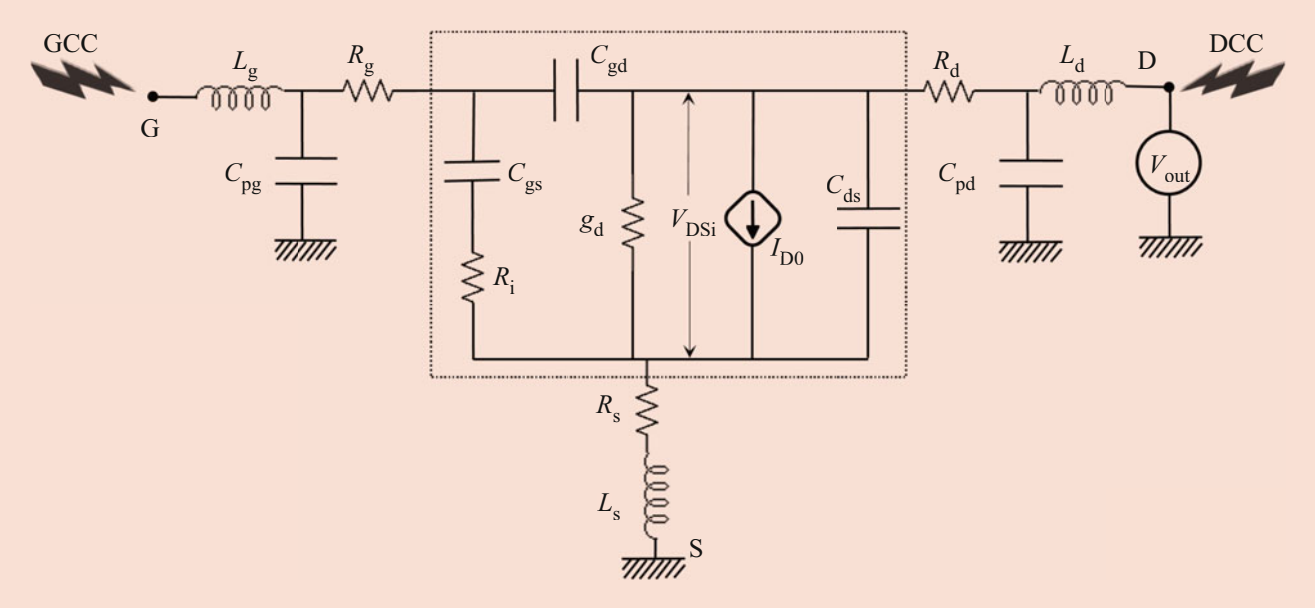

Fig. 22.16 Large signal FET equivalent circuit indicating the operation as RF detector in both DCC and GCC configurations. The intrinsic part of the transistor is enclosed in the dashed rectangle

fabrication of novel architectures of plasma-wave THz detectors [200, 201], like the asymmetrically interdigitated dual-grating gate (DGG) structures [202], a weak experimental support [194–196] of the resonant detection predicted in those seminal papers has been obtained, probably due to the too ideal assumptions about the device behavior introduced by the theory [203, 204]. Moreover, instead of the enhanced responsivity with frequency predicted by plasma-wave theory, a frequency roll off is found in experiments, which can well be interpreted in terms of a parasitic capacitance [205] or an increase of the effective resonant cavity due to cap layers [206].

The absence of a consensus about the plasma-wave origin of the experimental results has led to the search of other approaches, as the pseudo-two-dimensional hydrodynamic model [207] and the one presented in [191], using the well-established lumped element modelling of the transistors by means of the equivalent circuit of Fig. 22.16. This latter model is able to correctly explain the results obtained in graphene FETs up to 67 GHz and has been helpful for the optimisation of the design of the detectors. However, such quasi-static analysis and the lumped element model presented in [191] is valid only for low frequencies (<100 GHz); for higher frequencies the consideration of distributed elements is necessary [208]. It is also important to notice that this resistive self-mixing (rectification given by the nonlinearity of the $I_D - V_{DS}$ curves) can be further enhanced by resonant plasma waves at THz frequencies, but only to a very limited extent (much lower than expected by the Dyakonov–Shur theory) due to the high-frequency dependence of the channel impedance [209], not considered in the ideal plasma-wave models [198, 199].

22.5.2 FETs as THz Detector

Taking advantage of the better understanding of the FET detection mechanisms and making use of circuit models, the fabrication of THz detectors with FETs (TeraFETs) with specific designs (and often with integrated antennas for an improved free-space coupling) has been achieved recently. The concept of a heterodyne detector , based on the mixing of a beating photoexcitation and the incoming THz radiation, has also been proposed and theoretically studied [210].

Figure 22.17 reports a summary of the performances, both in terms of responsivity and noise equivalent power (NEP) for different technologies of TeraFETs. Apparently the best results are obtained with asymmetric DGG on InGaAs [211], reaching a NEP as low as 0.48 pW/Hz$^{1/2}$ @292 GHz. However, these results have been obtained after a normalisation of the input power taking into account the beam and the device area (results shown with dashed lines in Fig. 22.17). When the total optical power is considered, the results for those devices are modest when compared with the rest of technologies. Also, by using an amplifier at the output of a CMOS-based detector [208], the responsivity can be boosted, but the NEP (which is the important figure of merit) is significantly degraded. Figure 22.17 reports the available results for commercial GaAs Schottky-barrier diodes (SBDs).

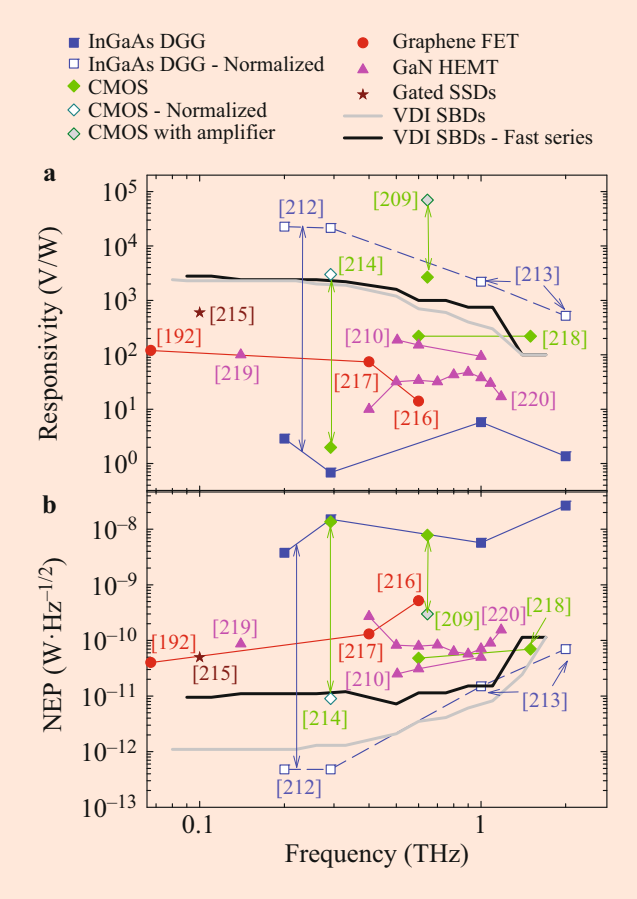

Fig. 22.17 (**a**) Responsivity and (**b**) NEP of different technologies of FET-based THz detectors found in the literature. Normalised values (using the detector and beam sizes) are shown with open symbols, and the corresponding raw values (connected with arrows) have been estimated. For comparison, the performances of commercial VDI THz detectors based on GaAs SBDs are also shown

It can be observed that, apart from the artificially normalised results of [211–213], no FET-based detectors have been able to obtain better results than SBD-based detectors. This is due to the fact that the nonlinearity of the SBDs is always higher than that of FETs (it is only approached near pinch off [214]). Not even graphene FETs, in spite of the promising characteristics of this material, are able to outdo the performances of SBDs [191, 215, 216]. Only at high frequencies (above 1.5 THz), 90 nm Si-CMOS [217] devices with integrated antennas and designed for improved impedance matching are able to compete due to the frequency roll-off suffered by SBDs. On the other hand, even if GaN does not seem to be the optimum choice for THz applications due to its much lower mobility, HEMTs with integrated antennas [218, 219] provide unexpectedly good performances as THz detectors. Also, exotic FETs based on GaN nonlinear asymmetric nanodiodes (gated self-switching diodes, G-SSDs) have also exhibited good THz response [214, 220].

These results, summarised in Fig. 22.17, seem to indicate that, presently, the technological maturity and a good design in order to correctly exploit plasmonic effects are the most important points for achieving good THz performances.

22.5.3 FETs as THz Emitters

THz emission by FETs has also been reported in the literature and interpreted in terms of the Dyakonov–Shur theory [198, 199] as the amplification of plasma waves upon reflection at the borders of the channel when appropriate bias and boundary conditions are fulfilled. As in the case of detection, emission takes place at frequencies beyond the typical cutoff frequencies of the transistors. Voltage-tunable emission, appearing in a threshold-like manner, has been observed in both InGaAs/InAlAs [221] and GaN/AlGaN transistors [222]. Plasmon-resonant terahertz emission has also been achieved by optically pumping an InGaP/InGaAs/GaAs HEMT incorporating DGG structures and a vertical cavity [223] or an AlGaAs/InGaAs/InP HEMT [224, 225]. Recently, emission from dedicated AlGaN/GaN high-electron-mobility transistors (multifinger and integrating antenna structures) has been measured, but it could not be attributed to plasmonic instability phenomena [226].

22.5.4 Perspectives

Due to the recent application of FETs to the field of THz detection and emission, there is still a lot of room for improvement of their performances. Indeed, up to now, apart from the integration of antennae or simple circuit elements (such as capacitors), the design of the devices has not been much modified with respect to that used for their classic operation as amplifiers. Most of the recent efforts made for optimising the performance of FETs acting as detectors have been made on GaN- and graphene-based devices, with promising results. However, classic high-mobility semiconductors such as InGaAs or InAs could also be a good option for obtaining the best frequency performances (at least until high-mobility graphene can be steadily obtained). On the other hand, a better understanding of the influence of the plasma waves on the practical performances of FET-based THz detectors and their possible use for the fabrication of emitters must be achieved by means of realistic modelling techniques accounting for all the complexities of the real devices (mainly parasitics and power losses).

22.6 Heterojunction Bipolar Transistors

A heterojunction bipolar transistor (HBT) is a bipolar transistor where the emitter-base junction (EBJ) is a heterojunction allowing an optimisation of the doping of the base and emitter layers to perform higher frequency operation.

22.6.1 Physics of the Heterojunction Bipolar Transistor

The PN Junction

Only NPN HBTs are addressed. Without detailing the physics of the PN junction which is a key element of microelectronics, we are interested in its dynamic behaviour. At high frequency, the electrical equivalent circuit of the junction, shown in Fig. 22.18 for forward biases, is such that, for reverse biases, the junction conductance G_d becomes very small and only the depletion part, C_T, of the capacitance remains. The resistance R and the self-inductance L in series account for anode and cathode accesses including the metal contact and the quasi-neutral region (QNR), with voltage drop and inductive effect.

The capacitance C_d results from the diffusion of minority carriers. It reproduces the ability of minority carriers to follow the electrical modulation. For a long diode, the cutoff frequency depends on recombination mechanisms of minority carriers, but this is less true for HBTs where the base thickness is small in comparison with the diffusion length. Parasitic capacitances around the junction contribute to the cutoff frequency, with an increasing importance for small junction area.

Such a circuit is valid for low and high frequencies but is questionable for sub-millimetre waves and THz frequency regimes. Beyond 300 GHz, the circuit should include elements to account for the non-stationary behaviour of carriers transport. If there is no publication on PN junction modelling at THz frequency, we can take a look at forward biased SBD: in these diodes, the transport only involves majority carriers. Even if the transport of minority and majority carriers is different between an abrupt PN junction and a Schottky junction, similar mechanisms can be converted with RLC cells in series (Fig. 22.19) able to reproduce inertial effects along the junction. Index d, N and N^+ are associated with depletion region below the anode metallisation, undepleted N region and heavily doped N^+ region for low resistivity cathode contact. The Schottky model in the THz frequency range may suggest the improvement of Fig. 22.18 model of the PN junction in the THz domain.

The Bipolar Transistor

Figure 22.20a shows the NPN bipolar junction transistor (BJT) built with two back-to-back PN junctions where the same P-type region is thin enough with regard to the electron/minority carrier diffusion length. In normal operation, emitter-base junction (EBJ) is forward biased, while collector-base junction (CBJ) is reverse biased.

The forward voltage V_{BE} allows to inject electrons from the emitter to the base (I_{nE}), as illustrated in Fig. 22.20b, and reciprocally holes towards the emitter (I_{pE}). The reverse voltage V_{BC} generates an electric field to collect electrons that diffuse through the base (I_{nC}), but this field lets few holes to diffuse from the collector to the base (I_{pC}) with an almost negligible intensity. Recombination mechanisms in each region, I_{RN} in the base QNR, I_{RE} in the EB Space Charge Region (SCR) and I_{RC} in the CB SCR, contribute to the holes current of the base (I_{pB}). When the electric field is high enough in the CB SCR, impact ionisation occurs, leading to I_{CBII}. Recombination current occurs in the volume as well as at the surface and interface of the transistor.

Without I_{CBII}, net values of the current at each terminal are: $I_B = I_{pE} + (I_{RE} + I_{RN} + I_{RC}) + I_{PC}$, $I_E = I_{nE} + I_{pE}$ and $I_C = I_E - I_B$. The injection efficiency factor, an important parameter for the NPN BJT, can be written as

$$\gamma = \frac{I_{nE}}{I_E} = \frac{I_{nE}}{I_{nE} + I_{pE}} = \frac{N_D W_E D_{nB}}{N_D W_E D_{rB} + N_A W_B D_{pE}} \quad (22.18)$$

where N_A and N_D are the P-type doping level in the base and the N-type doping level in the emitter, respectively, W_B and W_E are the thickness, and D_{nB} and D_{pE} are the diffusion coefficients of minority carriers in their respective regions. A high current gain (I_C/I_B) needs γ as close as possible to 1. The relative value of each parameter requires to moderate the BJT's base doping level. This leads to a high base resistance which affects dynamic performances.

Figure 22.21 shows the small-signal equivalent circuit used here to discuss important parameters involved in high-frequency figures of merit, where parasitic capacitances and distribution effects are removed. In common emitter, the transconductance g_m and the dynamic resistance R_π are

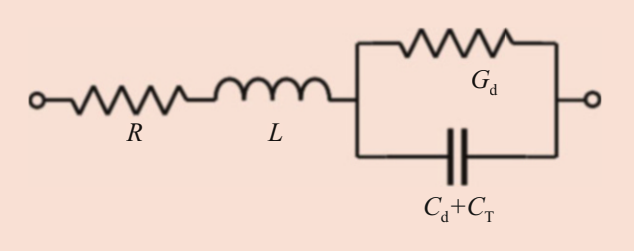

Fig. 22.18 Small-signal equivalent circuit of the PN homojunction (forward biased)

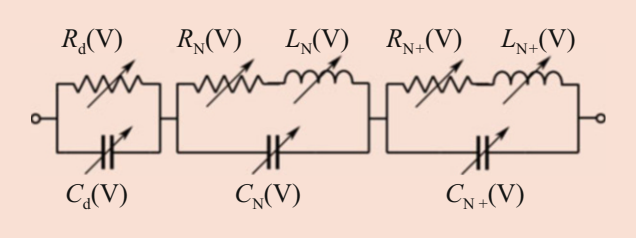

Fig. 22.19 Direct small-signal equivalent circuit of a Schottky diode at 1 THz including inertial effects

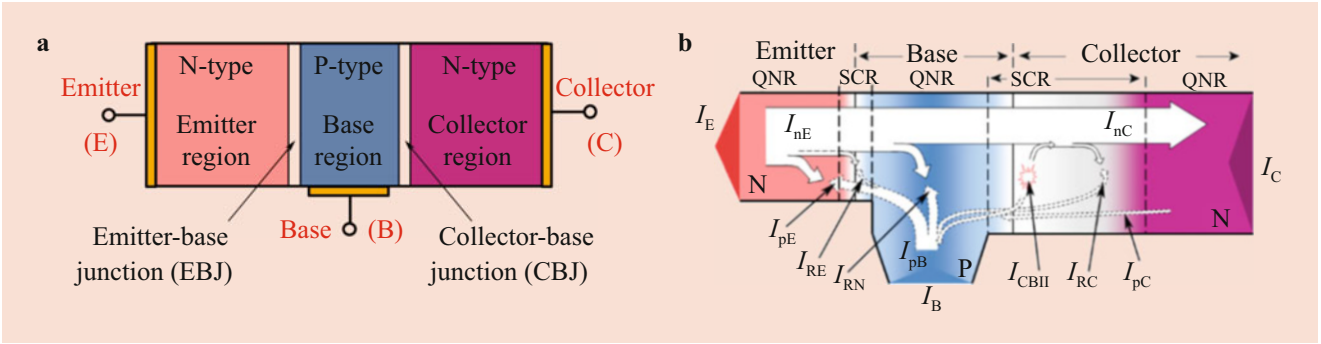

Fig. 22.20 (**a**) Schematic representation of the NPN transistor with emitter, base and collector terminals, and (**b**) sketch of different electron (I_n) and hole (I_p) current components (the size of the arrows highlights the magnitude of the current)

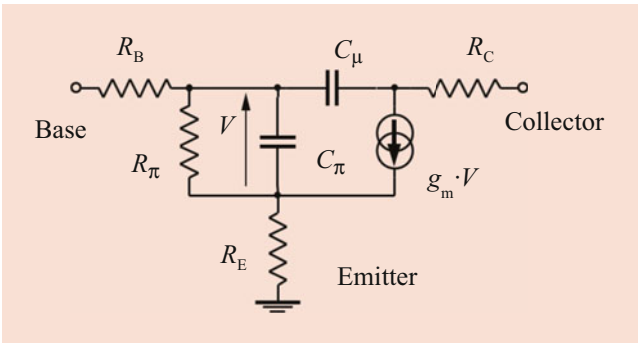

Fig. 22.21 Simplified small-signal equivalent circuit of the bipolar transistor (Π-topology)

$$g_m = \frac{qI_c}{k_B T} \quad \text{and} \quad R_\pi = \frac{k_B T}{qI_B} \tag{22.19}$$

where q, k_B and T are, respectively, the elementary charge, the Boltzmann constant and the device temperature. Intrinsic capacitance and access resistance complete this circuit.

The high values of the transition frequency where a gain crosses 0 dB are often extracted at lower frequencies corresponding to the measurement range of the network analyser (taking into consideration a –20 dB/dec frequency dependence of the gain). The transition frequency f_T of the current gain can be written as

$$f_T = \frac{g_m}{2\pi \left(C_\pi + C_\mu \left(1 + g_m \left(R_B + R_C\right)\right)\right)} \tag{22.20}$$

Among the different power gains, the invariant and unilateral gain of Mason U and its transition frequency can give the maximum oscillation frequency f_{max}, as

$$f_{max} \approx \frac{1}{4\pi} \sqrt{\frac{g_m}{R_B C_\mu \left(C_\pi + C_\mu \left(1 + g_m \left(R_B + R_c\right)\right)\right)}} \tag{22.21}$$

High performances require high value of f_T and of f_{max}. It is impossible for a BJT to build a thin and highly doped base layer leading to a low value of R_B (required for a high f_{max}) without degrading γ and inducing a lower value of g_m. A low value of R_B can be obtained with a thicker, lower doped base layer, but this leads to a higher value of C_π that affects f_T. Also a low doping level of the base reduces the current threshold of the limiting base punch-through and induces a detrimental high early effect. Such a limit for the BJT highlights the effort that needs to be done for the base design to reach THz transition frequencies.

The Heterojunction Bipolar Transistor (HBT)

In order to build a thin highly doped base layer without reducing the injection efficiency, EBJ is made with a heterojunction with a higher band gap for the emitter than for the base. Equation (22.18) can be derived as

$$I_{pE} = \frac{J_{nE}}{J_{pE}} = \left[1 + \frac{1 + \frac{D_{nB}}{S_{nE} W_B}}{1 + \frac{S_{nE} W_B}{S_{pE} W_E}} \frac{n_E^2 D_{pE} N_{AB}}{n_B^2 D_{nB} N_{DE}} \frac{W_B}{W'_E}\right]^{-1} \tag{22.22}$$

where n_{iB} and n_{iE} are the carriers' intrinsic densities of each region, and their ratio benefits from the difference of band gap ΔE_G:

$$\left.\frac{n_{iE}^2}{n_{iB}^2}\right|_{HBT} \approx \left.\frac{n_{iE}^2}{n_{iB}^2}\right|_{BJT} \times \exp\left(\frac{\Delta E_G}{k_B T}\right) \tag{22.23}$$

In the case of InP/InGaAs HBT, the ratio n_{iE}^2/n_{iB}^2 is about 10^{-10}, enabling a wide range of doping levels. With a lower doping level of the emitter near the EBJ, the transition capacitance can be lower. A high doping level of the base is possible, reducing all drawbacks already discussed for the BJT, and also limiting current-crowding effect.

Due to negligible value of I_{pE} in III-V HBT, the base current, I_{RN}, is mainly due to recombination among which mostly Auger effect dominates, which leads to a moderate current gain. The smaller Auger effect in Si/SiGe HBT (in

comparison to InP HBT) does not control the base current, and then the current gain can reach very high values.

High values of f_T and f_{max} need a high electron mobility in the highly doped base as well as a high current density. Moreover, at high-currents, the Kirk effect affects the transition frequency [227]. This is due to the spreading of the neutral base layer into the collector region of the device. The base layer spreading mechanism derives from an analysis of the effect of the current-dependent buildup of the mobile-carrier space-charge density in the collector transition layer. For a single heterojunction bipolar transistor (SHBT), the threshold current density associated with the Kirk effect is

$$J_K = qv_{sat}\left(N_{DC} + \frac{2\varepsilon_s\left(V_{CB} + V_{bi}\right)}{qW_c^2}\right) \tag{22.24}$$

where V_{CB} is the applied collector base voltage, V_{bi} the built-in voltage and W_C, the thickness of the collector layer of doping N_{DC}. One can conclude that the threshold of the Kirk effect is controlled by the collector doping and the collector thickness. The Kirk effect is a key physical mechanism in the modern HBT optimisation because the reduction of the whole delays across the device imposes the highest current density such as 15–25 mA/μm^2 at maximum f_T/f_{MAX} for InP HBTs and up to 34.4 mA/μm^2 for the highest f_T/f_{MAX} SiGe HBTs reported in 2016.

Some drawback effects also occur in THz HBT, limiting the performances such as the self-heating effect or impact ionisation. Some other mechanisms have to be taken into account in details for further performance improvement such as band gap narrowing (BGN) [228], minority transport properties in the heavily doped base [229] or the Kirk effect [227]. Let's focus on self-heating and breakdown voltage. Very high current densities of 15–30 mA/μm^2 are reached with relatively small area of EBJ and CBJ, whose EBJ is 100–200 nm wide, and few μm long. Self-heating becomes important and contributes to limiting dynamic performance because carrier transport properties are degraded with increasing temperature. SiGe HBTs can benefit from a better thermal conductivity of the Si substrate (κ_{Si} = 148 W/K/m) than for GaAs (κ_{GaAs} = 46 W/K/m) or InP (κ_{InP} = 68 W/K/m). Metallic levels have a higher contribution to thermal dissipation in III-V compounds, with wider contacts closer to the heat source and less interconnect levels than in BiCMOS. The size of the chip and the thickness of the substrate are crucial parameters as well as the spreading of the heat source in separated emitters. Mesa structure and trench isolation increase the thermal resistance, but substrate thinning, metallic through-wafer vias and the transfer of the initial substrate to a higher conductivity material such as SiC or diamond are proposed to reduce self-heating. The breakdown voltage also limits performances due to impact ionisation (II). For II, a large electric field across the collector depletion region induces hot electrons able to generate electron-hole pairs. The BV_{CEO} breakdown voltage is current gain dependent, in favour to larger values for III-V HBTs with lower current gains than for SiGe HBTs [230].

Complete Small-Signal Equivalent Circuit

Figure 22.22 shows the complete small-signal equivalent circuit where the CBJ capacitance is distributed in two parts to account for the base resistance repartition with a wider CBJ under the EBJ. Extrinsic capacitances and inductances are also included as well as intrinsic CB and output resistance. The transconductance g_m also brings an extra high-frequency delay τ_{hf} specific for the Π-topology circuit, but not included in charging and transit times.

In addition to the first simplified circuit, the high-frequency performance can be described with transit times and delay between the emitter and the collector, τ_{EC}, extracted from f_T: $\tau_{EC} = (2\pi f_T)^{-1}$. τ_{EC} sums up charging times and transit time along the structure

$$\tau_{EC} = g_m^{-1}\left(C_\pi + C_{be}\right) + \left(g_m^{-1} + R_E + R_C\right)\left(C_\mu + C_{bc}\right) + \tau_E + \tau_B + \tau_C \tag{22.25}$$

where C_{be} and C_{bc} are the extrinsic capacitances of the transistor between B/E and B/C.

The advantage brought by the band gap difference for EBJ for the injection efficiency contributes to reduce the emitter transit time τ_E. A simplified relation for the diffusion of holes in the emitter is

$$\tau_E \approx \frac{W_E^2}{2D_{pE}}\frac{G_B}{G_E}\exp\left(-\frac{\Delta E_G}{k_B T}\right) \tag{22.26}$$

where G_B and G_E are base and emitter Gummel numbers [230]. The base transit time depends on the fraction of electrons in diffusion $\tau_B = W_B^2/(\eta_B D_{nB})$ relaxed in the

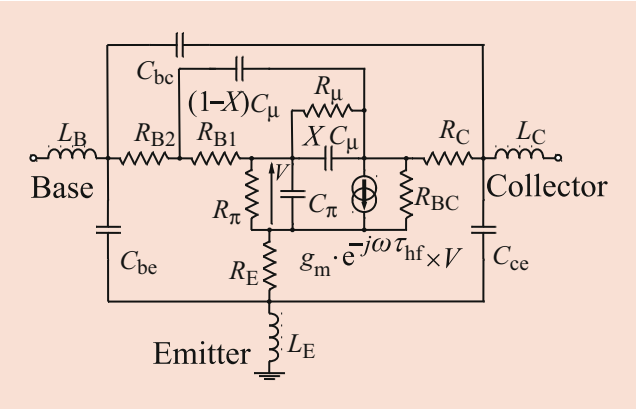

Fig. 22.22 Complete small-signal equivalent circuit of the bipolar transistor (Π-topology)

conduction band, and electrons with few interactions, in non-stationary regime at velocity v_B: $\tau_B = W_B/v_B$ (v_B can be higher than saturation velocity, v_{SAT}). The collector transit time is $\tau_C = W_C/(\eta_C\, v_C)$ where W_C and v_C are, respectively, the thickness of the CBJ SCR and the collector velocity ($v_C \approx v_{SAT}$). The factor η_C accounts for the collector transport specific case and is equal to 2 when electrons reach rapidly v_{SAT} with no overshoot velocity.

Reduction of the Total Emitter-Collector Transit Time τ_{EC} and the Base Resistance

Increasing f_T or decreasing τ_{EC} leads to an overall reduction of charging and transit times. Charging times can be reduced by lowering the access resistance, by increasing doping level at vicinity of wider Ohmic contact and thinning QNR. The improvement of the contact resistance between the semiconductor and the metal of the electrodes requires the use of suitable metal alloys. The EBJ dynamic resistance is a reverse function of the I_C collector current, and the maximum of f_T is obtained for a high I_C value. This current value indicates the end of "normal" operation of the transistor with the progressive occurrence of the Kirk effect. Thus, pushing back the Kirk effect by increasing the collector doping while reducing its thickness allows to increase the limit of the collector current density and thus the maximum value of f_T. However the impact ionisation threshold is lowered and the collector capacitance can increase.

One can try to decrease the depletion capacitances by decreasing the surface of the junctions, in particular the dissymmetry between EBJ and CBJ. These capacitances can also be reduced by decreasing the doping level in SCR or by acting on the doping profile. The electrostatic extrinsic capacitances should not be underestimated.

The emitter transit time related to the diffusion of charges from the base to the emitter can be reduced by increasing the energy barrier height of the EBJ heterojunction. A small base thickness, a band gap gradient and injection of "hot" carriers from the emitter will promote a low transit time in the base. Finally, the reduced thickness of the moderately doped collector will allow a shorter collector transit time.

All this requires a tradeoff because, for example, the increase of collector doping favourable to the decrease of the EBJ dynamic resistance (collector current—Kirk effect) also leads to an increase of the depletion capacitance. Breakdown voltage is also seriously affected, and the increase of self-heating due to the increase of the current density causes a temperature rise that degrades transport properties thus inducing higher transit times.

For the base, the tradeoff concerns the value of the base resistance which must not be too high in order not to penalise f_{max}. The leverage margins are the increase in base doping level jointly with the reduction of the EBJ width and of the distance to the lateral base contact.

For silicon-based devices, with the increase of the doping levels, sometimes at the limit of solubility, the shrinking of the whole HBT dimensions is limited by the diffusion of species, in particular with respect to the overall thermal budget (activation annealing, compatibility with other devices using high temperature process). The band gap discontinuity height needed to compensate for the decrease in the difference of doping levels of EBJ must also be taken into account.

Performances and Limitations of HBTs

In comparison with III-V field-effect transistors (FETs), III-V HBTs are volume devices with higher transconductance and current density, exhibiting uniform "threshold" voltage controlled by built-in voltage and less restrictive for lithography. However they require complex and expensive epitaxy. It appears easier to better control the thickness of the intrinsic base through epitaxy than the gate length of a tenth of nanometre through lithography. High transport properties of III-V material follow to be attractive for state-of-the-art HBT based on an ultra-thin and highly doped base. Such material open opportunities for the THz frequency range. Concerning SiGe HBT, the cutoff frequencies of the best RF-CMOS processes come close to those of SiGe HBTs, but at the expense of a significantly more advanced lithography, typically at least three lithography nodes [231].

The output conductance g_d of the HBT is low, and then the ratio g_m/g_d is very high (above 200). HBT are far less sensitive to capacitance parasitics associated with interconnections than FET for devices exhibiting the same f_T because the intrinsic capacitances are higher in the bipolar transistor. For instance, after a de-embedding step, the f_T value of HBT is closer to the raw f_T [231].

The output power can also be increased with device size. While it increases the device-related capacitances in both HBTs and MOSFETs, an increase in emitter length alone reduces all resistances in series in HBTs but a corresponding increase of the FET gate width leads to a larger gate resistance [231].

The flicker noise ($1/f$ noise) in III-V HBT, and thus the phase noise of the oscillator, can be lower than in FET-based circuits. SiGe HBTs also have much lower corner frequencies than MOSFETs, in which $1/f$ noise keeps increasing for more advanced nodes. HBT may show low HF noise despite the base current. Overall, HBTs appear to have a distinctive advantage in the area of mm-wave and THz amplifiers from a technical circuit design perspective [231].

22.6.2 Different Technologies of Heterojunction Bipolar Transistors

III-V HBTs

THz III-V HBTs commonly consist of an InGaAs base layer, featuring a single heterojunction at EBJ (SHBT) with an

InP emitter or consists of a double heterojunction (DHBT) with InP collector, or, alternatively, of a GaAsSb base layer between InP emitter and collector. The first HBTs have used AlGaAs/GaAs and GaInP/GaAs emitter heterojunctions. With AlGaAs/GaAs it is possible to reach high f_{max} (216 GHz [232]). The HF figure of merit of GaInP/GaAs was small but the HBT exhibits high linearity and low turn-on voltage. Nevertheless GaAs HBTs suffer from various drawbacks such as high self-heating, electron transfer in L Valley in the base and dramatic surface recombination. Therefore GaAs-based HBTs seem to be not good candidates for THz applications.

Most III-V HBTs are triple-mesa devices, with one layer built on top of the other with a pyramid shape: the upper layer always acts as a mask for the one below; therefore it is a self-aligned process. The emitter and the base-collector mesas form the transistor, while the third mesa is etched down to a semi-insulating substrate to provide isolation of devices. The transistor structure is designed emitter-up, since this layer sequence greatly simplifies the fabrication of the transistors for high-speed applications [233].

Figure 22.23 shows the drawing of such an HBT bordered by metallic contacts around the narrow EBJ and CBJ. The emitter under-cut reduces the extrinsic base resistance by reducing the space between the base metallisation and the active zone, while the base under-cut reduces the collector resistance and the CBJ capacitance (the $(1 - X)C_{\mu}$ part in Fig. 22.22).

One alternative to base under-cut is a collector up device. Then f_{max} can increase significantly up to 1.15 THz, as obtained in 2001 nearly 20 years ago [234], but it can require transferred-substrate process which is not compatible with MMIC technologies.

Some of the highest f_T and f_{max} figure of merit are represented in Fig. 22.24 for the two III-V HBTs and SiGe HBT discussed later.

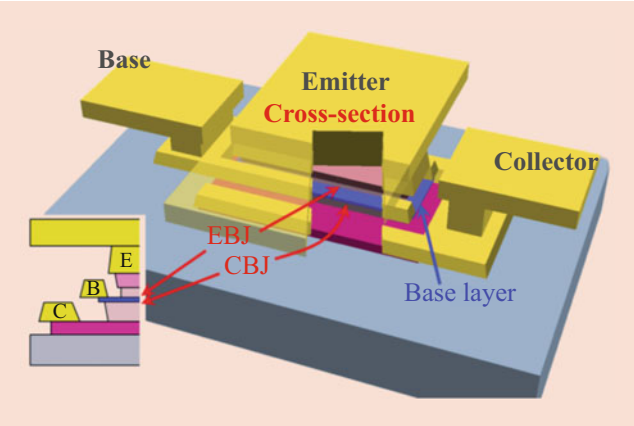

Fig. 22.23 Drawing of the HBT with metallic contact around the mesa, with a cross-section underlining the location of the EBJ over and CBJ under the base layer in blue

InP/InGaAs HBT InP-based HBTs realise an excellent tradeoff between a high output power, high f_T and f_{max} values and low noise. They are also fully compatible with 1.55 µm telecom wavelength systems technology.

The first InP HBTs were based on InP/InGaAs and AlInAs/InGaAs emitter heterojunction. State-of-the-art f_T and f_{max} were obtained with single heterojunction and double heterojunction. Figure 22.25 shows the layer stack and bands profile of an InP/InGaAs DHBT.

InP HBT exhibit some advantages when compared with GaAs ones: (i) better transport properties of electrons in InGaAs than in GaAs. (ii) $\Delta E_V = 0.37$ eV at the InP/InGaAs interface which is higher than in AlGaAs/GaAs heterojunction, while $\Delta E_C = 0.24$ eV. Such a low conduction band discontinuity leads to a low threshold voltage, but it is enough to boost the energy of injected electrons and reduce the base transit time. (iii) Surface recombination velocity is slower in $In_{0.53}Ga_{0.47}As$ than in GaAs (that is in favour of size reduction). (iv) Better thermal conductivity of InP substrate than in GaAs even if the $In_{0.53}Ga_{0.47}As$ thermal conductivity is 10 times smaller than the GaAs one. Chemical etching selectivity between InP and InGaAs is far better than between AlGaAs and GaAs and close to selectivity between GaInP and GaAs.

The breakdown voltage is very low in SHBT (with InGaAs collector layer). DHBT using InP emitter and collector regions are preferred due to the higher breakdown voltage provided by the wider band gap InP collector, even if it requires a complex quaternary alloy epilayers stack. However, current blocking effects can be observed at the CBJ due to ΔE_C. A proper base-collector gradual design is critical to avoid current blocking and to enable high current density operation. High-performance DHBTs have been realised with both InGaAs and GaAsSb base layers.

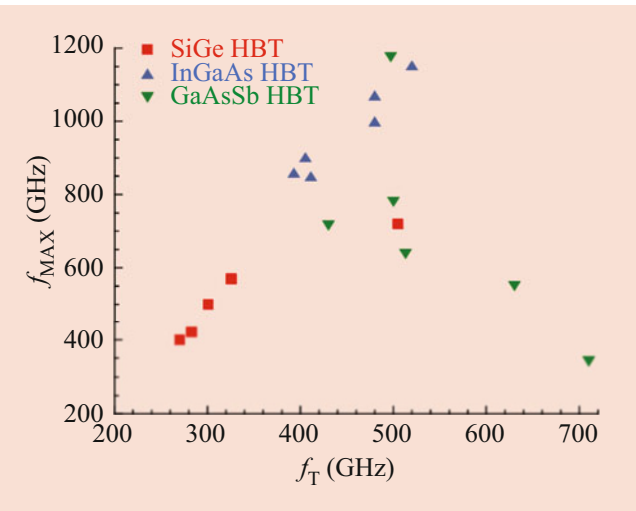

Fig. 22.24 Figure of merit f_{max} vs f_T for highest reported performances for SiGe, InGaAs and GaAsSb HBT [231, 235, 236]

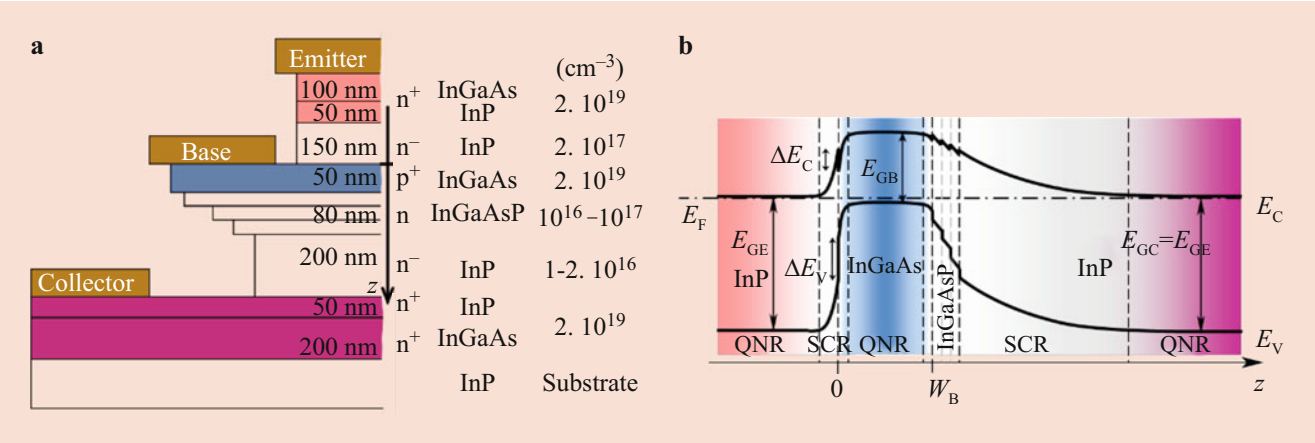

Fig. 22.25 (**a**) Layer stack and (**b**) bands profile of an InP/InGaAs HBT [237]

In state-of-the-art, InP/InGaAs HBT the base-collector region consists of a chirped superlattice of InAlAs/InGaAs layers with a linear varying composition followed by a pulse doping layer to compensate for the induced quasi-electric field [235].

The improvement of InP HBT technologies involves an increase of f_T and a steadily decrease of transit times thanks to the reduction of the base thickness. To a large extent, the improvement of f_T stems from the reduction of parasitics (capacitances and resistors) allowed by the self-alignment, by the reduction of EBJ area and by the increase of the Kirk effect threshold.

For THz devices, the base thickness is typically smaller than 30 nm, and base doping levels are made as high as possible to minimise layer and Ohmic contact resistances, while reducing the lateral spacing between EBJ and extrinsic base contact. P-doping levels greater than 8×10^{-19} cm^{-3} are routinely realised using a carbon doping source in both InGaAs and GaAsSb devices. Typical base sheet resistance for scaled-InP HBT epitaxy is in the range of 500–1000 Ω/sq. Ohmic contact resistivities are critical to down-scaled HBT performance. Very low Ohmic contact resistivities based on proper surface preparation and contact selection have been reported to highly doped n-type and p-type InAs and InGaAs layers [235]. Contact resistivities of $0.2 - 1 \times 10^{-8}$ Ωcm^2 were obtained for molybdenum-based contacts to n-type InAs layers with 8.2×10^{19} cm^{-3} active carrier concentration in [235]. To avoid surface oxidation and contamination, contacts were deposited in situ in the MBE growth chamber immediately after epitaxy growth [237].

As it can be seen in Fig. 22.24, the highest performances for InGaAs HBTs are $f_T = 520$ GHz and $f_{max} > 1100$ GHz [237]. Breakdown voltages are about 3.5–4.5 V. Further improvement of HF figure of merit will be obtained by the ongoing shrinkage of the emitter width and contact resistivity lowering.

InP/GaAsSb HBT InP/GaAsSb DHBTs are developed as an alternative to InP/InGaAs DHBTs. For InP/InGaAs/InP and AlInAs/InGaAs/InP DHBTs, the main concern is the conduction band potential barrier between the InGaAs base and the InP collector [236].

The staggered band alignment at InP/GaAsSb heterojunctions enables the use of a simplified device structure with a pure InP collector layer. Pure InP collectors increase the junction symmetry and provide good thermal conductivity as well as high breakdown voltages. GaAsSb has an additional advantage: it can be easily p-doped with carbon to levels of 1×10^{20} cm^{-3}. However, hole mobilities in GaAsSb are lower than those of InGaAs, resulting in higher base sheet resistances at comparable thicknesses and doping levels [233].

Even though GaAsSb-based DHBTs eliminate electron blocking at the base-collector heterojunction, InGaAs-based DHBTs remain highly competitive. The use of InP/GaAsSb emitters leads to fast junction turn-ons with collector current ideality factors of $n_C = 1.0$, which cannot be attained in abrupt InP/InGaAs or AlInAs/InGaAs emitters. Since the ternary GaAsSb alloy is characterised by a lower electron mobility than its InGaAs counterpart, one must employ base grading quasi-electric fields to speed up electron transport across the base layer [236].

Among the values shown in Fig. 22.24, InP/GaAsSb DHBTs were demonstrated f_T / f_{max} of 503 / 780 GHz with a breakdown voltage of 5 V [238].

At present, the highest reported f_{max} is 882 or 1175 GHz depending on the extraction method used with measurement limited to 110 GHz [239], with W_E of 200 nm and BV_{CEO} of 4.1 V, while f_T has reached 710 GHz for a 250-nm GaAsSb DHBT, where the thin collector layer is realised by a gradual InGaAs compound and with a breakdown voltage of 1.75 V [240].

The InP/GaAsSb DHBT energy band diagram at equilibrium is shown in Fig. 22.26. It consists of an InP emitter, a

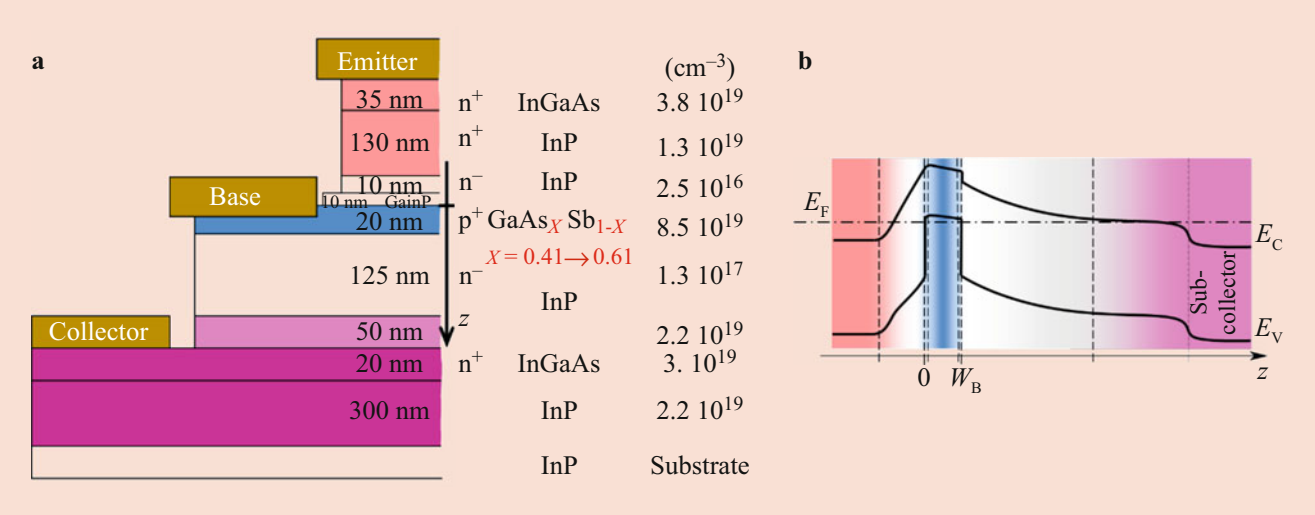

Fig. 22.26 (**a**) Layer stack and (**b**) bands profile of an InP/GaAsSb HBT [238]

$GaAs_xSb_{1-x}$ base and InP collector epitaxial layers [236]. The base layer has a non-constant composition. The purpose of the compositional grading is to generate an electron drift field and thus to reduce the base transit time. The base is built with an As fraction x linearly increasing from the collector to the emitter side and a doping grading N_B, from 0.41 to 0.61 and 4.5 to 9.2 $\times$ 10^{19} cm^{-3}, respectively, from CBJ to EBJ. Thus, the slope of the conduction band in the base creates an accelerating quasi-electric field that pushes electrons towards the collector. The higher doping at the base-emitter interface enables a low contact resistance and thus good base contacts.

The type-II InP/GaAsSb heterojunction between the emitter and the base layer results in conduction (ΔE_C) and valence (ΔE_V) bands discontinuities of 0.1 and 0.73 eV, respectively. To minimise electron blocking with ΔE_C, a thin gradual GaInP layer is added between GaAsSb base and InP emitter [233]. The edge of the conduction band of the $Ga_{0.22}In_{0.78}P$ emitter region is aligned to the conduction band of the $GaAs_{0.61}Sb_{0.39}$ base layer. The valence band edge at the heterojunction $Ga_{0.22}In_{0.78}P/GaAs_{0.61}Sb_{0.39}$ has a large offset which practically eliminates the injection of holes from the base into the emitter, and it enables very high base and low emitter doping levels. This allows to significantly reduced EBJ capacitance and base resistance. The InP collector provides a high breakdown voltage and therefore a high output power [236]. The low doped collector layer where the CBJ SCR can spread is followed by a highly doped sub-collector to provide good collector contact with low sheet resistance.

Further improvement of the device performance (in particular high-frequency figures-of-merit such as f_T and f_{max}) requires lateral and vertical scaling, together with an optimisation of the epitaxial layer design [236] like for InP/InGaAs device. Lateral scaling is beneficial to the reduction of charging times. Vertical profile scaling of the epitaxial base and the collector layers reduces transit times. Transistor scaling necessarily involves an optimisation of the device parasitics because they become progressively more significant with the decreasing size of the devices. The fabrication process and the epitaxial layer design must therefore be improved to broaden the transistor bandwidth [233]. In order to improve the figures of merit, some quaternary alloy, InGaAsSb, are investigated for the base [241] because the $\Gamma - L$ valley discontinuity can be higher in InGaAsSb than in GaAsSb and improvement of low field electron mobility at very high acceptor doping level could be observed like in GaAs or in InGaAs [229].

SiGe HBT SiGe HBT takes benefit from the high integration capabilities of silicon technology. This device is more recent than III-V transistors and band engineering take advantage of III-V HBT research. The core of the device is the SiGe base while the emitter and the collector use a silicon layer. Modern HBTs have a valence band discontinuity at EBJ with a moderate Ge content, and an internal electric field can exist when the Ge content increases gradually from EBJ to CBJ. Strain effects associated with carbon insertion in the base limit strongly the effect of boron diffusion even for doping as high as 5×10^{19} cm^{-3}. If the doping profile is limited by the thermal budget requested for CMOS compatibility, such SiGe HBTs are much more limited for enhancement towards THz figure of merit.

Figure 22.27 shows an HBT from STMicroelectronics with the effective EBJ width of about 100 nm. BiCMOS processes allows self-aligned architectures such as the double-polysilicon self-aligned (DPSA) using a selective epitaxial growth (SEG) of the base. The SEG of the base produce the boron-doped SiGe:C intrinsic layer and the link with the

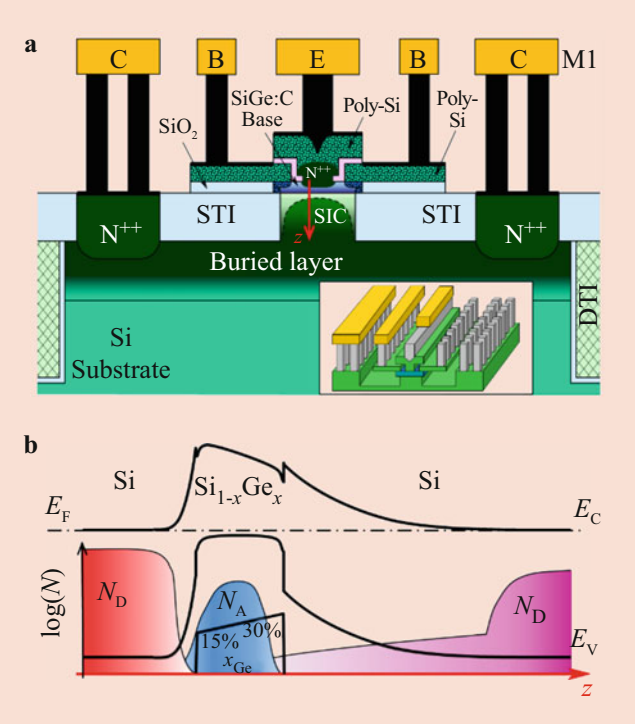

Fig. 22.27 (**a**) Schematic view in CBEBC configuration and (**b**) band and doping profiles of gradual base Si/SiGe HBT

boron-doped polysilicon (Poly-Si) of the base. The collector is built with a buried layer, an epitaxy, N^{++} collector sinker and shallow and deep trenches isolation (STI and DTI). It is used in production in the STM 55-nm BiCMOS technology with patterning capability that enables to reduce the difference between EBJ and CBJ area [236].

Doping, epitaxy layer growth and passivation steps are closely associated in silicon technologies leading to more compact devices than in III-V technologies. Here again, the increase of current densities and the reduction of extrinsic capacitances are crucial points to reach the THz domain. Above the heavily doped sub-collector, the low doped collector completed by the selectively implanted collector (SIC) allows to lower the $(1 - X)C_{\mu}$ and C_{bc} capacitance while maintaining a high Kirk effect threshold. STI reduces the collector capacitance. The process for the emitter with an epitaxial highly doped Si, the emitter poly-Si, and the thin spacer between the emitter and base poly-Si is used to reduce the emitter resistance R_E, the base resistance between the EBJ and the base poly-Si, and the parasitic collector capacitance.

Within the data displayed in Fig. 22.24, such HBTs exhibit f_T/f_{max} of 325/375 GHz with a breakdown voltage of 1.5 V [242] with an EBJ width of 100 nm. The main drawback of the DPSA HBT is the intrinsic to extrinsic base link (SEG to poly-Si) completely dependent of the SEG, restraining base resistance reduction. This can be overcome by replacing base poly-Si by sacrificial nitride, etched after the emitter formation and replaced by a well-controlled epitaxy of the extrinsic base [243].

Low temperature processing with millisecond annealing, with non-selective epitaxial base for optimised vertical doping profiles, self-alignment arrangement for EBJ and CBJ and later base link formation, in a small footprint BEC configuration, all together producing low resistances, capacitances and transit times, have led to half-THz f_{max}. The first results have shown values of f_T/f_{max} of 300/500 GHz in 2010 [244] with an EBJ width of 120nm. In 2016 these values have been improved to f_T/f_{max} of 505/720 GHz [245] with an EBJ width of 105 nm and a breakdown voltage of 1.6 V. The ability to produce high performance SiGe HBTs if the BiCMOS technology move from bulk Si to FD-SOI substrates currently used in CMOS must pay attention to achieve highly doped collector sinker and buried sub-collector and how to manage the thermal dissipation due to the less conductive Silica layer.

III-V and SiGe HBTs Comparison

The advantages of the silicon-based material system are mainly its low cost, its high yield of integration and its manufacturability. A main disadvantage of III-V technologies is their fairly low integration level and yield as well as the difficulty of structural downscaling due to strong surface recombination and the resulting low current gain. Hence, it will be difficult to leverage these technologies to their full extent to enable both more complex mm-wave systems and, in particular, mass-market wafer volume in the future. As a consequence, III-V material-based technologies do not achieve the same enhancement in functionality and energy efficiency as those of silicon technology, which in turn makes it difficult for them to compete also on cost. In addition, the relatively large process variations and the lack of accurate modelling tools have notoriously hampered efficient III-V circuit design. Therefore, the III-V semiconductor industry and the related investment have been focused strongly on high-frequency/high-speed low-volume niche applications [231].

22.6.3 HBT-Based Circuits

Compact Modelling for Circuit Design

HICUM is probably the best compact model for the design of THz circuits based on HBT transistors. The relevant physical effects occurring in advanced HBTs have been included in HICUM/L2 [246] which has been developed over many years simultaneously with SiGe and InP HBT technology, partially within large-scale research projects. HICUM is presently released in all commercial circuit simulators. Besides the main equivalent circuit representing the 3D device structure directly, some additional networks try to address non-quasi-

static (NQS) effects, HF noise correlation and self-heating. However, there is a lack of compact model validation above 300 GHz. Moreover, some physical mechanisms, such as Band-Band Tunnelling [230, 247] and impact ionisation, are not properly taken into account.

Performances of HBTs-Based Circuits

By operating at sub-millimetre wavelengths, the available gain per stage of amplifiers is relatively low, due to the small margin up to the transistor f_{max}, and with an increasing part of losses to compensate for all passive components. Designers should prefer CB topology rather than CE to avoid the Miller capacitance limiting effect. However, such a CB configuration is less stable. For instance, the base inductance coming from the grounding connection and the narrow base-metal contact along the emitter has a high impact on stability and bandwidth [235]. With f_{max} close to 1.1 THz, a 9-stages amplifier using 3 µm emitter-long, 130 nm wide InP HBTs reached 24 dB at 670 GHz, with a saturated output power ($P_{S,sat}$) of −4.0 dBm [248]. The same HBTs in a differential design topology are able to minimise bandwidth reduction, and stability issues give 20 dB gain at 620 GHz, with $P_{S,sat}$ of 2.8 dBm at 585 GHz [249].

In a 200 nm InP technology where the substrate is replaced by a high thermal conductivity SiC, a 9-stages CE amplifier demonstrated 9 dB gain at 521 GHz, while a 5-stages CB amplifier is able of 19 dB gain at 576 GHz, thus 3.8 dB per stage [250].

HBT amplifiers can be compared favourably with InP HEMT amplifiers with 10 stages of which 30 dB is achieved at 660 GHz using 30 nm gate-length HEMT (f_{max} ∼ 1.2 THz) [183], and 17 dB at 850 GHz [251], and 9 dB at 1 THz with 25 nm HEMT [185].

Fixed or voltage controlled oscillators use the fundamental frequency or less efficient harmonics when CW generation is close to f_{max}, requiring subharmonic filtering. For instance, with a 250 nm InP HBT technology (f_{max}∼ 660 GHz), oscillators based on CB cross-coupled topology can deliver 10 dBm at fundamental 280 GHz with a Wilkinson combiner and −17.4 dBm at the 2nd harmonic with 591 GHz in a push-push topology [252]. Such circuits are integrated as local oscillator for mixers and subharmonic mixers for direct or heterodyne THz imagers. Transmission signal demonstrator is also designed with transmitter and receiver circuits operating at 570 GHz with a 130 nm HBT technology [235].

Front-end development for mm-wave is also addressed by the SiGe HBT technology with the demonstration of fully integrated transceiver systems [231]. Triple-push type oscillators have been designed supplying −17 dBm at 490 GHz on chip for a single-ended oscillator [253], while 16 individual differential oscillators in parallel radiating in free-space with ring antennas generate 0 dBm at 530 GHz [254]. Output power of −6.3 dBm is radiated at 430 GHz from a frequency doubler fed with a fundamental differential Colpitts oscillator [255].

From a stable low-frequency source, a cascaded ×18 multiplier chain with 2 tripler stages followed by a balanced doubler generates −3 dBm at 325 GHz [256].

From a 0.25 µm SiGe BiCMOS technology (f_{max}∼ 435 GHz), an imager was built using a frequency multiplication chain of a lower frequency source for 164 GHz fundamental generation and using six harmonic mixers to cover from fundamental to the sixth harmonic around 1 THz. The radiated power generated for the fifth harmonic (820 GHz) reached −25 dBm that enables 90 dB SNR [257].

Original circuits are also investigated, like Terahertz Oscillations from Optical Hot Carrier Injection [258]. Radiation from ultrafast accelerating charges in Si or SiGe can be generated from femtosecond laser pulse excitation and first demonstration showed oscillations around 4.5 THz [259]. Photo-generated electron-hole pairs are separated with increasing velocity under high electric fields. Such a hot carrier transport property should be better understood to link radiation to saturated and overshoot velocity mechanisms in carrier separation.

22.6.4 Perspectives

Pushing HBTs to even higher frequencies needs to overcome limiting factors already discussed, such as self-heating, charge carriers transit time and parasitics. This addresses both fabrication aspects and modelling/simulation tools from the physics at the heart of the transistor, to a more precise circuits design for highest frequencies. The roadmap pushes to reduce the emitter and collector junction area, by thinning the base with high doped layer to maintain low access resistance and low junction capacitance, and by spreading the heat closely from the hot spot to surrounding 3D. InP MMIC integration on SiGe Bipolar CMOS (BiCMOS) can offer the best of each part for THz circuits, while MOS-like FET digital circuits aspire to a low power use for the bipolar counterpart. Concerning more specifically the III-V HBT, we can point out its integration on the same chip with MOS technologies (hetero integration), for optical telecoms and low-cost Terabits transmissions in datacentres. Concerning the application domains, the prospects for very fast silicon bipolar transistors fall fairly conventionally into three categories:

1. In telecom, the rise in frequency of networks with millimetre 5G but also 6G whose frequencies discussed are between 100 GHz and 300 GHz is an area that is already the subject of research in BiCMOS.
2. In THz sensors (or radars), but the CMOS/ BiCMOS positioning remains to be determined because the BiCMOS

will only really make a difference if power is required, especially for transmission. On this subject, we know that BiCMOS is potentially interesting but the field of THz sensors being vast and the markets still poorly identified, we remain in a hypothetical vision.

3. In more exotic applications such as radio-astronomy and quantum computing (signal processing circuits).

22.7 Complementary Metal Oxide Semiconductor Transistors

Over the past several decades the performance of silicon-based technologies, i.e. complementary metal oxide semiconductor (CMOS) and Bipolar CMOS (BiCMOS), has been improved at a remarkable rate. Field-effect transistors (FETs) and, in particular, silicon-germanium (SiGe) heterojunction bipolar transistors (HBTs) now report cutoff frequencies f_T and maximum oscillation frequencies f_{max} reaching or going above 300 GHz which directly enters into the THz frequency range [260].

This improvement of performance of FETs originates from the reduction in the minimum feature size as well as innovations, such as shifting to high-k dielectrics, implementing silicon-on-insulator (SOI), strained active regions, etc. The progress is driven almost exclusively by the requirements of higher density and efficiency in digital systems. From the progress in the field of analogue CMOS integrated circuits, there are indications that CMOS FETs already approached to their speed limits at about 45 nm and 65 nm nodes. However, a theoretical analysis of SiGe HBTs indicates that operating frequencies of 1 THz and beyond are plausible in the future [261].

The main advantage of the development of silicon technologies for applications in the THz frequency range, besides the ability to fabricate large-scale circuits, comes from the possibility to form large collaborative acting clusters that can offer opportunities different from other established technological approaches for the THz frequency range or even to enable new functionality for applications that other technologies cannot provide.

Here we will review the progress in the field of THz emitters and detectors concentrating on CMOS-based devices.

22.7.1 Emitters

In comparison with compound semiconductor technologies based on GaAs or InP and others, which are commonly used for high-frequency applications, the use of standard CMOS-based electronics is severely restricted by lower f_T and f_{max} frequencies and considerably low breakdown voltage of typical devices which, in addition to limitations in frequencies, poses a limitation in power. In order to achieve generation at THz frequencies, a number of different solutions for CMOS-based emitters have been proposed. For example, the rectified signals of several phase-shifted oscillators can be summed in order to produce higher harmonics by the so-called linear superposition technique and resulted in the first report of −46 dBm at 324 GHz [262]. One of the first reports to implement a signal emitter using device nonlinearity for simultaneous harmonic generation resulted in −49 dBm at 410 GHz [263]. The latter concept relies on the realisation of a strong fundamental oscillation, which typically is close to the half of f_{max} and efficient extraction of the harmonics. The schematics of two oscillators which got mostly used to implement this concept are given in Fig. 22.28. The oscillator schematics presented at the left side employ three transistors with inductive loads and inductive elements to provide a 120° shift. This, so-called triple-push, configuration provides several advantages over a two-transistor based push-push oscillator by allowing fundamental oscillations near f_{max} and higher voltage swing which is advantageous for higher harmonic generation [264]. The implementation of this concept, based on on-wafer measurements, resulted into generation of −7.9 dBm at 482 GHz frequency [264]. On the other hand, an efficient coupling of a number of oscillators was reported to generate −1.2 dBm at 290 GHz and −3.3 dBm and 320 GHz [265].

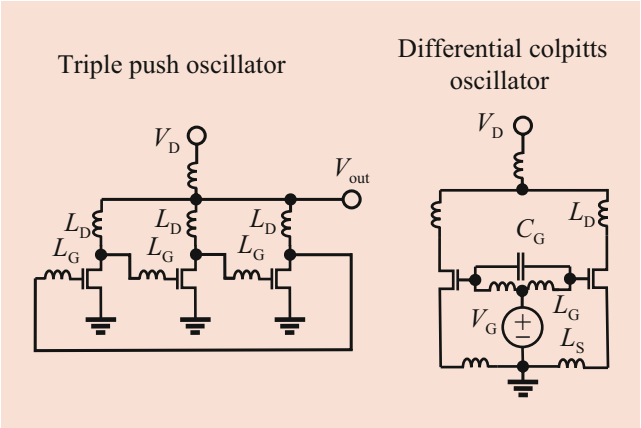

Fig. 22.28 Simplified schematics of triple-push and differential Colpitts oscillators

One of the common ways to extract generated power from the oscillator requires designing efficient antenna. Typically this is performed by driving a differential antenna and requires to perform special modifications for these purposes. Coupling between neighbouring oscillators imposes challenges for achieving maximal output levels. However, an efficient realisation allows emission into the free space of up to −4.1 dBm at 288 GHz [266].

The right side of the Fig. 22.28 presents the dual transistor design which is commonly named as differential Colpitts

oscillator. The fundamental oscillation frequency is primarily set by the *LC* resonator connected between the gates of transistors. This concept is also well suited to drive differential antenna and ensures efficient nonlinear conversion. Whereas first implementations into 90 nm CMOS technology resulted in −8.8 dBm at 217 GHz frequency [267], the shift to 65 nm technology and optimisation of the circuit allowed to improve the level of emitted power to −2.7 dBm at 293 GHz [268] and also to achieve currently the highest frequency for CMOS-based oscillators of 615 GHz with a −17 dBm of total emitted power [269]. Furthermore, with the help of an external synchronisation, an array of 30 equivalent densely packed emitters produces up to +9 dBm at 280 GHz [270].

Besides the technical availability to form clusters of oscillators which can be used for power combining, the maturity of CMOS technologies also offers the possibility to implement an array of synchronised devices which allows for beam steering at 338 GHz with angles of 45° and 50° along two axes [271] or making the part of spectroscopic THz instrumentation based on a set of circuits with different functionalities such as a 550 GHz frequency synthesizer [272].

Figure 22.29 presents a summary for total radiated power achieved with CMOS emitters. The closed symbols belong to nonlinear conversion-based concepts whereas open symbols represent results of multiplier-based (varactor-based) emitters being either active [273] or passive [274]. Although both nonlinear oscillator and varactor-based approaches produce comparable levels of output power below 600 GHz, the separation of nonlinear elements allows for a more efficient conversion and, therefore, to extend the frequency operation up to 1.4 THz [275]. It is worth noting that the development of radiation emitters relies, to a large extent, on the availability of high-frequency models for devices. Such models are typically validated for the GHz frequency range, yet their application to the THz range becomes disputable due to the increasing importance of high-frequency transport related phenomena such as skin currents or the excitation of plasma waves which gain importance in this frequency range and can affect the efficiency of mixing [276]. However, since the limits of operation of the active part is predetermined by unity gain frequencies which, for CMOS technologies, lay below 300 GHz, even existing models allow creating successful designs also for the extended frequency range.

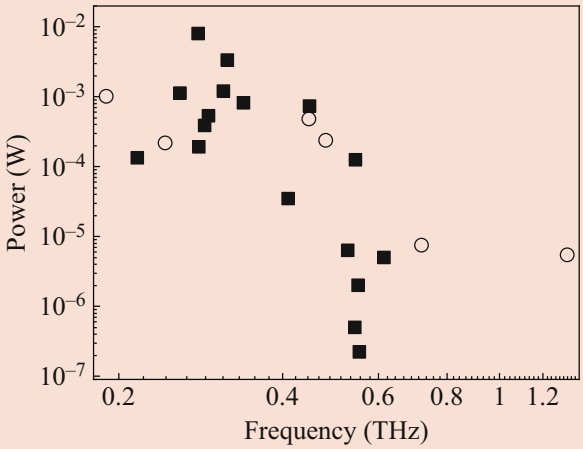

Fig. 22.29 The total radiated power is reported as a function of frequency for the state-of-the-art CMOS sources. The closed symbols correspond to nonlinear conversion-based concepts whereas open symbols represent results of multiplier-based emitters

22.7.2 Detectors

Similar to the situation with THz emitters, there are many different physical phenomena which can be used with CMOS technologies in order to produce detectors sensitive to THz radiation. These devices can be subdivided into two groups: thermal detectors (bolometers) and electrical nonlinearity-based rectifiers and mixers. The bolometer measures the increase of local temperature due to absorbed THz power and can be implemented on micromachined CMOS [277] with silicon devices used to measure the temperature change or in CMOS-compatible technology process [278]. The rectifier directly responds to electrical signals, and the detection is based on the nonlinear current-voltage dependence which is characteristic for diodes and transistors. It is interesting to note that a conventional diode with *pn* transition, due to transport limitations of minority carriers, is considered to be too slow. The small node size achievable with CMOS technologies allows fabricating devices with zero-bias cutoff frequencies in the 1–2 THz frequency range with reported efficient detection at 0.78 THz [279]. Being the standard for other technologies, Schottky-diode approach can be used for the implementation of efficient detectors in CMOS and BiCMOS technologies [263, 280]. The diode-like characteristics can be realised with diode-connected field-effect transistors (FETs) [281]. However, it has been shown that efficient detection can be realised in antenna-coupled CMOS detectors even when the detection frequency is much higher than the transistor cutoff frequency [208]. The modelling and optimisation of devices for the efficient detection of radiation which extends deeply into the THz frequency range require accounting for peculiarities of high-frequency electrical transport which is captured by the hydrodynamics-based physical models.

The first investigations about using silicon-based transistors for THz detection were performed on devices without appropriate antennas for radiation coupling [197, 282] as a part of research dedicated to prove predictions made by Dyakonov and Shur [198]. Initially, the first antenna coupled devices achieved comparably moderate sensitivity values.

The sensitivity of power detectors is typically characterised by the level of input power which produces electrical signal equal to the amplitude of detectors electrical fluctuations with 1 Hz equivalent noise bandwidth, i.e. noise equivalent power (NEP). The first devices designed for 600 GHz frequency range reported NEP of 300 pW/$\sqrt{\text{Hz}}$ [208]. The currently achieved optical performance is now approaching the value of 10 pW/$\sqrt{\text{Hz}}$ [283]. Moreover, detectors with substrate lens demonstrate broad-band operation with nearly flat frequency response from 400 GHz up to 1.5 THz [217] and can be used with THz radiation generated using low-average-power emitters like photomixers [217] or photoswitches [284].

The summary of published noise equivalent power values for state-of-the-art CMOS detectors is given in Fig. 22.30. Performance of FETs-based detectors is given with open symbols, whereas closed symbols represent the shot-noise limited NEP of CMOS-based Schottky diodes. One can note that although a database for FET detectors is much larger than that of CMOS detectors, deep in the THz frequency range both detector concepts experience a similar roll-off with comparable performance values for FETs [205,285] and for Schottky diodes [280].

For the case of emitters, one of the key advantages of silicon technologies is the ability to form detector arrays which can be used for imaging applications [286, 287]. Moreover, the availability of both types of components, i.e. emitters and detectors, makes it possible to realise all-electronic silicon-based applications spanning from raster-scan imaging [288] to near-field imaging [289] or even time-domain like spectroscopy [290]. Later applications either partially or fully employ the BiCMOS approach, which is extending the frequency range of operation of FET-based CMOS devices for emitters with higher oscillation frequencies as well as for detectors. A broad overview of the performances achieved using both technologies and their comparison can be found in Ref. [260].

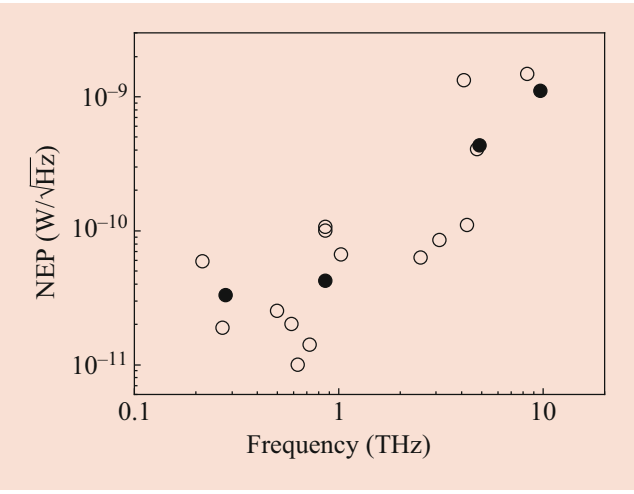

Fig. 22.30 Summary of reported noise equivalent power values for state-of-the-art CMOS detectors. Open symbols represent FETs, closed symbols—shot-noise limited NEP of Schottky diodes

In summary, over the last decade analogue electronic device concepts in silicon technologies advanced deeply into the THz frequency range. Literature reports on a variety of emitters reaching up to 1.4 THz, detectors enabling sensitive detection in the 0.3–10 THz frequency range and lighter and more compact systems able to promote new and emerging applications.

22.7.3 Perspectives

Over the last two decades the technological progress achieved in CMOS technologies enabled implementations of high-frequency analogue circuits which can directly compete with other established technologies. By now, the oscillation frequencies of fundamental oscillators fabricated directly in CMOS can easily exceed 100 GHz, whereas nonlinear conversion-based devices such as multipliers, mixers or detectors are proven to operate even above 1 THz with the state-of-the-art performance. Furthermore, one of the key advantages that CMOS technologies is offering to the development of THz electronics is its exceptional affinity to form circuits on the large scale thus allowing the combination and integration of hybrid electronic and photonic concepts on a chip level. This allows for improvements of the performance and efficiency of current concepts as well as provides with the potential for the invention of novel devices.

22.8 Ballistic Rectifiers

Ballistic rectifiers (BRs) are fundamentally different from most rectifying elements in the sense that they do not rely on any doping junctions or tunnelling barriers. Instead, their non-linear behaviour arises from the ballistic regime of electron transport where the mean free path of carriers is longer than the characteristic length of the device. This leads to the carriers scattering of the edges of the sample rather than random crystal defects and phonons in the conductive medium. As will be explained in this section, the 2D nature of the device and its zero threshold operation are ideal for THz detection applications. To date there has been no indication of a cutoff frequency in BRs fabricated from graphene up to 1 THz [291].

While it has been possible to observe ballistic effects for many years (in 2D III-V quantum wells at cryogenic temperatures), nanostructures below about 100 nm are necessary to observe these effects at room temperature [292]. The emergence of graphene and subsequent advancements in fabrication techniques allows for mean free paths above

1 μm without the need to cool the sample [293]. This section will explain how BRs operate and review how they could be used as THz detectors .

22.8.1 Ballistic Formalism

Figure 22.31 is a schematic of two different types of BR; both are four terminal devices with two input leads and two output leads. The grey region denotes the conductive region of the device, and the orange regions are the contacts. In both schematics shown the input contacts are labelled Source (S) and Drain (D), while the output contacts are labelled Lower (L) and Upper (U). While the geometry of the devices depicted in Fig. 22.31a, b is different, the operating principle is similar. Figure 22.31b has the narrowest part of the current injector S labelled W_{SD} (the width of both S and D leads is designed to be the same), similarly for the narrowest part of the channel between L and U (W_{LU}). A naive explanation describing the operation of these devices is to consider carriers like billiard balls on a table shaped like the device in the figure. The carriers are free to travel down potentials and bounce off the edges of the sample. In both cases the two input leads are angled such that most carriers arriving from either source or drain (forward and reverse bias) end up at one of the two output leads. In the figure, typical carrier trajectories are shown with arrows to guide the eye. The result of this is that an AC or indeed an RF signal applied between S and D is rectified into a DC voltage between L and U (indeed the voltage drop between L and U keeps the same sign).

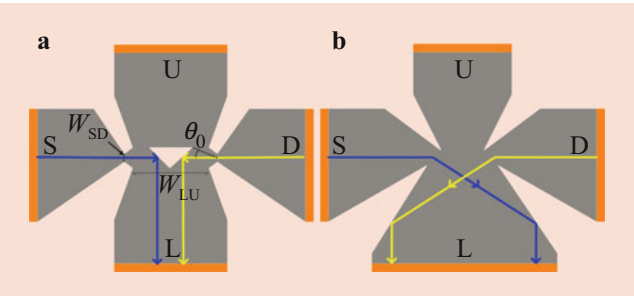

Fig. 22.31 Schematics of two ballistic rectifiers both with and without a triangular scatterer (etched region to scatter electrons), (**a**) and (**b**), respectively. In case (**b**) scattering takes place at the edges of the structure. The grey regions denote the conducting regions, and the orange regions represent the contacts. The input contacts are labelled Source (S) and Drain (D). The output contacts are labelled Lower (L) and Upper (U) with blue and yellow lines demonstrating typical carrier trajectories through the device. W_{SD} has been labelled for S to indicate the narrowest part of the current injectors, similarly for W_{LU}. The angle θ_0 has been labelled to indicate above what angle electrons exiting D will reach U instead of L

The billiard ball model for the ballistic regime of electron transport only goes so far to describe the behaviour of these devices. Instead, a more rigorous approach would be to use an extended Landauer-Büttiker formalism generalised for many conductance channels [294, 295]. In this model the conductance between lead β and α is given by

$$G_{\beta\alpha} = \frac{2e^2}{h} T_{[\beta,\alpha]}(I_{[\beta,\alpha]}) \,, \tag{22.27}$$

where e is the charge of an electron, h is Planck's constant and $T_{[\beta,\alpha]}(I_{[\beta,\alpha]})$ is the transmission probability from contact α to β (which can be S, D, L and U in our case); $T_{\beta\leftarrow\alpha}(I_\alpha)$ if the chemical potential in lead α $\mu_\alpha > \mu_\beta$ or $T_{\alpha\leftarrow\beta}(I_\beta)$ if $\mu_\beta > \mu_\alpha$. Setting the boundary conditions $I_S = -I_{-SD}$, $I_L = I_U = 0$ and $V_S = 0$ reduces the fourfold conductance matrix to a threefold matrix (**G**). Taking the inverse of this matrix gives you the matrix of resistances **R**. To model the device output we need the four probe resistance $R_{SD,LU} \equiv V_{LU}/I_{SD}$ (analogous to Hall resistance):

$$R_{SD,LU} = \mathrm{Det}(\mathbf{G})^{-1}(G_{US}G_{LD} - G_{UD}G_{LS}) \tag{22.28}$$

Reference [295] goes into detail how Eq. (22.28) can be used to determine $R_{SD,LU}$ for various geometries of BR with a triangle. This leads in this specific case to

$$R_{SD,LU} \approx -\frac{h}{e^2}\frac{3\hbar}{4eE_F N_{SD}}\frac{\sin 2\theta_0}{2N_{LU} - 3N_{SD}(1-\sin\theta_0)} I_{SD} \tag{22.29}$$

Here, N_{SD} and N_{LU} are the number of conduction modes that can travel through the narrowest constrictions of S or D and L or U, respectively. N_{SD} is related to the width of the narrow input leads by $N_{SD} = \frac{k_f W_{SD}}{\pi}$ where k_f is the Fermi wavevector of the carriers; the equivalent is true for N_{LU}. θ_0 is the angle relative to the normal vector of the narrowest part of the S or D leads where a carrier ejected from the lead will end up at U rather than L. These geometric factors (W_{SD}, W_{LU} and θ_0) have been labelled on Fig. 22.31a for clarity.

An important step during the derivation of Eq. (22.28) is including the excess momentum of carriers emerging from the narrow junctions, a result of the large potential drops and high field gradients over these regions. The effect of this is to collimate emerging carriers and decollimate carriers travelling towards these leads. This collimation and decollimation is a non-linear effect and is the true origin of the rectification in a device of this type. While the model is simple and ignores some of the subtleties, such as how the resulting trajectories change for higher numbers of modes and electron-electron interactions, it does give some insight into what we can expect from the output of the device. Firstly, there is a quadratic dependence of voltage on current and

therefore a linear voltage output with input power for small input signals; this can be shown from Eq. (22.29):

$$V_{\mathrm{LU}} = R_{\mathrm{SD,LU}} I_{\mathrm{SD}} \approx -\frac{h}{e^2}\frac{3\hbar}{4eE_{\mathrm{F}}N_{\mathrm{SD}}} \frac{\sin 2\theta_0}{2N_{\mathrm{LU}} - 3N_{\mathrm{SD}}(1-\sin\theta_0)} I_{\mathrm{SD}}^2 \quad (22.30)$$

Secondly, we can expect the device to work best when there are fewer conduction modes; this is the case when the dimensions of the device are small.

There are several reasons to use a BR rather than a different THz rectifier such as a Schottky diode or a metal-insulator-metal (MIM) diode. The two-dimensional nature of BRs reduces parasitic capacitance to a minimum thus decreasing the *RC* time constant. This is an important value to consider when looking at cutoff frequencies for such devices and could indicate that BRs may operate at higher frequencies, although they have not been tested above 1 THz at the time of publication. At the present time, BRs are among the most sensitive THz diode detectors with a high responsivity at room temperature [291]. They have relatively low resistances and can even be stacked in parallel for even better impedance matching, one of the most important characteristics for a high-frequency device. BRs demonstrate very low noise values; this is because the input and output contacts are mostly decoupled so that the output signal is largely uninfluenced by the noise of the input signal. This decoupling allows the resistance between L and U to be low without compromising the sensitivity of the device by changing the resistance between S and D. They have a zero voltage onset due to the fact that they do not rely on any doping junctions of barrier structures allowing them to rectify very small signals. They have a linear voltage response with power input (which is not the case for most diode detectors), a desirable feature in sensing technology. In some applications it might be useful to be able to tune the resistance of the device by changing the carrier density dynamically with a small local gate; for the case of graphene BRs the polarity of the output could even be changed. Moreover, the planar nature of the device also means that its fabrication is simple and scalable, no need for very challenging nano-scale alignment accuracy between structures in different layers. Finally, the planar nature also makes it straightforward to integrate a planar antenna to the BR without need for interconnects.

Conversely, BR devices also require materials characterised by a high mobility of majority carriers ($30{,}000\,\mathrm{cm^2V^{-1}s^{-1}}$), and for most commercial applications this must be true at room temperature. While GaAs quantum wells have extremely high mobility at low temperature, this is not true at room temperature. Graphene, on the other hand, can have a mobility of $200{,}000\,\mathrm{cm^2V^{-1}s^{-1}}$ at room temperature but not yet in scalable samples. However, the mobility and scalability of these materials is always improving.

22.8.2 BR Electrical Characteristics

Work started on BRs in the late 1990s as fabrication procedures became sufficiently advanced to reliably produce sub-micron devices in GaAs-AlGaAs and GaInAs-InP compounds, initially for DC [296, 297] and then for RF up to 50 GHz [298]. graphene, being one of the materials with the highest carrier mobility at room temperature, is a very promising candidate for BRs with DC and AC measurements [299–301] and then RF up to 700 GHz [291] with no sign of a cutoff frequency.

As discussed in the previous section BRs are expected to have symmetric quadratic DC I-V characteristics, while this is the case, experimental results often show some asymmetric components; see Fig. 22.32a. These asymmetric components are a consequence of small fabrication defects. However, this effect averages out when an AC input is applied and only the non-linear component of the I-V characteristic needs to be considered. The figure shows when electrons dominate (positive V_{G}) the curvature is negative; the opposite is true for holes.

In Fig. 22.32b the DC output V_{LU} is plotted against gate voltage (V_{G}) for a range of different applied AC currents. The output demonstrates the same ambipolar behaviour where electrons give a positive V_{LU} and holes give a negative one. What is true for both carrier types is that as the neutrality point is approached V_{LU} increases due to a reduction in the number of conduction modes through the channel reducing the spread in trajectories from each lead and increasing the effect of collimation. Close to the Dirac point there is a linear change in carrier type; this is a direct result of competing electron and hole conduction coexisting due to thermal excitation. Figure 22.32c shows how V_{LU} depends on AC and DC input power (P_{SD}) for two different gate voltages corresponding to peeks in the output for electrons and holes. At low power the device demonstrates a linear dependence of the output voltage vs input power; however there is a clear saturation effect at higher powers; this is likely due to an increase in phonon scattering from Joule heating. The peek responsivity of the device shown here was 23,000 V/W, an extremely high value for a THz diode detector. However, it is important to note that this is only a measurement of the intrinsic device properties which ignores effects such as impedance mismatch which often dominate losses at high frequency.

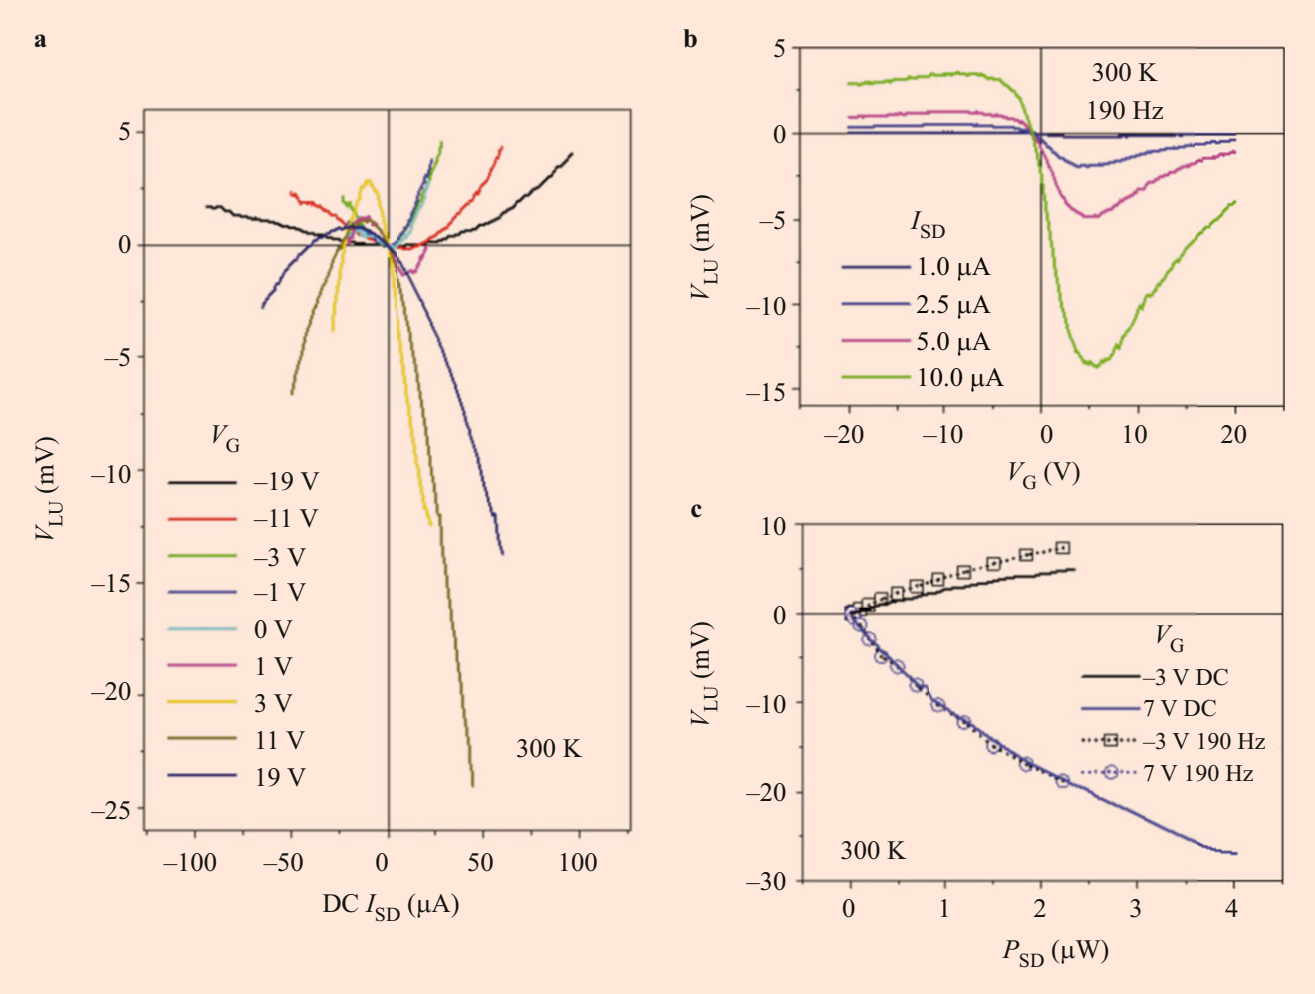

Fig. 22.32 (**a**) shows the DC I-V characteristics of a graphene BR with no triangle at various gate voltages (V_G). (**b**) and (**c**) demonstrate the rectifying properties of the same device while V_G is changed (for various input currents) and while input power is changed, respectively. 22

22.8.3 THz BR Detection

The initial high-frequency characterisation of BRs made from GaAs 2DEGs was done using a specially designed RF mesas where the ground plane wraps around the input and output contacts so they behave like strip lines. The strip lines allow microwave power to be applied to the device with the use of an RF probe station in conjunction with a vector network analyser (VNA) with minimal losses. Reference [298] shows how a BR made from InGaAs/InP can be used to rectify a 50 GHz signal at room temperature. Here the responsivity of the device at high frequency is nearly 2 orders of magnitude lower than at low frequency because of impedance mismatch with the contacts and VNA. Impedance mismatch is one of the limiting factors for all diode detectors because VNAs typically need to be matched at 50 Ω.

In order to detect THz radiation a BR must be coupled to a suitable antenna. The combination of an antenna with a rectifier is known as a rectenna and is the primary potential use for the BR . The rectenna was first demonstrated by Brown in the 1960s for wireless microwave power transfer to a small helicopter with an array of 28 rectennas operating at 2.45 GHz, and the helicopter was able to reach a height of 20 m [302]. Today they have been demonstrated as wireless on-chip interconnects [303, 304], energy harvesting devices [305, 306] and wireless power transfer in medical applications [307]. However, most of these examples are below 10 GHz and do not take advantage of the unique properties of the THz part of the EM spectrum. In Ref. [291] the BR is demonstrated to have a peak responsivity of 764 V/W, a minimum noise equivalent power (NEP) of 34 $pWHz^{-1/2}$, a linear voltage response over 3 orders of magnitude power

input and no signs of a cutoff frequency up to 700 GHz. The same paper demonstrates BRs as a tool for imaging THz radiation in transmission mode.

With regard to the cutoff frequency in the BR, it is likely to be very high due to the fact that the resistance of the BR is relatively low (as low as 1 kΩ) and the capacitance of the device is extremely small due to the planar nature of its structure. The dominant sources of the capacitance come from the antenna/device contact and from the self-capacitance of the device. When graphene is encapsulated by boron nitride, 1D contacts can be made where the same polymer mask is used to reveal the graphene edge and perform lift-off after metallisation allowing for self-aligned contacts with <10 nm of overlap [301]. This small overlap minimises contact capacitance and decreases the resistance of the contact [308].

22.8.4 Perspectives

BRs are a young but exciting technology, still not used outside of research laboratories. They require further development before they can be used in practice. They could have one of the highest cutoff frequencies of any diode detector. They have demonstrated very high sensitivities and low noise levels with linear output voltage to input power ratios over a wide range. These properties make them ideal for use in conjunction with an antenna for a wide variety of applications in THz security imaging, medical imaging, power transfer and communications. At even higher frequencies they could be used for heat energy harvesting and recovery.

22.9 Conclusions

In this chapter we have provided a summary of the most important electronic devices used for the development of THz detectors, emitters and associated systems. The information can be used as the starting point for advancing fundamental and applied research and to better understand the physical principles exploited in the field of THz-wave technologies. It is evident that the involved technologies, even if well developed since some years, still need great advances in many theoretical and experimental domains: in particular, while different types of detectors (direct and heterodyne) are already commercially available, the choice of emitters (CW or pulsed) is more limited, and probably it will represent the main technological bottleneck for the next years. When a large range of detectors and emitters with different performances and costs will become available, more and more circuits and systems will be developed and realised opening the way to a huge panel of practical applications.

Gregory Auton received his PhD from the University of Manchester in 2015. He worked at the National Graphene Institute Manchester and the London Nanotechnology Centre. His research interests are transport properties of low dimensional systems and their applications in high frequency electronics.

David Cumming (BEng, EEE; PhD, microelectronics) is Professor of Electronic Systems at Glasgow University. He works on semiconductor devices, microsystems, and sensors. He was a founder of Mode DX, and his research enabled the development of the Ion Torrent gene sequencing system. He is FRSE, FREng, and FIEEE.

Frédéric Aniel received the PhD degree from Université Paris Sud in 1995 and became Assistant Professor in 1996 at the same university where he is currently a professor. He heads a research team, at Centre de nanosciences et nanotechnologies (C2N), concerned with the analysis of physical phenomena in very high-frequency devices based on III-V or IV-IV semiconductors.

Michael Feiginov received PhD from the Institute of Radio-engineering and Electronics, Russian Academy of Sciences at Moscow in 1999. He worked at Technical University (TU) of Darmstadt, Germany, at Tokyo Institute of Technology and Frontier Research Centre of Canon in Japan, and at TU Wien, Austria. His research work is focused on resonant-tunneling diodes, plasmonics, THz sources, detectors, and systems.

Sebastian Gebert received his Master of Science from the University of Regensburg (Germany) in 2018. At the time of publication, he is aiming for his PhD at the University of Montpellier (France) devoted to novel THz detectors/emitters based on 2D Dirac materials.

Alvydas Lisauskas received his PhD from the Royal Institute of Technology, Stockholm, in 2001. He worked at Goethe University Frankfurt, Germany, and the Center for Physical Sciences and Technology, Vilnius, Lithuania. He is Professor at Vilnius University and also with CENTERA Laboratories, Institute of High Pressure Physics, Warsaw, Poland. He works on physics of semiconductor devices focusing on terahertz electronics.

Tomás González received his PhD from the University of Salamanca in 1994, where he is Full Professor of Electronics in the Applied Physics Department since 2007. His main research activity is in the fields of high-frequency III-V electronic devices, microscopic modeling of electronic noise, and development of novel nanodevices for THz detection and emission.

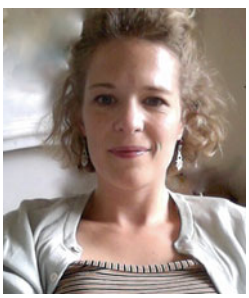
Hugues Marinchio was trained in the Ecole Normale Supérieure de Cachan. He received his PhD from the University of Montpellier in 2009 for his studies on plasma waves in nanotransistors. He is currently working as Physics Professor in French Higher School Preparatory Classes.

Chong Li received his PhD degree from the University of Glasgow in 2012 and then worked there as a Research Associate until 2014. He subsequently worked for UK National Physical Laboratory as a Higher Research Scientist until 2017. His current research interests include millimeter-wave and terahertz semiconductor devices, circuits and applications for RADAR, communications, and imaging.

Javier Mateos is Full Professor of Electronics in the Department of Applied Physics at the University of Salamanca. He has a long experience in the Monte Carlo modeling of the high frequency and low-noise performance of III-V HEMTs, and his main present research interest is in the development of novel device concepts for THz generation and detection.

Christophe Palermo received his PhD from Montpellier University in 2004. He works on Monte Carlo modeling and simulation of electron transport in novel semiconductor materials and devices in the field of TeraHertz electronics.

Professor Aimin Song obtained PhD in the Chinese Academy of Sciences in 1995. After fellowships from the Royal Society and von Humboldt Foundation at Glasgow University and Munich University, he was a Guest Lecturer at Lund University before moving to the University of Manchester as a Lecturer in 2002. He was promoted to a Full Professor in 2006.



Jeanne Treuttel received the PhD from the Observatory-of-Paris (OBSPM), CNES, and the Rutherford-Appleton-Laboratory-STFC in 2011. From 2015 to 2017, she developed the first all-solid-state 2 Terahertz heterodyne receiver at the Jet-Propulsion-Laboratory, NASA. She designs at LERMA-OBSPM Schottky Terahertz mixers and multipliers, and is responsible since 2018 of R&D programs and as system engineer of the technical contribution for the Submillimeter-Wave-Instrument Jupiter-ICy-moon-Explorer ESA mission.

Luca Varani received the PhD degree in Physics from the University of Modena (Italy) and the PhD degree in Electronics from the University of Montpellier (France). He is currently a Full Professor with the Institute of Electronics and Systems. His current research interests include theoretical and experimental transport phenomena in semiconductor materials and devices with a special attention to terahertz phenomena.

Nicolas Zerounian received his PhD from the University Paris-Sud, Orsay, in 2000. Since 2002, he is Associate Professor at Univ. Paris-Saclay (formerly Univ. Paris-Sud). His research interests include the high-frequency behavior of semiconductor devices at room and at low temperatures, and the development of sub-millimeter wave devices and THz characterization tools at the Centre for Nanoscience and Nanotechnology, Palaiseau.

Abstract

This article discusses the basic operation principle, material engineering aspects, and different architectures for the design of semiconductor lasers. The laser fundamentals are summarized in Sect. 23.1, whereas technical properties and a discussion of device dynamics are presented in Sect. 23.2. Section 23.3 addresses more detailed aspects such as materials and architectures for different diode laser systems. Finally, Sect. 23.4 reviews the most relevant application fields and gives an outlook on technological challenges and future developments.

23.1 Fundamentals

The three major ingredients of any laser are the (optical) gain medium, the pump process required to achieve population inversion in the gain medium, and a resonator to provide optical feedback. In the following, we discuss these basic aspects for the semiconductor laser systems separately before we proceed to the analysis of more specific properties.

23.1.1 Gain Medium

Crystalline solids have a characteristic band structure $E_\lambda(\boldsymbol{k})$, which specifies the quantum mechanical states that can be occupied by the crystal electrons. Here, the band is labeled by λ and $\boldsymbol{k}$ denotes the quasi-momentum vector of the electron. Of particular importance for the optical and electronic properties of a material are the energetically highest bands that are *completely filled* by electrons – the valence bands – and the next higher band – the conduction band – which is partially filled by electrons in metals but completely empty in insulators. As semiconductors, one usually denotes insulators where the energetic difference between the top of the valence bands and the bottom of the conduction bands, i.e., the bandgap E_g, is

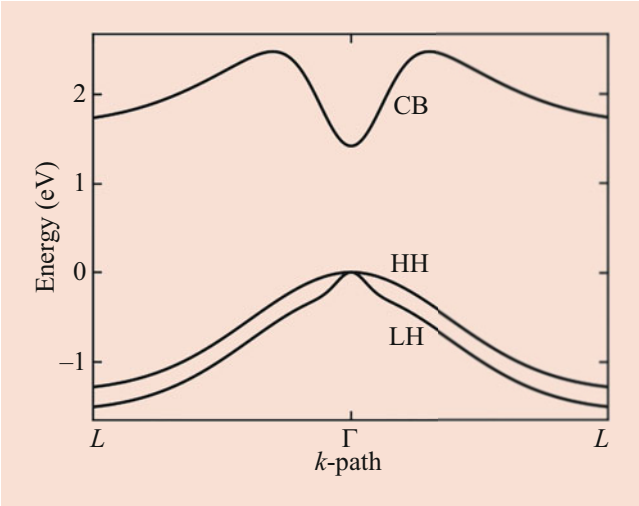

Fig. 23.1 Computed band structure (energy versus carrier momentum) of bulk GaAs in the vicinity of the Γ-point where the direct optical transitions take place. Shown are the conduction band (CV) together with the heave-hole (HH) and light-hole (LH) valence bands

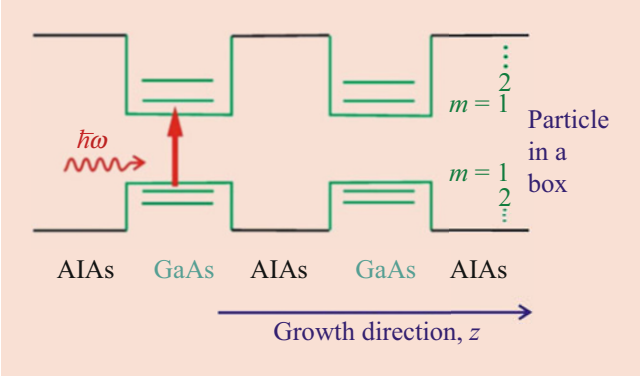

Fig. 23.2 The direct band gaps of GaAs and AlAs are plotted as function of the growth direction. The GaAs parts of the structure form the quantum wells which provide quantum confinement in one dimension. The corresponding eigenstates for the particle-in-a-box, here a one dimensional box, are indicated and it is shown how a resonant optical excitation induces a transition between the quantum confined states

in the energy range of visible light or below. The value of E_g defines the energy needed for light to resonantly interact with the particular semiconductor system.

To be useful as laser gain medium, a semiconductor material has to efficiently couple to the light field. For this, its bandgap has to be *direct*, i.e., the conduction-band minimum and valence-band maximum have to occur at the same $\boldsymbol{k}$ value. Furthermore, it needs conduction and valence bands with the proper symmetries that allow for a large matrix element of the optical dipole operator, i.e., a significant value of the dipole moment.

The best known material satisfying the necessary requirements is the binary compound semiconductor GaAs which was discovered by Heinrich Welker in the early 1950s [20]. An excerpt of the GaAs band structure in the region interesting for semiconductor laser applications is shown in Fig. 23.1.

In fact, the historically first semiconductor laser was based on bulk GaAs [18]. However, the breakthrough for these devices came with the invention of semiconductor *heterostructures* which typically consist of several layers with different material compositions. Most noteworthy in this context are the $Al_xGa_{1-x}As$ compounds, where the Aluminum concentration x can be up to 40% for the material to have a direct bandgap which increases with increasing x. Since the lattice constants of GaAs and $Al_xGa_{1-x}As$ are almost identical, heteroepitaxy allows for the lattice matched layer-by-layer growth of materials with different compositions.

Sandwiching several atomic layers of $Al_xGa_{1-x}As$ with a low x_{QW} between layers with higher aluminum concentration, $x_{\text{barrier}} > x_{\text{QW}}$, yields a so-called quantum well (QW) structure where the low x compound constitutes the well and the higher x material acts as barriers, see Fig. 23.2. Such a heterostructure arrangement inhibits the movement of low energy carriers in the growth direction, i.e., they experience a one-dimensional potential well. At the same time, the carrier mobility is unrestricted in the two-dimensional plane perpendicular to the growth direction.

Quantum mechanical treatment of such a particle-in-a-well configuration results in discrete energy states whose spacing scales inversely with the square of the well thickness. The energetically lowest state is determined by the fundamental uncertainty principle, representing the zero-point motion of the quantum confined electron. Effectively, in semiconductor QWs this ground-state energy occurs additively to the bandgap energy with the consequence that the minimum energy for resonant optical excitation increases as a consequence of the quantum confinement in one dimension. Since energy and wavelength are inversely proportional to another, one often refers to this energy increase as a *blue shift* of the optical transition.

The width of a QW can be chosen relatively freely in the epitaxial growth process thus allowing for a certain degree of freedom to engineer important aspects of the optical material properties. Additional design flexibility can be gained by realizing that modern growth techniques not only allow for the realization of heterostructures using materials with the same lattice constant. To some degree also lattice mismatched compounds can be utilized, provided that the mismatch is not too large. Under ideal conditions, epitaxial growth leads to an adaption of the lattice constant in the growing layer to that of the underlying substrate. Effectively, the resulting deviations from the lattice constant of the unperturbed material are equivalent to a certain degree of elastic strain which can be tensile or compressive, depending on whether the lattice

constant of the growing layer is larger or smaller than that of the underlying substrate, respectively.

In such strained layer QWs, one has to carefully monitor the amount of accumulated strain such that the formation of fractures, islands, or other unwanted features is avoided. However, the advantages outweigh the structural problems since strained-layer growth not only broadens the range of suitable materials but also allows one to deliberately use the strain effects to modify the in-plane QW band structure in a desirable way. Therefore, many commercially available semiconductor lasers these days are based on gain media consisting of a QW heterostructure made of lattice mismatched semiconductor layers.

In addition to the band structure, also the quantum mechanical interactions in the semiconductor material system strongly influence its laser gain medium properties. In the fundamental light absorption process, a single photon excites an electron from the filled valence band into the conduction band of the medium. Starting from the original unexcited state with N negative elementary charges in the valence band, $N(-e)$, the excitation leads to $(N-1)(-e)$ in the valence band and a single negative charge $(-e)$ in the conduction band. Since the *removal of a negative charge* is equivalent to the *addition of a positive charge*, $(N-1)(-e) = N(-e) + (+e)$, one introduces the concept of the positively charged *valence-band hole* , or simply *hole,* as a new semiconductor quasi-particle. Referring to the conduction-band electron as *electron*, one describes the absorption of a single photon as a process in which an *electron-hole pair* is created. Similarly, the system can emit light when a conduction-band electron jumps back into the valence band and releases its excess energy to the photon. Since this process involves the generation of a photon under simultaneous annihilation of an electron and a hole, it is referred to as *radiative electron-hole* recombination.

From basic electrodynamics, we know that positive and negative charges experience the mutually attractive Coulomb interaction. On the elementary particle level, this may even lead to quantum mechanically bound states with the hydrogen atom as the most prominent example where a single electron is Coulomb bound to a positively charged proton. In a very similar fashion, there are bound electron-hole-pair states in semiconductors which are referred to as *excitons*. However, despite the identical physical concepts, the properties of excitons are significantly different from hydrogen, showing up most prominently in the much smaller value of the binding energy which is close to 13.6 eV in hydrogen and only around a few *meV* for most semiconductor excitons.

In order to utilize a semiconductor structure as a laser gain medium, one has to *pump* the system, i.e., one has to prepare a condition where the probability for light emission is larger than for absorption. In an electron-hole plasma, the possibility for light emission from a state $\mathbf{k}$ is determined by the probability $f^{\mathrm{e}}_{\mathbf{k}}$ to find an electron in that state times the probability $f^{\mathrm{h}}_{\mathbf{k}}$ to find the matching hole, i.e., $\propto f^{\mathrm{e}}_{\mathbf{k}}\, f^{\mathrm{h}}_{\mathbf{k}}$. This probability for emission has to be larger than that for absorption which needs unoccupied electron and hole states, i.e., $\propto (1 - f^{\mathrm{e}}_{\mathbf{k}})\,(1 - f^{\mathrm{h}}_{\mathbf{k}})$. Note that for Fermions, the Pauli exclusion principle applies with the consequence that the maximum occupation probability of a given state is unity, such that the probability to find a free state is unity minus its occupation probability. For emission to exceed absorption, $f^{\mathrm{e}}_{\mathbf{k}} f^{\mathrm{h}}_{\mathbf{k}} > (1 - f^{\mathrm{e}}_{\mathbf{k}})\,(1 - f^{\mathrm{h}}_{\mathbf{k}})$, or

$$\left(f^{\mathrm{e}}_{\mathbf{k}} + f^{\mathrm{h}}_{\mathbf{k}} - 1\right) > 0 \quad \text{(condition for electron-hole population inversion)} .$$

The term $(f^{\mathrm{e}}_{\mathbf{k}} + f^{\mathrm{h}}_{\mathbf{k}} - 1)$ is referred to as the (population) *inversion* factor, which has to be positive under light amplification conditions. Whereas details of the pump process are discussed in Sect. 23.1.2, all we need to know at this point is that pumping is utilized to promote a reasonably large number of electrons from the valence into the conduction band to create a positive inversion for the quantum states contributing to the lasing process. Under room-temperature conditions, the resulting configuration is referred to as an *electron-hole-plasma* state.

The relatively high density of electron-hole pairs in the plasma leads to a significant weakening of the effective Coulomb interaction potential via *plasma screening*. As a result, the attractive interaction is typically no longer strong enough to allow for the formation of bound excitons under room-temperature lasing conditions. However, Coulombic effects are still very important for a quantitative modelling of the semiconductor gain medium properties. Referring to the literature for more details [3, 7, 11], we just mention here as important consequences of the microscopic interaction effects the phenomena of (i) band renormalization, (ii) carrier scattering, and (iii) excitation induced dephasing (EID).

(i) The most obvious consequence of the band renormalization is the gap reduction with the consequence that the lowest energy for optical transitions is no longer the bandgap E_{g} of the unexcited material but the renormalized gap, $E^{\mathrm{ren}}_{\mathrm{g}} < E_{\mathrm{g}}$. Hence, we have a red shifting of the optical transitions that becomes more and more prominent with increasing electron-hole-pair density.

(ii) In a typical electron-hole plasma in semiconductor lasers, the elastic Coulomb scattering among the charge carriers leads to the very fast equilibration of the electrons and holes. Thus, on the timescale of tens to hundreds of femtoseconds ($1\ \mathrm{fs} = 10^{-15}\ \mathrm{s}$), the carriers assume Fermi distributions within their respective bands. This scenario is called *quasi-equilibrium*, since it is characterized by thermodynamic equilibrium

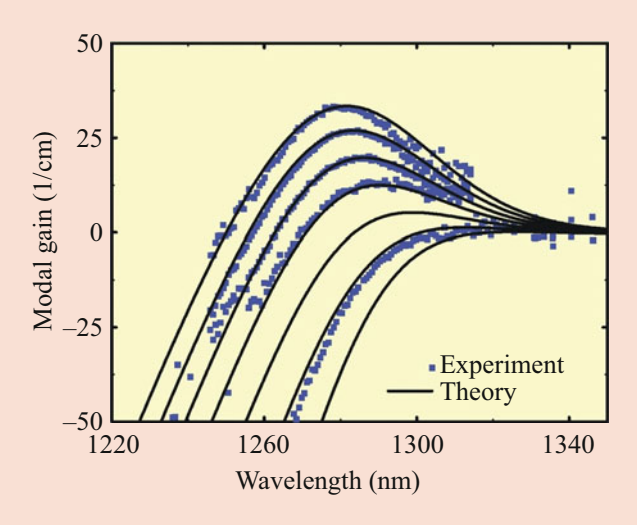

Fig. 23.3 Experimentally measured (squares) and theoretically calculated (solid lines) gain spectra for a (GaIn)(NAs)/GaAs semiconductor heterostructure. The different curves are obtained for increasing electron-hole densities (lowest on the bottom). (From Ref. [9])

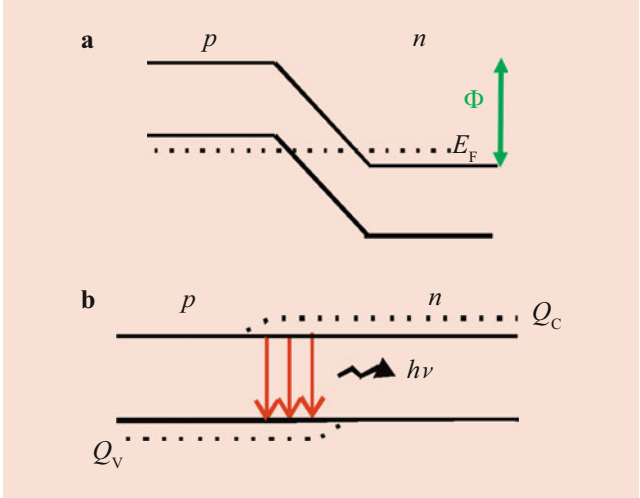

Fig. 23.4 Band diagram (Energy versus space coordinate in growth direction) of p-n-junction without (**a**) and with (**b**) applied bias

conditions among the carriers *within each band*. Clearly, the overall state of the semiconductor is still far away from true thermodynamic equilibrium since this would amount to the unexcited configuration where no electrons are in the conduction band.

(iii) An often overlooked and underappreciated Coulombic interaction effect is the phenomenon of EID. With the term *dephasing*, one usually refers to the loss of coherence, i.e., to the temporal decay of an electromagnetic wave. However, transforming this scenario from the time into the frequency domain, the dephasing determines the spectral lineshape of the signal which can be expressed via a lineshape function $L(\omega,\mathbf{k})$. Since this function enters in the equation relating the population inversion to the gain spectrum the detailed spectral shape of the gain strongly depends on the microscopic interactions via EID, i.e.,

$$g(\omega) \propto \int d^3k \left(f^{\mathrm{e}}_{\mathbf{k}} + f^{\mathrm{h}}_{\mathbf{k}} - 1\right) \; L(\omega, \mathbf{k}) \,.$$

Including all the discussed effects in a systematic microscopic theory allows for the calculation of the optical spectra for a wide variety of semiconductor compounds [3, 7, 11]. An example of a successful theory/experiment comparison is shown in Fig. 23.3.

23.1.2 Pump Process

To generate and maintain a population inversion in the semiconductor laser gain medium, one needs to supply a sufficient influx of energy which "pumps" carriers from the valence into the conduction band. The presence of a population inversion constitutes a non-equilibrium situation which would spontaneously decay without pumping.

Technically, the pumping process can be realized in several different ways. The most straight forward concept is *optical pumping* where light is absorbed to excite carriers from the valence into the conduction band. This optical excitation requires an intense light source providing the pump light with higher photon energy than the laser emission. This usually adds considerable complexity to the overall laser configuration with the consequence that optical pumping is typically not used in semiconductor lasers with the notable exception of vertical external cavity surface emitting lasers (VECSELs) which will be discussed in a subchapter below.

Most commercial semiconductor lasers today are *electrically pumped* by carrier injection via a p-n-junction. To understand the fundamental principle of this electrical pumping, we look at the schematic band diagram in the space domain in Fig. 23.4 [18].

After the generation of contact between a p- and an n-doped region, diffusion drives electrons into the p-region and holes into the n-region, respectively. The electrons leave positively charged atoms and the holes negatively charged atoms behind (space charges) which induce an electric field. In equilibrium, the corresponding field current balances the diffusion current with the consequence that there is no net current. The space-charge region is characterized by a built-in electric field and a potential step Φ which is characteristic for a p-n-junction, see Fig. 23.4a.

When a voltage V in forward direction is applied to this configuration, the potential step is reduced. As soon as V reaches the value of $V = \Phi/e$ (with the electron charge e), the potential step disappears as shown in Fig. 23.4b. Under

this condition, a current flows and delivers electrons and holes into the active region where they contribute to the inversion. In an idealized quasi-equilibrium situation where the occupation probabilities $f^{e}_{\mathbf{k}}$ and $f^{h}_{\mathbf{k}}$ can be expressed by quasi-Fermi functions, the carrier inversion condition from Sect. 23.1.1. can be translated into the condition that the difference between the quasi-Fermi levels Q_C (for the conduction band) and Q_V (for the valence band) becomes larger than the bandgap E_g. Far away from the p-n-junction, the energetic distance between Q_C and the conduction band edge with bias (right scheme in Fig. 23.4) is equal to the energetic distance of the Fermi energy E_F to the conduction band edge in equilibrium (left scheme in Fig. 23.4). The same holds for Q_v, E_F, and the valence band edge. Altogether, this implies that inversion by carrier injection can only be achieved for very strong doping of the n- and p-regions so that the Fermi-level is above the conduction band edge in the n-region and below the valence band edge in the p-region, respectively.

A simple p-n-junction like the one shown in Fig. 23.4 fundamentally allows one to achieve inversion and, as a consequence, semiconductor laser action. However, even though it was used in the first demonstration of a semiconductor diode laser in the early 1960s, this so-called homojunction scheme is rather inefficient. As a consequence, inversion can only be obtained at rather low temperatures using strong and temporally pulsed injection currents in order to avoid excess heating. The reason for the unsatisfactory pumping efficiency is the rather low achievable electron-hole pair density in the active region. The injected carriers are spread out over a rather large region which is only limited by the finite carrier diffusion length – typically on the order of micrometers – which limits the depth of penetration for the electrons into the p-region and the holes into the n-region, respectively.

A spatially reduced extension of the active region for the same number of injected carriers amounts to a higher density thus that inversion conditions can be realized much more easily. For this purpose, one resorts to a so-called double heterostructure arrangement, which is similar to the quantum well configuration discussed in Sect. 23.1.1, with the exception that the barrier material on the one side of the well is n-doped and on the other side it is p-doped, respectively. Such a structure not only provides a potential well for the electrons and holes but also allows for effective carrier injection. In this configuration, the extension of the active region is determined by the well thickness which typically is in the range of 100 nm. The carrier confinement in double-heterostructure p-n- junctions dramatically decreases the required current for laser operation and thus enables room-temperature operation with a few 10's of mA operation current. Moreover, the layer sequence in the double heterostructure also constitutes a refractive index profile acting as a transversal waveguide for the propagating laser light. Thus, the heterostructure not only provides carrier but also photon confinement. In so-called quantum well structures, the well thickness is typically below 10 nm such that quantum effects come into play as discussed in Sect. 23.1.1. In that case, carrier and photon confinement have to be handled separately (see Sect. 23.3).

Modern diode laser structures typically contain more complex layer sequences [1]. Some examples are discussed in Sect. 23.3 (Materials and architectures).

23.1.3 Resonator

Besides the gain medium, one also needs optical feedback to initiate and sustain laser action. In most configurations, this feedback is provided by a resonator (or optical cavity) which should be considered an integral part of the diode laser structure.

Since many of the materials used for semiconductor lasers, such as GaAs, have a high refractive index of about 3.5, the interface between semiconductor and air provides a reflectivity around 32%. Hence, the easiest realization of an optical cavity is a Fabry-Perot type resonator achieved by cleaving the semiconductor crystal such that the facets act as plane parallel mirrors. To check if 32% reflectivity is sufficient for laser operation, we look at the gain-loss conditions. The gain needed for laser operation (threshold gain g_{th}) can be estimated by balancing gain and loss for each roundtrip of the light in the cavity. The result is:

$$g_{th} = b_I - 1/2L \ \ln (R_1 R_2)$$

where b_I denotes the internal losses, L is the cavity length and R_1 and R_2 are the facet reflectivities. The internal losses combine radiative losses due to spontaneous emission not into the laser mode, Auger losses due to carrier recombination where the excess energy is not transferred to a photon but rather used to excite another carrier into a higher band, as well as losses due to defects, imperfections, etc. Typical cavity lengths are in the range from a few hundred micrometers up to a few millimeters and, for cleaved facets, $R_1 = R_2 = 0.32$. To modify these values, one may apply high reflection coatings (increased R) or antireflection coatings (decreases R).

In order to allow for stationary laser operation, the resonator feedback provided at each roundtrip of the light in the cavity has to be in phase. This means that stable operation can only occur for selected wavelengths λ for which the optical cavity length L fulfills:

$$nL = m\,\lambda/2 \text{ with the refractive index } n \text{ and } m = 1, 2, 3, \ldots$$

These selected wavelengths are called *resonator modes*. In the frequency domain, the eigenfrequencies are defined by

$$\nu_m = m\, c/2nL$$

which corresponds to an equidistant comb of modes

Since the semiconductor gain spectrum is relatively wide, the inverted semiconductor medium provides optical gain not only for one photon energy or wavelength but for a rather broad wavelength range. Generally, laser operation starts as soon as the gain overcomes the losses at one of the resonator modes. Since a semiconductor gain spectrum is rather flat on the scale of the intracavity mode separation, it happens frequently that the gain exceeds the losses for more than one mode. As a consequence, diode lasers with Fabry-Perot resonators often exhibit multi-mode emission behavior. Since such a multi-mode operation is undesirable for certain applications, one has developed concepts such as external cavity configurations, distributed feedback (DFB), or distributed Bragg reflector (DBR) scenarios [1].

For external cavity configurations, usually one of the diode laser facets is antireflection coated. The light output from this facet is then collimated with a collimation lens and coupled to an external resonator. To enforce single mode operation with narrow linewidth, this resonator includes a diffraction grating for wavelength selective feedback. Whereas this may be arranged in different ways, most commonly one utilizes the Littrow- or Littman geometries.

In the Littrow configuration, the light coupled out of the antireflection coated facet is directed onto the grating and the first diffraction order is redirected into the diode. One may tilt the grating to tune the feedback wavelength and thus the emission wavelength of the laser. However, usually the 0th order beam, i.e., the reflection from the grating, is used as the laser output. For the Littrow geometry, the direction of the output changes with tuning which is uncomfortable for applications. In contrast, in the Littman geometry, the first order diffracted beam is directed onto a mirror and the tilting of this mirror provides the tuning. In that case, the direction of the 0th order output beam remains stable. External resonator diode lasers with Littrow and Littman geometry provide tunable single mode emission with linewidths in the kHz range. Thus, they are attractive sources for spectroscopy applications.

Applications in optical data transmission require stable single mode emission even under modulation. External cavity configurations are too complex for these applications and therefore, alternative feedback concepts have been developed and implemented. These are based on so-called distributed feedback. The fundamental principle of distributed feedback is a periodic modulation of the refractive index in the laser diode. When, for a certain design wavelength λ_0, the periodicity of the refractive index modulation is $\lambda_0/4$, the partial waves reflected from this refractive index modulation add up constructively.

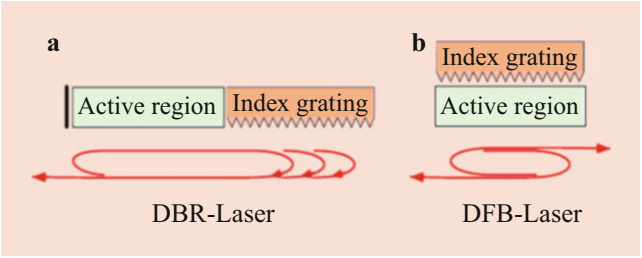

Fig. 23.5 (**a**) DBR-Laser, (**b**) DFB-Laser. Green areas: active regions, orange areas: structured refractive index [15]

The explicit reflectivity spectrum and the mode structure of such DFB lasers are usually calculated with the help of coupled mode theory. For a standard DFB laser, the structured refractive index extends over the entire device length as shown in Fig. 23.5b. Typically, both facets of the device are antireflection coated in order to suppress feedback from the facets. For this geometry, coupled mode theory predicts the emission of two modes separated by the so-called stop band. These two modes are of the same strength in the ideal case. In reality, residual reflections from the facets often disturb the system and lead to the desired single mode operation. However, in order to achieve a well determined single mode emission, a distortion of the periodicity is implemented in the form of an intentional $\lambda/4$ phase shift. For that case, coupled mode theory predicts one single mode in the center of the stop band.

A DBR laser as shown in Fig. 23.5a is a possible alternative to a DFB laser. In such a DBR laser, distributed Bragg reflection areas and gain areas are separated from each other. Such DBR lasers also provide single mode emission. They enable wavelength tuning but they also introduce higher technological effort in production as compared to DFB lasers.

23.2 Technical Properties

23.2.1 Introduction

Due to their specific architecture, semiconductor lasers have many properties which are different from other lasers. Besides the favorable aspects such as the compact dimensions and low price of laser diodes, there are unfavorable features including their relatively low output power and relatively poor beam profile. We discuss some of these aspects in the following sections and analyze their physical background. Further details can be found in Sze [18], Chuang [4], Bhattacharya [1].

23.2.2 Fundamental Behavior

Most commercial semiconductor lasers except for vertical external cavity surface emitting lasers and quantum cascade lasers (see Chap. ▶3) are electrically pumped via a p-n-junction. Their operation requires currents of a few *mA* at voltages of a few *V*. Current and voltage are related via the Shockley relation for a semiconductor diode. When the output intensity is recorded as a function of current one obtains the following characteristic behavior: For currents lower than the threshold current I_{th}, there is no laser operation. The laser diode emits spontaneous emission which is spectrally broad and often modulated by the Fabry-Perot modes of the cavity. When reaching the threshold current, the gain compensates the losses and lasing starts. The emission spectrally narrows down to one or a few modes. Further increasing the current above the threshold leads to an ideally linear increase of the emitted light intensity. The slope of the curve in that regime determines the internal or differential quantum efficiency $\eta_{diff} = \frac{e}{h\nu}\frac{\partial P_{opt}}{\partial I}$ with the electron charge e, Planck's constant h and the frequency ν. The external quantum efficiency is $\eta_{ext} = \eta_{diff}\frac{E_g[I-I_{th}]}{I^2eR+IE_g}$ where E_g is band gap energy and the series resistance of the diode is denoted by R. Here, one considers the ratio between emitted optical power and invested electrical power. In real devices, external quantum efficiencies above 50% can be achieved rendering laser diodes by far as the most efficient laser systems.

23.2.3 Dynamics

The dynamical behavior of laser diodes is governed by the coupled charge carrier – photon system. This coupled carrier-photon system has an intrinsic eigenfrequency which is called relaxation oscillation frequency ω_r. Using simple rate equations, the relaxation frequency can be derived as

$$\omega_r \approx \sqrt{\frac{a v_{gr}\ \rho_{av}}{\tau_{ph}}}$$

where a is the differential gain, i.e., the derivative of the gain with respect to the carrier density. This differential gain is a material property depending on the active material. The other parameters are the group velocity v_{gr}, the average photon density ρ_{av}, which is proportional to the average emitted power and the photon density τ_{ph} [1].

The laser reacts to perturbations, such as a sudden switch-on or a rapid change in operating conditions, with a damped relaxation oscillation. In practical applications, this feature may be utilized for the generation of short optical pulses. The concept is to use short (a few hundred picoseconds) current pulses in order to start relaxation oscillations, but make the current pulse sufficiently short such that only the first spike of the relaxations is emitted. This approach, which is called gain switching, may provide pulses as short as a few tens of picoseconds at a repetition rate determined by the sequence of the driving current pulses. Unfortunately, however, the generated pulse sequences usually exhibit a high temporal jitter since each pulse starts statistically independent from spontaneous emission. Shorter pulses with less timing jitter can be obtained by mode locking [5, 8], which will be mentioned later in this article in the context of microcavity laser systems.

The modulation response of a diode laser shows a strong resonance at ω_r and drops with ω^2 for higher frequencies. The maximum modulation frequency is thus determined by the relaxation oscillation frequency and can become only slightly higher than this value. Due to the intrinsic limits given by the parameters that determine ω_r, the best results obtained so far are somewhat below 50 GHz. The differential gain can be optimized by band structure engineering, for example by using strained quantum wells in the active region. The photon lifetime cannot be reduced too far as that would also decrease the cavity quality. Finally, the average intensity, respectively, the photon density $\rho_{av,}$ is typically chosen as high as possible but is limited by the maximum emission of the laser. So no further dramatic increase of ω_r and thus of the maximum intensity modulation frequency can be expected.

23.2.4 Spectral Properties and Coherence

As mentioned above, edge emitting diode lasers with Fabry-Perot cavities tend to emit on multiple longitudinal modes. The width of the emission spectrum is directly linked to the coherence properties of the emitted light. For multimode lasers, typical values of the coherence length, $l_c = c/\Delta\nu$, are in the range of a few hundred micrometers. While for some applications, this may be advantageous, for example to avoid speckle patterns in imaging, in many cases higher coherence or narrower spectral linewidth is desired. This can be achieved with DFB or DBR lasers which enable single mode emission even under strong modulation.

A simple rate equation analysis shows that in the case of single-mode emission, the semiconductor-laser linewidth is determined by a modified Schawlow-Townes formula [17]:

$$\Delta\nu = \frac{\beta}{4\pi\tau_{ph}\left(\frac{I}{I_{th}}-1\right)}\left(1+\alpha^2\right)$$

The standard Schawlow-Townes formula describes the linewidth of a laser governed by the spontaneous emission coupling β, the photon lifetime τ_{ph}, and the intensity. The spontaneous emission factor quantifies the amount of spon-

taneous emission coupled into the lasing mode. The intensity is expressed here by the deviation of the current I from the threshold current I_{th}. The modified Schawlow-Townes formula for diode lasers includes the multiplies $(1 + \alpha)^2$ where the so-called linewidth enhancement factor α phenomenologically considers the strong coupling of real and imaginary parts of the refractive index in semiconductors. Typical values for α depend on the detailed operation conditions and vary between 0 and approximately 10. The typical linewidths for single mode emission are in the range of cm to m, but narrower linewidths down to the kHz range can be realized with external cavity configurations. Such systems have coherence lengths in range of tens of km.

23.2.5 Beam Quality

Typical diode lasers are very compact and their emission aperture is small and asymmetric. The thickness of the active region is only a fraction of a micrometer while its width depends on the detailed laser architecture. In so-called ridge waveguide lasers, the lateral mode dimension is confined to a few micrometers by a lateral refractive index profile. Thus, the laser operates in its fundamental lateral mode. But the small dimensions in lateral and transversal directions lead to diffraction which causes a large beam divergence. Due to the asymmetry, the divergence is different in transversal and lateral direction. Typical emission angles are >30° for the transversal and around 10° for the lateral direction. Moreover, the emission beam is astigmatic, i.e., the origins of the lateral and the transversal beam cones are at different positions. Consequently, the collimation of the diode laser emission is not trivial and requires either combinations of suitable cylindrical lenses or more complex collimators.

In contrast to ridge waveguide lasers, broad area lasers have no lateral mode confinement by a refractive index profile. Here, the lateral beam extension is determined by the current path through the device and can reach several hundred micrometers. Thus, the emitted power may be much higher than for ridge waveguide lasers with the drawback that the lateral mode profile becomes more complicated. In particular, this profile contains higher lateral modes and it may even split up in filaments with complex spatiotemporal dynamics. Thus, beam shaping of the broad area laser output is even more challenging than for ridge waveguide lasers. In fact, the beam quality of broad area lasers is often too poor for applications where well controlled laser beam or a diffraction limited laser spot is required.

23.2.6 Polarization

Diode lasers usually emit linearly polarized light with the laser architecture, its waveguide geometry and the active material as the polarization direction determining factors. Typically, the waveguide and mirror losses are a bit smaller for transversal electric (TE) polarization than for transversal magnetic (TM) polarization. Thus, for active media with isotropic gain, like bulk material in standard double heterostructures, the emission will be TE-polarized with the electric field oscillating in the plane perpendicular to the growth direction.

When the active region contains quantum wells, the polarization selection is more complex. The optical dipole selection rules that can be derived from a quantum mechanical analysis of the optical transitions in the semiconductor band structure, determine which transitions support which polarization [3]. The transition from conduction band to the heavy hole band, for example, supports only the TE polarization whereas the transition from the conduction band to the light hole band supports the TM polarization more than the TE polarization. For bulk active materials, heavy- and light hole bands are degenerate in the vicinity of the band edge. Therefore, both polarizations are equally supported and the gain is isotropic. In a quantum well, the degeneracy of light and heavy hole bands is lifted and the light hole band shifts away from the band edge. Thus, the optical transitions take place between conduction band and heavy hole band and the TE-polarization dominates.

As discussed in Sect. 23.1.1, strain can be introduced if the lattice constant of the quantum well material is chosen to be slightly different from the surrounding barrier material. This strain has an influence on the band structure by shifting the relative positions of light – and heavy-hole bands. Typically, for tensile strain, the light-hole band shifts up in energy with respect to the heavy-hole band and may become the dominant band for optical transitions. Then, the dominant emission is TM polarized. So, diode lasers with tensile strain in the quantum wells emit TM polarized light when the amount of strain is strong enough. A clever material design with strained quantum wells may be implemented to create equal TE and TM gain for polarization insensitive semiconductor optical amplifiers (for more details see, e.g., [3])

For other quantum structures like quantum wires or quantum dots, the optical selection rules and thus the polarization properties of the gain depend on the geometry of the structure. The optical selection rules have to be determined for the specific design in order to predict the polarization of the emission.

23.2.7 Optical Power

The optical output power of a laser diode strongly depends on its architecture. A standard ridge waveguide laser diode typically emits a few mW of average power. With optimized design even above 100 mW can be achieved with laterally

single mode emission. For higher powers in the W to kW range, other laser types have to be used. Broad area lasers, for example, provide much higher output power than ridge waveguide lasers but, as mentioned above, they yield a poor beam profile with multiple lateral modes. The same holds for laser bars which consist of groups of single emitters arranged in arrays in the lateral direction. To obtain high power with good mode profile, tapered amplifiers and lasers have been developed. They contain a ridge waveguide section and a tapered gain section in which the single lateral mode defined by the ridge waveguide section is smoothly expanded and dominantly maintains its lateral single mode structure.

23.2.8 Temperature Dependence

Many of the fundamental semiconductor laser properties are temperature dependent. Not only does the bandgap shrink in energy with increasing temperature but also the carrier distributions in the bands change with temperature according to the quasi-Fermi distribution functions. Both the bandgap variation and the varying carrier distribution influence real and imaginary part of the susceptibility, i.e., the gain and refractive index of the diode laser material. With increasing temperature, the gain is generally reduced and spectrally shifted to lower energies. At the same time, the variation of the refractive index varies the optical length of the cavity and thus the spectral position of the cavity modes. Consequently, the most important laser specifications degrade with increasing temperature. The laser threshold increases and the quantum efficiency decreases due to the reduced gain and stronger non-radiative recombination processes. Thus, at higher temperature, the achievable output power is lower even if higher current is injected. Since the Ohmic heating contributes to the temperature increase, a thermal rollover may occur where the output power decreases with increasing current. Thus, it is important to provide the laser diode with an efficient heat sink and, even better, with an active cooling via a thermoelectric cooler. The increase of the laser threshold with temperature can be empirically described by a characteristic temperature T_0 according to: $I_{th}(T) = I_{th,0} \exp(T/T_0)$. The characteristic temperature T_0 is a device specific quantity and typically ranges between 50 and 300 K.

The spectral laser properties are influenced in a more complicated way due to the change of both gain and refractive index with temperature. The refractive index modification induces a change in the optical cavity length. Thus the spectral position of the laser modes shifts with temperature. Since also the spectral position of the gain maximum is temperature dependent, the mode competition is modified and different modes may become dominant for different temperature conditions. These changes may lead to so-called mode hops which are difficult to predict and to control.

23.3 Materials and Architectures

23.3.1 Semiconductor Materials

As pointed out in Sect. 23.1.1, semiconductor lasers require direct bandgap semiconductors with excellent material quality. This imposes severe restrictions to the choice of possible materials for semiconductor laser devices. Furthermore, a high material quality is crucial because defects due to dislocations or impurities induce non-radiative recombination channels and thus reduce the lasing efficiency. As a consequence, a high crystal quality is required which is achieved by growing the semiconductor devices by modern epitaxial techniques such as molecular beam epitaxy (MBE) or metal organic vapor phase epitaxy (MOVPE) onto high quality substrate crystals that define the structure of the crystal. To avoid dislocations, the lattice constant of all layers grown within the device structure should not differ too much from the lattice constant of the substrate material which imposes further restrictions to the selection of suitable semiconductor compounds.

In general, the bandgap energy of the active region roughly determines the spectral range of the emission that can be achieved with the laser. This bandgap energy can be varied in alloys as, for example, $(Ga_xIn_{1-x})(As_yP_{1-y})$, by changing the percentages of the material composition. To obtain an overview of realizable laser material combinations, it is helpful to create a diagram in which the band gap energy is plotted versus the lattice constant for the relevant materials and alloys. Then, strategies can be extracted how to achieve a defined bandgap energy with a material alloy whose lattice constant is compatible with a certain substrate (e.g., GaAs, InP, or GaN). An example of such a material map is shown in Fig. 23.6.

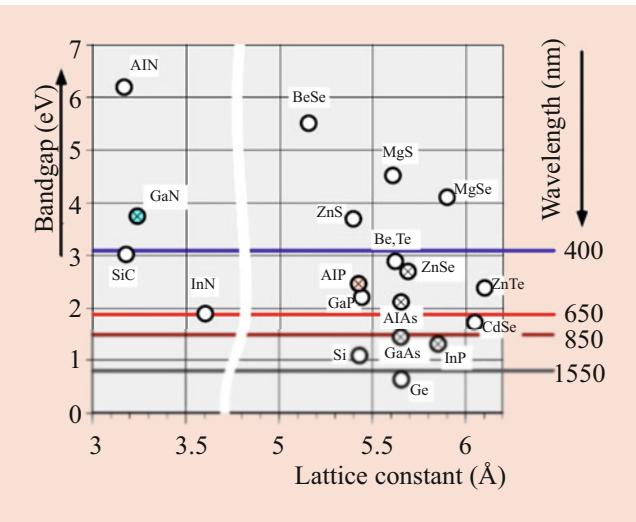

Fig. 23.6 Material map, bandgap energy as a function of lattice constant [15]

Many different material systems have been developed for specific emission wavelengths and applications. The most important examples are GaAs/$Al_xGa_{1-x}As$ heterostructures on GaAs substrates, $(Ga_xIn_{1-x})(As_yP_{1-y})$, heterostructures on InP substrates, and (AlGaIn)N heterostructures on GaN substrates, respectively. In a way, GaAs/$Al_xGa_{1-x}As$ heterostructures on a GaAs substrate serve as a model system since the first semiconductor lasers were developed using these materials. This material system is particularly attractive since the lattice constant of GaAs and AlAs is almost equal so that alloys with a lattice constant compatible with that of GaAs can be produced that cover the near infrared range around 800 nm. The only important restriction is that $Al_xGa_{1-x}As$ becomes indirect for $x > 0.4$. The material $(Ga_xIn_{1-x})(As_yP_{1-y})$ on InP substrate is the most prominent choice for lasers operating in the telecommunication range defined by the fiber windows at 1300 nm and 1550 nm. The (AlGaIn)N – based materials emit in the violet to green spectral range and were developed for blue ray DVD optical storage.

From the material map, it becomes obvious that there is a spectral range in the visible regime for which so far no diode lasers are available. Hence, the realization of yellow or orange emitting semiconductor diode lasers may be one of the major challenges for the future. An even more challenging problem is to realize diode laser structures that are compatible with Si technology, for example CMOS (complementary metal-oxide semiconductor) architectures. This is the basis of modern electronic circuits and there is a growing demand to include optical functionalities onto electronic systems. But, unfortunately, Si is an indirect semiconductor, and no direct semiconductor materials compatible with the lattice constant of Si have been available. Accordingly, the fusion of electronic and optoelectronic circuits to OEICs (optoelectronic integrated circuits) induces major technological effort. However, material research is continued and, for example, recently the direct semiconductor material Ga(NAsP) was developed [13] that may close this technological gap in the future.

23.3.2 Quantum Confinement Structures

As discussed above, semiconductor QW systems have a number of advantages for semiconductor laser applications over bulk materials. As a consequence of the carrier confinement, the threshold gain can be achieved with a much lower overall carrier density as compared to bulk material. Therefore, the threshold current is lower and the modulation speed is higher in QW lasers as compared to bulk heterostructure lasers of the same material. In addition, a certain amount of band structure engineering is possible due to the quantization effects and by introducing small controlled amount of strain to the active layer.

An additional important aspect to be considered in QW laser design is that the small QW width reduced the overlap of the active region with the optical mode and the waveguiding properties. To ensure sufficient optical waveguiding, a further larger scale band structure variation, the so-called separate confinement, has to be introduced.

Besides semiconductor QWs, also other quantum confined semiconductor configurations are used as gain media in modern semiconductor lasers. They provide even higher degrees of quantum confinement than QWs; however, they are more difficult to produce in homogeneous ensembles. Most noteworthy in this context are the so-called semiconductor quantum wire and quantum dots (QD) systems. As QDs, one commonly denotes structures where the excited carrier mobility is restricted in all three spatial dimensions. Hence, instead of the one-dimensional barriers in QWs, one imposes fully three dimensional quantum confinement leading to a particle-in-a-box, respectively particles in a sphere configuration. Quantum wires are somewhat in between QWs and QDs in the sense that they provide quantum confinement in two dimensions, leaving one unconfined degree of mobility.

One consequence of the full confinement in QDs is the discretization of the allowed energy states resembling the situation in atomic systems. Ideally, this would modify the spectrally continuous absorption/gain of usual semiconductors into a set of discrete resonances whose spectral position scales inversely with the square of the QD extension. However, in order to realize spectrally separated absorption/gain peaks in QD ensembles, on needs a high degree of size uniformity since any size variation immediately leads to pronounced inhomogeneous broadening.

Current technology allows for the growth of wire and QD structures with various degrees of precision. Lasers devices utilizing these quantum confined systems have been developed and overall desirable properties have been identified [2]. However, it remains to be seen if these systems will be able to outperform to successful commercial QW laser devices.

23.3.3 Quantum Cascade Lasers

While standard diode lasers are available for many spectral regions in the visible and near infrared regime, the realization of mid-infrared or far infrared lasers becomes challenging, in particular because the Auger losses in narrow-gap semiconductor systems are dramatically increased in comparison to, e.g., GaAs-based materials. Therefore, alternative concepts have been introduced that are based on intraband optical transitions within the conduction band instead of interband transitions between conduction and valence band. The fundamental idea is to use transitions between different quantized states in QWs. The energy splitting of these states can be well tailored by the QW geometry. However, to achieve

inversion in such structures is somewhat challenging. While the lifetime for interband transitions is of the order of a nanosecond, the lifetime in an higher QW state is only of the order of a picosecond. Thus, without further effort, it would not be possible to accumulate carriers in the upper state to achieve inversion. One fundamental achievement in the realization of quantum cascade lasers is to reduce the lower state lifetime to about 0.1 picoseconds by a resonant tunneling process into an adjacent quantum well. This may even be arranged in a way that the resonant state in the adjacent well is the upper laser level in this well. In this way, many QWs may be arranged in series and the injected electrons follow a cascade process though this series. This quantum cascade process provides multiple photons for each injected electron and increases the efficiency of quantum cascade lasers. Such quantum cascade lasers are unipolar lasers, i.e., they work with electrons injected by an applied electric field only. Their realization is challenging since practical devices contain hundreds of individual layers. After their first realization in 1994 by Capasso et al., quantum cascade lasers have been further developed to become very useful systems for spectroscopic applications like trace gas analysis in the mid infrared. The emitted power for these lasers is in the *mW* regime and they operate with moderate currents at room temperature.

Quantum cascade lasers for longer wavelengths or lower frequencies down to the THz-range are much more difficult to realize. THz quantum cascade lasers still only work at cryogenic temperatures, and it is yet unclear whether room-temperature quantum cascade lasers at 1 THz will ever be realized. For further reading about quantum cascade lasers we refer to Faist [6].

23.3.4 Microcavity Lasers

As *microcavity lasers* , one often denotes very small semiconductor laser structures with dimensions in the range of a few times the wavelength of the emitted light. Nowadays, such systems can be routinely realized by systematically utilizing the advantages of epitaxial growth. As the first microcavity device, vertical-cavity surface-emitting lasers (VCSELs) (see Fig. 23.7) have been developed in the 1990s [16].

Generically, these VCSELs are Fabry-Perot type laser systems where distributed Bragg reflectors (DBRs) serve as the cavity end-mirrors. These DBRs consist of a series of layers with different refractive index, where each layer has the optical thickness of a quarter of the emission wavelength. In VCSELs, the DBRs are epitaxially grown using semiconductor material combinations with sufficiently different refractive index such as GaAs and $Al_xGa_{1-x}As$.

During the growth process, the gain medium is deposited on top of the first DBR in the form of one or more QWs with proper barriers and spacer layers, followed by the second DBR needed to complete the Fabry-Perot cavity. The total thickness of the QWs together with the barriers and spacer layers defines the cavity length, which is on the order of a few times half the emission wavelength in typical VCSELS.

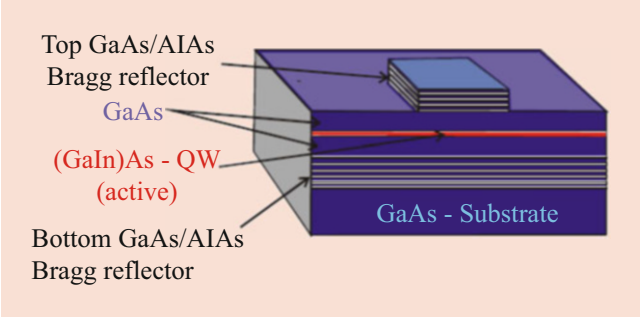

Fig. 23.7 Schematic geometry of a VCSEL

Under operation conditions, the light is emitted parallel to the growth direction such that the lasing occurs out of the surface of the epitaxial heterostructure. As a consequence of the relatively small number of QWs in the gain region, the light circulating in the cavity experiences only weak round-trip amplification. This gain has to exceed the losses in order for lasing to occur, such that very high mirror reflectivities are needed which are typically in the range of 99% or more in most configurations. Luckily, such high reflectivities can routinely be realized with semiconductor DBRs having on the order of 20 or more layer pairs.

For most practical applications of VCSELS, it is desirable to generate the needed carrier inversion in the gain QWs via electrical pumping. Thus, it is necessary to implement a p-n-junction into the overall design and to develop strategies for effectively injecting charge carriers into the active region. As a consequence, such electrically pumped VCSEL structures have an even more complex architecture than the schematic structure shown in Fig. 23.7.

Taking advantage of the small microcavity dimensions, one can design VCSEL systems such that only one longitudinal mode is amplified by the gain QWs. As a consequence, these microlasers are well suited to realize single-mode output characteristics. Another desirable feature for practical applications of VCSELS is that one can engineer a round aperture for light emission with a diameter of a few micrometers so that diffraction is weak and the beam profile is almost perfectly circular.

A further development based on the successful VCSEL concept is the so-called VECSEL (Vertical External Cavity Surface Emitting Laser) [12]. In these systems, one of the DBRs is replaced by an external outcoupling mirror. See Fig. 23.8 for an example of the schematic VECSEL design.

The single remaining DBR plus the gain QWs grown on top of it constitute the “active mirror,” i.e., the VECSEL chip.

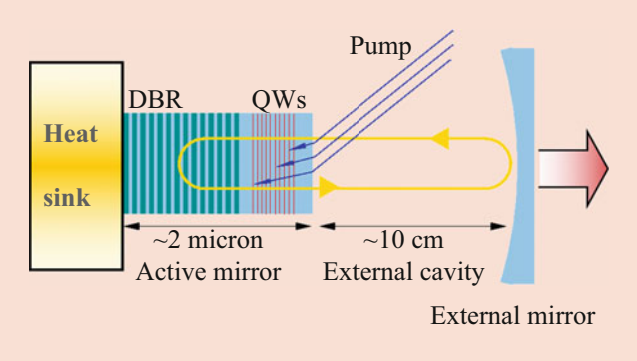

Fig. 23.8 Schematic layout of a VECSEL device showing the QW structure grown on a distributed Bragg reflector (DBR) mirror stack consisting of quarter-wave-length thick layers of alternating semiconductor materials with high and low refractive index. Together, the DBR and the quantum wells constitute an "active mirror". The spacing between the typically 8–12 quantum wells is chosen to match half the wave length of the desired laser emission, constituting the resonantly periodic gain medium. The structure is pumped using external optical sources. Lasing is achieved by using an external high-reflectivity (out coupling) mirror to form a closed cavity. The generated heat is removed by a heat sink typically consisting of a diamond heat-spreader on a copper block

The laser cavity is completed by a high-reflectivity external mirror, which is also used for the outcoupling of the laser emission. The VECSEL chip is mounted on a heat sink which typically consists of a diamond heat spreader on top of a copper block. The QWs are optically pumped using commercially available high-power pump sources. Figure 23.8 shows a simple generic VECSEL layout. Besides the depicted linear cavity arrangement, also more elaborate geometries with so-called V-cavities or even more complicated configurations are in practical use.

A wide variety of semiconductor materials can be used as the VECSEL gain medium allowing for lasing at many desirable wavelengths. Since the total VECSEL cavity can easily have an extension in the range of many centimeters, there is sufficient space to incorporate additional elements. One example are suitable nonlinear crystals that allow for intracavity frequency up-conversion which significantly extends the wavelength range of VECSEL emission, well into the visible and even UV.

Generally, in VECSELs, the emission intensity scales with the pumped area such that high-power performance is possible. For this application, one epitaxially grows the different QWs in the gain medium in a particular spatial arrangement, referred to as RPG (resonant periodic gain) configuration. Here, the center-to-center distance between the wells is precisely half the wavelength of the emitted light. Under this condition, the contributions from the individual QWs are all in phase and maximize the total output of the device for this particular wavelength. Using RPG VECSEL configurations, multi-mode output in excess of 100 W CW (continuous wave) and single mode emission of more than 20 W CW has been reported [19].

In addition to the application as bright source for CW emission, VECSELs can also be used for ultra-short pulse generation. Here, one typically utilizes the concept of passive mode locking by replacing the high-reflectivity outcoupling mirror by a SESAM (semiconductor saturable absorption mirror). The SESAM introduces an additional loss into the cavity, which is relatively large for low intensities but is gradually saturated with increasing intracavity field strength. This favors the build-up of short pulses because the high intensity at the pulse peak saturates the absorber more efficiently than its low intensity wings.

SESAM mode locking in VECSELs with RPG gain configurations has been demonstrated and ultrashort pulses with durations in the 100 fs regime have been generated. Recently, it has been realized that the spatial arrangement of the gain QWs can be optimized to achieve even shorter pulse durations [10]. Whereas first demonstrations yielded pulses with FWHM of 95 fs, the full potential of this new concept has not yet been exploited, mainly due to technical difficulties with pulse induced SESAM degradation and proper management of the group delay dispersion. Hence, this field is still an area of active current research.

23.4 Applications and Outlook

23.4.1 Applications

As already mentioned throughout this article, semiconductor lasers are attractive for numerous applications due to their specific properties including their compact dimensions, high efficiency, low price and the enormous flexibility to adapt their design for the specific application. It is almost impossible to list all semiconductor laser applications. They include, for example, laser pointers, laser printers, barcode scanners, metrology systems for measuring distance or speed, light detection and ranging (LIDAR), biomedical imaging, display technology (e.g., laser TV), optical data storage, optical data transmission, material processing, and many others. In the following, we discuss three important applications and point out the corresponding challenges for the device development.

For optical storage on compact discs (CDs) or digital versatile discs (DVDs), a good beam quality is required. To read out the tiny bits and lands on a CD or DVD, the laser spot has to be focused to a spot as small as possible. The diffraction limited spot size scales with the wavelength. Accordingly, much more date can be stored on a blue ray DVD which is read out at 405 nm than on a CD which is read out at 780 nm. This was the major driving force for the development of (AlGaIn)N lasers emitting in the blue-violet spectral range. This development was accompanied with many challenges

but has finally led to the nowadays commercially available blue lasers with extremely long lifetimes.

The internet is based on optical data transmission via glass fibers. Here, high speed modulated diode lasers are the key elements needed for sending the optical data streams. These lasers have to be adapted to the fiber properties, most importantly they should emit at the fiber window of 1550 nm. This is realized with lasers based on the $(Ga_xIn_{1-x})(As_yP_{1-y})$ material system grown on InP substrates. These lasers should emit a good beam profile to enable coupling into single mode optical fibers. This is usually realized with the help of lateral waveguiding via ridge structures.

To achieve high transmission rates, the lasers should enable fast modulation. The maximum modulation frequency is limited by the relaxation oscillation frequency to the range below 50 GHz. Material engineering is used to optimize the lasers for such high frequencies. For advanced wavelength division multiplexing, it is necessary that the lasers operate in one longitudinal mode at a well-defined wavelength. This is commonly achieved using DFB lasers.

For high power applications, completely different optimization schemes are performed. In those cases, usually the spectral quality of the emission is not crucial and multimode emission can be tolerated. The most straight forward approach to increase the output power is to scale up the emission surface in broad area lasers. Thus, power levels in the few W range become accessible. Even higher power levels are accessible with diode laser arrays. Such arrays enable output powers up to the kW range as they are required for material processing applications like, for example, laser welding.

23.4.2 Outlook

Nowadays semiconductor lasers are essential tools for our communication society. Most important, they are fundamental components for the internet data traffic. As the internet traffic is continuously growing, there is an ongoing demand for faster lasers and high modulation bandwidths. Since fundamental limits of the current technology will be reached soon, there is need for new concepts as, for example ultrafast spin lasers in which the polarization state of the light is modulated instead of the intensity [14].

Since optical communication will play a major role also for short range interconnects, potentially even between and inside chip, there is a big demand for the combination of electronic and optoelectronic devices into optoelectronic-electronic integrated circuits (OEICs). This is a challenge because electronic systems are based on silicon technology and optoelectronic systems are based on III-V-semiconductor technology. Unfortunately, common III-V laser materials have lattice constants differing strongly from that of silicon. Thus, the combination of both within OEICs is technologically challenging and primarily requires major breakthroughs in the development of semiconductor lasers compatible with silicon technology. While wafer fusion of silicon and III-V-based devices is a technologically demanding approach, new material systems as, for example, the direct semiconductor Ga(NAsP) [13], are developed that may be integrated into silicon technology due to their suitable lattice constant.

Another research field is the realization of better lasers for the visible range. While red, blue and green lasers are available, yellow and orange diode lasers still have to be developed. Such lasers would be extremely interesting for display applications, for example for compact laser television systems.

Laser diodes with higher output power are interesting for material processing applications. Due to the high efficiency of diode lasers, it is extremely attractive to replace larger solid state or CO_2 lasers in such applications, when sufficient output power is available.

A further area still awaiting a major breakthrough is the realization of room-temperature semiconductor lasers emitting in the regime of 1 THz. They would be extremely interesting for material sensing or free space THz communication systems.

Abstract

The tunnel field-effect transistor (TFET) relies on interband tunneling to achieve subthreshold swing below the 60 mV/dec fundamental limit at room temperature of bipolar and field-effect transistors. Since the first successful demonstration of a subthermionic TFET in 2004, research efforts have been devoted to the study and engineering of TFETs for low-power and energy-efficient integrated circuit applications. Starting from band-to-band tunneling theory, this chapter aims to give a comprehensive overview of the TFET and its principles of operation. This sets the stage for understanding electrical characteristics, design trade-offs, critical challenges, and source of nonidealities. In light of the physical challenges, the benefits of adopting a heterojunction device architecture are presented. After about 15 years of intense research and steady progress across a plethora of materials systems, spanning from group IV materials, such as Si, to III–V compounds, to two-dimensional materials and mixed-dimensional heterostructures, as well as through different device architectures, an updated benchmark of best reported TFETs is provided to benchmark the state of the art across materials systems.

24.1 Introduction

The relentless and persevering scaling of the silicon metal oxide semiconductor field-effect transistor (MOSFET), the building block of almost every electronic system, has been geared by an ever-increasing demand for denser, higher-performance, and more energy-efficient integrated circuits (ICs). For more than five decades, as predicted by Gordon Moore in 1965 [1, 2], semiconductor manufacturers have succeeded in exponentially increasing the number of transistors per chip at a factor of 2× every 2 years. This incredible engineering quest can be divided into two eras: the "geometrical scaling" era, spanning nearly 30 years from 1974 until the

early 2000s, followed by the "effective scaling" era that we are now witnessing, which is around its midpoint. A third era of "hyper-scaling" is unfolding [3].

The fundamental principles of "geometrical scaling" were first laid out by Dennard in 1974 [4]. The design criteria are somewhat simple: simultaneously reduce the transistor length (L), width (W), oxide thickness (t_{OX}), and supply voltage (V_{DD}) by a factor k and increase the channel doping, N, by the same factor. With no penalty in terms of power density, the net result is constant improvement in cost (area), speed, and energy. Dennard scaling survived until the 130-nm node.

Due to limitations on oxide thickness scaling imposed by exponentially increasing leakage currents and impediments to supply voltage reduction as a consequence of nonideal electrostatics, the "effective scaling" era started around 2003 with the addition of distinct performance boosts such as strained silicon at the 90-nm node, high-κ dielectric and metal gate starting from the 45-nm node, and finally the adoption of a 3D multigate transistor architecture, the FinFET, at the 22-nm node. Despite all the technological advancements that have enabled the reduction of the minimum feature size from 50 μm, starting in 1965, to about 10 nm in today's leading technologies, Si MOSFETs operate under the same physical principle and suffer the same limitations.

In the simplest picture, an FET consists of two reservoirs of mobile charges, named source and drain, separated by the channel potential barrier whose shape and height can be modulated upon the application of a proper bias at the gate electrode. The gate is insulated from the semiconductor channel by a gate oxide. For digital applications, the MOSFET is designed to behave like an electronic switch, transitioning an insulating (OFF) state for V_{GS} below a certain threshold voltage (V_T) to a highly conductive (ON) state for V_{GS} greater than V_T. A typical semilogarithmic plot of the drain current vs. gate voltage, I_D–V_{GS}, characteristic of an n-channel MOSFET is shown in Fig. 24.1a. In the subthreshold regime, $V_{GS} < V_T$, the drain current turns off exponentially, and its inverse slope is defined as the subthreshold swing (SS). Specifically, SS refers to the gate voltage required to change the drain current by one order of magnitude. In a MOSFET, the current governing mechanism is thermionic emission over an energy barrier (Fig. 24.1b), and this sets a fundamental limit on the minimum attainable SS due to the Maxwellian tails of the source Fermi-Dirac distribution given by [5]

$$\begin{aligned} SS &= \left(\frac{d\log_{10} I_D}{dV_{GS}}\right)^{-1} = \underbrace{\frac{dV_{GS}}{d\psi_S}}_{m}\underbrace{\frac{d\psi_S}{d\left(\log_{10} I_D\right)}}_{n} \\ &\cong \left(1+\frac{C_S}{C_{OX}}\right)\ln(10)\frac{k_B T}{q}. \end{aligned} \tag{24.1}$$

In the above equation, ψ_S is the channel electrostatic potential; C_S and C_{OX} are the semiconductor and oxide capacitances, respectively; k_B is the Boltzmann constant; T is the absolute temperature; and q is the electron charge. The brackets in Eq. (24.1) highlight the two different contributions to SS: m is the transistor body factor, and n is a term that identifies the underlying transport mechanism in the channel. The SS limit at room temperature imposed by

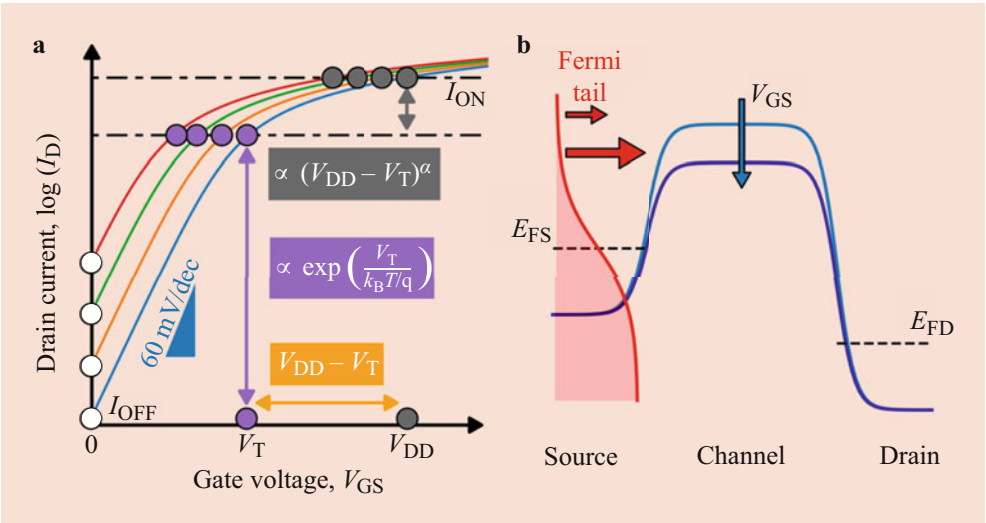

Fig. 24.1 (**a**) MOSFET transfer characteristics. The simultaneous scaling down of both the supply voltage (V_{DD}) and the threshold voltage (V_T) to meet the ON-state current requirement (I_{ON}) leads to an exponential increase in the OFF-state current (I_{OFF}). (**b**) Energy band diagram showing the conduction band with Fermi levels in the source and drain labeled E_{FS} and E_{FD}, respectively. The current governing mechanism in a MOSFET is thermionic emission over the channel potential barrier. In the subthreshold regime, the Fermi tail limits the subthreshold swing (SS) to the fundamental limit of 60 mV/dec at room temperature

thermionic emission is equal to 60 mV/dec. Figure 24.1a indicates that a reduction of V_T will translate into an exponential increase in I_{OFF}, and as a consequence, static power increases, $P_S = V_{DD}\ I_{OFF}$. Therefore, a reduction of V_{DD} at matched overdrive cannot be achieved. Because of these fundamental limits, a third era of hyper-scaling is dawning, in which new physics, materials, and devices will be essential for meeting Moore's law requirements for next-generation computing devices.

24.2 Tunnel FET Operation Principles

The tunnel FET (TFET) is a transistor concept compatible with CMOS technology and able to overcome the 60 mV/dec MOSFET limit. In contrast to MOSFETs, TFETs rely on interband tunneling through a potential barrier [5–7]. In simple terms, the TFET is a gated reverse-biased p-i-n diode. Figure 24.2a exemplifies the archetype of an n-type TFET; it consists of a p^+ source and an n^+ drain, connected with a fully gated intrinsic channel. Structurally, the peculiar feature of a TFET is the asymmetric doping of the drain and source with respect to a conventional MOSFET. The corresponding band diagrams of an nTFET transitioning from the OFF to the ON state are shown in Fig. 24.2b under positive V_{DS} bias. As in a backward diode, the interband overlap of the source and channel regions enables the conduction of carriers by means of band-to-band tunneling (BTBT) (Zener tunneling). However, in the OFF state, the band gap in the channel acts as an energy filter, cutting off the availability of states for tunneling. As a consequence, I_{OFF} in a TFET results ideally only from thermionic emission above a barrier approximately equal to the energy band gap, E_G. Other processes that contribute to the OFF-state leakage currents are associated with Shockley-Read-Hall (SRH) generation and trap-assisted tunneling (TAT) [8], Auger generation [9], and direct source-to-drain tunneling at scaled channel lengths [10].

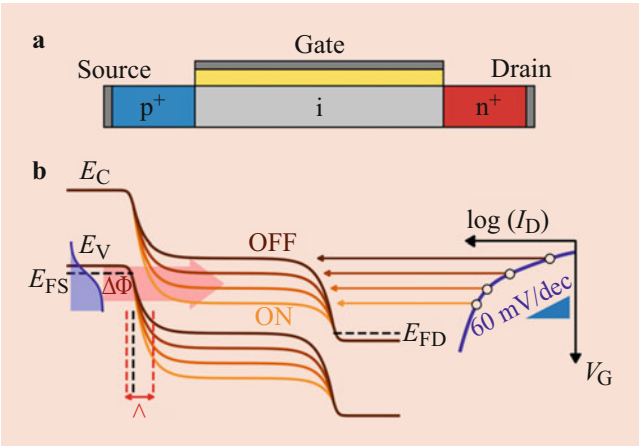

Fig. 24.2 (**a**) Schematic cross section of an n-type TFET. It consists of a p^+ source, a fully gated intrinsic channel, and an n^+ drain. (**b**) Energy band diagrams for different V_{GS} biases. Each band diagram corresponds to a specific point in the I_D–V_{GS} characteristic indicated in the right panel. The tunneling window is labeled $\Delta\Phi$, and Λ denotes the tunneling distance from source to drain; the conduction and valence band energies are E_C and E_V, respectively

Referring again to Fig. 24.2b, if a positive gate voltage is applied, the bands in the channel move to lower energies reaching a crossing point where the conduction band in the channel begins to overlap with the valence band in the source. This corresponds to the onset of BTBT where electrons tunnel from the source valence band into the channel through a tunneling width Λ. The tunneling probability is exponentially dependent on the tunneling distance. The BTBT generation processes can result either from direct transition between the maximum of the valence band and the minimum of the conduction band at the Γ-point or via a phonon-meditated indirect transition. The gate voltage plays a twofold role in the operation of a TFET. It modulates both the tunneling probability and the availability of states to tunnel into, within a tunneling window given by the interband overlap. These two contributions allow for two different mechanisms for realizing SS steeper than 60 mV/dec. Unlike the MOSFET where the slope of the I_D–V_{GS} transfer characteristic has a fixed swing in the subthreshold regime, the SS of a TFET is not constant but depends on V_{GS}. The key voltage defining the upper bound of this region is defined as V_{60}, the voltage at which the slope of the characteristic $d\log I_D/dV_{GS}$ is 60 mV/dec. The drain current at $V_{GS} = V_{60}$ is denoted I_{60}, which is a useful figure of merit, discussed in Sect. 24.4.

A short historical perspective of the discoveries that have led to the conceptualization and demonstration of the TFET begins with the theory of BTBT, i.e., "electrons passing from one band into another under the action of a constant electric field," written by Zener in 1934 [11] to explain electrical breakdown in solid dielectrics. Zener tunneling is the core transport mechanism in a TFET. It was not until 1958 with the pioneering work by Esaki [12] that BTBT manifested itself in the characteristic negative differential resistance (NDR) in the forward bias regime of a degenerately doped p^+n^+ Ge homojunction. A gated p-i-n device called the "surface channel tunnel junction," the prototype of the TFET, was reported by Quinn [13] in 1978 as a means to investigate subband splitting in quasi-2D systems. BTBT was then identified as the working principle in a trench transistor cell leading to a three-terminal planar MOS tunneling device proposed by Banerjee in 1987 [14]. In the early 2000s, several research groups highlighted that subthermal SS could be achieved in a tunneling transistor [15–18], and the first experimental demonstration of SS <60 mV/dec was demonstrated in a carbon nanotube TFET by Appenzeller [18]. The benefit of employing heterostructures in the optimization of TFETs' performance followed shortly afterward [19]. Since then,

TFETs have attracted significant research interest, and an amazing number of steep-slope devices have been proposed and reported exploiting different device architectures and materials systems [20]. The prior art leading to the TFET is further detailed by Ionescu and Riel [5] and Seabaugh and Zhang [6].

24.3 Band-to-Band Tunneling

In this section, a simple analytical theory is derived to lay out some general TFET design rules and to illustrate under what circumstances subthermal SS can be achieved. As illustrated in Fig. 24.2b, only carriers within the tunneling window $\Delta\phi = E_{V,S} - E_{C,CH}$ contribute to the transport, where $E_{V,S}$ is the valence band in the source region and $E_{C,CH}$ is the conduction band in the channel far away from the tunnel junction such that the bands can be considered flat. Using Landauer formalism [21], the drain current per unit width can be written as

$$I_D = \frac{2q}{h}\int_{E_{C,CH}}^{E_{V,S}} T_{BTBT}(E)\left[f_S(E) - f_D(E)\right] dE \tag{24.2}$$

where h is Planck's constant, $f_{S,D}(E)$ are the source and drain Fermi distribution functions, and $T_{BTBT}(E)$ is the BTBT tunneling probability. The direct BTBT probability can be evaluated analytically by means of the Wentzel-Kramers-Brillouin (WKB) approximation:

$$T_{BTBT} = \exp\left(-2\int_{x_1}^{x_2} k_X(x, E)\, dx\right) \tag{24.3}$$

where x_1 and x_2 are the classical turning points defining the tunneling path length and k_X is the imaginary wave vector obtained through the Kane two-band model [22, 23]. Assuming a triangular potential barrier at the source/channel interface, i.e., constant electric field over the tunneling path, the transmission probability can be written as [24]

$$T_{BTBT} = \exp\left(-\frac{4\Lambda\sqrt{2m^*}E_G^{3/2}}{3q\hbar(\Delta\phi + E_G)}\right) \tag{24.4}$$

In Eq. (24.4), Λ is the width of the transition region at the source/channel interface, i.e., the tunneling width, m^* is the reduced tunneling mass, $\hbar$ is the reduced Planck's constant, and E_G is the semiconductor energy gap. The reduced tunneling mass is often approximated $m^* = \left(1/m_e^* + 1/m_h^*\right)^{-1}$, which averages both the electron, m_e^*, and the hole, m_h^*, effective masses. The tunneling width is given by the sum of the depletion width in the source, W_D, and the scaling length of the gated region, λ, i.e., $\Lambda = W_D + \lambda$. The scaling length for double-gate TFETs has been discussed by Taur [25]. Equation (24.4) considers a semiconductor with a direct band gap such as InAs, where carriers tunnel from a single conduction band to a single valence band. In indirect semiconductors, e.g., Si and Ge, the WKB model breaks down due to the many interacting bands involved in the tunneling process [26]; however, the same general dependencies on Λ, m^*, and E_G are maintained. Substituting Eq. (24.4) back into Eq. (24.2), I_D can be rewritten as

$$\begin{aligned} I_D &= \frac{2q}{h}\exp\left(-\frac{4\Lambda\sqrt{2m^*}E_G^{3/2}}{3q\hbar(\Delta\phi + E_G)}\right)\int_{E_{C,CH}}^{E_{V,S}}\left[f_S(E) - f_D(E)\right] dE \\ &= \frac{2q}{h}T_{BTBT}F(\Delta\phi) \end{aligned} \tag{24.5}$$

Equation (24.5) indicates that the BTBT current is determined by both the transmission probability and the occupation functions at the two sides of the tunnel junction within the tunneling window. If we assume a drain-source bias large enough to suppress any back injection from the drain to the source, I_D simplifies to [27–29]

$$\begin{aligned} I_D &\approx \frac{2q}{h}T_{BTBT}k_BT\left[F_0\left(\frac{E_{FS} - E_{C,CH}}{k_BT}\right) - F_0\left(\frac{E_{FS} - E_{V,S}}{k_BT}\right)\right] \\ &= \frac{2q}{h}T_{BTBT}k_BT\ln\left[\frac{1 + \exp\left(\frac{E_{FS} - E_{V,S} + \Delta\phi}{k_BT}\right)}{1 + \exp\left(\frac{E_{FS} - E_{V,S}}{k_BT}\right)}\right] \end{aligned} \tag{24.6}$$

where F_0 indicates the complete Fermi-Dirac integral of order 0. Typically, T_{BTBT} <1; therefore, TFETs are not able to match the MOSFET in terms of I_{ON} at large overdrives. On the other hand, the low SS, if achieved across a range of at least three to four orders of magnitudes, makes TFET a legitimate alternative for low-voltage and low-leakage applications [30].

Thanks to their simplicity, Eqs. (24.3) and (24.4) are particularly appealing to model Zener tunneling and will be used extensively in the following sections to build an understanding of how the various design parameters affect TFET performance. It is though important to gain a grasp of the tunneling physics itself. Equation (24.3) states that BTBT occurs when an electron travels through the forbidden energy gap having a complex wave vector along the tunneling direction. Therefore, an accurate description of the evanescent modes is necessary to analyze the electron trajectory, i.e., complex band structure, and understand the interactions between the different complex branches involved in the BTBT.

Using a nearest neighbor $sp^3d^5s^*$ tight-binding method, Luisier and Klimeck [26] computed the band structures for three different nanowire channel materials of interests for

TFETs, namely, InAs, Si, and Ge, featuring both real and imaginary bands, and provided a comparison of the transfer characteristics obtained using the WKB approximation and more complex quantum transport models for 1-D nanowire TFETs. From a pedagogical point of view, the three materials investigated give a general and broad description of the different BTBT processes at play and, as examples, illustrate the transport in a wide variety of other materials systems.

Figure 24.3a shows the real and imaginary bands of an InAs nanowire having diameter $d = 3.35$ nm and $E_G = 1.175$ eV. The peculiar feature of its complex energy dispersion is the presence of a single, nondegenerate imaginary branch, highlighted in gray, connecting the highest valence subband to the lowest-lying conduction subband. Along this imaginary path, no crossing between imaginary bands is found. Transfer characteristics computed using this complex "least action for tunneling" branch, i.e., path with the smallest imaginary wave vector, within the WKB approximation, and quantum transport models, with and without phonon-assisted tunneling, showed excellent agreement from the OFF state to the full ON state of the 1-D TFET nanowire geometry [26]. More generally, these results validate the use of the WKB approach to model BTBT for a semiconductor with direct band gap at Γ, showing a single dominant imaginary branch connecting the valence band with the conduction band. Moreover, if direct tunneling is the dominant leakage mechanism at scaled channel lengths, the WKB approximation can be expected to yield a good description of the subthreshold current in the device OFF state.

A different situation is encountered in Si, as shown in Fig. 24.3b. The computed band structure refers to a Si nanowire with $d = 3$ nm and $E_G = 1.619$ eV. The imaginary dispersion highlights that multiple band crossing points are present. A description of such band mixing goes beyond the standard WKB approximation, therefore preventing the identification of a path of least action for tunneling connecting the top of the valence subband with the bottom of the conduction subband. Moreover, not all the complex branches start from a conduction subband minimum or a valence subband maximum at the Γ point, i.e., having a purely imaginary wave vector. If originated away from the Γ point, these imaginary paths have also a real wave vector component; therefore, the transition between different complex bands requires the absorption and emission of a phonon to satisfy momentum conservation. These nuances have been highlighted by Luisier and Klimeck [26], where they compared the BTBT currents obtained following the imaginary path with the smallest κ (dashed gray line in Fig. 24.3b) against the results computed via a quantum transport model accounting for phonon-assisted tunneling and found that the WKB approximation overestimated the device current by two orders of magnitude.

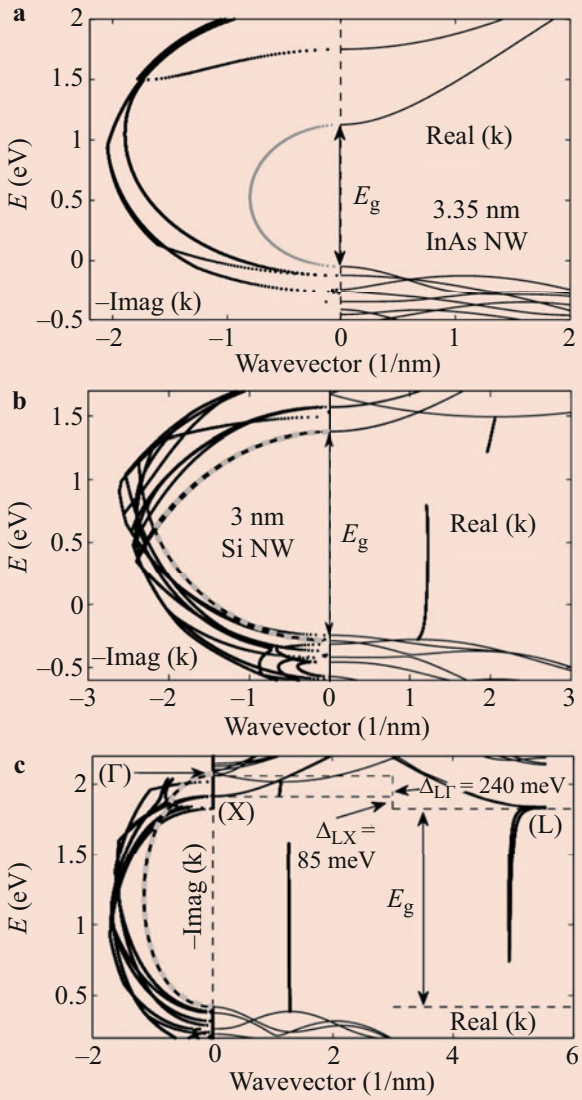

Fig. 24.3 Imaginary and real band structure of (**a**) 3.35-nm-diameter InAs nanowire, (**b**) 3-nm-diameter Si nanowire, and (**c**) 3.12-nm-diameter Ge nanowire. (Figure from Luisier and Klimeck [26])

A peculiar case emerges from the study of Ge nanowires as shown in Fig. 24.3c ($d = 3.12$ nm, and $E_G = 1.409$ eV). The lowest conduction subbands at the L point have nonzero real part, and do not have any imaginary path connecting directly to the highest valence subbands. The lowest conduction subband originates from the bulk Ge Γ valley, labeled (Γ). This subband is nondegenerate, has zero imaginary part, and is directly connected to the maximum of the valley subband. In proximity to the conduction band minimum, several band crossings are also present with four of the bulk X valleys, labeled (X), that are projected to Γ due to quantum confinement in the 1-D geometry. The least action for tunneling path is indicated by the dashed gray lines in Fig. 24.3c and the BTBT

current computed with the WKB approximation matches the quantum transport models only for the ON state, i.e., direct tunneling between the top of the valence subband and the (Γ) conduction subband dominates. However, it fails in the OFF state, where the subthreshold current is a combination of direct tunneling from the top of the valence band and the (X) subbands as well as phonon-assisted tunneling to the (L) subbands.

The analysis by Luisier and Klimeck [26] reveals that the WKB approximation represents a viable approach to the modeling of TFETs in those cases where BTBT develops along a single, nondegenerate imaginary band connecting the top of the valence band to the bottom of the conduction band. For a full analytical description of BTBT processes that can be employed for fast assessment of TFET performance and the development of compact models of tunneling devices, analytical expressions of the complex branches are needed. Unlike the MOSFET where, due to the thermal statistics, only carriers within a small range of energies around the band extrema determine current transport, therefore a parabolic effective mass description of the real band structure is sufficient; in the case of a TFET, carriers need to follow a path along the entire semiconductor band gap, and therefore it is of great importance to resolve the full range of energies with accuracy to precisely compute BTBT probabilities [31]. To this purpose, Guan [32] showed that the nonparabolic approximation of real bands works well to describe the complex band structure of common semiconductor materials within the energy gap, thus revealing the intrinsic elliptic nature of the imaginary branches. Assuming a semiconductor with direct band gap at Γ, the nonparabolic approximation prescribes that the imaginary wave vector, κ_Γ, takes the form [32]

$$\kappa_\Gamma = \begin{cases} \frac{1}{\hbar}\sqrt{2m_h^* E\left[1-E/\left(2E_q^\Gamma\right)\right]}, & 0<E<E_q^\Gamma \\ \frac{1}{\hbar}\sqrt{2m_e^*\left(E_G^\Gamma-E\right)\left[1-\left(E_G^\Gamma-E\right)/\left(2E_G^\Gamma-2E_q^\Gamma\right)\right]}, & E_q^\Gamma<E<E_G^\Gamma \end{cases} \tag{24.7}$$

where E_G^Γ is the direct energy gap at the Γ point and $E_q^\Gamma = E_G^\Gamma\, m_e^*/\left(m_c^*+m_v^*\right)$ is the branch point at which the conduction and valence branches join continuously. The elliptic and analytically integrable expression of Eq. (24.7) can then be substituted in Eq. (24.3) for an accurate calculation of the BTBT probability. From a knowledge of complex band structure and the interactions between the different branches obtained from first principle calculation, a similar expression of the complex wave vector applicable for indirect semiconductors can be obtained [32].

As a last remark, Eq. (24.3) is valid for a 1-D tunneling mode where the tunnel path starts at the valence band edge and terminates at the conduction band edge, which has zero perpendicular momentum. For a bulk direct semiconductor, we can write the total energy as the sum of two components, i.e., $E = E_X + E_\perp$, where E_X is the energy along the tunneling direction, and $E_\perp = \hbar^2\left(k_Y^2+k_Z^2\right)/2m^*$, where k_Y and k_Z are the wave vectors in the directions transverse to tunneling [6]. The transverse energy, $E_\perp$, must be conserved during the tunneling process; therefore, the net effect is that the effective tunneling gap increases and the tunneling probability diminishes. In fact, carrying out the WKB integral, one obtains that the 3D tunneling probability can be written from [6]

$$\begin{aligned} T_{WKB}^{3D} &= \exp\left(-\frac{4\sqrt{2m^*}(E_G+E_\perp)^{3/2}}{3q\hbar\xi}\right) \\ &\cong \exp\left(-\frac{4\sqrt{2m^*}E_G^{3/2}}{3q\hbar\xi}\right)\exp\left(-\frac{E_\perp}{\overline{E}}\right) \end{aligned} \tag{24.8}$$

where ξ is a (constant) junction electric field and $\overline{E} = q\hbar\xi/2\sqrt{2m^*E_G}$ is a factor that takes into account the degradation of the tunneling probability due to the transverse energy state. The larger the factor $\overline{E}$, the smaller the attenuation of the tunneling probability due to carriers having nonzero transverse energy. The simple expressions of Eq. (24.8) also indicate that in order to simultaneously engineer small $E_\perp$ and large $\overline{E}$, one has to rely on materials having elliptic band structures, with light effective mass in the tunneling direction for enhanced transmission and heavier mass in the perpendicular direction to minimize the transverse momentum.

24.4 Subthreshold Swing

It is instructive to show how sub-60 mV/dec swings arise from the simple model of Eq. (24.5). Recall the definition of SS:

$$SS = \left[\frac{d\log_{10} I_D}{dV_{GS}}\right]^{-1} = \ln(10)\left[\frac{1}{I_D}\frac{dI_D}{dV_{GS}}\right]^{-1} \tag{24.9}$$

Assuming that the channel potential varies one to one with the applied gate voltage, SS becomes [24]

$$\begin{aligned} SS &= \frac{\ln(10)}{q}\left[\frac{1}{I_D}\frac{dI_D}{d\Delta\phi}\right]^{-1} \\ &= \frac{\ln(10)}{q}\left[\frac{2q/h}{I_D}\left(\frac{dT_{BTBT}}{d\Delta\phi}F(\Delta\phi)+T_{BTBT}\frac{dF(\Delta\phi)}{d\Delta\phi}\right)\right]^{-1} \\ &= \left[\frac{1}{SS_{TUN}}+\frac{1}{SS_{DOS}}\right]^{-1} \end{aligned} \tag{24.10}$$

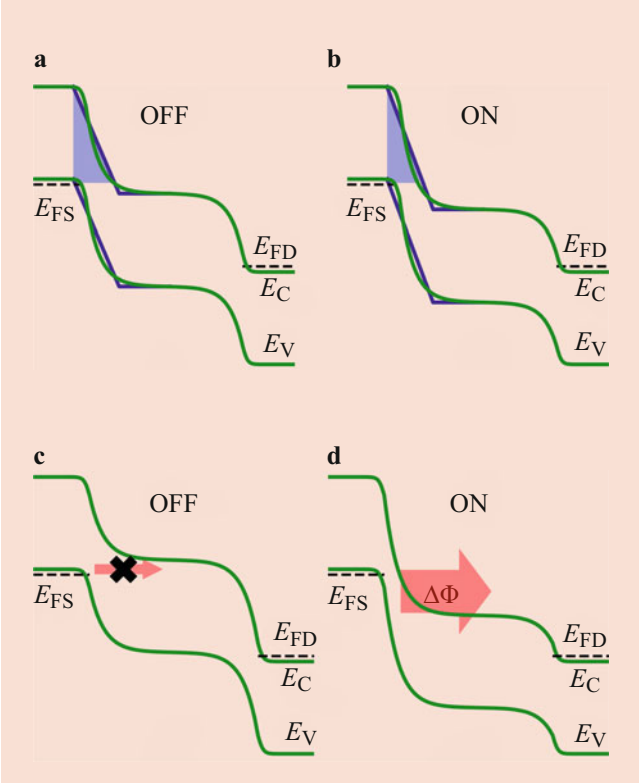

Fig. 24.4 Energy band diagram illustrating the two different methods for achieving steep swings. (**a**–**b**) Tunneling width modulation. The thickness of the tunneling barrier can be modulated by changing the gate voltage and thus the electric field across the tunneling junction. (**c**–**d**) Density-of-state modulation. The alignment of the conduction and valence band is used to cut off the available states for current flow

It can be seen in Eq. (24.10) that two distinct mechanisms contribute to the change of the drain current as a function of V_{GS}; hence, two mechanisms lead to SS <60 mV/dec. These are labeled SS_{TUN} and SS_{DOS} denoting subthreshold swing components based on tunneling width and density-of-state modulation, respectively. The first mechanism, SS_{TUN} , reflects the change of tunneling probability as a function of gate voltage (Fig. 24.4a, b), a process which dominates when T_{BTBT} is small and rapidly changing with V_{GS}:

$$\begin{aligned} SS_{TUN} &= \frac{\ln(10)}{q}\left[\frac{1}{T_{BTBT}}\frac{\partial T_{BTBT}}{\partial \Delta\phi}\right]^{-1} \\ &= \frac{\ln(10)}{q}\frac{3\hbar q(E_G+\Delta\phi)^2}{4\Lambda\sqrt{2m^*}E_G^{3/2}} \\ &= \frac{\ln(10)}{q}\left|\frac{(E_G+\Delta\phi)}{\log(T_{BTBT})}\right| \end{aligned} \tag{24.11}$$

Careful examination of Eq. (24.11) reveals that SS_{TUN} is not limited by the Boltzmann factor. By making Λ larger and for narrow tunneling windows, SS_{TUN} can be made very steep relative to (kT/q)ln(10). Equation (24.11) also indicates a quadratic dependence on $\Delta\phi$; hence, subthermal SS will only occur within a narrow range of gate voltages. It is evident that these requirements are satisfied only for extremely low drain current densities, since SS_{TUN} increases as tunneling probability tends toward unity, i.e., large current densities.

On the other hand, the second term in Eq. (24.10), the DOS switching behavior (Fig. 24.4c, d), rules SS when T_{BTBT} is close to unity, this mechanism controls ON-state current levels, and when this term dominates, SS_{TUN} varies only slightly as a function of V_{GS}. It follows from Eq. (24.10):

$$\begin{aligned} SS_{DOS} &= \frac{\ln(10)}{q}\left[\frac{1}{F(\Delta\phi)}\frac{\partial F(\Delta\phi)}{\partial\Delta\phi}\right]^{-1} \\ &\approx \frac{\ln(10)}{q}\Delta\phi \end{aligned} \tag{24.12}$$

where the integral $F(\Delta\phi)$ is expanded to first order for small $\Delta\phi$. For vanishing $\Delta\phi$, SS can be made arbitrarily small, and the linear dependence on $\Delta\phi$ implies that subthermal SS can be maintained for a wider range of current swing. This particular condition justifies the term density-of-state switching, because the energy filtering action of the conduction and valence band edges cuts off the high and low tail of the Fermi distributions. It follows that the Fermi level in the source needs to be aligned close to the valence band edge (for an nTFET, Fig. 24.5a). If the source degeneracy is too large, this hampers cutoff of the low-energy exponential tails of the Fermi distribution as shown in Fig. 24.5b, leading to a deterioration of the SS. This aspect can be highlighted by computing SS_{DOS} starting from Eq. (24.6) and using the definition of Eq. (24.12):

$$SS_{DOS} = \frac{k_BT}{q}\ln(10)\left[\frac{F_{-1}\left(\frac{E_{FS}-E_{V,S}+\Delta\phi}{k_BT}\right)}{F_0\left(\frac{E_{FS}-E_{V,S}+\Delta\phi}{k_BT}\right)-F_0\left(\frac{E_{FS}-E_{V,S}}{k_BT}\right)}\right]^{-1} \tag{24.13}$$

where we used the property of the Fermi-Dirac integrals, $F_{-1}(\eta) = \partial F_0(\eta)/\partial\eta$. By substituting the analytical solution of the Fermi-Dirac integral of order -1, $F_{-1}(\eta) = [1 + \exp(-\eta)]^{-1}$, back into Eq. (24.13), SS_{DOS} can be written as [29]

$$SS_{DOS} = \frac{k_BT}{q}\ln(10)\left[1+\exp\left(-\frac{E_{FS}-E_{V,S}+\Delta\phi}{k_BT}\right)\right] \ln\left[\frac{1+\exp\left(\frac{E_{FS}-E_{V,S}+\Delta\phi}{k_BT}\right)}{1+\exp\left(\frac{E_{FS}-E_{V,S}}{k_BT}\right)}\right] \tag{24.14}$$

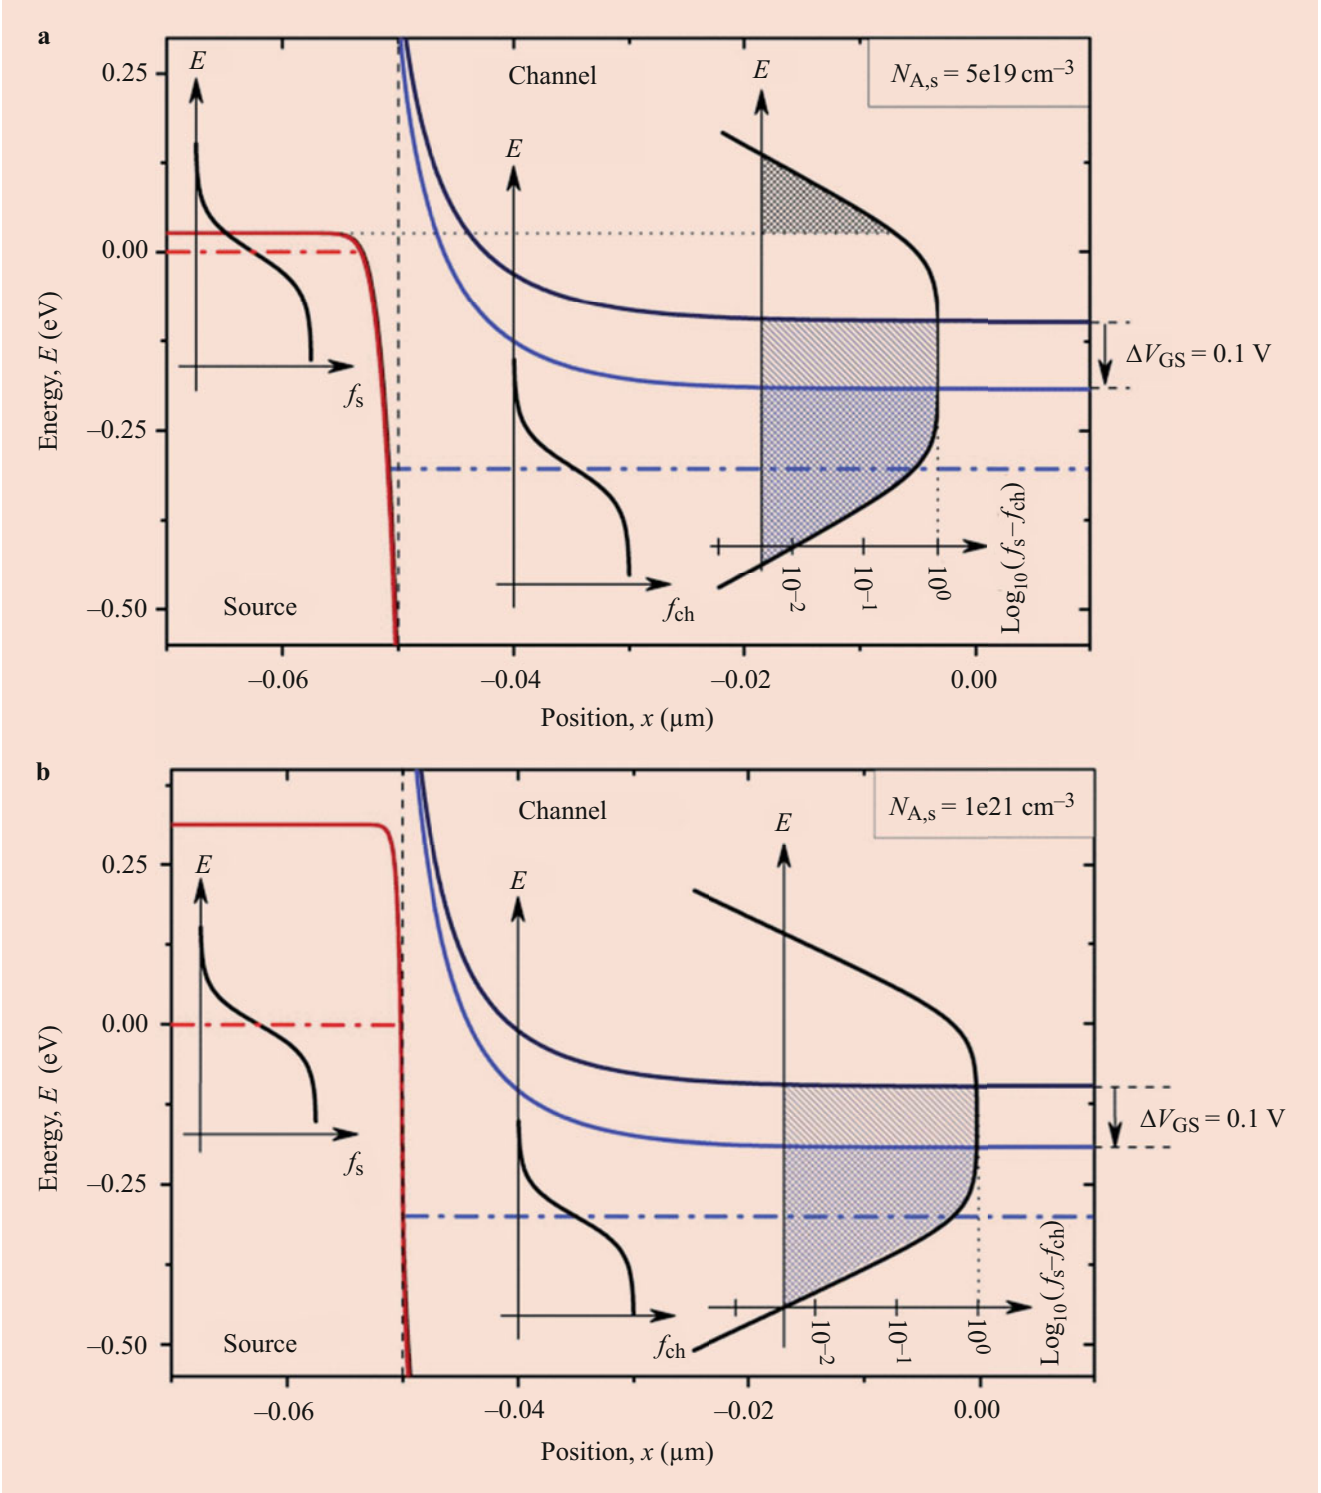

Fig. 24.5 Energy band diagrams of an n-type TFET for (**a**) weak degenerate and (**b**) highly degenerate source doping. When the Fermi level is no longer aligned to the conduction band, the low-energy exponential tails are no longer filtered by the source band gap. (Figure from De Michielis [29])

showing explicitly the dependence on the source hole degeneracy, $\xi_p = E_{V,S} - E_{Fs}$. For nondegenerate to weakly degenerate source doping levels, $\xi_p < 0$, Eq. (24.14) simplifies to $SS_{DOS} \approx \ln(10)\Delta\phi/q$, as previously shown. For a highly degenerate source, $\xi_p > 3k_BT$, SS_{DOS} still vanishes for small $\Delta\phi$. For large tunneling windows such that

$E_{Fs} - E_{C,CH} > 3k_BT$, $SS_{DOS} \approx \ln(10)(E_{FS} - E_{C,CH})/q$. Consider the case of a large source degeneracy, $\xi_p \gg 3k_BT$, where the conduction band lies above the source Fermi level such that $\Delta\phi > 3k_BT$ and $E_{C,CH} - E_{Fs} > 3k_BT$. Under these conditions, SS_{DOS} reduces to the thermionic subthreshold swing of a MOSFET, $\ln(10)k_BT/q$.

The detailed dependences of the subthreshold swing on conduction band energy and gate voltage, respectively, from Eq. (24.14), are shown in Fig. 24.6a, b. In the highly degenerate case, it is possible to distinguish three different regions as outlined above: an initial turn-on where SS is proportional to the tunneling window, a region of almost constant SS at 60 mV/dec, and a region of further increase, proportional to $E_{FS} - E_{C,CH}$. As pointed out by De Michielis [29], Fig. 24.6a, b suggests that a highly degenerate source is preferable since it allows for a wider energy window over which SS is subthermal.

Figure 24.6c shows the separate contributions of tunneling and occupation probabilities for the case of weakly degenerate (top left) and highly degenerate (top right), source doping, and their combined product (bottom). For the highly degenerate case, the larger modulation of the tunneling probability takes place in an energetic window where the combined product is small, and does not translate to an effective drain current change. This also affects the absolute tunneling current levels, because while a narrower tunneling width is expected with increasing source doping, the reduction of the occupation probability of the Fermi-Dirac thermal tails impedes drain current enhancement.

Moreover, other sources for SS degradation lie in parasitic conduction mechanisms, such as TAT, that occur in parallel to the desired BTBT processes. Due to the presence of localized traps originating from defects in the material, vacancies, or dangling bonds, either in the bulk or at the channel interfaces, carriers outside of the tunneling window may contribute to the current flow by means of direct and phonon-assisted tunneling into and out of trap levels.

Another important fact to highlight is that in Eqs. (24.11) and (24.12), the temperature dependences cancel out, meaning that in the OFF state the TFET should display an SS insensitive to temperature. In this description, temperature dependence of the band gap is not considered. When TAT processes are present, the transfer characteristics exhibit a strong temperature and field-dependent dispersion in the subthreshold region [33, 34].

Whether the switching dynamics is governed by tunneling barrier width modulation or DOS switching, SS of a TFET is not limited by k_BT/q ln (10); however, SS as described by Eqs. (24.11) and (24.12) is not constant with respect to the gate voltage. Therefore, while it is possible to obtain a steep slope smaller than 60 mV/dec for a particular V_{GS}, as is often the case for small I_D, this "point slope" is not a good metric to assess TFET performance. To enable supply voltage scaling, an average SS < 60 mV/dec has to be attained over several orders of magnitude change in drain current. Bhuwalka [35] proposed a definition of average swing, $\overline{SS}$:

$$\overline{SS} = \frac{V_T - V_{OFF}}{\log_{10}(I_T/I_{OFF})} \tag{24.15}$$

where V_T is a threshold voltage computed at a particular threshold current, I_T, and V_{OFF} is the gate voltage for which the drain current is minimum, I_{OFF}. Boucart and Ionescu [36] suggested an alternative definition for V_T, corresponding to the gate voltage for which the energy barrier narrowing starts to saturate which is characterized by a transition point between a quasi-exponential dependence and a linear dependence of drain current with respect to V_{GS}. For practical reasons, an $\overline{SS}$ over the full V_{DD} window can be written as [37]

$$\overline{SS} = \frac{V_{DD} - V_{OFF}}{\log_{10}(I_{DD}/I_{OFF})} \tag{24.16}$$

The definitions in Eqs. (24.15) and (24.16) are subject to the supply voltage, $V_{DD,}$ and OFF current, I_{OFF}, of the target application. To compare different TFET configurations independently of the device geometry or the choice of V_{DD} and I_{OFF}, Vandenberghe [38] suggested the I_{60} metric; I_{60} is defined as the current at which the SS is 60 mV/dec, i.e., the current at V_{60} . For voltages less than V_{60}, SS is less than 60 mV/dec, and the TFET has steeper swing than the ideal MOSFET. To outperform MOSFETs for low supply voltage applications, $V_{GS} = V_{60}$ should be approximately 0.1 V with I_{60} in the range 1–10 μA/μm [38]. This provides 0.1 V over which the steep TFET swing can act to provide orders of magnitude OFF-current reduction vs. the MOSFET.

24.5 ON Current

In order to be attractive for low-voltage, low-energy applications, Dehaene and Verhulst argue that TFETs should deliver current of $I_{ON} \approx 100$ μA/μm for sub-0.4 V supply voltages [30]. ON current less than 100 μA/μm will directly impact circuit delay performance since $\tau_D = CV_{DD}/I_{ON}$, where C indicates the gate-source capacitance. Equation (24.5) provides the general guidelines for increasing the tunneling probability and ON current; this can be achieved by increasing the junction electric field and reducing E_G, both of which lead to shorter tunneling paths. By using materials with lighter m^*, there is smaller attenuation of the evanescent mode with imaginary dispersion in the band gap. Small E_G and reduced m^* lead to higher tunneling current, which then points to III–V materials as promising candidates for TFETs, either in homojunction or heterojunction configurations.

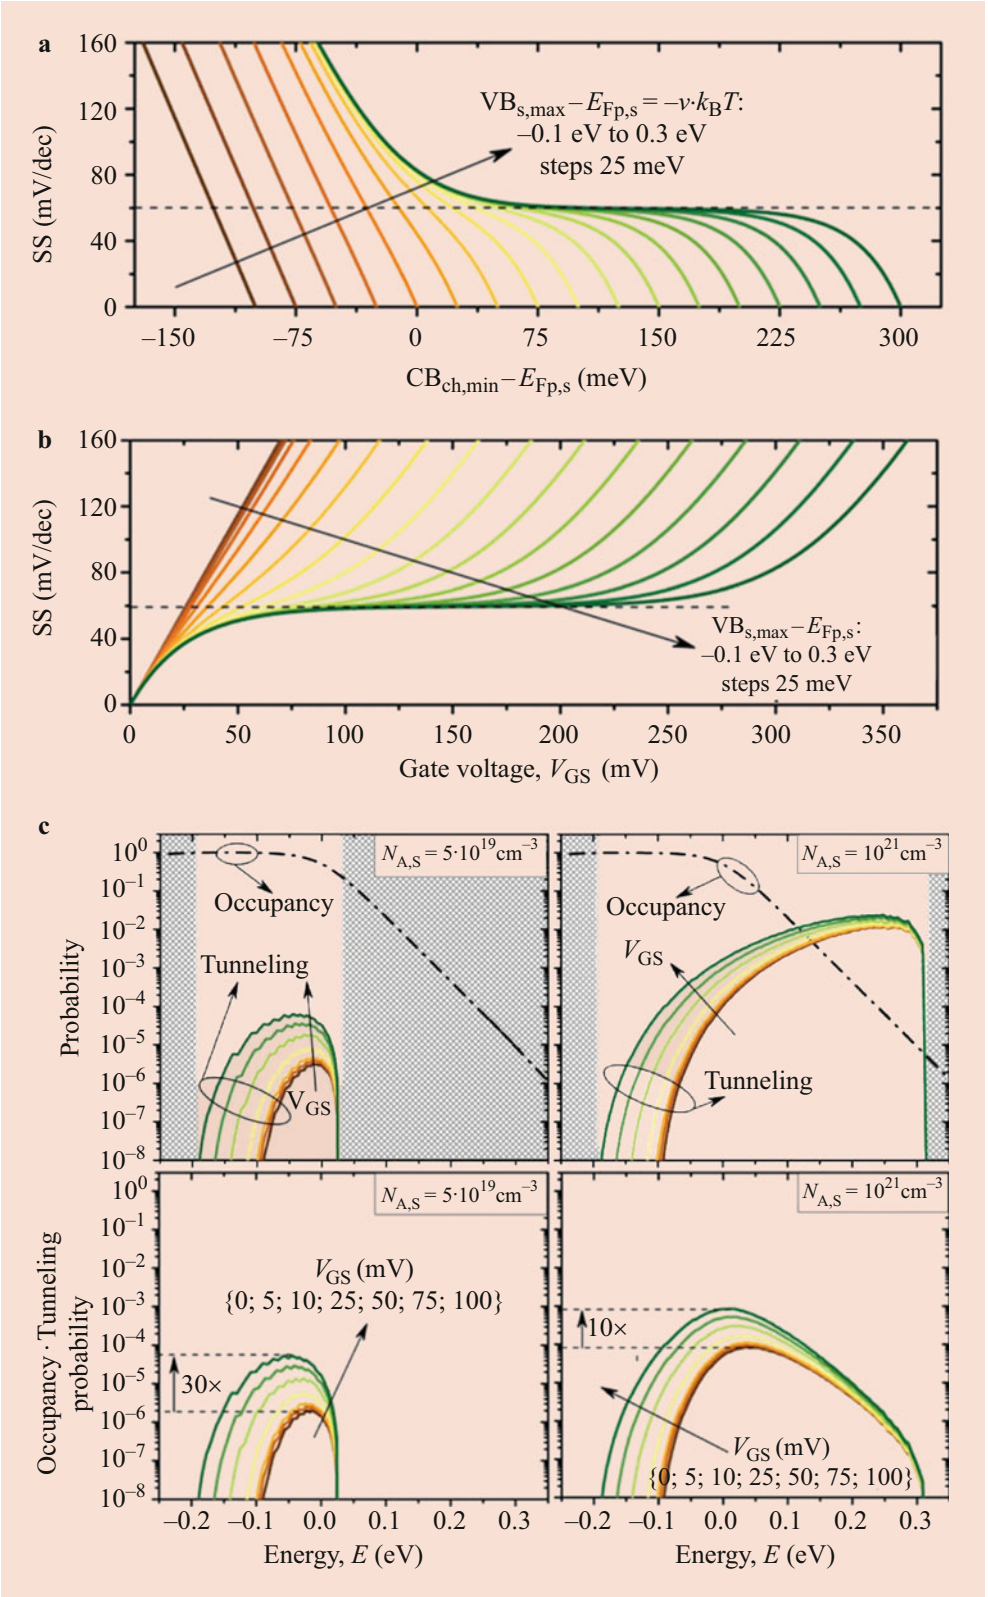

Fig. 24.6 Subthreshold swing (SS) as a function of (**a**) conduction band edge and (**b**) gate voltage evaluated from Eq. (24.14), for different source degeneracies. (**c**) Contribution of the occupancy and tunneling probabilities (top) and their combined product (bottom), for two TFETs having (left) weakly degenerate and (right) highly degenerate source doping. (Figure from De Michielis [29])

It is useful to relate the source depletion width and channel scaling lengths to the device parameters; we can approximate W_D with the Debye length in the source region:

$$W_D = \sqrt{\frac{\varepsilon_S k_B T}{q^2 N_D}} \tag{24.17}$$

where ε_S is the semiconductor permittivity and N_D is the doping in the source. The expression for the channel scaling length depends on the channel geometry [39–41]. In the case of a planar single-gate (SG) structure assuming a parabolic expansion of the vertical potential distribution, the natural length is given by

$$\lambda = \sqrt{\frac{\varepsilon_S}{\varepsilon_{OX}} t_{OX} t_S} \tag{24.18}$$

where ε_{OX} is the oxide permittivity, t_{OX} is its thickness, and t_S is the semiconductor body thickness. It follows from Eqs. (24.5) and (24.17) that I_{ON} improves if the active doping concentration in the source increases. The reason is twofold [42]: Firstly, higher doping in the source reduces W_D and thus enhances the junction electric field. Secondly, E_G is reduced due to band gap narrowing and so then is the tunneling barrier. In optimizing the source doping concentration, an SS- I_{ON} trade-off arises. As discussed in Sect. 24.4, high source doping degrades SS if the source degeneracy becomes too large. The source degeneracy in a pTFET (nTFET) is determined by the DOS in the conduction (valence) band; therefore, from a material standpoint, a large source DOS is desirable for keeping the degeneracy and SS degradation small [38, 43]. For all the common bulk semiconductors, the DOS in the conduction band is lower than in the valence band, and therefore more stringent trade-offs exist for the realization of high-performance pTFETs [44, 45]. Dopant pocket structures have been proposed to ameliorate this imbalance [45].

Equation (24.17) assumes abrupt doping profiles and therefore neglects lateral smearing of the dopant profile into the channel region due to dopant diffusion resulting in an increase of the tunneling path [46]. Materials systems which can achieve abrupt doping are clearly favored for source-channel junction formation. This points to materials system where the junctions can be grown, e.g., by molecular beam epitaxy (MBE) or chemical vapor deposition (CVD), to minimize dopant compensation within the depletion layer.

The gate control of the surface potential in the TFET must be as efficient as possible. As in a MOSFET, increasing the coupling of the gate voltage with the channel potential requires a reduction of the effective oxide thickness (EOT). Oxide thickness scaling and the introduction of high-κ dielectrics have been shown to enhance the tunneling current [47–51]. Enhanced gate control over the channel near the source junction can also be attained by going from a single gate (Fig. 24.7a) to a double gate (or multigate) (Fig. 24.7b) or to a gate-all-around configuration (Fig. 24.7c) [52, 53]. Due to the exponential dependence of the tunneling currents with respect to the dielectric properties, dielectric engineering will achieve a superlinear improvement in the TFET's I_{ON}. Furthermore, when a second gate is added or wrapped around the channel, the equipotential lines crowd toward the source in the device ON state, enhancing the junction electric field locally. This results in shorter tunneling paths and a greater I_{ON} improvement. As far as gate control, these results have also a beneficial impact on the SS favoring an abrupt transition from the device OFF state to the ON state with high tunneling probability.

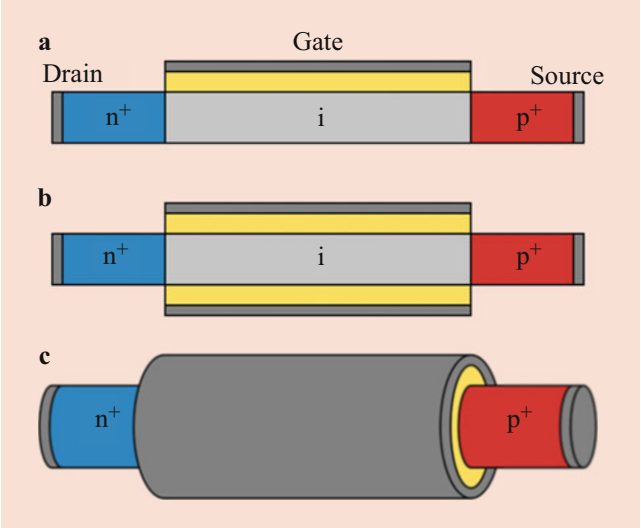

Fig. 24.7 (**a**) Single-gate (SG), (**b**) double-gate (DG), and (**c**) gate-all-around (GAA) TFET geometries

The curvature of the equipotential lines can be further strengthened with the reduction of the channel body thickness. Due to desirable low m^*, when the Bohr radius becomes comparable to the thickness or diameter of the channel t_S [54], size-induced quantum confinement effects result in global increase of the material band gap and hence an increase in tunneling path lengths. These effects are more pronounced for the GAA configuration, with the result of a smaller I_{ON} for the GAA configuration [53].

A double-gate geometry in conjunction with nanometer-scaled body thickness can further enable an additional class of TFETs, the electron-hole bilayer TFET (EHB TFET). Originally proposed by Lattanzio [55–57], a schematic representation of the EHB TFET is shown in Fig. 24.8a. It resembles a DG TFET with the addition of a slight offset between the top and the bottom gate; however, the peculiarity of this device structure consists in adopting an asymmetric configuration between the top and bottom gate to enable perpendicular BTBT in line with the gate electric field. To

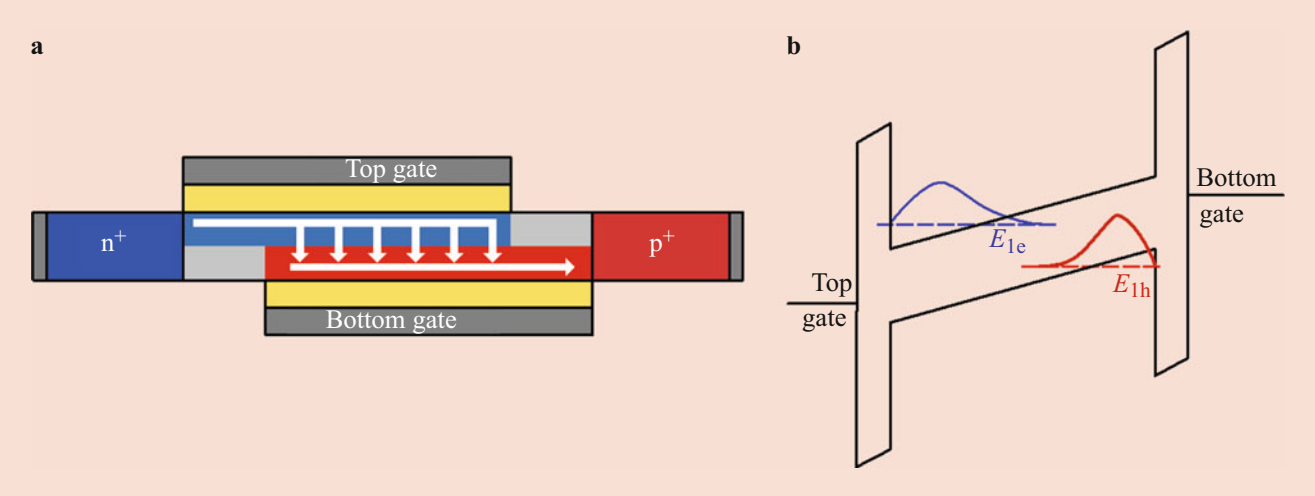

Fig. 24.8 (**a**) Schematic of the EHB TFET. (**b**) Corresponding energy band diagram along a vertical cut in the channel region. E_{1e} and E_{1h} indicate the electron and hole eigenstates

operate as an n-type TFET, the bottom gate bias is fixed in order to electrostatically p^+ dope the bottom part of the channel. On the other hand, the top gate is swept to form an electron-rich top layer. The two gates extend to fully connect the hole-rich bottom layer to the p^+ source and, conversely, the electron-rich top layer to the n^+ drain. Due to the narrow body thickness, in this highly quantized structure, tunneling will occur when a sufficient bias is applied to the top gate such that the electron eigenstate aligns in energy with the hole eigenstate, as exemplified in Fig. 24.8b. In this case, the offset between the two gates is needed to prevent parasitic lateral tunneling leakage paths that degrade SS and enhance ambipolar conduction.

One of the main advantages of this TFET structure is that BTBT takes place within the intrinsic portion of the channel, therefore minimizing the detrimental effects related to dopant-induced band-edge smearing and TAT. Since the total BTBT current depends on the spatial overlap between the electron and the hole wave function, the channel body thickness needs to be aggressively scaled in the 10-nm range. The resulting increase in quantization energies presents a major drawback since it increases the gate voltage needed to align the electron and hole eigenstates (which can only be partially recovered by tuning the work function difference between the top and the bottom gate) while also reducing the gate efficiency. A detailed analytical framework able to capture the trade-offs between ON-state performance and gate efficiency has been developed by Agarwal [58].

The dielectric in the region adjacent to the gate can also play a role in coupling the gate electric field to the tunnel junction internal field. Dielectric sidewall spacers which clad the gate metal concentrate the fringing fields of the gate, thereby setting the position of the maximum electric field and the length of the tunneling path. Chattopadhyay and Mallik [59] studied the impact of spacer dielectric constant on the extent of the source tunneling junction with the help of the contour plots of Fig. 24.9. The simulation results are for a DG TFET with (a) high-κ HfO_2 and (b) low-κ SiO_2 spacers. Fringing fields coming out of the spacer regions are more pronounced for the HfO_2 rather than the SiO_2 case, resulting in a reduction of the band bending at the tunneling junction. This has the detrimental effect of reducing the TFET's ON current. An additional effect concerns the location of the maximum electric field and minimum tunneling distance at the junction. While for the SiO_2 spacer these are located near the surface, for the HfO_2 case, the same are positioned toward the middle of the channel [59]. This leads to a degradation of device performance limited to not only the ON current but also SS. Design criteria for specifying dielectric spacers are highly dependent on the TFET geometry: single-gate, double-gate, gate-all-around, dielectric permittivity, channel permittivity, channel thickness, gate length, and gate-to-junction alignment (underlap vs. overlap) [59, 60].

Dopant pockets can be important performance boosters in TFETs, improving both I_{ON} and SS while simultaneously reducing short-channel effects and possibly providing a pathway for the optimization of pTFETs. Stemming from the proposal of Nagavarapu [61], a pocket TFET presents a localized counterdoped region at the source/channel interface. A pocket nTFET utilizes a p^+-n^+-i-n^+ doping profile (conversely an n^+-p^+-i-p^+ profile is used in a pocket pTFET), where the tunneling junction is formed between the source p^+ region and a narrow, fully depleted n^+ region underneath the gate. The gate also covers the intrinsic channel region. The dopant pocket enhances the built-in electric field, thus increasing the band bending at the junction and reducing the tunneling width, which results in higher drive currents and steeper SS, and causes a shift of the tunneling onset voltage

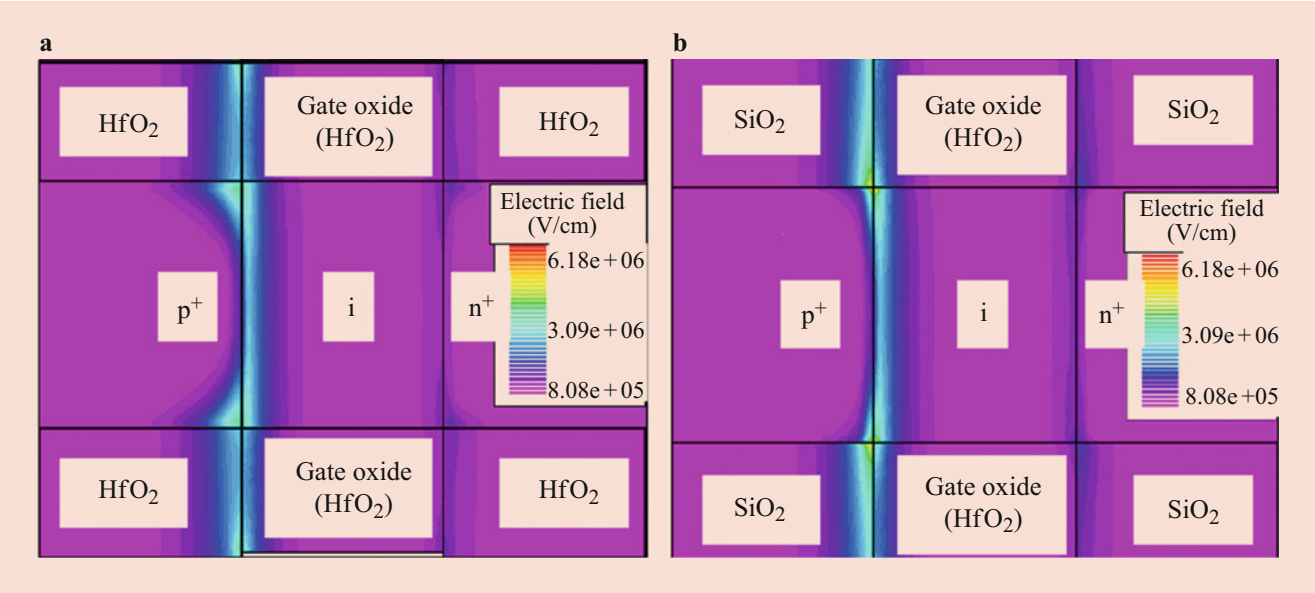

Fig. 24.9 Electric field contour plot for a DG TFET with (**a**) a high-κ HfO_2 and (**b**) low-κ SiO_2 spacers. The TFET is biased at an overdrive voltage $V_{GS} - V_T = 0.5V$ and $V_{DS} = 1V$. (Figure adapted from Chattopadhyay and Mallik [59])

to lower V_{GS} [61, 62]. Moreover, since the enhanced electric field forces the tunnel paths to be more strongly aligned longitudinally with respect to the gate, a lesser impact of field-induced quantum confinement can be anticipated [62].

A properly designed pocket must be fully depleted in order to gain these advantages; this is explained with the help of the energy band diagrams of Fig. 24.10 computed for a Si-on-insulator (SOI) pocket nTFET geometry at the onset of tunneling (simulation described by Nagavarapu [61]). For a thin pocket thickness (Fig. 24.10a), the band diagram at the tunnel junction resembles the case of a canonical p-i-n TFET, where the gate voltage controls the BTBT injection in the channel and the doping pocket serves to shorten the tunneling path. On the other hand, for a thick pocket as shown in Fig. 24.10b, the pocket region is only partially depleted, and the free carrier concentration in the pocket becomes larger than the free carrier density in the channel region at the onset of tunneling. This effect manifests itself in a dip in the band diagrams in proximity to the tunnel junction followed by a hump in the channel region, as it can be seen in Fig. 24.10b. For such a wide pocket, the gate loses control of the band bending at the tunnel junction, and the overall device operation is similar to a p^+-n^+ tunnel diode in series with an n^+-i-n^+ MOSFET; thereby, its switching abruptness is limited to 60 mV/dec at best. Therefore, for a fixed pocket doping, the pocket thickness needs to be minimized while keeping the same fully depleted; this can be attained for a pocket thickness in the range of the depletion width at the tunnel junction [61, 62].

Further optimization can be achieved with the addition of a doping or heterojunction doping pocket at the source side of the tunneling junction as proposed by Verreck [63]. This source design is an especially useful tweak for pTFETs, which typically suffer from a low conduction band DOS resulting in a large source doping degeneracy in conventional p-i-n TFET structures. In such cases, the electron Fermi level is pushed well above the conduction band edge, thereby disabling the energy filtering of the source Fermi tails and degrading SS. The pTFET doping configuration becomes n-n^+-p^+-i-p^+, where the low source doping reduces its degeneracy. This comes at the cost of an increased source resistance; the n^+ pocket retains a high electric field at the tunnel junction to promote BTBT. Also, at the source side, careful tuning of the width of the n^+ pocket is required to minimize the tunneling length and source degeneracy. This aspect is important since carrier thermalization to lower-energy states within the potential well on the source side of the tunnel junction can open a tunneling path to the channel even when the device is in the OFF state. This strategy can also be implemented employing a heterostructure by choosing a source material with a lower electron affinity than the channel (ideally also with a larger conduction band DOS) [63].

24.6 OFF Current

Equations (24.11) and (24.12) predict vanishing SS at the onset of BTBT; however, in the OFF state, other leakage contributions dominate TFET leakage current. Equation (24.5) indicates that low band gap materials are necessary to achieve BTBT transmission probability close to unity. When a low band gap material is employed, I_{ON} increases according to

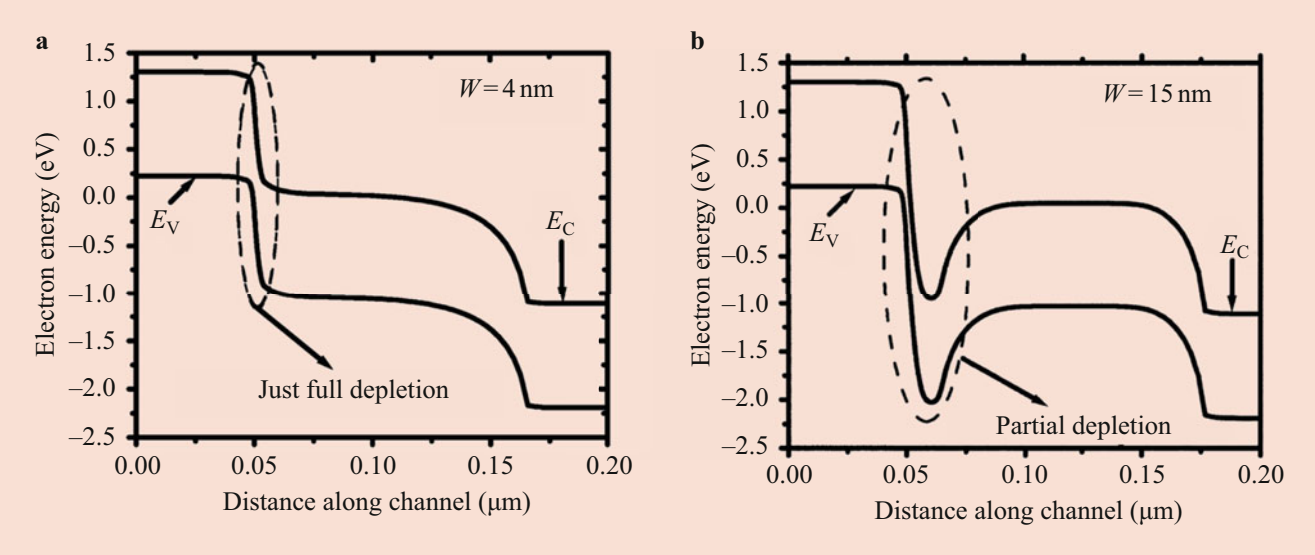

Fig. 24.10 Energy band diagrams of (**a**) a fully depleted vs. (**b**) a partially depleted pocket nTFET. (Figure from Nagavarapu [61])

Eq. (24.5), but also the thermionic current, I_{TH}, becomes significant [28]:

$$I_{TH} = \frac{2q}{h}\int_{E_{C,S}}^{+\infty} f_S(E)\mathrm{d}E \approx \frac{2q}{h}k_B T \exp\left(-\frac{E_G + E_{V,S} - E_{F,S}}{k_B T}\right) \tag{24.19}$$

for the case of an nTFET. At scaled gate lengths, L_G, direct source-drain tunneling, I_{TN}, dominates the OFF-state leakage, especially for low E_G and small m^* materials. Figure 24.11a shows the schematic band diagram for an nTFET in the ON and OFF states.

To obtain a semi-analytical expression for I_{TN}, the simplified band diagram of Fig. 24.11b is considered for the device OFF state, where a rectangular barrier of height equal to E_G and width equal to L_G ($\gg\Lambda$) is assumed for carrier tunneling and qV_{OFF} represents the energy offset between the source Fermi level and the channel conduction band. Under these assumptions, the OFF-state tunneling transmission coefficient, T_{OFF}, and I_{TN} can be computed [10]:

$$T_{OFF}(E) = \exp\left(-\frac{2\sqrt{2m^* L_G}}{\hbar}\sqrt{E\,(1 - E/E_G)}\right) \tag{24.20}$$

$$I_{TN} = \frac{q}{\pi\hbar}\int_0^{qV_{DD}} T_{OFF}\left(E + qV_{OFF}\right) dE \tag{24.21}$$

Figure 24.11c shows the computed I_{TN} versus E_G for the case of a 5-nm-diameter nanowire (NW) and a graphene nanoribbon (GNR) TFETs, for two different L_G, namely, 10 and 15 nm. Figure 24.11c indicates also two different OFF-state targets; for the low-power threshold of 5 nA/μm, the minimum $E_G \approx 0.77$ eV for a gate length of 15 nm. Below a minimum channel length, the OFF current increases sharply, and subthermal SS can no longer be achieved, and the advantages of tunnel FETs disappear [64, 65]. A reduction of I_{TN} can be achieved by increasing L_G: for a planar TFET configuration, this will come at the cost of an increase device footprint, unlike for a vertical TFET where L_G and device footprint are decoupled. The analysis of Zhang [10] shows that the gate length and supply voltage of the technology node where the TFET is inserted ultimately set the minimum band gap needed to achieve a given ON/OFF current ratio.

Trap-assisted tunneling is another important parasitic conduction mechanism often called into play to explain the deviations observed between simulated and measured TFET characteristics. Using Fig. 24.12a, Sajjad [8] depicts the basic physical mechanisms represented in TAT. First, an electron from the valence band (for nTFET) tunnels to a trap state via a heat- or light-mediated transition, followed by thermionic or thermionic-field emission to the conduction band. The latter step is greatly enhanced in the presence of the high built-in electric field of the source-to-channel tunnel junction. Therefore, any effort aimed to increase BTBT generation by boosting the local electric field will similarly increase the TFET leakage current. In general, a strong temperature dependence in the TFET OFF-state and subthreshold characteristics is a signature of TAT.

A good starting point for the modeling of TAT is represented by the SRH generation/recombination theory. The SRH formalism describes a generation process where an electron in the valence band is promoted by heat or light to a trap state in the band gap of the semiconductor, before

(**c**) OFF-state current, I_{TN}, vs. E_G for nanowire (NW) (solid lines) and graphene nanoribbon (GNR) TFETs. (Figure adapted from Zhang [10])

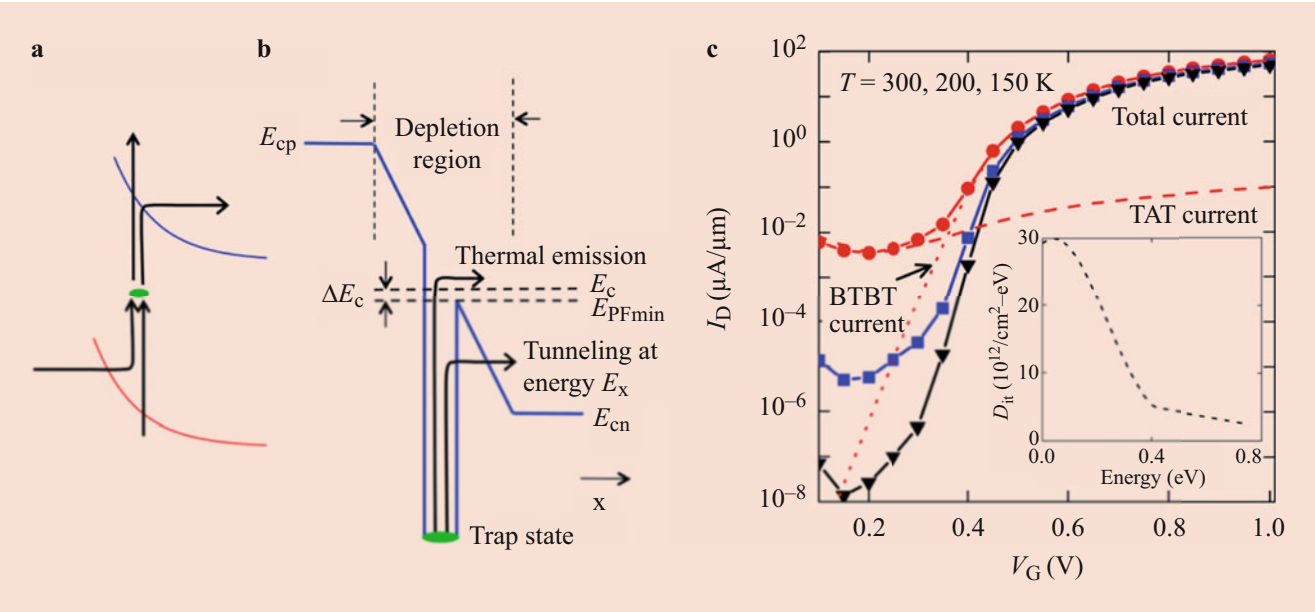

Fig. 24.12 (**a**) Schematic of the TAT process at the source-channel junction of an nTFET, which is mediated by phonon/photon absorption and tunneling. (**b**) Electron emission from the trap occurs via thermal emission, which can also be assisted by tunneling. (**c**) TAT impact on the transfer characteristic of an $In_{0.53}Ga_{0.47}As$ homojunction TFET at different temperatures. Inset: trap distribution vs. energy. (Figure adapted from Sajjad [8])

being emitted to the conduction band by similar interactions. However, in the presence of a strong electric field, defect-to-band tunneling becomes significant and can even dominate. In this case, the SRH formalism has been adapted to take into account the enhancement factor due to the high electric field at the tunneling junction. An analytical framework for the study of electric field-enhanced carrier generation via TAT has been presented by Sajjad [8]. The net generation rate per unit area can be written as [8, 66]

$$G = \int \frac{n_i^2 - np}{\tau_p \left(\frac{n+n_1}{1+\Gamma_p}\right) + \tau_n \left(\frac{p+p_1}{1+\Gamma_n}\right)} D_{it} dE \qquad (24.22)$$

In Eq. (24.22), n_i represents the intrinsic carrier concentration; n and p are the electron and hole carrier densities, respectively; and τ is the minority carrier lifetime. The parameter Γ is the tunneling enhancement factor; it accounts for the electric field dependence and acts to decrease the minority carrier lifetime. The terms $n_1 = n_i \exp\left(\frac{E_t - E_i}{k_B T}\right)$ and $p_1 = n_i \exp\left(\frac{E_i - E_t}{k_B T}\right)$ are derived from the principle of detailed balance, where E_i is the semiconductor intrinsic Fermi level and E_t is the trap state energy. Figure 24.12b depicts how, after an electron is emitted from the valence into the trap state, the same electron can then be emitted to the conduction band for energies exceeding E_{PF}, which is the activation energy for trap emission that has been lowered by the trap's presence in a high electric field, the Poole-Frenkel effect. It is also possible to emit to the conduction band by thermionic field (tunneling field) emission in the energy range between E_{Cn} and E_{PF} indicated in Fig. 24.10b. Therefore, the electron enhancement factor, Γ_n, is given by the sum of two terms, $\Gamma_n = \Gamma_{PF} + \Gamma_{TN}$, where Γ_{PF} represents the enhancement factor due to a thermal jump over a reduced barrier due to the Poole-Frenkel effect and Γ_{TN} the enhancement factor due to tunneling. As shown by Furlan [67], the electron enhancement factor can be written

$$\Gamma_n = \frac{1}{k_B T} \int \exp\left(\frac{E_C - E_X}{k_B T}\right) T(E_X)\, dE_X \qquad (24.23)$$

where E_X is the energy to which the electron is tunneling. The tunneling probability is computed with the aid of the WKB approximation for a triangular barrier:

$$T(E_X) = \exp\left(-\frac{4\sqrt{2m^*(E_{PF} - E_X)^3}}{3q\hbar F}\right).. \qquad (24.24)$$

The enhancement factor, Γ_n, can then be expressed as follows after Sajjad [8]:

$$\Gamma_n = \underbrace{\frac{1}{4}\exp\left(\frac{E_C - E_{PF}}{k_B T}\right)}_{\Gamma_{PF}} + \underbrace{\frac{\Delta E_n}{k_B T}\int_0^1 \exp\left[\frac{\Delta E_n}{k_B T}u - K_n u^{3/2}\right] du}_{\Gamma_{TN}} \qquad (24.25)$$

where $K_n = 4\sqrt{2m^*\Delta E_n^3/3q\hbar F}$, $E_C - E_{PF} = q(qF/\pi\varepsilon)^{1/2}$ is the electric field-induced lowering of the barrier due to Poole-Frenkel effects, and ΔE_n is the tunneling barrier height. ΔE_n is the difference between the top of the (reduced) barrier and the minimum energy where the electron can tunnel to, which can vary from $\Delta E_C = E_{PF} - E_t$, if $E_t > E_{Cn}$, to $\Delta E_C = E_{PF} - E_{Cn}$, if $E_t < E_{Cn}$ [66]. A similar treatment follows for Γ_p. The TAT tunneling current can be calculated, $I_{TAT} = \int G(x)dx$. Therefore, both the spatial and the energetic location of the traps determine the exact bias dependence of I_{TAT} while also affecting the device electrostatics.

Figure 24.12c shows the computed transfer characteristics for an $In_{0.53}Ga_{0.47}As$ TFET at various temperatures to reveal the signatures of TAT and how it can severely degrade both I_{OFF} and SS [8]. At all temperatures, well above the crossing of the band, the total current mainly comes from BTBT, and the ON current is shown to be only weakly dependent on temperature. However, close to the onset of BTBT, the drain current is dominated by TAT for the higher-temperature range, thus hiding the steepest part of the BTBT branch. At lower temperatures, below 200 K for this calculation, the intrinsic SS is observed, and in this case, the minimum SS is limited by the rate of change of BTBT. This is because TAT is highly dependent on temperature; therefore, the lowest achievable OFF-state current is a function of temperature (ambipolar current can further increase I_{OFF}).

Teherani [9] has shown that parasitic leakage currents can also arise due to Auger generation/recombination processes, and this can also limit TFET performance, affecting both I_{OFF} and the minimum achievable SS. Since Auger generation is an intrinsic phenomenon highly dependent on the material band structure, its effects cannot be alleviated with improved material quality or device processing. Auger generation, also known as impact ionization, consists of a three-particle process, where a high kinetic energy hole collides with an electron in the valence band. In the process, the former loses most of its kinetic energy, while the latter is excited to the conduction band, thus generating an electron-hole pair. The reverse process, Auger recombination, involves the annihilation of an electron-hole pair that either excites an electron to higher energies in the conduction band or pushes a hole deeper into the valence band. Since Auger generation is limited by the probability of finding a high-energy carrier, in conventional semiconductors, this becomes significant only at high carrier densities or very large electric fields or at lower carrier densities for narrowband gap materials.

In the context of TFET, the band gap of interest is not the actual semiconductor band gap, but rather the effective band gap separating the electron and hole eigenstates at the two sides of the tunneling junction. This situation is illustrated in the band diagrams of Fig. 24.13 for the case of a bilayer TFET. In the device OFF state, the energy separation between the two eigenstates is large (Fig. 24.13a); however, as the device transitions toward the ON state (Fig. 24.13b), the effective band gap is reduced, resembling the situation of a gate-modulated small band gap semiconductor. Before the bands uncross and the BTBT current dominates, the spatial overlap and small energy difference between the electron and hole eigenstates can promote Auger generation as well as other generation/recombination processes. Once an elec-

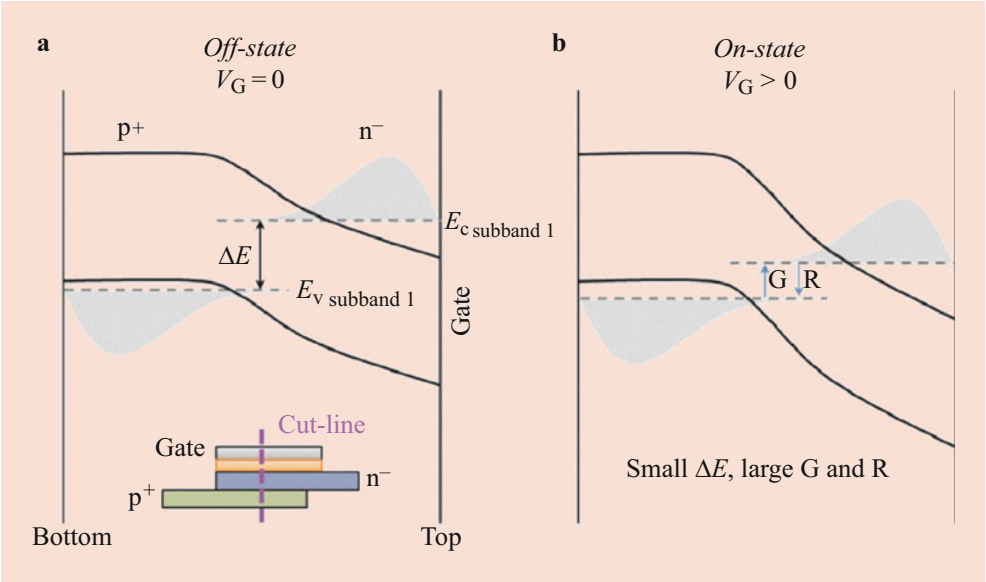

Fig. 24.13 (**a**) Energy band diagram across the tunneling region of a vertical nTFET in the OFF state and (**b**) ON state. Shaded gray areas indicate the hole and electron wave functions. (Figure from Teherani [68])

tron/hole pair is generated across the junction, due to the applied bias, the electron (hole) is swept to the drain (source). The Auger generation current, I_{AU}, across the device increases exponentially as the energy separation between the eigenstates, ΔE_{EG}, is reduced, as discussed by Teherani [9, 68]:

$$I_{AU} \propto \exp\left(-\frac{\left(2\frac{m_e^*}{m_h^*}+1\right)}{\left(\frac{m_e^*}{m_h^*}+1\right)}\frac{\Delta E_{EG}}{k_B T}\right) \tag{24.26}$$

It follows from Eq. (24.26) that if the Auger generation current dominates the device OFF state, this will also affect the minimum achievable SS. In fact, assuming perfect gate efficiency, $d\Delta E_{EG}/dV_{GS} = 1$ at room temperature SS $\approx$ 30 mV/dec when the hole mass is much heavier than the electron mass. On the other hand, if the carrier masses are comparable, SS $\approx$ 40 mV/dec.

24.7 Output Characteristics

The tunneling window in an nTFET is set by the difference between the valence band in the source and the conduction band edge in the drain. Therefore, $\Delta\phi = (E_{Fp} - E_{Fn}) + \xi_p + \xi_n$, where the difference between the hole quasi-Fermi level in the source, E_{Fp}, and the electron quasi-Fermi level in the drain, E_{Fn}, is equal to $-qV_{DS}$ and ξ_p (ξ_n) is the source (drain) degeneracy. It follows that $\Delta\phi$ is controlled by both the drain-source and the gate-source potential modulating the position of the conduction band in the channel region. For a fixed V_{GS}, sweeping V_{DS} starting from 0 V enlarges $\Delta\phi$, and as a consequence, I_D increases. When the valence band in the source is lowered below the conduction band in the channel, increasing V_{DS} does not impact the energy extent of the tunneling window, and I_D saturates. Similar to a MOSFET, a saturation voltage, $V_{DS,\,SAT}$, can be defined, and since the conduction band edge in the channel is dependent on V_{GS}, the larger V_{GS}, the more $V_{DS,\,SAT}$ is shifted to higher values.

A significant difference between MOSFETs and TFETs lies in the shape of the output characteristics for low V_{DS}. Fig. 24.14 compares the common source measurements of three III–V nanowire nTFETs [69] with different source doping, ranging from (a) unintentionally doped $10^{17} - 10^{18}$ cm^{-3}, (b) 10^{19} cm^{-3}, and (c) 4×10^{19} cm^{-3}. A superliner onset and delayed saturation is observed for the lowest doping case, as well as lower ON-state currents. As the source doping is increased, the turn-on at low V_{DS} becomes linear, and $V_{DS,\,SAT}$ is reduced. These features are generally unwanted, as they increase the switching delay. However, if properly engineered in a TFET with $V_T \approx 0$, intrinsic gain larger than unity can be attained in the superlinear region enabling TFET circuit to operate at supply voltages under 400 mV [70].

To understand the origin of the superlinear onset, it is important to understand how V_{DS} affects both the tunneling window and the device electrostatics. In a MOSFET under high drain bias, channel inversion is maintained due to source-injected carriers, i.e., the gate-source capacitance dominates the gate-channel capacitance. However, this is not true for a TFET because the source-channel tunneling barrier limits the

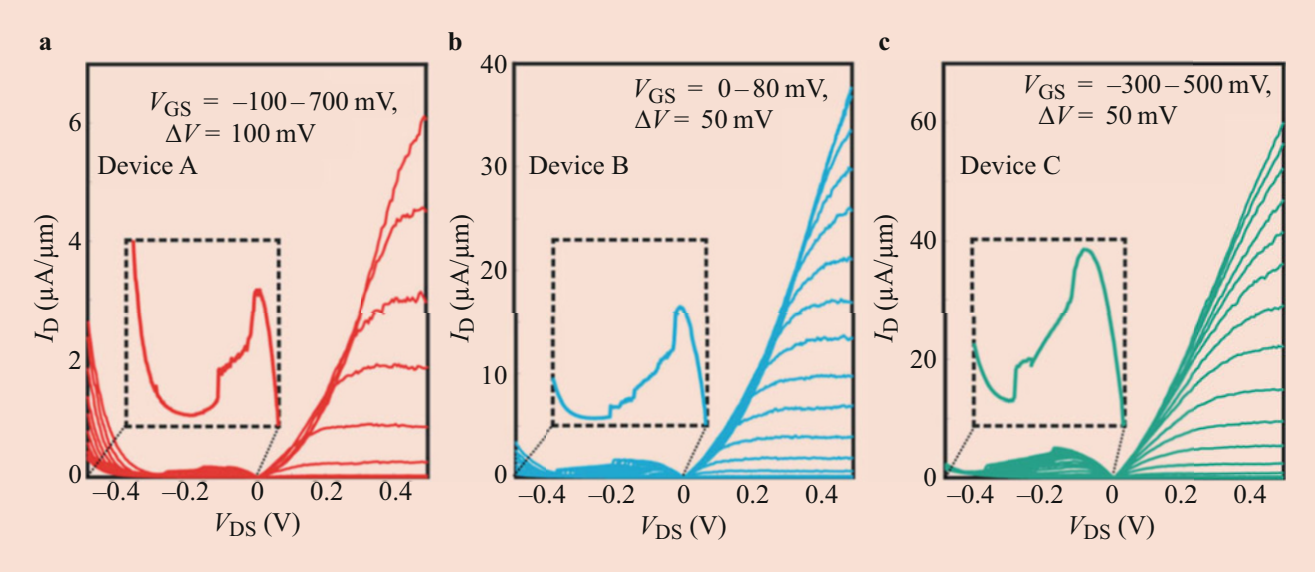

Fig. 24.14 Comparison of the measured output characteristics of InAs/InGaAsSb/GaSb NW nTFETs. From (**a**) low, (**b**) medium, and (**c**) high source doping. Device A shows the lowest ON current performance due to source depletion effects as well as the strongest pronounced superliner onset behavior. Negative differential resistance is observed for all three devices for negative V_{DS} corresponding to the Esaki tunneling branch. (Figure from Memisevic [69])

inflow of carriers; therefore, the gate-channel capacitance is dominated by the gate-drain capacitance. If V_{DS} increases, then the drain channel increases, and the channel charge reduces, resulting in an increment of the surface potential [71]. Moreover, for low V_{DS}, the majority of the applied bias drops across the tunnel junction; therefore, the drain-source bias controls both the quasi-Fermi level in the channel and its conduction band. To gain insight, Eq. (24.5) for the nTFET can be rewritten in the following way:

$$\begin{aligned} I_D &= \frac{2q}{h} T_{BTBT} \int_{E_{C,CH}}^{E_{V,S}} [f_S(E) - f_D(E)]\, dE \\ &\propto \int_{E_{C,CH}}^{E_{V,S}} [f_S(E) - f_{CH}(E)]\, dE \end{aligned} \tag{24.27}$$

where for simplicity $T_{BTBT} = 1$ and the quasi-Fermi level in the channel is aligned to the drain Fermi level. The integral of Eq. (24.27) can be expressed in closed form in terms of the Fermi integrals of order 0 as [72]

$$I_D \propto [F_0(\alpha) - F_0(\beta) - F_0(\gamma) + F_0(\delta)] \tag{24.28}$$

and the arguments of the Fermi integrals read

$$\begin{aligned} \alpha &= (E_{Fp} - E_{C,CH})/k_B T \\ \beta &= (E_{Fp} - E_{V,S})/k_B T \\ \gamma &= (E_{F,CH} - E_{C,CH})/k_B T \\ \delta &= (E_{F,CH} - E_{V,S})/k_B T \end{aligned} \tag{24.29}$$

Further, we assume that $E_{Fp} = 0$ is the energy reference and that the drain bias controls in a one-to-one fashion the $E_{F,CH}$ as well as $E_{C,CH}$ such that $\partial E_{F,CH}/q\partial V_{DS} = \partial E_{C,CH}/q\partial V_{DS} = -1$. It follows that α and δ follow a linear relation with respect to V_{DS}, β is a parameter fixed by the source degeneracy, while in γ the V_{DS} dependencies cancel out. Following the analysis by De Michielis [72], it is assumed that in the TFET ON state for $V_{DS} = 0$ V, $E_{C,CH}$ is below E_{Fp} and $E_{V,S}$ by at least $3k_BT$ and two different cases can be studied.

For a degenerately doped source, $(E_{V,S} - E_{Fp}) > 3k_BT$, in Eq. (24.28), we can approximate the Fermi integrals with $F_0(\alpha) \approx \alpha$ ($\alpha \gg 0$) and $F_0(\delta) \propto e^{\delta}$ ($\delta \ll 0$), and it follows that the drain current is linearly dependent with the drain bias, $I_D \propto -E_{C,CH}$. Therefore, the superlinear contribution in the output characteristics is evaluated by calculating the derivative of the output conductance, g_o, with respect to V_{DS}:

$$\frac{\partial g_o}{\partial V_{DS}} \propto \exp\left(\frac{E_{Fch} - E_{V,S}}{k_B T}\right) \tag{24.30}$$

On the other hand, for the nondegenerate case, i.e., $(E_{V,S} - E_{Fp}) < -3k_BT$, Eq. (24.30) becomes

$$\frac{\partial g_o}{\partial V_{DS}} \propto \frac{\exp(-\alpha)}{[1 + \exp(-\alpha)]^2} + \frac{\exp(\delta)}{[1 + \exp(\delta)]^2} \tag{24.31}$$

The derivative of the output conductance expressed as in Eq. (24.31) shows a nonmonotonic trend, exhibiting a maximum for $V_{DS} = -E_{V,S}/q$. For this case, the output char-

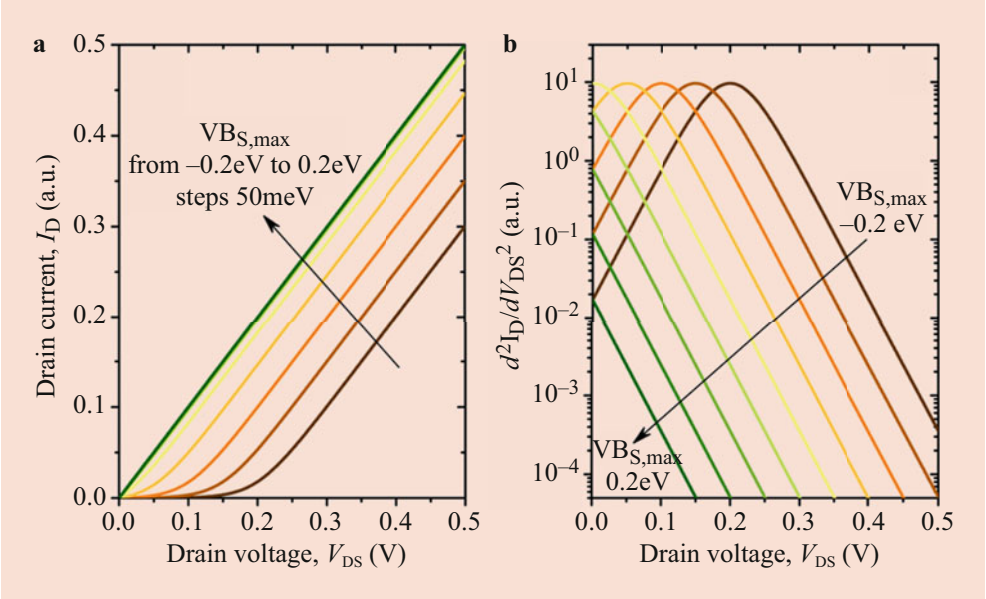

Fig. 24.15 (**a**) Output characteristics evaluated using Eq. (24.28) and (**b**) derivative of the output conductance for different source degeneracies ranging from −0.2 to 0.2 eV. (Figure from De Michielis [72])

acteristics show the detrimental superlinear onset as shown in Fig. 24.15, qualitatively in agreement with experiments with low source doping.

24.8 Ambipolar Conduction

The TFET presents two tunneling junctions, at the source-channel and at the channel-drain interfaces; thus, it exhibits ambipolar conduction , meaning that an nTFET can operate as a pTFET when a negative V_{GS} is applied. In fact, for negative V_{GS}, the crossover between the channel valence band and the drain conduction band opens up a tunneling path where holes are injected into the channel, and I_D increases for decreasing V_{GS}. Ambipolar tunneling current is, in general, undesirable since it leads to higher OFF-state leakage current especially for materials having low E_G and light m^*. Under these circumstances, the ambipolar BTBT current could be the dominant conduction mechanism in the OFF state and thus need to be abated. In the opposite manner as described in Sect. 24.5, reducing ambipolar conduction requires to weaken the gate control at the drain-channel junction and reduce the BTBT generation efficiency. Therefore, this can be achieved by reducing the drain doping, at the expense of increasing the channel resistance, using materials with higher E_G and heavier m^*. For a homojunction TFET, a wider band gap material then can directly reduce I_{ON}. A weaker gate control also results in weaker tunneling electric field which occurs when introducing a gate-drain underlap [73]. In fact, in a TFET, it is required to have a tight gate control at the source side where the desired BTBT processes take place. Adding a gate-drain underlap increases the tunneling path at the drain tunneling junction and consequently reduces BTBT efficiency. Optimization of the ungated region is necessary, such that a higher resistance near the drain region does not impact significantly I_{ON}. An alternative is represented by the introduction of a dual material gate [74] – introducing two different metals with different work functions in the gate of a TFET (biased at the same V_{GS}) permitting an independent optimization of the amount of band bending at the source-channel and drain-channel junctions to obtain a good trade-off in terms of I_{ON}, I_{OFF}, and V_T, as well as SS improvements. Similar improvements can be attained also with a heterogeneous gate dielectric [75], where a small EOT is used to control the source-channel junction and a large EOT is employed at the drain-channel junction. A larger EOT can be realized using either a thicker oxide or a dielectric with low dielectric permittivity.

From a circuit design perspective, proper design methodologies relying on controllable ambipolarity have been proposed, enabling the design of complex logic circuit with fewer components [76]. For these applications, ambipolarity must be optimized in order to obtain symmetric I_{ON} current levels for both the source-channel and drain-channel tunneling branches.

24.9 Heterojunction Tunnel FETs

The analysis conducted in the previous sections results in very stringent trade-offs for the simultaneous optimization of both I_{ON} and I_{OFF}, since the boost of the former leads

to the unwanted increase of the latter. Decoupling the two factors cannot be achieved in a homojunction TFET, i.e., in a device configuration consisting of only one material. On the other hand, a heterojunction TFET provides the extra degree of freedom, i.e., different source and channel semiconductors, to set the desired band alignment. Materials exhibiting different electron affinities and band gaps can align to form straddled, staggered, and broken gap. In such a heterostructure, the effective tunneling band gap at the source-channel junction is given by the difference between the conduction band at the channel side of the junction and the valence band at the source side of the junction.

The goal of a heterojunction TFET (HTFET) is to combine a small effective band gap at the source-channel junction, thus resulting in high I_{ON}, with a large effective band gap at the channel-drain junction to keep I_{OFF} low. In a broken gap alignment, the effective band gap is negative, meaning that there is no forbidden region to tunnel through and thus the transmission probability is unity. This is the preferable condition to boost I_{ON} performance, although careful attention has to be paid to additional phonon-assisted leakage paths in the device OFF state [77]. The associated thermal jumps are affected by the quantization effect resulting from the triangular wells at the junction due to the conduction band rising in the device OFF state and the interaction strength with the available photon. An additional flexibility is given by the choice of the source materials DOS. A large band gap material is usually associated with a large DOS [10] to limit the source degeneracy at large doping concentration. If the band alignment at the junction is highly staggered, the peak of the BTBT generation rate moves closer to the source-channel junction leading to a reduced drain-induced barrier thinning, thus improving device electrostatics [78, 79].

III–V semiconductors are well suited to realize heterojunction TFETs; by tuning the mole fraction of the constituent material in ternary compound materials, III–V materials show a wide variety of band gaps and band alignments. The same variety can be found in the effective masses. Depending on the choice of materials, heterostructures can be either lattice-matched, i.e., both materials have the same lattice constant such as $In_{0.53}Ga_{0.47}As/InP$ (straddled) and $GaAs_{0.5}Sb_{0.5}/ In_{0.53}Ga_{0.47}As$ (staggered), or lattice-mismatched, resulting in nonuniform strain. The stress has an impact in the local band structure and can be explored to improve device performance. The build-up of stress can also result in interfacial defects at the junction if relaxation sets in. Moreover, due to the splitting of light and heavy hole bands under uniaxial or biaxial strain conditions, the valence band DOS is reduced, therefore increasing the source degeneracy that could lead to a degradation of SS.

Starting from Eq. (24.2), the impact of a staggered band alignment in the performance of a 1-D TFET can be analyzed, as shown in Fig. 24.16a from Lind [80]. For weakly degenerate source doping, the source Fermi-Dirac distribution is approximately unity, $f_S(E) \approx 1$, and for a large enough drain bias such that $f_D(E) \approx 0$, Eq. (24.2) simplifies to

$$\begin{aligned} I_D &= \frac{2q}{h}\int_{E_{C,CH}}^{E_{V,S}} T_{BTBT}(E)\mathrm{d}E \\ &\approx \frac{2q}{h}\int_{0}^{qV_{ON}} T_{BTBT}(E)\mathrm{d}E \end{aligned} \tag{24.32}$$

where qV_{ON} is the allowed tunneling window. The transmission probability is computed from Eq. (24.3), and the electric field at the junction, ξ, is given by

$$\xi \approx \frac{E_G - \Delta E_V + qV_{ON}}{\lambda} \tag{24.33}$$

where the tunneling path is approximated to be equal to the geometric scaling length and ΔE_V is the valence band offset. The classical turning point for a staggered band alignment is then modified as follows:

$$\begin{aligned} x_1 &= -\frac{E_G}{2q\xi} + \frac{\Delta E_V - E}{q\xi} \\ x_2 &= \frac{E_G}{2q\xi} \end{aligned} \tag{24.34}$$

with the energy E measured with respect to the valence band edge. The integration of Eq. (24.3) yields [80]

$$T(E) = \exp\left(-\frac{\sqrt{m^*}E_G^{3/2}}{2\sqrt{2}q\xi\hbar}\left[\frac{\pi}{2} - \left(\sqrt{1-y_S^2}y_S + \arcsin(y_S)\right)\right]\right) \tag{24.35}$$

where the dimensionless parameter $y_S(E) = 2(\Delta E_V - E)/E_G - 1$, within the energy range $0 < E < \Delta E_V$, defines the enhanced transmission probability due to the staggered band alignment. For $E > \Delta E_V$, $y_S = -1$, and Eq. (24.4) is recovered. On the other hand, $y_S = 1$ corresponds to a broken gap band alignment, and the transmission probability is unity.

The ON-state current vs. ΔE_V is calculated and plotted in Fig. 24.16b for a 5-nm- and a 10-nm-diameter InAs NW, for a tunneling window $qV_{ON} = 0.3$ eV. Due to quantization effects for narrowband NWs, the relevant subband position will shift, and the NW band gap increases as diameter decreases as shown in Fig. 24.16c [80]. The bulk valence band offset is $\Delta E_V = 0.56$ eV. Zero valence band offset in Fig. 24.16b indicates the case of an InAs homojunction TFET. The lower I_{ON} for the 5 nm NW is due to the larger band gap with respect to the 10-nm case.

As can be seen in Fig. 24.16b, for small ΔE_V, I_{ON} decreases because the electric field at the junction is reduced (cfr. Eq. (24.33)); hence, this simple model reveals the condition that ΔE_V has to be a substantial fraction of E_G in order

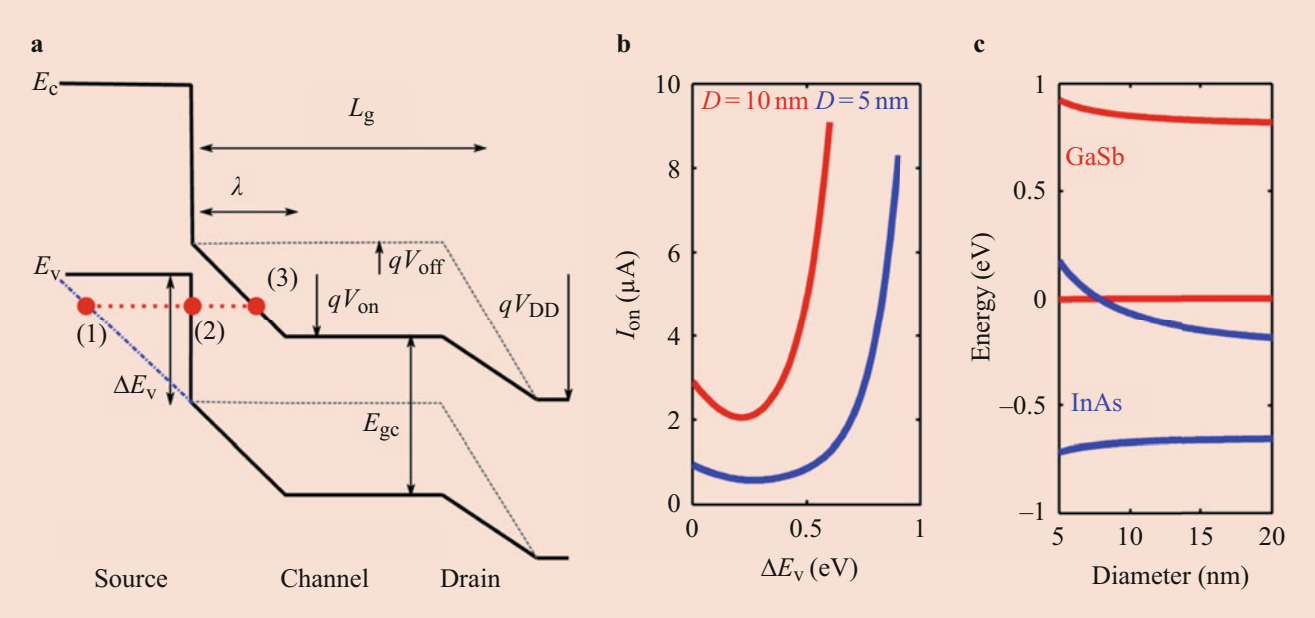

Fig. 24.16 (**a**) Schematic band diagram of a staggered band gap nTFET. Solid (dotted) lines represent the band edges for the device ON (OFF) state. The tunneling path of the heterojunction TFET occurs from point (2) to point (3), while for the homojunction TFET, the same path occurs from point (1) to point (3). (**b**) Calculated ON current vs. valence band offset, ΔE_V, for InAs nanowire having diameter $D = 10$ nm and $D = 5$ nm. (**c**) Conduction and valence subband edges for GaSb and InAs. (Figure from Lind [80])

to observe an improvement in the ON-state performance. For the InAs/GaSb materials system, for a 5-nm-diameter wire, $\Delta E_V \approx 0.18$ eV, while a broken gap band alignment is expected for NW diameters greater than 8 nm (Fig. 24.16c). The use of ternary compounds such as $In_xGa_{1-x}As$ and AlGaSb can be exploited to obtain the desired alignment. However, in a heterostructure TFET, a careful accounting of the effective tunneling gap is required in order to correctly interpret the device measurements. A calibrated simulation of a p-i-i-n $GaAs_{0.5}Sb_{0.5}/In_{0.53}Ga_{0.47}As$ Esaki diode by Bizindavyi [81] highlighted how the temperature-dependent band gap narrowing of the heterojunction tunneling gap can be properly modeled using an adapted Varshni equation, whose fitting parameters are dictated by the individual compounds forming the heterojunction. As a result, despite the fact that the effective band gap is small, its temperature dependence is nevertheless consistent, introducing large temperature variations in the subthreshold regime, which then need to be decoupled from other parasitic mechanisms such as TAT.

The EHB TFET can also benefit from the use of heterojunctions to reduce the tunneling barrier and cut down voltage required to align the electron and hole eigenstates. As a result, the tunneling probability and current can significantly increase while at the same time lowering the device operating voltage. Additionally, due to the impact of quantization, one can engineer the thickness of the two materials constituting the heterojunction to modulate the electron and hole confinement energies. This is exemplified with the aid of the band diagram of Fig. 24.17 in which a narrow, trapezoidal p-

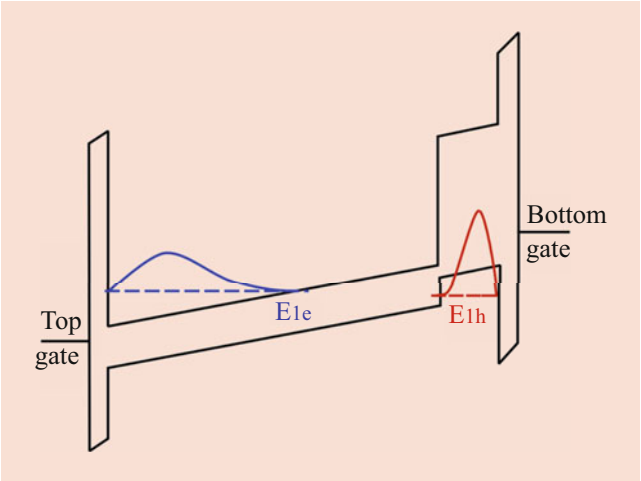

Fig. 24.17 Schematic band diagram of a heterojunction EHB TFET

quantum well defines a hole eigenstate energy that is almost "pinned" as a function of the gate bias, while the n-well width can be optimized to allow for the maximum gate efficiency [58].

24.9.1 Vertical Heterojunction TFET

Realizing high-performance HTFETs requires the growth of electronic-quality crystalline materials to minimize defect and interface trap densities and variability and create

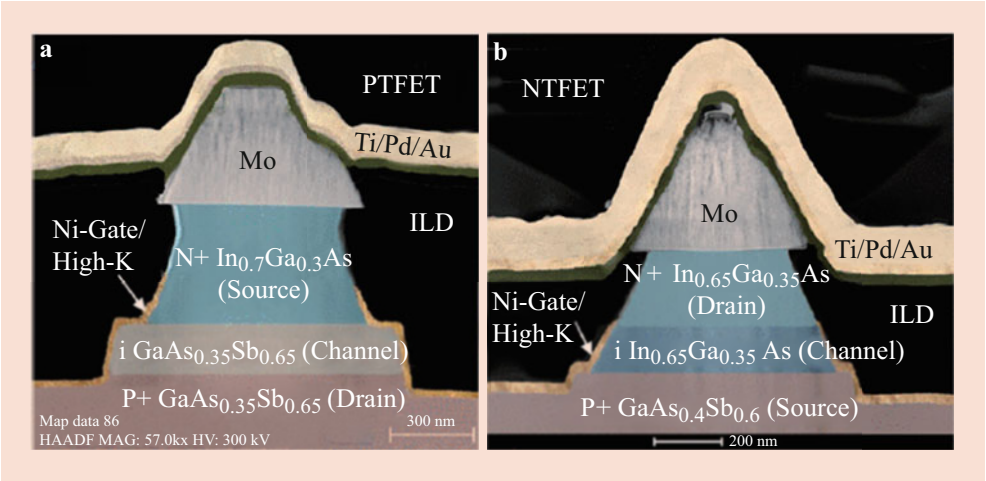

Fig. 24.18 (**a**) Cross-section transmission electron microscope images of the Sb-channel pTFE and (**b**) the As-channel nTFET. (Figure from Pandey [85])

abrupt tunnel junctions. Efficient gate control requires the deposition of low EOT gate stacks with minimal density of interface and border traps. Since the early demonstration by Baba [82], molecular beam epitaxy (MBE) has been widely utilized to achieve atomically controlled interfaces and high degenerate doping densities. In the sidewall approach, a p + in+ heterojunction is grown by MBE and then etched to form a mesa. The gate dielectric is deposited by atomic layer deposition (ALD) on the sidewalls of the etched structure [83, 84], and modulation of the channel conduction is at the sidewall of the mesa with current flowing vertically. In 2015, Pandey [85] demonstrated As-channel nTFETs and Sb-channel pTFETs for complimentary III–V TFET logic applications. The transmission electron microscope (TEM) cross sections of the $GaAs_{0.35}Sb_{0.65}$ pTFET and the $In_{0.65}Ga_{0.35}As$ nTFET are shown in Fig. 24.18a, b, respectively. This work highlighted the separate optimizations required for the deposition of high-κ dielectrics on the different III–V channel materials, which is essential for achieving both high ON currents and steep SS. For the pTFET, the process consisting of an H_2 plasma clean, for the desorption of the native oxide, followed by ALD of 3.5 nm of HfO_2 to achieve the highest accumulation capacitance on the $GaAs_{0.35}Sb_{0.65}$ channel, the gate stack on the nTFET $In_{0.65}Ga_{0.35}As$ channel used a 4-nm ZnO_2 gate dielectric with its own specialized clean.

Vertical heterojunction TFETs have also been demonstrated in alternative geometries, with the tunneling oriented in line with the gate. Li [86] and Zhou [87] demonstrated TFETs in this geometry with Zhou achieving ON current densities up to 180 μA/μm ($V_{DS} = 0.5$ V) using the InAs/GaSb heterojunction broken gap tunnel junction [87]. While the III–V materials are well suited to HTFET demonstrations, adding these to a CMOS process requires the addition of two transistors and a cost-effective approach for growing or transferring III–V to Si substrates.

24.9.2 Lateral Heterojunction TFET

Lateral HTFETs have also been explored as an approach for co-integrating TFETs in a foundry-like complementary process. The key issue is the formation of self-aligned, steep-doping, and high-quality source tunnel junctions. Utilizing group IV materials, Takagi [88] demonstrated an HTFET comprised of a Ge source and strained SOI channel. This design exploits the benefits of the staggered heterojunction between Ge, which presents a higher E_V with respect to Si and the lower E_C of strained Si, which results in a reduction of the tunneling band gap at the source for improved ON currents while maintaining the large band gap of strained Si at the drain to suppress the ambipolar current branch.

For III–V materials, much of the early work was focused on optimizing the doping processes to achieve steep tunnel junctions, mainly in a homojunction TFET configuration. In this context, studies on solid-phase Zn-diffused source junctions in InGaAs achieved p^+ doping profiles as steep as 3.5 nm/decade [88, 89]. Using this approach, an $In_xGa_{1-x}As$ quantum well TFET was proposed [90]. The quantum well is formed by tuning the In content in a $In_{0.53}Ga_{0.47}As$/ $In_xGa_{1-x}As$/ $In_{0.53}Ga_{0.47}As$ heterostructure. The higher In content results in a smaller band gap in the quantum well, thus improving the BTBT current, while the larger band gap of the Ni-InGaAs alloy present in the drain region reduces the ambipolar conduction.

IBM pioneered the development of a template-assisted selective epitaxy (TASE) technique that utilizes metal organic chemical vapor deposition (MOCVD) growth of III–V materials directly on an SOI substrate [91]. In brief, the method consisted of first defining the device region by patterning the SOI substrate. The Si body was then covered with an oxide and subsequently etched back selectively while leaving a Si seed. Selective III–V epitaxy was then carried out

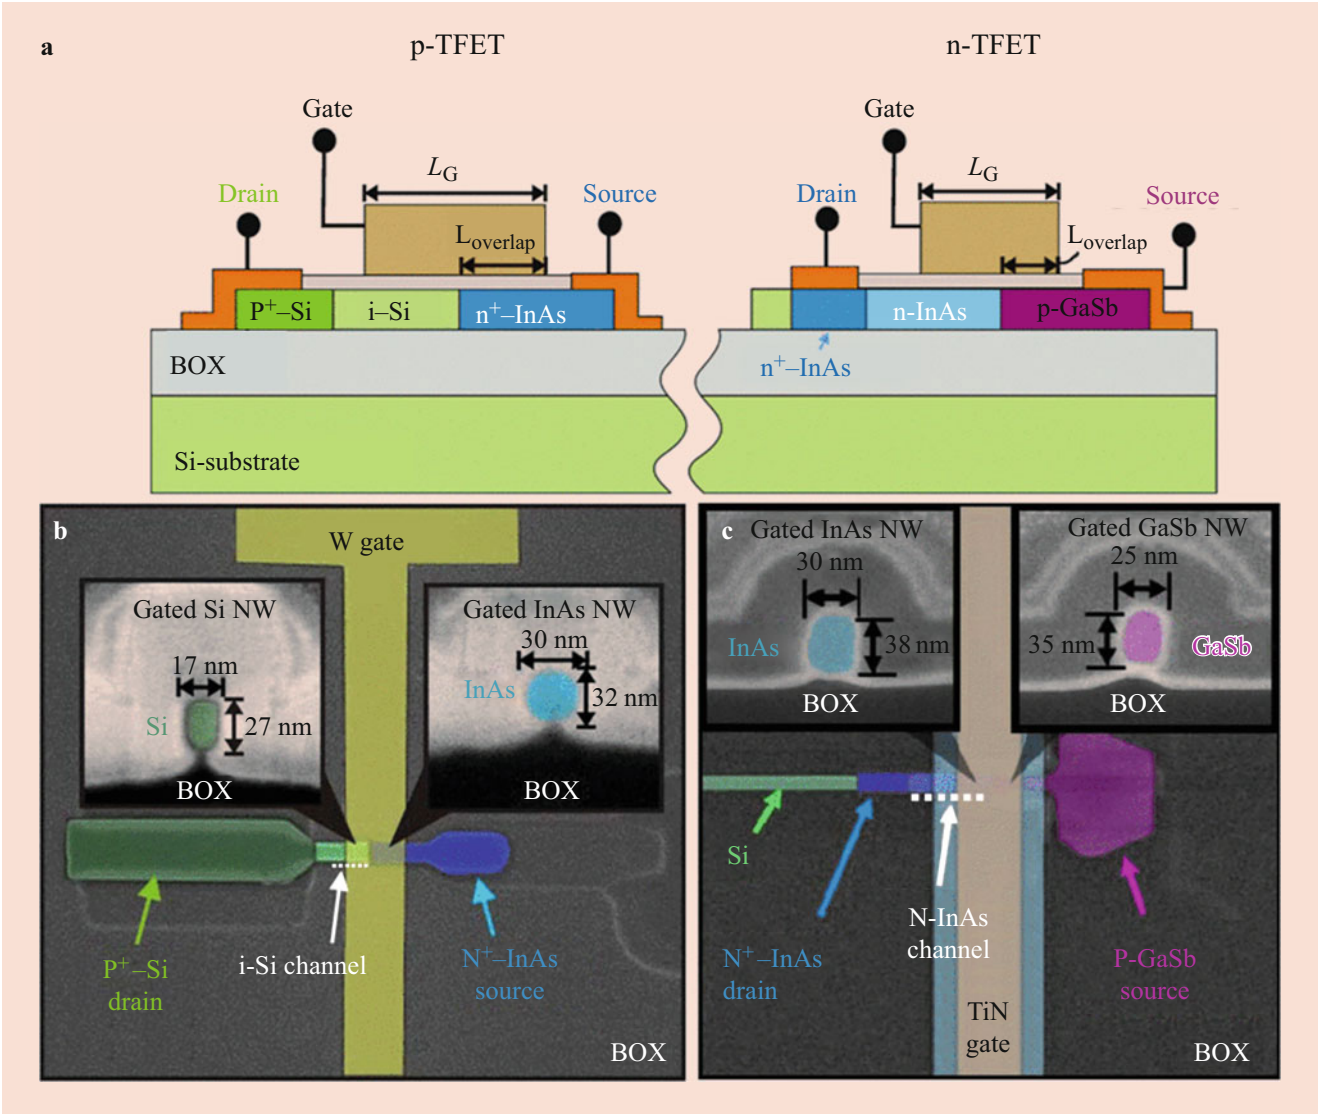

Fig. 24.19 (**a**) Schematic cross section of the pTFET and nTFET fabricated via TASE. Scanning electron microscope image of the top view of the (**b**) pTFET and (**c**) nTFET, respectively. (Figure from Cutaia [92])

inside these hollow structures starting from the Si seed. The oxide template was then removed, and the device fabrication was completed using more conventional processes. Details of TFET gate stack formation and contact deposition were reported by Cutaia [92]. Figure 24.19a shows the TFET schematic cross sections: the p-channel HTFET consisted of an n^+ InAs source, a gated i-Si channel, and a p^+ Si drain, whereas the n-channel HTFET used a p-GaSb/n-InAs/n^+-InAs heterostructure. As can be shown from the device schematics, an overlap region is present at the source side since the gate formation is not self-aligned with respect to the tunneling junction. Scanning electron microscope (SEM) images showing the top view of the fabricated HTFETs are shown in Fig. 24.19b, c for the pTFET and nTFET, respectively, and the insets elucidate the geometry of the III–V nanowire channels. The SS of the InAs/Si pTFET was approximately 70 mV/dec, with current drives of ~4 μA/μm, at $V_{GS} = V_{DS} = -0.5$ V. The InAs/GaSb nTFET exhibited ON currents reaching approximately 40 μA/μm, with much larger SS (>1 V/decade) due to an unoptimized geometry and source doping [92]. Moreover, a significant temperature dependence was observed in the subthreshold regime, suggesting TAT. This work documented an innovative approach to the monolithic integration of planar complementary HTFETs on Si.

24.9.3 Vertical Nanowire HTFET

Vertical nanowire HTFETs have achieved the best device performance for nTFETs in any materials system and in

any geometry to date, e.g., [93]. Nanowire HTFETs with wraparound gates enable superior electrostatic control, which improves both SS and I_{ON}. Suppression of ambipolar conduction through a gate underlap at the drain/channel junction has been implemented without increasing the device footprint, and the approach allows the integration of staggered or broken gap heterojunctions with large lattice mismatch and low defect density due to radial strain relaxation [69].

Best device results have been achieved through a bottom-up approach for the nanowire growth by means of metalorganic vapor phase epitaxy utilizing the vapor-liquid-solid growth starting from Au-seeds [93]. The III–V heterostructure consists of an n^{++}-InAs/n^{-}-InAs/p^{++}-GaAsSb/p^{++}-GaSb as reported by Memisevic [93] and is shown in Fig. 24.20a, where the band alignment at the heterojunction is tunable by substituting the ternary GaAsSb compound with quaternary $In_xGa_{1-x}As_ySb_{1-y}$ [69, 94, 95]. One peculiar feature of these heterostructures is represented by the larger diameter of the GaSb segment with respect to the InAs, which makes the gate metal deposition nearly self-aligned to the tunneling junction, thanks to its "shadowing" effect (Fig. 24.20b). Best $I_{60} = 0.3$ μA/μm at $V_{DD} = 0.3$ V was measured (Fig. 24.20c), and benchmarked device performance showed the performance benefits of this approach versus best TFET reports (see Sect. 24.11).

The same growth method has also been exploited to realize GaSb/InAs core-shell nanowires, where the tunneling occurs in the radial direction [96]. A core-shell nanowire TFET can increase the in-line tunneling current at fixed device footprint. Vasen [97] demonstrated a vertical GAA core-shell nanowire nTFET based on an InAs/GaSb heterostructure. The device consisted of an n^{+}InAs stem, a GaAs barrier layer, and a p^{+}GaSb source. The nanowire was clad by an undoped InAs shell that covered the whole structure. Room-temperature subthermal SS, down to 40 mV/dec, was obtained at low V_{DS} (10 mV), as well as ON currents up to 40 μA/wire at $V_{DS} = 0.3$ V, for a 50-nm-diameter device. Double sweep transfer characteristics showed low hysteresis, with distinct current steps attributed to TAT and thermal emission at the InAs/high-κ interface.

Another notable approach for the selective area growth of III–V nanowires directly on Si has been reported by Tomioka and Fukui [98]. Despite the large lattice mismatch and mismatch in thermal conductivity, HTFETs were demonstrated starting from a p^{+} (111) Si substrates covered with 20 nm of SiO_2, with 30- to 90-nm-diameter etched windows through the oxide layers to enable growth on Si. The vertical nanowire growth proceeds from the openings to yield an undoped InAs channel and a Si-doped n^{+}InAs drain to form the vertical nanowire heterostructure. Steep SS TFETs were fabricated through optimization of the nanowire geometry [99].

III–V HTFETs have also been notably realized via a top-down approach starting with an MBE III–V heterostructure [100]. Zhao demonstrated subthermal swings of 53 mV/dec and $I_{60} = 4.3$ nA/μm at $V_{DS} = 0.3$ V [101]. The tunneling heterojunction consists of a p + $In_{0.53}Ga_{0.47}As$ source, a 2-nm i-InAs/8-nm i-$In_{0.7}Ga_{0.3}As$ "notch," and an i-$In_{0.53}Ga_{0.47}As$ channel. The notch serves to reduce the tunnel barrier height and yield steeper SS and higher ON current. Careful control of the etching and passivation steps yielded highly vertical and smooth sidewalls. The process avoided the need for metal catalysts like Au.

24.9.4 Layered Two-Dimensional HTFET

The energetic abruptness of the band minima and maxima in the TFET can be degraded by atomic-scale variations in body thickness, dopant fluctuations, trap states resulting from dangling bonds, and thermal fluctuations. Two-dimensional (2D) van der Waals materials present some intriguing attributes with respect to HTFETs. They are intrinsically atomically smooth surfaces and, ignoring defects' they have no surface dangling bonds [102, 103]. 2D materials can be prepared atomically thin representing the ultimate in body thickness scaling, thus enabling best case single- or double-gate electrostatic control. Given the ability to obtain abrupt pn junctions, BTBT is possible [102, 103]. A cornucopia of layered materials is available, and there is no fundamental impediment to stacking dissimilar 2D materials to make heterojunction tunneling devices. Impediments to utilizing these materials are the difficulty in nucleating oxides on surfaces free from dangling bonds; the weak forces holding the layers together mean that they easily translated when temperature is cycled or in the presence of strain. Substitutional doping is not well established, so electrostatic doping schemes using charged surface layers are being developed and utilized.

Graphene represents the most well-studied material within this group of 2D materials; however, since it is a zero-band gap semiconductor, symmetry-breaking methods need to be adopted in order to open up a band gap. BTBT device architectures based on laterally confined graphene nanoribbons have been proposed [104] and demonstrated [105, 106]. Tuning of the transport band gap in bilayer graphene with a vertical electric field [107] has also been proposed as a control mechanism [108].

Semiconducting transition metal dichalcogenides (TMDs) have served as a first test bed for steep transistors. Layered TMDs have the form of MX_2, where M is a transition metal (e.g., Mo, W, Hf) and X is a chalcogen atom (e.g., S, Se, Te), and each layer is composed of a three-atom thick sheet where the metal atom is sandwiched in between the two chalcogenides. TMDs exhibit a wide range of band gaps that are suitable for the realization of atomically thin-body TFETs [109–114] or present favorable band alignments for HTFETs by stacking layers of different TMDs, bonded by

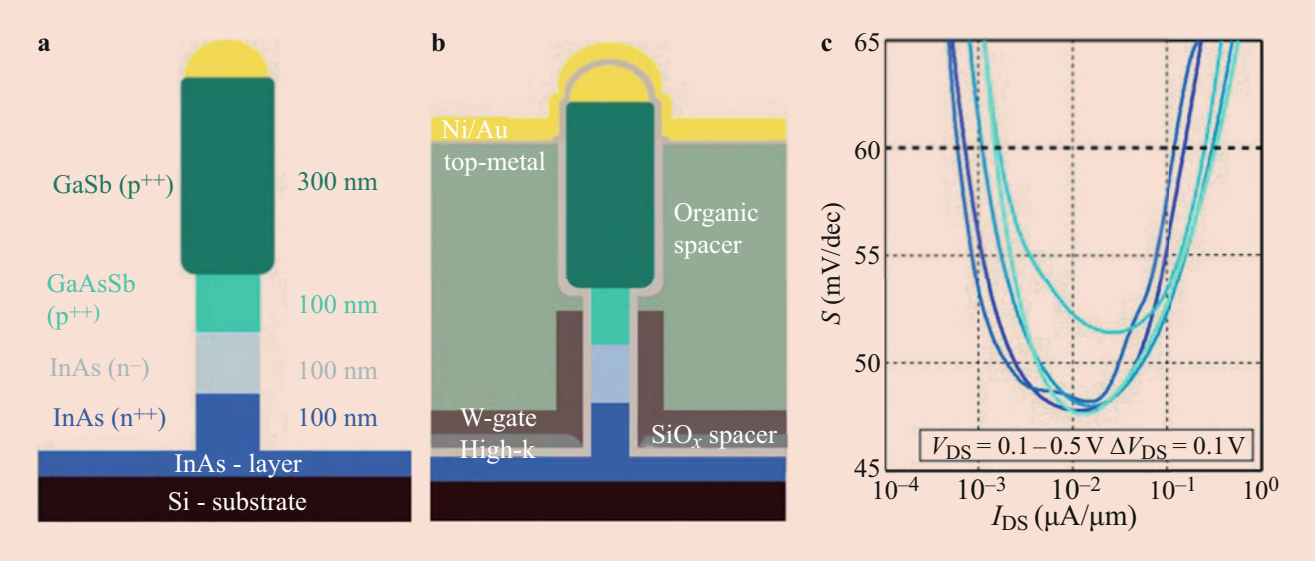

Fig. 24.20 (**a**) Schematic of the completed nanowire heterostructure growth and (**b**) cross section of the InAs/GaAsSb/GaSb HTFET. (**c**) Measured subthreshold swing vs. drain current for various V_{DS}. (Figure from Memisevic [93])

van der Waals interactions [115–118]. In striking contrast with respect to conventional heterostructures formed between epilayers of group IV or III–V semiconductors, TMD heterostructures can be formed among materials with highly mismatched crystal structures. Tunneling then occurs in the overlap region of the two layers, perpendicular to the gate. Such 2D HTFETs still maintain the advantages of conventional bulk heterostructures. Moreover, the same stacking method can also be employed to form 3D/2D heterostructures, as shown by Sarkar using bilayer MoS_2 on top of a bulk Ge source [119].

24.9.5 III-Nitride HTFETs

III-nitride materials , such as GaN and InN, present another intriguing materials system for TFET design with band gaps of 3.4 eV and 0.7 eV, respectively. The wideband gap GaN can be utilized to provide low OFF-state currents, while the narrower gap InN can be utilized in the tunnel junction. In Fig. 24.21a, Li shows the simulated energy band diagram of a GaN pn homojunction with symmetric abrupt doping of $N_D = N_A = 3 \times 10^{19}\text{cm}^{-3}$ highlighting how, despite the degenerate doping levels, the tunneling width $\Lambda \approx 15$ nm due to the large energy built-in voltage [120].

The III-nitride materials system features spontaneous and piezoelectric polarization which results in uncompensated sheet charge densities at heterointerfaces between materials exhibiting different internal polarizations. If properly engineered as in the case of GaN/InN/GaN heterostructures, the polarization-induced sheet charges can generate large built-in fields on the order of 20 MV/cm, five times higher than can be obtained using heavy doping in groups IV and III–V tunnel junctions [121]. Figure 24.21b, c illustrates this concept and shows the tunability of the effective energy gap for tunneling by adjusting the InN layer thickness. As a function of the InN interlayer thickness, the band alignment changes from staggered (Fig. 24.21b) to broken gap (Fig. 24.21b). As in conventional heterostructures, the tunneling energy gap can be tuned further by adjusting the In molar fraction of an $In_xGa_{1-x}N$ tunneling layer.

The III-nitride in-line TFET proposed by Li [120] is shown in Fig. 24.21d, together with the corresponding band diagrams of the device in the OFF (Fig. 24.21e) and ON states (Fig. 24.21f) to elucidate the operational principles. In the OFF state, the conduction band in the channel is pulled to energies that cut off available states for tunneling, and the large GaN band gap suppresses the OFF-state leakage current. In the ON state, a tunneling energy window is opened, and electrons can tunnel from the p-type source to the n-type channel, through the narrow gap of InN. In maximizing the III-nitride HTFET I_{ON}, an optimum InN thickness exists since increasing the thickness has the effect of increasing the tunneling distance which reduces the tunnel current but also shifting the band alignment from staggered to broken gap which increases tunnel current.

Several technological hurdles need to be overcome for the optimization of the GaN-based TFETs. Incomplete ionization of deep-level acceptors represents a major obstacle since a significant depletion width in the source leads to a pronounce superlinear onset in the output characteristics and a reduction of the BTBT current by widening the tunneling path. Polarization engineering of graded $In_xGa_{1-x}N$ layers in between the InN interlayer and the p-type GaN source may

In a III-nitride heterojunction, the band alignment can be tuned by changing the InN interlayer thickness. (**d**) Proposed in-line III-nitride HTFET design and corresponding band diagrams of the device (**e**) OFF and (**f**) ON state. (Figure from Li [120])

mitigate this effect [122]. The epitaxial growth of GaN/InN/GaN heterostructures is challenging due to the significant difference in optimal growth temperature for the two alloys and their lattice mismatch [120]. Li [120] simulated the I_{ON} dependence on the In molar concentration for the case of a GaN/$In_xGa_{1-x}N$/graded-InGaN/GaN TFET. A reduced In molar concentration results in larger tunneling energy gap, smaller polarization charges due to a reduced piezoelectric contribution, and thus smaller electric fields leading to a significant degradation of the BTBT current.

Performance projection for GAA III-nitride nanowire TFETs by Li [123] quantified the benefits of the relatively large DOS masses ($m_E = 0.2, m_H = 1.5$), namely, a mitigation of quantization effects. The latter though starts playing a significant role in increasing the tunneling gap for sub-10 nm NW diameters. It is found that a diameter around 20–30 nm should offer a good compromise between electrostatic integrity and ON-state performance.

Through quantum simulation accounting for the different multiphysics processes at play, Ameen [124] pointed out that in order to optimize the subthreshold characteristics of III-nitride TFETs, carrier thermalization through confined state at the heterointerface must be prevented. Due to the high electric fields at the heterojunction, confined states are induced at the source, which inject hot carriers over the channel barrier in the OFF state, degrading the steepness of the TFET's turn-on. A well-designed structure is aimed to reduce the number of these confined states, i.e., shallow quantum wells, while also keeping the induced polarization intact. It is proposed that this can be achieved by adopting a 3.5-nm-thick $In_{0.9}Al_{0.1}N$ as the interlayer and an $In_{0.75}Ga_{0.25}N$ channel in spite of the InN and GaN materials [124].

Experimental demonstrations of steep III-nitride TFETs are only just emerging. Chaney [125] reported a surrounding gate GaN/$In_{0.25}Ga_{0.75}N$/GaN NW TFET, formed from a top-down approach. The extracted SS was reported to be approx-

imately 110 mV/dec and with ON current of 30 μA/μm at $V_{DS} = 1$ V. Current saturation was observed in the device output characteristics in conjunction with the suppression of the TFET ambipolar branch.

24.10 Band Tails

In TFETs, the spectral shape of the semiconductor band edge, the band-tail states, controls the steepness of the current-voltage characteristics as the tunneling window closes [126]. The spectral shape of the band edge is observed experimentally to be exponential, often called the Urbach tail [127]. Smearing of the band edge can be anticipated from lattice thermal vibrations, heavy-doping effects, dopant inhomogeneity, structural disorder, and size quantization in transistors resulting from semiconductor inversion layers and ultrathin-body transistors.

A method to investigate band-edge steepness directly from transport was proposed by Agarwal and Yablonovitch [128]. An analytical treatment was developed that correlates the joint density of states (DOS) in an Esaki/backward diode to the absolute conductance of the DC characteristics, by measuring the conductance slope in the NDR region of the I–V characteristic of a tunnel diode, and predictions about the corresponding steepness of the TFET SS were derived based on this extraction.

At the core of the method stems the observation that, for a tunnel diode, a semilog plot of absolute conductance $|G|$ vs. applied voltage, V, decreases smoothly going from negative voltages, backward diode branch, to positive voltage within the forward Esaki tunneling branch. This aspect offers the possibility of a physical interpretation in terms of the semiconductor intrinsic properties.

Considering the joint DOS, $D_J(E)$ taking into account the valence band states on the p-doped side of the junction and the conduction band states on the n-doped side, the tunneling current can be expressed as [128]

$$I \propto \int (f_C(E) - f_V(E))\, T_{BTBT} D_J(E) \mathrm{d}E \tag{24.36}$$

where $f_C(E) - f_V(E)$ represents the difference of the Fermi-Dirac occupation probabilities at two sides of the junction. A qualitative plot of $D_J(E)$ at various bias points is shown in Fig. 24.22d–f. For simplicity, the conduction and valence band tails roll off exponentially with the same slope. As the conduction and valence band edges uncross in forward bias, the band tails still overlap, and $D_J(E)$ decreases exponentially. In Fig. 24.22d–f, the area under the difference in occupation function is proportional to the applied voltage. By multiplying and dividing (24.36) by the integral $\int f_C(E) - f_V(E) \mathrm{d}E$

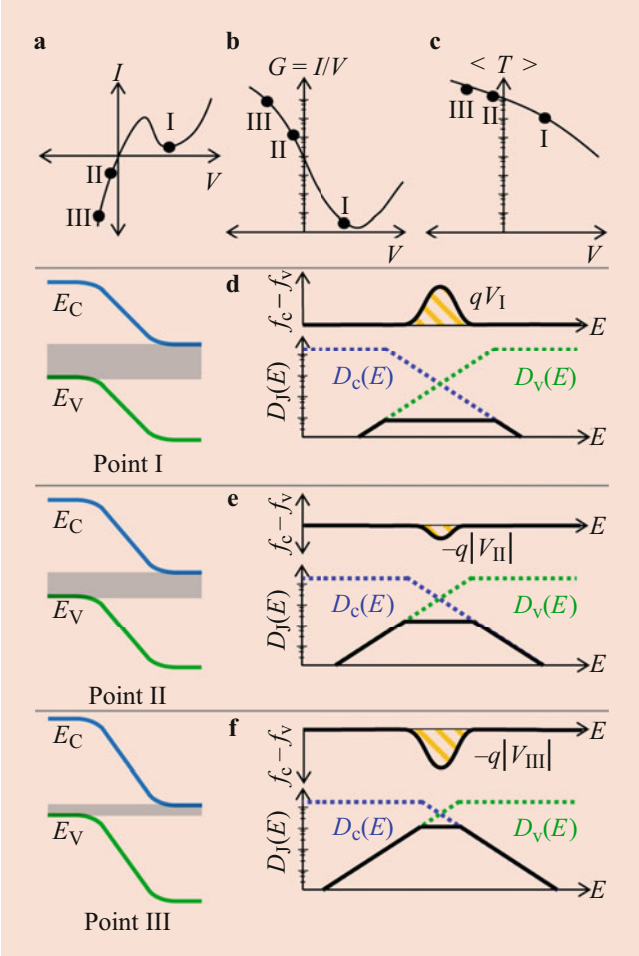

Fig. 24.22 (**a**) I–V curve, (**b**) absolute conductance G-V curve of an Esaki diode. (**c**) Tunneling probability vs. applied bias. Qualitative band diagrams, Fermi-Dirac occupation probability difference, and $D_J(E)$ corresponding to bias points (**d**) I, (**e**) II, and (**f**) III, respectively. (Figure from Agarwal and Yablonovitch [128])

$$\begin{aligned} I &\propto \int (f_C(E) - f_V(E))\, \mathrm{d}E \frac{\int (f_C(E) - f_V(E))\, T_{BTBT} D_J(E) \mathrm{d}E}{\int (f_C(E) - f_V(E))\, \mathrm{d}E} \\ &\propto qV \frac{\int (f_C(E) - f_V(E))\, T_{BTBT} D_J(E) \mathrm{d}E}{\int (f_C(E) - f_V(E))\, \mathrm{d}E} \\ &= qV \langle T_{BTBT} D_J(E) \rangle \end{aligned} \tag{24.37}$$

where the terms $\langle T_{BTBT}\, D_J(E) \rangle$ indicate a weighted average of the product $T_{BTBT} D_J(E)$ over the Fermi window. As pointed out in [128], the ratio $f_C(E) - f_V(E)/V$ barely changes for $|V| < 4k_BT$; hence, within this range, the change in conductance is governed by the change of $T_{BTBT}\ D_J(E)$ (even for the case $|V| > 4k_BT$, the exponential change of T_{BTBT} $D_J(E)$ dominates despite a correction due to the broadening of $f_C(E) - f_V(E)/V$). Therefore, the steepness of the absolute conductance is related to the steepness of D_J by

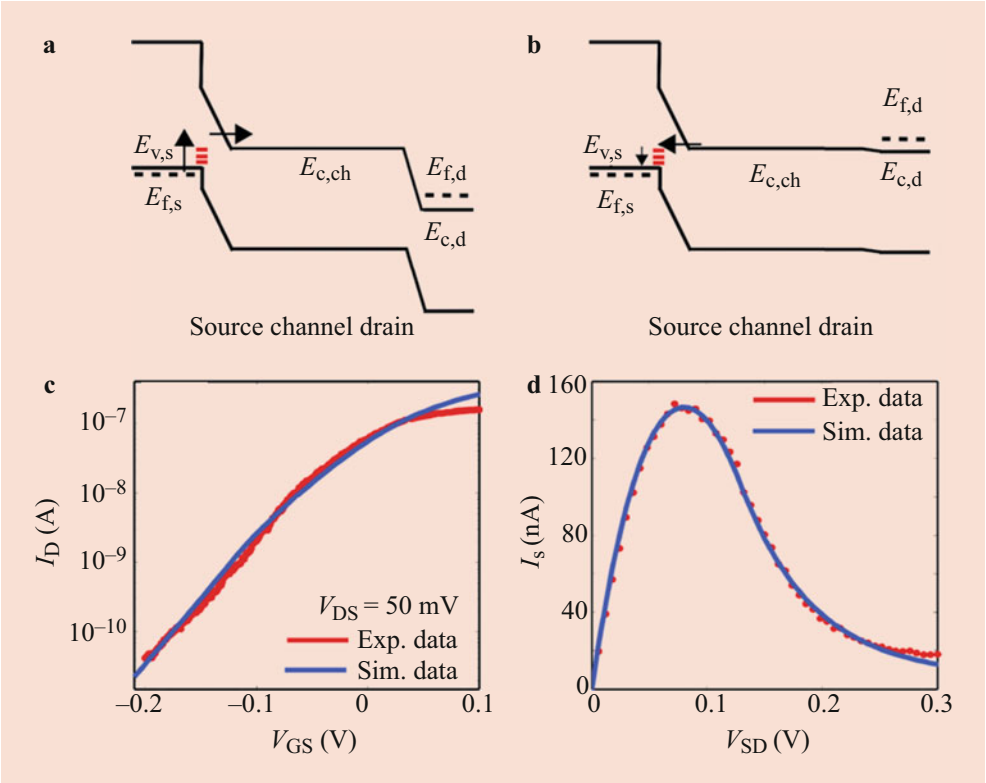

Fig. 24.23 (**a**) Schematic band diagram for a heterostructure TFET in the OFF state (**b**) and in the NDR region, respectively. (**c**) Experimental vs. model transfer characteristics. (**d**) Fitting of the output characteristic in the NDR region. (Figure from Memisevic [94])

$$SS_{T-D_J} = \left[\frac{d\log\langle T_{BTBT} D_J(E)\rangle}{dV}\right]^{-1} \approx \left[\frac{d\log(I/V)}{V}\right]^{-1} \tag{24.38}$$

expressed in mV/dec. While the voltage dependence of the conductance slope can be dominated by either the change in tunneling probability or the joint DOS, Eq. (24.11) showed that for large tunneling probabilities, i.e., large current densities, the change in tunneling probability is small, and thus the conductance slope is determined by the exponential change of D_J. While this analysis has been carried out for a two-terminal Esaki diode, a TFET is a three-terminal device, and this implies that by measuring the SS from the transfer characteristics, the impact of the DOS switching needs to be distinguished from the degradation induced by nonideal electrostatics. On the other hand, if the critical tunneling junction lies at the source-channel interface, a two-terminal-like measurement can be accomplished by fixing the $V_G - V_D$ voltage while measuring the I_D– V_S characteristics. In this manner, the drain voltage will not have an impact on the channel potential which is controlled by the gate bias.

Starting from a similar argument, Memisevic [94] proposed a simple model to link the band-edge decay parameter, i.e., Urbach energy, to the NDR current swing, instead of the conductance swing [128], and compare it with the subthreshold swing obtained from measurements of a III–V HTFET. Figure 24.23a shows the schematic band diagram of an HTFET in biased in the OFF state of the device. The conduction band in the channel, $E_{C,\,Ch}$, lies at higher energy than the source valence band edge, $E_{V,\,S}$. Despite the fact that the uncrossing of the bands suppresses BTBT, exponentially decreasing band gap states close to the valence band opens up an alternative tunneling path. This impact as well the NDR region of the HTFET for a V_{SD} bias past the peak voltage is shown in Fig. 24.23b. Assuming an energy decay parameter, E_0, the described OFF-state decay current can be expressed as

$$I_{OFF} = \frac{2q}{h}\int_{E_{C,CH}}^{+\infty} T_N(E)\,[f_S(E) - f_D(E)]\exp\left(-\frac{E}{E_0}\right)dE \tag{24.39}$$

where T_N is the tunneling transmission. In the device OFF state, it is assumed that only charges in the Fermi tails contribute to transport, such that the source Fermi-Dirac distribution can be simplified with its Boltzmann approximation, and V_{DS} is large enough such that the drain occupation function can be omitted. Additionally, T_N is considered to be energy-independent, such that Eq. (24.39) simplifies to [94]

$$I_{OFF} \propto \int_{E_{C,CH}}^{+\infty} \exp\left(-\frac{E}{E_0}\right) \exp\left(\frac{E_{FS}-E}{k_B T}\right) \propto \exp\left(-\frac{E_0 + k_B T}{E_0 k_B T} E_{C,CH}\right) \tag{24.40}$$

The conduction band in the channel is modulated by the gate voltage; however, the presence of interface traps degrades the gate efficiency:

$$-\frac{\partial E_{C,CH}}{\partial V_{GS}} = \frac{q}{1 + \frac{C_{IT}}{C_{OX}}} \tag{24.41}$$

and C_{IT} represents the interface trap capacitance. Using the definition of Eq. (24.1), SS is equal to

$$SS = \left[\frac{d \log_{10} I_D}{dV_{GS}}\right]^{-1} = \underbrace{\ln(10)\frac{k_B T}{q}}_{60\,mV/dec} \left(1 + \frac{C_{IT}}{C_{OX}}\right) \frac{E_0}{E_0 + k_B T} \tag{24.42}$$

Equation (24.42) states that subthermal slopes can be obtained in the case of exponentially decaying band tails limiting the OFF-state current. The presence of band tails results also in temperature-dependent swings. Additionally, Eq. (24.42) highlights how subthermal swing can be achieved even in the case of E_0 >60 meV. However, interface traps deteriorate the SS.

To determine E_0 independently, an expression for the current in the NDR must be evaluated. In order to observe NDR, $E_{FD} \gg E_{C,CH}$, such that degenerate conditions in the channel are met (Fig. 24.23b), assuming that the source valence band is shifted by an amount qV_S, the drain current exhibits an exponential dependence on the source voltage [94]:

$$I_S = \frac{2q}{h} T_N \int_{E_{C,CH}}^{E_{FS}} \exp\left(-\frac{E}{E_0}\right) dE \propto \exp\left(-\frac{qV_S}{E_0}\right) \tag{24.43}$$

The method laid out by Memisevic [94] consists of fitting the exponential decay in NDR region to obtain E_0, while the subthreshold swing reveals a dependence on E_0, T, and C_{IT}. The results of the analytical model are compared with experiments in Fig. 24.23c, d for the transfer and output characteristics, respectively, showing good agreement with experiments. The BTBT current is computed using Eqs. (24.32) and (24.35).

The models developed in [94] and [128] do not allow for a quantitative extraction of the band-tail DOS. Recent work by Bizindavyi [129] describes a calibration method based on semiclassical transport models of the tunneling contribution stemming from high doping induced band tails to match experimental p-i-n Esaki diode I–V data. Starting from a spherically symmetric dispersion relation, an expression of the conduction and valence band-tail DOS was derived, as shown in Fig. 24.24a. The band-tail DOS is constituted of spatially extended states within the first 100 meV from the unperturbed band edges, with an abrupt transition to strong localized states deeper into the band gap. For a p-i-n Esaki diode, only band-tail states stemming from the majority

bands, valence or conduction bands on the p+ or n+ doped sides of the junction, contribute significantly to the tunneling current (Fig. 24.24b). A good match for two different Esaki diodes with the intrinsic region thickness of 9 and 18 nm, respectively, is obtained.

From a careful analysis of the current spectral contribution, it is found that it is not the Urbach energy factor, E_0, alone, but rather the integrated DOS within the first ~20% energy window close to the transition point between extended and localized band-tail states that is actually being calibrated (Fig. 24.24c). In fact, the DOS in the shaded area of Fig. 24.24c is actually comparable for multiple E_0 values. This aspect was missing in the analytical arguments presented above.

Bizindavyi [129] and coauthors also looked at these implications in a TFET configuration. Similar to the Esaki diode case, it is the integrated band-tail DOS, not E_0, that affects the SS. The effect of the band tail is to reduce the onset voltage of the device, which decrease the I_{ON}–I_{OFF} ratio for a fixed V_{DD}, and therefore a deterioration of $\overline{SS}$. However, it was found that I_{60} remains unchanged for the cases investigated.

Despite the recent efforts to include the band-tail DOS in the modeling of tunneling-based devices, the impacts of dopant concentration, dopant atom species, and corresponding activation energy on the former are still poorly understood.

24.11 Composite TFET/MOSFET

It is possible to combine the low-voltage, low-power aspects of the TFET with the high-current, high-speed capability of the MOSFET in a composite structure in which the TFET controls the subthreshold transition and a parallel MOSFET is used to boost the current at higher gate voltage. The basic concept is illustrated in Fig. 24.25, for planar p and n device configurations in both (a) layout and (b) circuit schematic representations. The n-TFET in Fig. 24.25a, lower drawing, has a p-i-n doping structure from the source to the drain, while the nMOSFET has an n-i-n arrangement. A shared ohmic contact is made to both the n and p source regions, and the gate contact over the i region is also shared. The action of the two side-by-side transistors is to provide a drain current which is the sum of the two devices in parallel. The transfer characteristic of the two transistors is shown in Fig. 24.25c, where for V_{GS} lower than approximately 0.4 V the drain current is dominated by the TFET, while for voltages exceeding 0.4 V, the MOSFET current dominates.

In a series of papers by Huang and Zhan [130–133], the transistor concept was developed and refined. One of the several versions of the composite transistor structure is shown in Fig. 24.25d from Zhan [132]. Nickel silicide was used to contact the source. A T-shaped gate was utilized to provide a three-sided source tunnel injection region to the channel to increase the tunnel injection. Since the tunnel current is largely independent of gate length, the width-dependent gate length is not detrimental to the transport. The source was made symmetric with the p + source regions for the TFET set on either side of the T-gate. At high drain and gate bias, the Schottky nMOSFET turns on providing additional current over and above the TFET drive current. Huang explains in [133] that lateral self-depletion of the source p + n junction lowers the off-state current of the Schottky MOSFET relative to a traditional Schottky MOSFET, thereby lowering the OFF current of the composite transistor.

Oliva [134, 135] demonstrated the parallel transistor combination in 2D materials by connecting a steep-slope $WSe_2/SnSe_2$ TFET with a WSe_2 MOSFET to show the benefits of the combination, which they call a dual-transport steep-slope FET. The 2D materials were exfoliated, and the transistors were wired together in parallel for the demonstration. As new processes for the TFET emerge, there appears to be value in considering ways to add the parallel MOSFET.

24.12 Complex Gate Dielectrics

The subject of complex gate dielectrics for TFETs to lower the subthreshold swing is one that is receiving considerable attention especially with regard to the use of ferroelectrics [136, 137]. Any complex dielectric innovation that boosts current and lowers SS in a MOSFET (in, for example, ferroelectrics, piezoelectrics, or phase changing material) is generally also applicable to the TFET. Complex dielectrics generally have some RC delay associated with the dynamic response of the material going through its reconfiguration. Owing to the importance of these effects, the dynamics of ferroelectric and other complex dielectrics are under investigation by many groups. Any RC delay in the gate dielectric can lead to a slew rate and direction-dependent SS which influences the measured SS [138–140]. Even a conventional MOSFET can exhibit a dynamic SS, which can be shown by simply introducing a series resistance in the gate to lower the SS [141].

24.13 Technology Benchmarks

The transfer characteristics of selected best reported nTFETs are shown in Fig. 24.26. Only TFETs sustaining subthermal swings for at least a decade of change in drain current and V_{DS} <0.5 V are considered in the comparison. Additionally, I_D–V_{GS} characteristics were shifted horizontally so that the gate voltage corresponding to the device OFF state is at the origin. Experimentally this can be achieved by engineering the work function of the gate metal. Since fewer pTFET realizations have been demonstrated [142–148], with generally worse performance with respect to the nTFET counterpart, these are not included in the benchmarking plots in Fig. 24.26. A comparison between best reported pTFETs has been given by Lu and Seabaugh [20].

Across materials systems, TFETs with subthermal SS have generally not yielded ON currents exceeding 10 μA/μm with the exception being in the III–V materials system. In agreement with theoretical predictions, Group IV materials such as Si and Ge exhibit smaller I_{ON} stemming from their indirect band gap resulting in lower tunneling probability. Performance boosters such as strain engineering or Si-Ge co-integration have been employed to improve ON-state performance [88, 146, 149]. Group III–V materials such as high-In content InGaAs alloys have higher tunneling currents due to their narrower and direct band gaps [90, 150, 151]. The use of III–V heterostructures further boosts the ON currents by shortening the tunneling distance [69, 83, 93, 152, 153]. While III–V materials can provide high-performance nTFETs, the performance of p-channel devices is limited by the low conduction band DOS. The carbon nanotube TFETs [18, 154] demonstrated to date do not show the high current drives predicted by the theory [77, 155], but these transistors do not have optimized geometries. SS steeper than 60 mV/dec was reported for a 3D Ge/2D MoS_2 heterojunction by Sarkar [119]; however, TFETs relying on 2D crystal channel still require improvements in terms of material growth quality, surface preparation and deposition of high-κ oxides, control of abrupt doping profiles, and band gap engineering.

The corresponding SS vs. I_D is shown in Fig. 24.26. Remarkably, Si-based TFETs show the steepest slopes: Knoll [146] reported ~30 mV/dec for a strained Si NW, employing a Ge source TFET embodiment, Kim [149] obtained SS_{MIN} ~33 mV/dec, and Takagi [88] achieved a point slope of ~29 mV/dec. However, the steepest SS are obtained for extremely low I_D, and I_{60} of 10 pA/μm [149], or well below it. Similar considerations apply for the Ge-MoS_2 TFET demonstrated by Sarkar [119] that is reported to maintain an averaged SS ~31 mV/dec over four decades of I_D change, yet I_{60} <50 pA/μm. The multigate CNT TFET by Lu [154] reached SS_{MIN} ~34 mV/dec and a crossover between subthermal and superthermal slope at around 1 nA/μm. The reported values of I_{60} and low I_{ON} do not meet the desired device performance metrics [30, 38] to make TFETs suitable for low-power application.

On the other hand, III–V-based TFETs do not match these extreme SS, but they are able to significantly push both I_{60} and I_{ON} to higher values, thanks to the adoption of heterostructures and nanowire geometries. Alian [152] demonstrated a pocketed vertical NW InGaAs/GaAsSb TFET using a top-down approach with SS_{MIN} ~47 mV/dec and I_{60} in the range of 5 nA/μm. Within the same materials system, InGaAs/GaAsSb, Convertino [156] showed similar performance, SS_{MIN} ~47 mV/dec, and I_{60} ~10 nA/μm at V_{DS} = 0.05 V, for a lateral HTFET directly integrated on a SOI platform. In this case, a self-aligned tunneling junction was formed, thanks to a raised GaAsSb p^+ source regrown under a SiN_X spacer, after the InGaAs channel is selectively etched. A top-down approach was employed by Zhao [153] to define a 20-nm-diameter InGaAs/InAs NWs and reported SS_{MIN} ~53 mV/dec with I_{60} ~4 nA/μm at V_{DS} = 0.3 V. A significant increase in I_{60} comes from the adoption of InAs/GaAsSb/GaSb NW heterostructures [93], where the NWs used in this study were grown by

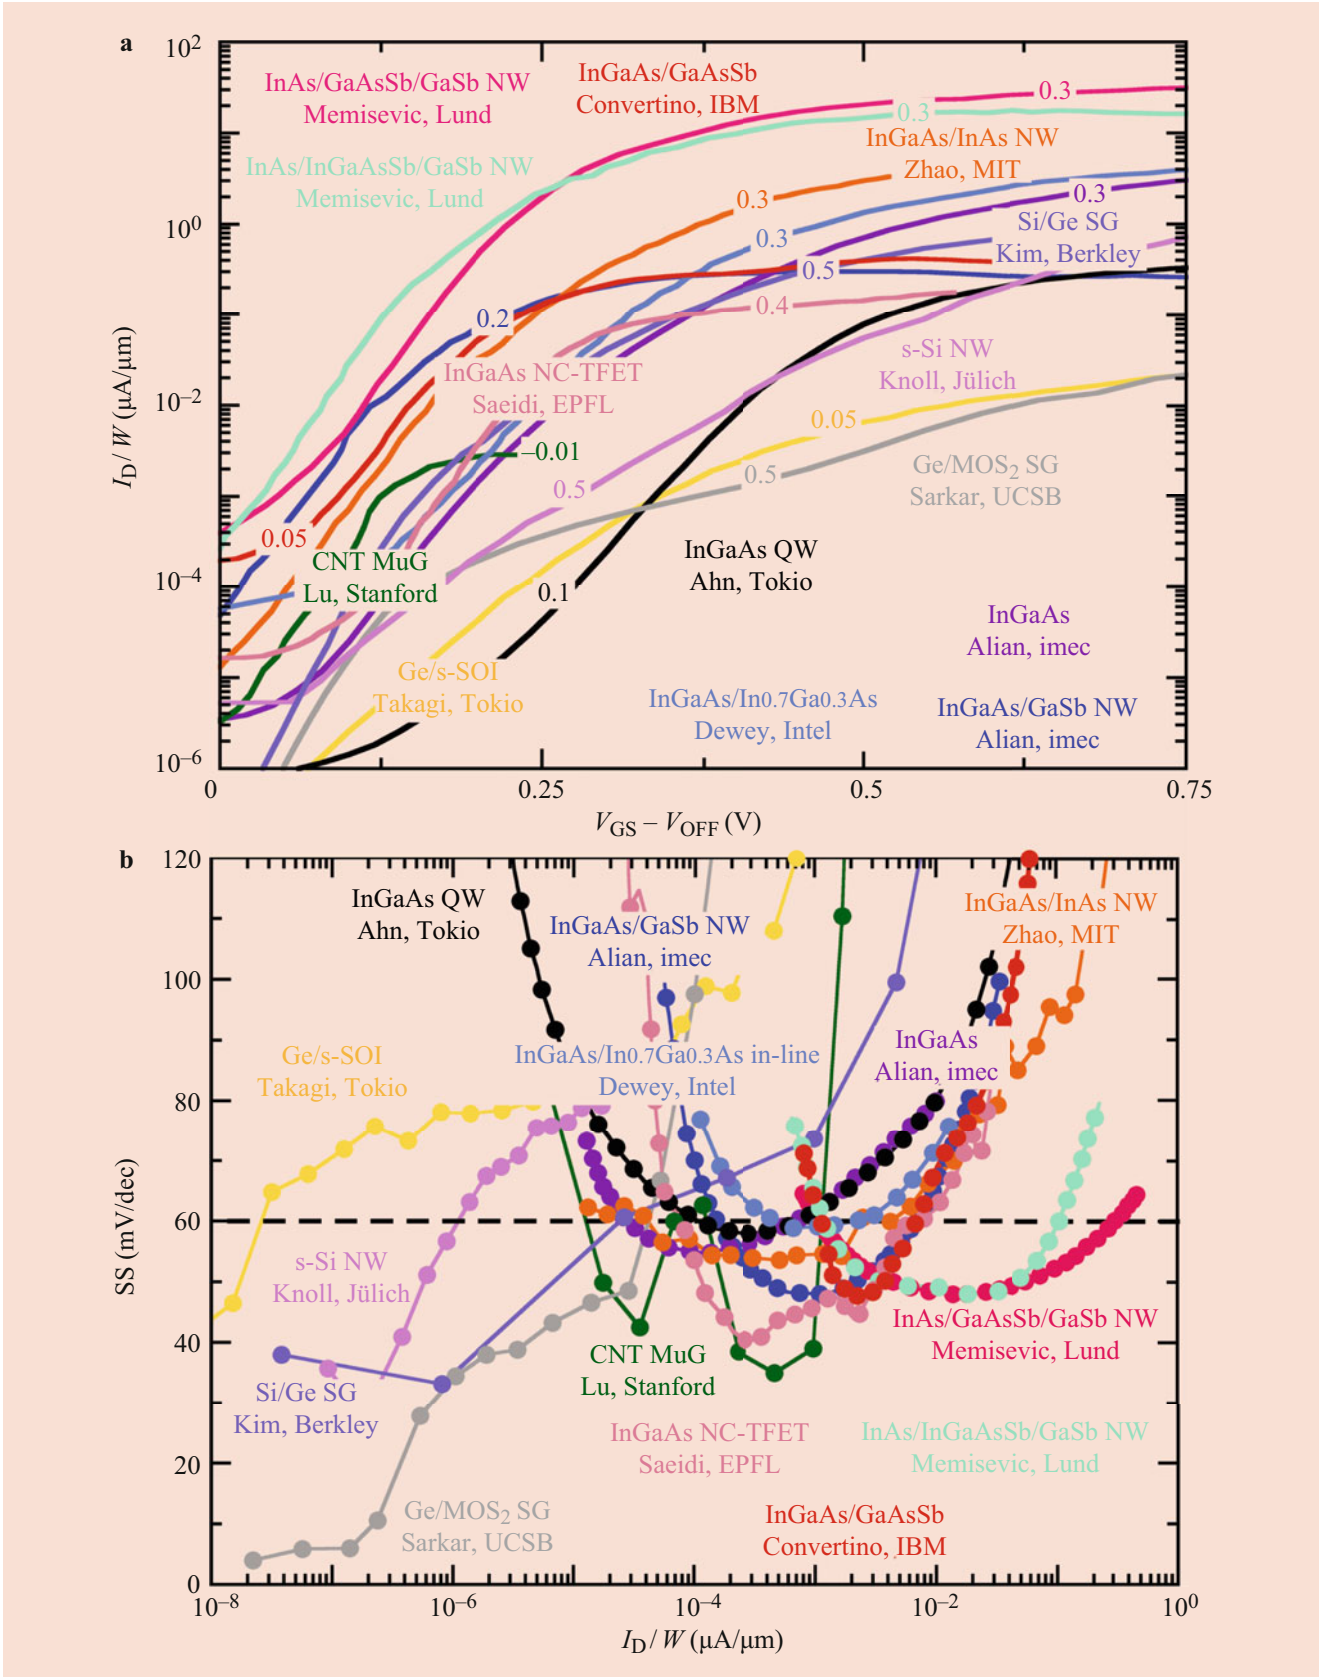

Fig. 24.26 (**a**) Comparison of published nTFET drain current per unit width versus gate-to-source voltage. (**b**) Extracted TFET SS versus drain current for the same nTFETs. Only TFETs that show SS near or below 60 mV/dec at room temperature for at least one order of magnitude change in I_D and V_{DS} <0.5 V are considered for the comparison

metalorganic vapor phase epitaxy. The devices exhibit SS_{MIN} ~48 mV/dec with I_{60} ~0.3 μA/μm at $V_{DS} = 0.3$ V, which is very close to requirements laid out by Vandenberghe [38] of SS below 60 mV/dec for current levels extending up to 1–10 μA/μm. Finally, Saeidi [151] demonstrated the coexistence of subthermal transport factor n and subunity body factor m (cfr. Eq. (24.1)) in a negative capacitance InGaAs TFET. Starting from an InGaAs TFET with SS_{MIN} ~55 mV/dec and I_{60} ~0.1 nA/μm, the addition of a PZT ferroelectric capacitor connected in series to the gate of the TFET resulted in the improvement of the abruptness of the transition from the OFF to the ON state with a reduction of SS_{MIN} down to ~40 mV/dec, a 100× I_{60} enhancement, as well as a widening of the subthermal region, internal voltage amplification, all within of minimal hysteresis window, below 10 mV.

24.14 Summary and Concluding Remarks

This chapter has sought to summarize the underlying physics and key findings in the development of the TFET, from the first discussions of a low subthreshold swing TFET (2004) to the present (2019). Some specialized advances in the wide breadth of materials systems and device geometries have been omitted to focus on the concepts that are most widely applicable. There are still many materials and process advancements that are needed before TFETs can be implemented in commercial foundries. As discussed, band tails are still not well understood, and assessment of subthreshold swing limits depends on understanding these transitions. Basic and applied materials studies are still needed to unravel the transport mechanisms at I_{60} and below and to then seed innovation and optimization. For any new materials system, the MOS heterostructure is always critical, and fundamental studies are still needed to understand the nature of interface and border traps and the processes needed for optimization.

Abstract

Carbon-based nanomaterials such as graphene and carbon nanotubes (CNTs) are considered as promising candidates for various applications in electronics. This chapter provides a wide-range review of different devices and applications in this field, with a focus on high-frequency analog electronics as well as digital circuits. We start from the band structure of graphene as well as CNTs to explain why these materials may outperform conventional electronic materials in specific areas. Graphene-based field-effect transistors, hot electron transistors, and metal-insulator-graphene diodes are elaborated particularly for applications in high-frequency electronics. Graphene field-effect transistors on flexible substrates are also discussed, which could exploit the excellent mechanical properties of graphene. The scope is then expanded to digital circuits with CNTs. We describe CNT-based CMOS integrated circuits, including recent prototype microprocessors with high complexity. The purpose of this chapter is to provide readers with the basic concepts on carbon-based device physics, an understanding of typical characteristics of nanoelectronic devices, and an overview of the state of the art in the field.

25.1 General Properties of Graphene and Carbon Nanotubes

Carbon-based nanomaterials such as graphene and carbon nanotubes (CNTs) are considered as very promising materials for various applications in electronics, such as high-speed electronics, optoelectronics, sensors, and so on [1, 2].

Graphene, the two-dimensional carbon allotrope, has been intensively investigated due to its excellent properties such as extraordinarily high carrier mobility (exceeding 100,000 cm^2/Vs) at room temperature [3], high saturation

velocity of 5.5 × 10^7 cm/s [4], ultimately thin body of only one atomic plane, and high flexibility as well as mechanical stability due to the strong covalent carbon-carbon bonds. In this chapter, we will first start with the band structure of graphene, followed by the basic transistor device geometry and considerations on contact optimization. Analog radio frequency (RF) transistors will also be in the focus since the combination of high mobility and high saturation velocity makes graphene an intriguing candidate for RF electronics, despite inherent shortcomings due to the gapless band structure. In addition, the flexibility of graphene enables high-performance flexible RF electronics. Furthermore, we will introduce hot electron transistors with a with graphene base electrodes (graphene base transistors, GBTs), potentially enabling operation at >1 THz [5].

CNTs as a prominent example of one-dimensional materials also provide very high charge carrier mobility and very high saturation velocity depending on the diameter of the tube. Compared to graphene, an advantage of CNTs is that they exist also in semiconducting form depending on the chirality, so that they can be utilized for digital circuits with higher intrinsic performance than that of the state-of-the-art silicon technology [6]. In this part, we will first explain the electronic structure of CNTs. Due to the advantage of CNTs with a proper bandgap, our focus will be on digital circuits. We will discuss the way toward realizing CNT-based CMOS technology, i.e., controllable p- and n-type transistors. In the end, we will give an outlook on CNT-based microprocessors.

Both graphene and CNTs can be grown by chemical vapor deposition processes, typically on catalytic substrates like copper, nickel, or iron. The materials can then be transferred onto the desired rigid or flexible substrates or grown directly on the target substrate via templated growth. The details of these growth methods are beyond the scope of this chapter, and we therefore refer to the literature in the field [7–9]. In addition, there are hundreds of related two-dimensional materials under investigation, including semiconductors like MoS_2 (molybdenum disulfide) or WSe_2 (tungsten diselenide). These materials are also suitable for transistors, including logic gates, but a detailed discussion is beyond the scope of this chapter.

25.2 Graphene-Based Transistors

Since graphene is straightforward in terms of atomic structure, we will start to discuss it first, although the experimental investigation of graphene-based transistors started much later than CNT-based ones.

25.2.1 Band Structure of Graphene

Graphene has a two-dimensional (2D) hexagonal crystal structure as shown in Fig. 25.1. The unit cell consists of two carbon atoms, marked with A and B. The 2D crystal structure is constructed based on this unit cell according to a triangle lattice. The primitive vectors of the lattice can be written as

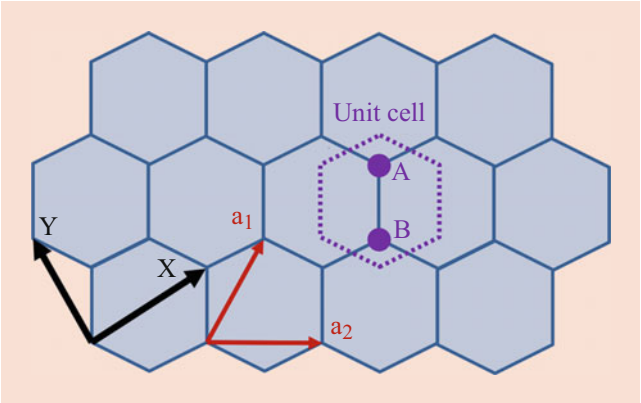

Fig. 25.1 Atomic structure of graphene. A unit cell consists of two atoms marked with A and B. The primitive vectors are defined as a_1 and a_2

$$a_1 = \frac{a}{2}\left(3, \sqrt{3}\right), a_2 = \frac{a}{2}\left(3, -\sqrt{3}\right) \tag{25.1}$$

where $a \cong 1.42$ Å is the distance between two directly neighbored carbon atoms, i.e., the distance between atoms A and B.

If we only consider the hopping between the directly neighbored atoms with tight-binding approximation (TBA), we can derive the energy dispersion of graphene [10]:

$$E_{\pm}(\mathbf{k}) = \pm t\sqrt{3 + 2\cos\left(\sqrt{3}k_y a\right) + 4\cos\left(\frac{3}{2}k_x a\right)\cos\left(\frac{\sqrt{3}}{2}k_y a\right)} \tag{25.2}$$

where $k \equiv (k_x, k_y)$ is the wave vector and $t \cong 2.8$ eV is the hopping energy between the directly neighbored carbon atoms. The signs plus and minus correspond to the conduction band and the valence band, respectively. If we plot the energy band in 3D space, it becomes apparent that the conduction band and the valence band intersect at specific points, which are called K and K' points. Their coordinates in the momentum space are

$$K = \left(\frac{2\pi}{3a}, \frac{2\pi}{3\sqrt{3}a}\right), \quad K' = \left(\frac{2\pi}{3a}, -\frac{2\pi}{3\sqrt{3}a}\right). \tag{25.3}$$

Due to the presence of K (or K') points, the bandgap of graphene is 0, so graphene is considered as a semimetal. If we focus the band structure around K (or K') points, Eq. 25.2 can be expanded as [10]

$$E_{\pm}(\mathbf{q}) = \pm v_F |\mathbf{q}| + O\left[\left(\frac{q}{K}\right)^2\right] \tag{25.4}$$

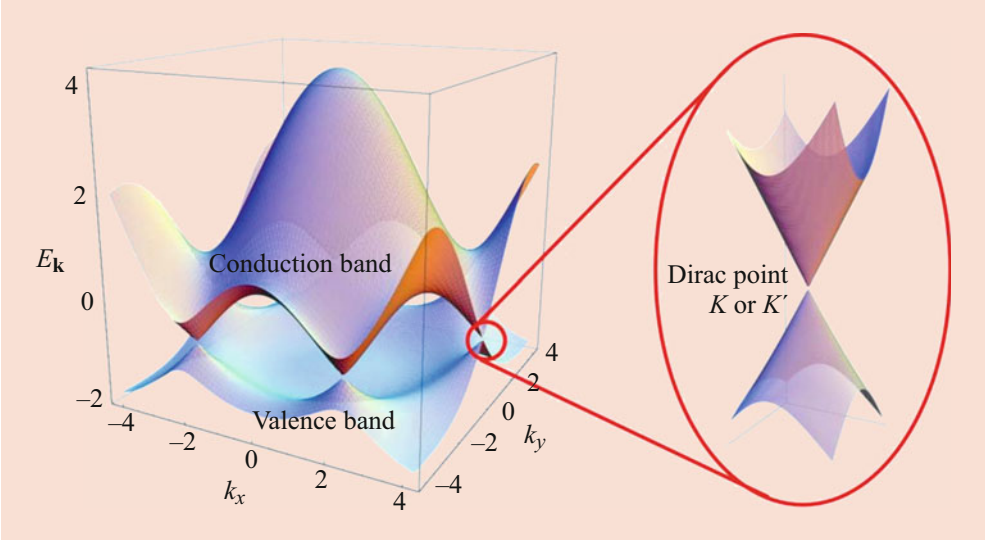

Fig. 25.2 The 2D band structure of graphene, with the Dirac cone zoomed in the band structure to K or K' points. (Reprinted figure with permission from Ref. [11]. Copyright (2009) by the American Physical Society)

where the wave vector $\mathbf{q} \equiv \mathbf{k} - \mathbf{K}$ and $v_F \cong 1 \times 10^8$ cm/s is the Fermi velocity around the K (or K') point. In the first-order approximation, the dispersion is linear around the K (or K') point, so that the effective mass of the charge carrier is 0, similar to that of photons (Fig. 25.2). The behavior of charge carriers around the K (or K') point can thus be described by the Dirac equation rather than the Schrödinger equation, and the K (or K') points are consequently also called Dirac points. The Dirac points define some of the special properties of graphene which are very interesting for fundamental research as well as engineering.

25.2.2 Basic Device Geometry and Characterization

A graphene-based field-effect transistor (GFET) consists of a layer of graphene that forms the channel, a gate dielectric, metallic contacts to the graphene, and a gate electrode [12]. The gate electrode can be used to electrostatically shift the Fermi level in graphene, as illustrated in Fig. 25.3. When the Fermi level lies at the Dirac point, the conduction band is empty, and the valence band is fully occupied. Ideally the carrier density in this situation is zero at zero temperature. However, due to thermal electron-hole pair generation as well as a finite number of negative or positive charges induced by impurities in the graphene and the surrounding dielectric layers, there are a finite number of charge carriers. The carrier concentration therefore shows a minimum value defined by the random distribution of electrons and holes across the graphene channel. The Dirac point is thus also called charge

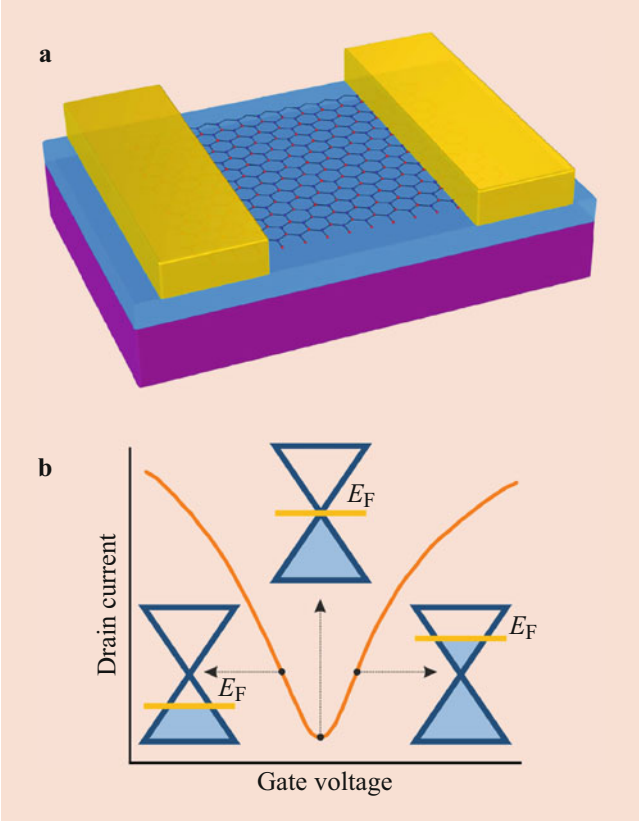

Fig. 25.3 (**a**) Basic geometry for graphene-based transistor. Graphene is contacted by metal from both ends with substrate as the gate electrode. (**b**) The field-effect ambipolar conduction due to the shift of the Fermi level. If a negative gate voltage is applied, the channel is dominated by hole conductions. While if a positive gate voltage is applied, the channel is dominated by electron conduction

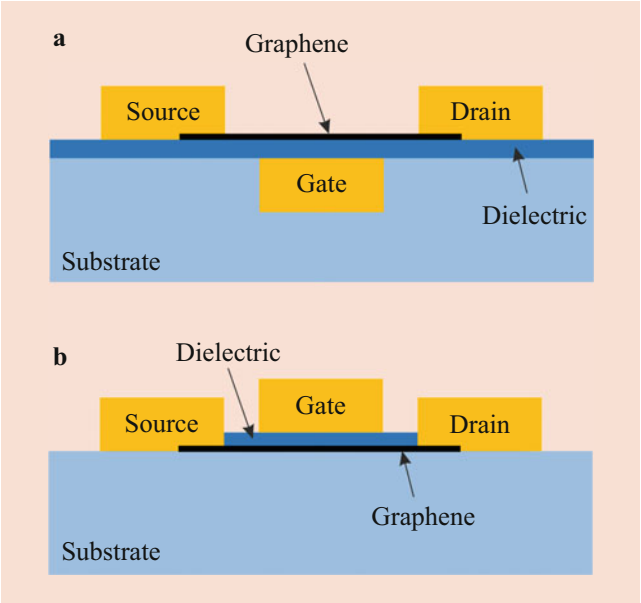

Fig. 25.4 Schematic of (**a**) top-gate and (**b**) back-gate configuration for a GFET

neutrality point [13]. When the gate voltage is changed, the Fermi level shifts upward or downward, and the electron or hole concentration starts to increase, respectively. As a consequence, GFETs typically show ambipolar conduction behavior, with minimum conduction at the Dirac point.

GFETs can be fabricated similar to thin-film transistors in either a back-gate configuration or in a top-gate configuration as shown in Fig. 25.4. The back-gate configuration has the advantage of fewer process steps after the graphene is introduced and hence is preferred in terms of process control and yield. The top-gate configuration can deliver higher performance, in particular for RF electronics, since the parasitic capacitances between gate and source/drain are minimized and the gate resistance can be minimized by T- or Gamma-shaped gate electrodes. However, the deposition of high-quality and thin dielectrics on top of graphene is still challenging.

Typical ambipolar transfer characteristics of a GFET are shown in Fig. 25.5. In principle, GFETs behave like conventional MOSFET, but because of the gapless band structure of graphene, they cannot be turned off completely. The typical current modulation in GFETs by the gate voltage results in an on-state to off-state current ratio in the range of 3–15, depending on the graphene quality and parasitic effects from electrostatic doping. It is important to note that the term "doping" is often used to describe the effect of charges near the graphene on the carrier density in graphene, which is different from the classic meaning of the term doping to describe replacing lattice atoms in bulk semiconductors. The lack of a distinct off-state makes it clear that classical CMOS logic operation cannot be addressed by GFETs, but only

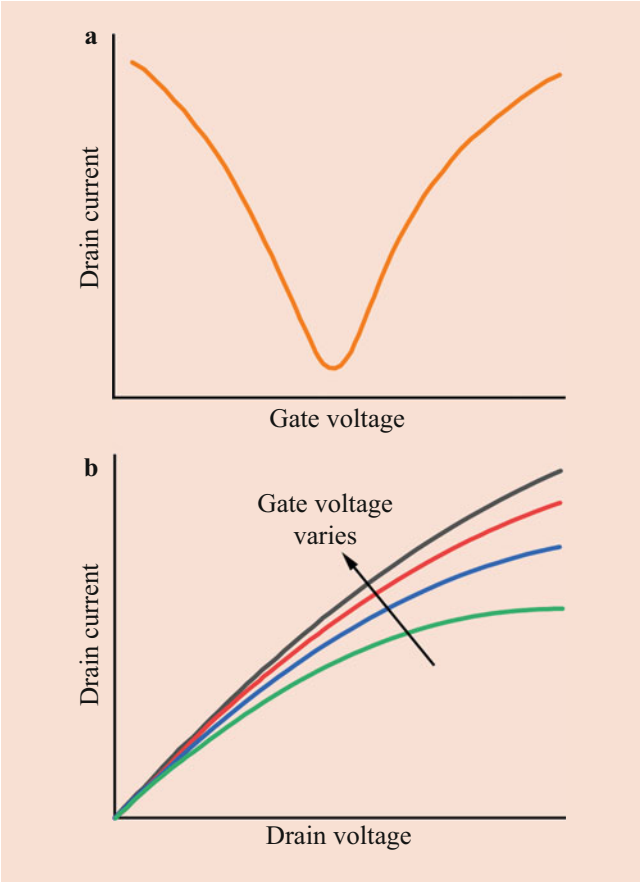

Fig. 25.5 Typical transfer (**a**) and output (**b**) curves of a GFET

analog operations are feasible, where transistors are operated in the on-state (amplifiers, mixers, oscillators, etc.). In an ideal GFET, the Dirac point should be located at zero gate voltage, but it is typically shifted due to unintentional doping of the graphene. From the slope of the transfer curve, we can derive the transconductance of the device

$$g_{\mathrm{m}} = \frac{\partial I_{\mathrm{ds}}}{\partial V_{\mathrm{gs}}} \tag{25.5}$$

where I_{ds} is the source-drain current and V_{gs} is the gate voltage. g_{m} can be used to calculate the field-effect mobility of graphene, which is similar to the calculation for a thin-film transistor in the linear regime:

$$\mu = \frac{1}{V_{\mathrm{ds}}} \frac{1}{C_{\mathrm{g}}} \frac{L}{W} g_{\mathrm{m}} \tag{25.6}$$

where V_{ds} is the source-drain voltage bias, C_{g} is the gate capacitance per unit area, and L and W are the length and width of the channel, respectively. However, large contact resistances between graphene and metal contacts, which may further be dependent on the (back-)gate voltage, can lead to an underestimation of the mobility when extracting the mobility with this method [15–16].

The absence of a bandgap in graphene means that it is impossible to achieve proper current saturation due to a pinch-off in the output characteristics of GFETs. This is because the channel undergoes a direct transition from an n-type to a p-type variable conductor [17] and thus there cannot be a pinch-off of the channel as in long-channel semiconductor MOSFETs. Nevertheless, current saturation can be obtained through velocity saturation in a certain drain voltage window, if high-quality material is used [18]. If the drain voltage is increased further, the GFETs continue to conduct more current. Figure 25.5 shows the typical output characteristic of a GFET with standard graphene quality, which can be fabricated by CVD graphene on the wafer scale.

25.2.3 Contact Resistance

The electrical contact between metal and graphene, R_C, is determined by the limited density of states in graphene. As in any electronic device, the contact resistance should be significantly smaller than the device resistance in order to obtain high-performance GFETs. In contrast to area contacts in three-dimensional semiconductors, the contact to graphene is typically a line contact and therefore should be normalized by the channel width (R_C W), with unit Ω·μm. To characterize the contact resistance, the transfer length method (TLM) is typically used. TLM requires a set of devices with different channel length. The resistance of the device normalized by its width is then plotted against the channel length, which usually results in a linear relationship. After linear fitting of the data points, the intercept of the line with the y-axis corresponds to twice the contact resistance of the device ($2R_C$), while the slope of the fit corresponds to the sheet resistance R_{sh}. There are several pitfalls with TLM for graphene devices, since the contact resistance is gate voltage-dependent, i.e., the carrier density in graphene has an influence on both R_C and R_{sh} [19, 20]. The TLM layout and procedure are illustrated in Fig. 25.6.

There are two different configurations for graphene-metal contacts, surface contacts, and edge contacts (Fig. 25.7). The former can be subcategorized into top contacts, bottom contacts, or sandwich contacts. In this case, there is an overlapping area between the metal and the graphene surface. The carrier injection from the metal to graphene mainly occurs by tunneling between the metal and the graphene within the transfer length since there are no dangling bonds on graphene (for the ideal case of defect-free graphene). The efficiency of this process is rather low, i.e., the contact resistivity typically remains high. In contrast, edge contacts allow charge carriers to be injected into graphene via the dangling bonds at the one-dimensional edge of graphene, which form a covalent bond with the metal. Therefore, edge contacts result in lower contact resistivity, with reported values approaching 100 Ω·μm

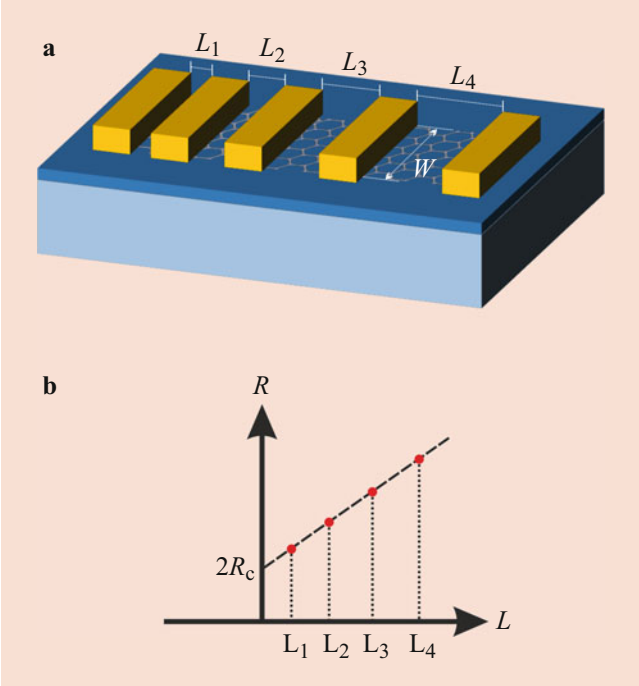

Fig. 25.6 TLM in order to extract the contact resistance of metal-graphene contact. (**a**) A set of devices need to be fabricated with the same channel width W and different channel length L_1 to L_4. (**b**) The total resistance is plotted against channel length, with a linear fitting. The channel resistance is proportional to the channel length. The slope of the line is related to the sheet resistance of graphene, and the intercept of the line with y-axis is the contact resistance from both sides ($2R_c$)

[3]. The combination of the two methods can be exploited by etching holes into graphene under the contact areas. Here, reported values are below 100 Ω·μm [21–23]. While good ohmic contacts are obviously feasible, the experimental results on contact resistance are still scattered, since the contact resistance is affected by many factors. These include metal-type, deposition method, graphene-type, contact-type, interfacial contamination, and characterization method [15, 24]. In addition, the specification for the required contact resistivity depends clearly on the device application. Hence, there is no solid conclusion today to indicate which method provides suitable and reliable results.

25.2.4 Radio Frequency Transistors

The main figures of merit for RF transistors are the cutoff frequency f_T and the maximum oscillation frequency f_{MAX}. f_T is defined as the frequency, where the current gain of a transistor reaches unity. f_{MAX} is defined as the frequency, where the power gain of a transistor reaches unity. These two quantities describe how fast a transistor can operate. It shall be noted that for most applications, f_{MAX} is more relevant, while f_T describes the intrinsic properties of the channel. For these

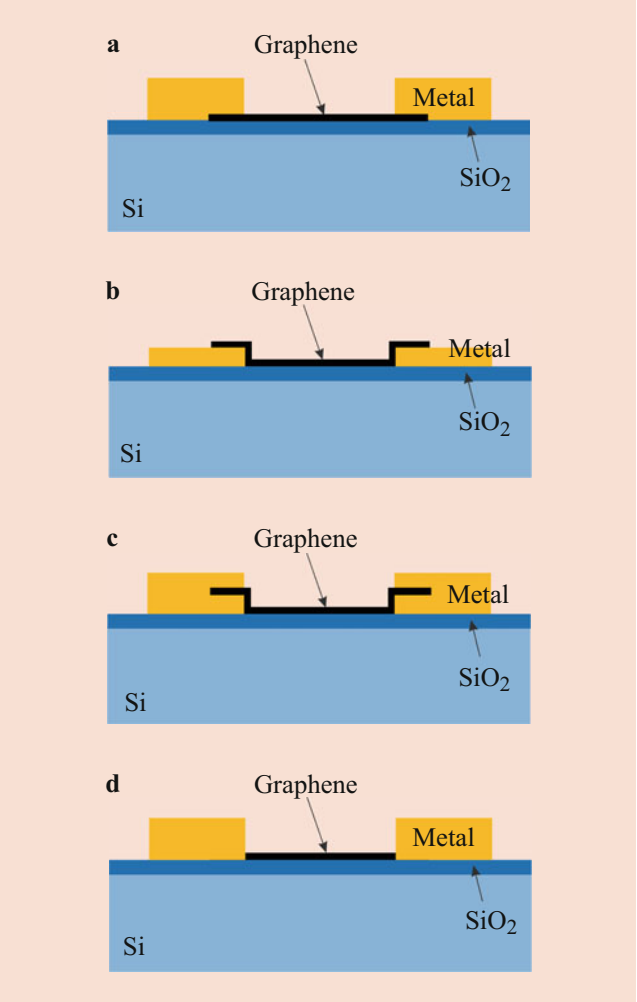

Fig. 25.7 Different contact mode between graphene and metal electrodes. (**a**) Top contact, (**b**) bottom contact, and (**c**) sandwich contact are known as surface contact. In contrast, (**d**) edge contact usually results in lower contact resistance

parameters, there are usually intrinsic and extrinsic values. Intrinsic values reflect the performance of the device itself without the parasitic effect, from, for example, substrates or testing pads. The procedure of data processing to obtain the intrinsic property is called de-embedding. In contrast, extrinsic values are those directly from the measurement without de-embedding. The intrinsic properties are only affected by the device itself, so it can be used to benchmark between devices with different substrates or layout designs. However, we have to note that the extrinsic properties are also important since it sets a performance limit that a device can deliver in such a specific process or design environment.

Based on the small-signal model of a GFET shown in Fig. 25.8, Eq. 25.7 describes the extrinsic f_T by considering the RC time constant and the time response of the charge carriers [25]:

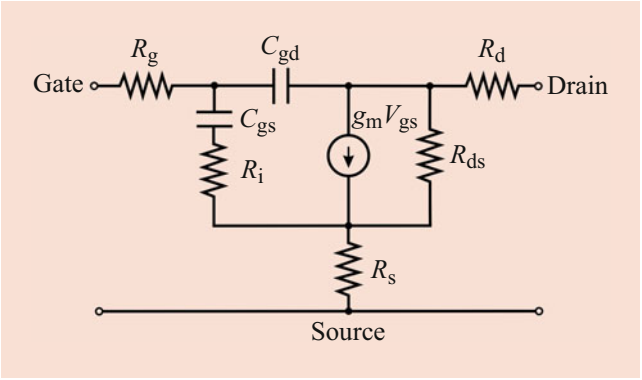

Fig. 25.8 Small-signal equivalent circuit of a GFET

$$f_T = \frac{g_m}{2\pi} \frac{1}{(R_s + R_d)\, g_m C_{gd} + \left(C_{gs} + C_{gd}\right)\left[1 + g_{ds}\left(R_s + R_d\right)\right]} \tag{25.7}$$

where R_s and R_d are the source and drain access resistance, C_{gd} and C_{gs} are the gate-drain and gate-source capacitances, and $g_{ds} = \partial I_{ds}/\partial V_{ds}$ is the differential conductance.

One critical parameter to enhance f_T of a GFET is to reduce C_{gd} or increase g_m. Scaling down the channel length of the device is a good way to reduce C_{gd} and increase g_m. In addition, reducing R_s or R_d will also have a positive impact on f_T, as in any given technology. If the device can reach the saturation regime in the output characteristics, g_{ds} will be minimized (an ideal saturation results in $g_{ds} = 0$), and therefore f_T will be increased.

If we consider the intrinsic property of the GFET, i.e., neglect the parasitic effect from R_s and R_d, we arrive at the simplified equation:

$$f_{T-int} = \frac{g_m}{2\pi\left(C_{gs} + C_{gd}\right)}. \tag{25.8}$$

The extrinsic f_{MAX} can generally be written as Eq. [25]

$$f_{MAX} = \frac{g_m}{4\pi C_{gs}} \frac{1}{\sqrt{g_{ds}\left(R_i + R_s + R_g\right) + g_m R_g C_{gd}/C_{gs}}}, \tag{25.9}$$

and the intrinsic one can be written as

$$f_{MAX-int} = \frac{g_m}{4\pi C_{gs}} \frac{1}{\sqrt{g_{ds} R_i}}. \tag{25.10}$$

where R_i is the resistance shown in Fig. 25.8. Early RF data of GFETs were published in 2008/2009 by Meric et al. and Moon et al., who observed f_T of 14.7 GHz and f_{MAX}/f_T of 14/4 GHz, respectively [26, 27]. Since then, there has been significant progress in terms of RF performance by reducing

the physical gate length, improving the graphene quality and reducing parasitic resistances like contact and gate resistance, with f_T values reaching several hundred GHz. This is on par with InP transistors and state-of-the-art Si transistors in terms of f_T at least for a given gate length. Since 2012, there has been no further improvement in terms of f_T in literature, which is probably due to a shift of the research focus on other properties of GFETs. In the same timeframe, f_{MAX}, which is important for applications in low-noise amplifiers (LNAs) and oscillators, has been reported up to 44 GHz [28]. Thus, while f_T increased by a factor of 100, f_{MAX} increased only by a factor of 3. This difference can be explained by parasitic effects that mainly limit f_{MAX}, but not f_T: the high resistance of the metallic gate electrodes and the high (non-saturating) output conductance g_{ds}. To increase f_{MAX}, a T-gate structure has been employed that reduces the gate resistance [29], and also the graphene quality has been improved so that in 2016 the benchmark for f_{MAX} was finally increased to 200 GHz [30], which is a value close to Si transistors at the corresponding gate length.

Numerous theoretical calculations of f_{MAX} and f_T for GFETs have been performed in order to predict the ultimate performance limits of GFET. Several publications report values for both parameters significantly above 1 THz (sometimes even up to 10 THz), which would outperform all existing transistors based on Si and III/V materials by far. However, in those simulations, one has to carefully weigh the input parameters, especially for the contact resistance and for the graphene mobility. Using still realistic, but very good values as input parameters, several simulation studies arrive at a range of 1–3 THz for both f_{MAX} and f_T [31, 32].

The noise Figure (NF) is also an important quantity for assessing the performance of an RF transistor. In this respect, only little work has been performed, mainly because the transistors often did not show gain in a 50 Ω environment typically used in RF application scenarios. In addition, most of the GFETs have relatively low extrinsic f_T due to parasitic capacitances, which also has a significant negative impact on the measured noise value. Early work reported a noise figure of 3.3 dB at 1 GHz, which is a very high value compared to Si and InP, where NF < 1 dB [33]. In 2017, a noise figure of 1.5 dB at 10 GHz was reported [34], which is close to Si CMOS transistors at these frequencies. In these GFETs, the intrinsic noise figure was estimated to be 0.8 dB at 10 GHz, which would be a competitive value.

In order to identify the main bottlenecks for GFETs, the key parameters of the best GFET in terms of f_{MAX} are compared with the best InP transistor in Table 25.1. Both transistors implement a low-resistance T-gate structure. The gate length for the InP transistor is shorter by a factor of 1.7, which translates into lower gate capacitance and faster operation. In terms of contact resistance, both transistors are similar, and hence the contact resistance is not a limiting factor for the GFET performance. A clear difference between the GFET and the InP transistor can be found for the carrier mobility and the ratio between f_{MAX} and f_T. The lower mobility for the GFET translates directly into lower transconductance, which affects both f_{MAX} and f_T. Thus, improving the material quality for GFETs will directly pay back into a significantly improved RF performance. The main limitation for the mobility in graphene is the process integration flow, with each step impacting mobility. The issues with process integration have generally been identified, and improvements can be expected as the technology matures [2, 36]. The rather low ratio between f_{MAX} and f_T of the GFET is related to poor saturation of the output conductance. Therefore, an urgent issue in order to improve the RF performance of GFETs is to engineer output current saturation, which can be achieved for high-quality graphene through velocity saturation.

Table 25.1 Comparison of key parameters of the best GFET with the best InP transistor

	InP [35]	Graphene [30]
f_T (GHz)	385	255
f_{MAX} (GHz)	1200	200
Gate length (nm)	35	60
Contact resistance (Ωμm)	50	50–100
Transconductance (S/mm)	2.3	1.1
Mobility (cm^2/vs)	15,000	3500

Hence, it can be expected that the RF performance of GFETs will be significantly improved if high-quality graphene with mobility values approaching the highest reported values (>> 10,000 cm^2/Vs) is maintained throughout the device fabrication process. This requires work especially on identifying suitable substrates and encapsulation materials like 2D hexagonal boron nitride, but on large scale, and in addition to an optimized graphene transfer process.

25.2.5 Flexible Transistors for High-Frequency Applications

Flexible electronics is a field of great promise. It is expected to provide human beings with smaller, lighter, and more comfortable electronic devices, particularly with potential applications in wearable consumer electronics, electronics for healthcare, flexible displays, flexible solar cells, tissue-like electronic devices, e-skin, etc. The thickness of the flexible substrate (typically <50 μm) is only about one-fifteenth of the thickness of 300 mm silicon wafers, which may have been beneficial for specific applications.

Graphene does not only have excellent electrical properties as discussed in the previous sections, but it also provides ultrahigh mechanical strength due to the strongest bond in nature, carbon-carbon σ covalent bonding. Free-standing single-layer graphene has a very high breaking strength of

about 42 N/m, which translates to a Young's modulus of about 1 TPa and an intrinsic strength of about 130 GPa [37], which is about 200 times higher than that of steel. Graphene can withstand extreme bending conditions [38]. The outstanding mechanical properties of graphene in combination with its electrical properties (especially high carrier mobility and high saturation carrier velocity) enable its applications in flexible high-frequency electronics.

Charge carrier mobility is a crucial parameter for transistors, especially those targeted for high-frequency applications. Although the theoretical limit or mobility in graphene is extremely high, different material synthesis methods, handling, and other fabrication procedures result in graphene with different qualities, i.e., different mobility values. Table 25.2 summarizes reported graphene transistors fabricated on flexible substrates. Different gate dielectrics were utilized for flexible transistors, such as thin-film technology-based oxides (naturally oxidized Al_2O_3, ALD Al_2O_3, ALD HfO_2, thermally oxidized YO_x, etc.), flexible materials (ion gel, nanoscale PI, etc.), or other 2D materials (graphene oxide, hBN). Bending and straining experiments with up to 8.7% surface strain have shown suitability for many application scenarios. The highest mobility for graphene-based transistors on flexible substrates is higher than 20,000 cm^2/Vs, which was achieved by using thermally oxidized yttrium oxide as the gate dielectric [39]. This value is comparable to data on rigid substrate. Based on this approach, excellent high-frequency performance can be expected. In addition, it has been reported that high-quality graphene is more resistant to repeated bending, because defects in graphene usually weaken the mechanical property of graphene significantly [40].

The frequency response of graphene-based flexible transistors has been investigated through S-parameter characterization, from which the f_T and f_{MAX} can be determined. Table 25.3 summarizes literature that reports f_T and f_{MAX}. The graphene in those experiments is from chemical vapor deposition unless noted otherwise. The table clearly shows that the gate length is very critical for the performance enhancement, as is typical for conventional RF transistors. The record extrinsic f_T is 39 GHz for 100-nm gate length [64], and the record extrinsic f_{MAX} is 20 GHz for 200-nm gate length [57]. Strain up to 2.5% has been applied without significant degradation of RF performance [57].

Gate length normalized frequency parameters, such as $f_T \cdot L_g$, can also be used as a figure of merit for benchmarking when there is only a small range of experimental data available. Moreover, there is often a lack of structural information to fully compare the de-embedding procedures, so it is often not fair to compare the values after de-embedding. For example, in reference [62], where values of 198 GHz and 28.2 GHz were reported for f_T and f_{MAX}, respectively, a full de-embedding process was used, in which the source and drain electrodes were also in the open structure. Hence, these reported values should not be compared with values from other reports, where no de-embedding procedure or a de-embedding procedure with less parasitic parameters was applied. Therefore, we use extrinsic parameters in Table 25.4 to benchmark different flexible RF transistors. The state of the art for $f_T \cdot L_g$ is 6.4 GHz·μm (extrinsic) for the device geometry as well as the frequency response characterization as shown in Fig. 25.9. The ratio between f_T and f_{MAX} approaches unity in the transistor from [61], equivalent to the best value achieved on rigid substrate [66].

There is also intensive research for different analog applications such as low-noise amplifiers (LNAs) [57], frequency doublers [39, 55], frequency mixers [57], and radio receiver [67]. LNAs operating at 5.5 GHz and featuring a noise figure of only 1.34 dB with an associated gain of 11.95 dB have been reported [57]. Ambipolar frequency doublers operate at the 10 MHz range, but there is no gain higher than unity [39, 55]. A two-tone test of a graphene mixer shows high-frequency performance which extends well into the gigahertz range [57]. In addition, a flexible graphene-based amplitude modulated radio receiver operating at 2.4 GHz has been demonstrated recently [67]. The receiver consists of a graphene transistor demodulator, graphene speaker, and graphite antenna. Albeit the interesting performance, the integration level of these circuits and systems is not yet very high. Only one transistor is typically used on chip, while all passive components are not monolithically integrated with the active device.

At higher integration level, i.e., two or more transistors, a flexible all-graphene modulator circuit with the capability of encoding a carrier signal with quaternary digital information has been reported [49]. Two types of quaternary modulation were demonstrated: quaternary amplitude-shift keying (QASK) and quadrature phase-shift keying (QPSK), with 1 and 2 all-graphene transistors, respectively. Its all-graphene design with every component (channel, interconnect, load resistor, and source/drain/gate electrodes) fabricated from graphene makes it not only flexible but also highly transparent.

The basic requirement of flexible electronic is the bendability, stretchability, or even foldability of the substrate in combination with all (di-)electric layers on top of that. The mechanical and electrical properties of these layers must be stable during the course of bending. The retention capability of all device and circuit parameters should be high over a relatively long timeframe. Figure 25.10a summarizes the carrier mobility of different materials that are compatible with thin-film flexible technology. Organic semiconductor materials such as pentacene have rather poor mobility, with the highest demonstrated values typically approximately

10 cm^2/Vs, which largely limits the high-frequency response of the transistors [68]. Metal-based oxide semiconductors and polysilicon are very compatible with thin-film large-scale processing, but the performance is not high enough for most RF applications (mobility <100 cm^2/Vs). Nevertheless, these materials may find suitable applications in low-cost electronics. Other low-dimensional materials such as carbon nanotubes (CNT) or two-dimensional transition metal dichalcogenides (TMD) such as molybdenum disulfide may also be suitable for flexible electronics in terms of flexibility. Conventional semiconductor thin films such as silicon or III–V compound semiconductors can be applied for flexible electronics, but the flexibility of such materials is rather limited, even when thinned down considerably [69, 70]. Figure 25.10b compares different potential materials for flexible electronic in terms of f_{MAX} and maximum strain. Among all the candidates, graphene is the only material that delivers power gain in the gigahertz regime at an applied strain of more than 1%. Thus, graphene devices currently provide the best performance among the materials listed in Fig. 25.10, concerning both frequency response and strain limit capability [57].

A qualitative overview and evaluation of the different materials under consideration are shown in Table 25.5. Although the scalability and manufacturability of graphene still require further development, the outstanding performance of prototype graphene RF devices strongly underlines its potential for flexible RF electronics.

Graphene-based flexible RF electronics could find first industrial applications on flexible Wi-Fi transceivers for consumer electronic devices. This kind of technology can be used for wearable devices or smartphones in order to save the interior space. Applications in the frequency range of Wi-Fi signals (several GHz) are already attainable with graphene in terms of frequency response, with the added advantage of mechanical flexibility. Graphene-based flexible MMICs are

certainly capable of providing the RF back-end circuitry. For flexible applications, the RF front end and signal processing circuits have not yet been demonstrated, but would be preferable over heterogeneously integrated solutions on rigid substrates. Applications with higher target frequency range or higher-power flexibility are not necessarily required, and graphene on rigid substrates can provide higher performance for this application space, where flexible RF electronics is not the best option.

25.2.6 Vertical Transistors/Hot Electron Transistors

Vertical hot electron transistor structures with graphene (or other 2D materials) as the material for the transistor base are investigated for their potential for high-frequency operation. These devices are similar to heterojunction bipolar transistors (HBTs) and sometimes also referred to as "graphene base transistor" (GBT) or graphene hot electron transistor. Here, we summarize the experimental and theoretical state of the art in graphene ballistic hot electron transistors, i.e., GBTs. Performance predictions indicate potential for (up to several) THz operation, even with current models that take nonidealities into account. Experimental results clearly demonstrate the basic DC functionality, with on/off current switching over several orders of magnitude and high transmission coefficient, but further developments are required to exploit the full potential of the GBT device family. In particular, interfaces between graphene and semiconductors or dielectrics are far from perfect and thus limit experimental device integrity, reliability, and performance and have prevented researchers from obtaining RF data.

Vertical electronic device concepts utilizing graphene have been proposed to overcome an intrinsic limitation of graphene, i.e., the absence of an electronic bandgap. One of these novel device concepts, introduced by Mehr et al. in 2012, is the vertical GBT [73]. The concept of the GBT is based on the metal base hot electron transistors (HETs) introduced originally by Mead in 1961 [74] and followed up by Heiblum and others in the 1980s with semiconductor heterostructures [75, 76]. HETs utilize high-energy tunneling injected electrons (hot electrons) as the main charge carrier. The first HETs were composed of metal emitters, metal bases, and metal collectors, which were isolated from each other by thin oxide barrier layers. One of the main challenges for the HETs as well as heterojunction bipolar transistors (HBTs) is that the cutoff frequency is limited by base transit

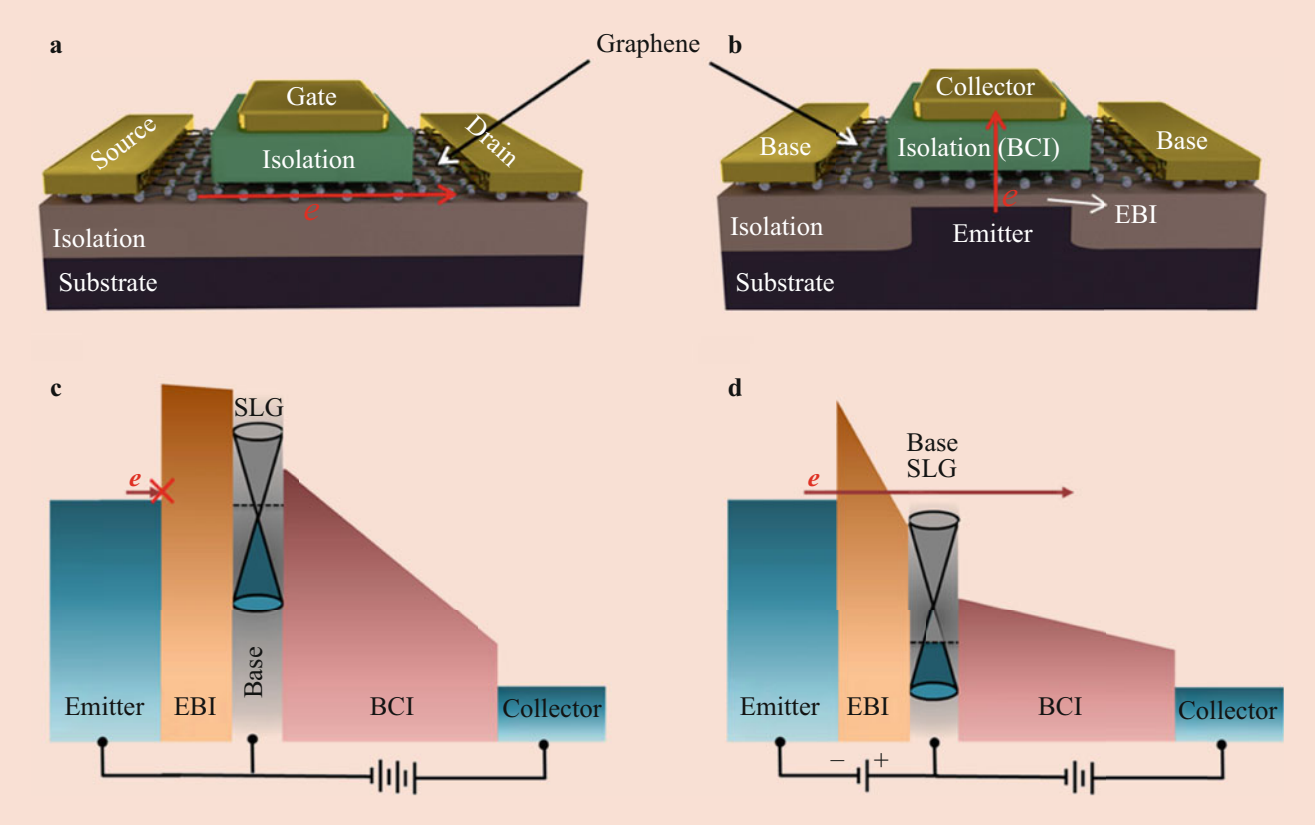

Fig. 25.11 Schematics of (**a**) GFET and (**b**) GBT. The red arrow shows the direction of electron transport in the on state of these devices. (c,d) Simplified band diagram of the GBT in the (**c**) off state and (**d**) on state in the common emitter configuration. We note that in (**c**) and (**d**), the energy difference between Fermi level and Dirac potential in graphene represents graphene's quantum capacitance effect. (Reprinted from [78], Copyright (2015), with permission from Elsevier)

time. While thinning down the base mitigates this issue, it dramatically increases the base resistance, resulting in high RC delay and self-bias crowding. The GBT addresses these issues by exploiting the high conductivity and the single atomic thinness of graphene as the base material, as it minimizes both the base transit time and the base resistance to enable high cutoff frequencies [73]. This concept is distinctly different from vertical graphene field-effect tunneling transistors as introduced by Britnell et al. [77]. While the latter functions due to the limited density of states in single-layer graphene and electrostatic gate control of the carrier transport between two isolated single-layer graphene (SLG) sheets, the GBT operates through emitter-base barrier modulation analogous to the bipolar technology (see Fig. 25.11).

In 2013, Vaziri et al. demonstrated the first experimental proof-of-concept GBT [79], where DC measurements confirmed the working principles of the devices. These first GBTs comprised of n-doped silicon emitters, 5-nm-thick thermal silicon dioxide (SiO_2) emitter-base insulator (EBI) tunneling barriers, a graphene base, 15–25-nm-thick atomic layer deposition (ALD) aluminum oxide (Al_2O_3) base-collector insulators (BCI), and metal (titanium/gold) collectors. The fabrication was done on 8-inch wafers, and the GBTs were isolated by 400-nm SiO_2 shallow trench isolation (STI) making the fabrication scheme potentially CMOS compatible. Figure 25.12a illustrates the transfer characteristics of a GBT at a base-collector voltage of $V_{BC} = 2$ V. The devices showed emitter-base threshold voltages of approximately 4.5 V, very low off-state currents and more than four orders of magnitude on/off ratio. Figure 25.12b shows temperature-dependent I–V characteristics of the emitter-base tunneling diode (input characteristics). Clearly, the dependence of the current to the temperature diminishes for high-voltage range. This fact together with the excellent linear fit of the I–V characteristics to the Fowler-Nordheim model (inset of Fig. 25.12b) confirms that the transport mechanism is dominated by tunneling. In addition, in Fig. 25.12b the onset of the emitter-base tunneling current is well matched to the onset voltage of the collector current in Fig. 25.12a. Nevertheless, the overall DC on current is not sufficient to use these poof-of-concept devices, e.g., as amplifiers.

High-frequency performance of the GBT requires high on-state collector currents I_C. In an ideal device, I_C is equal to the emitter current I_E, which consists of injected hot elec-

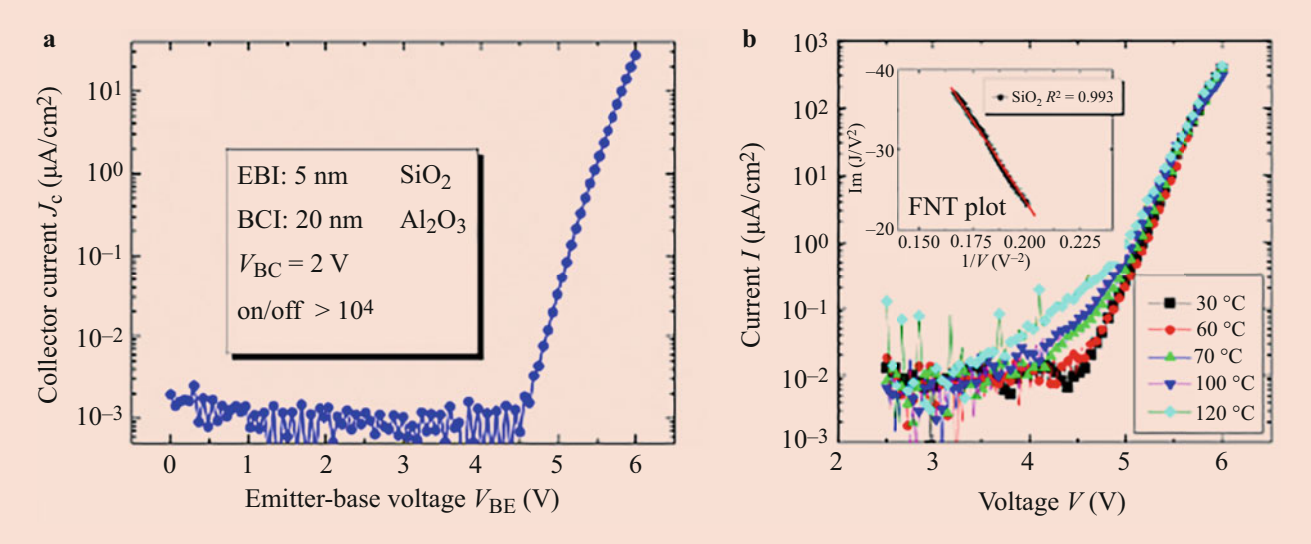

Fig. 25.12 (**a**) Transfer characteristics of a GBT with 5-nm-thick SiO_2 and 20-nm-thick Al_2O_3 as the EBI and the BCI, respectively. The transfer characteristics show an on/off ratio exceeding 10^4. (**b**) Temperature dependence I–V for the injection tunnel diode with 5-nm SiO_2 as the tunnel barrier. The inset FN plot shows an excellent linear fit. (Reprinted from [78], Copyright (2015), with permission from Elsevier)

trons, i.e., the common-base current gain or current transfer ratio $(\frac{I_C}{I_E}) = \alpha = 1$. Hence, the EBI barrier should be low and thin enough to provide a high current of hot electrons, yet block cold electron emission. For example, replacing a 5-nm SiO_2 EBI with 6-nm-thick ALD HfO_2 results in an improved threshold voltage and a higher emitter current (Fig. 25.13a). However, the choice of dielectric materials to form a low band offset barrier is limited to high-k dielectrics, which are known for reduced film and interface integrity compared to SiO_2. This means that for thin tunneling layers, defect-mediated carrier transport or unfavorable direct tunneling could become the dominant transport mechanisms. One possible solution is bilayer dielectric tunnel barriers, where a first thin layer in contact with the emitter provides a high-quality interface and material integrity, while a second layer reduces off-state leakage. Together, the bilayer dielectric minimizes defect-mediated carrier transport. This approach facilitates the application of low bandgap (high electron affinity) dielectrics to improve the emitter current by promoting Fowler-Nordheim or step tunneling [80] (Fig. 25.13b). Figure 25.13a shows a dramatic improvement in the emitter current by utilizing a novel $TmSiO/TiO_2$ (1 nm/5 nm) bilayer tunnel barrier, which is dominated by tunneling [81].

Experimental data combined with theory allows fairly accurate performance predictions. The performance of GBTs strongly depends on design parameters that should be chosen to maximize the current and minimize the loss mechanisms. Although the scattering of hot electrons in the base is minimized by using graphene, EBI parameters need to be accurately chosen to guarantee high injection current densities. Yet, the EBI needs to also prevent emission of cold electrons via defect-mediated electron transport or direct tunneling. These cold electrons are not able to surpass the base-collector barrier and lead to parasitic base current that limits α. Furthermore, the BCI needs to act as an electron filter, which allows the passage of the hot electrons and blocks cold electron emission from the base to the collector. This requires a low barrier to minimize the quantum mechanical backscattering of hot electrons at the BCI barrier and, simultaneously, suppress thermionic, tunneling, and defect-mediated electron transport from base to collector. Based on experimental data and theoretical considerations, the following requirements for the emitter current can be defined [81]:

(a) The current must be dominated by injection of hot electrons to the graphene or 2D material base (tunneling or thermionic emission). When these electrons have energies well above the Fermi level of the graphene base and the collector barrier height, they can overcome the collector barrier and contribute to the collector on current. This leads to a high current gain of the device.
(b) Emitter-base emission of cold electrons should be prevented. Electrons with energies comparable to the graphene-based Fermi level are backscattered from the base-collector barrier and contribute to the high parasitic base current. Since the emission of cold electrons is due to defects and direct tunneling (DT), high-quality barriers must be present, sufficient to prevent direct tunneling.
(c) High collector current density is required to enable high-frequency operation.
(d) High nonlinearity is essential to obtain high transconductance.
(e) A low threshold voltage is ideal for low-voltage operation.

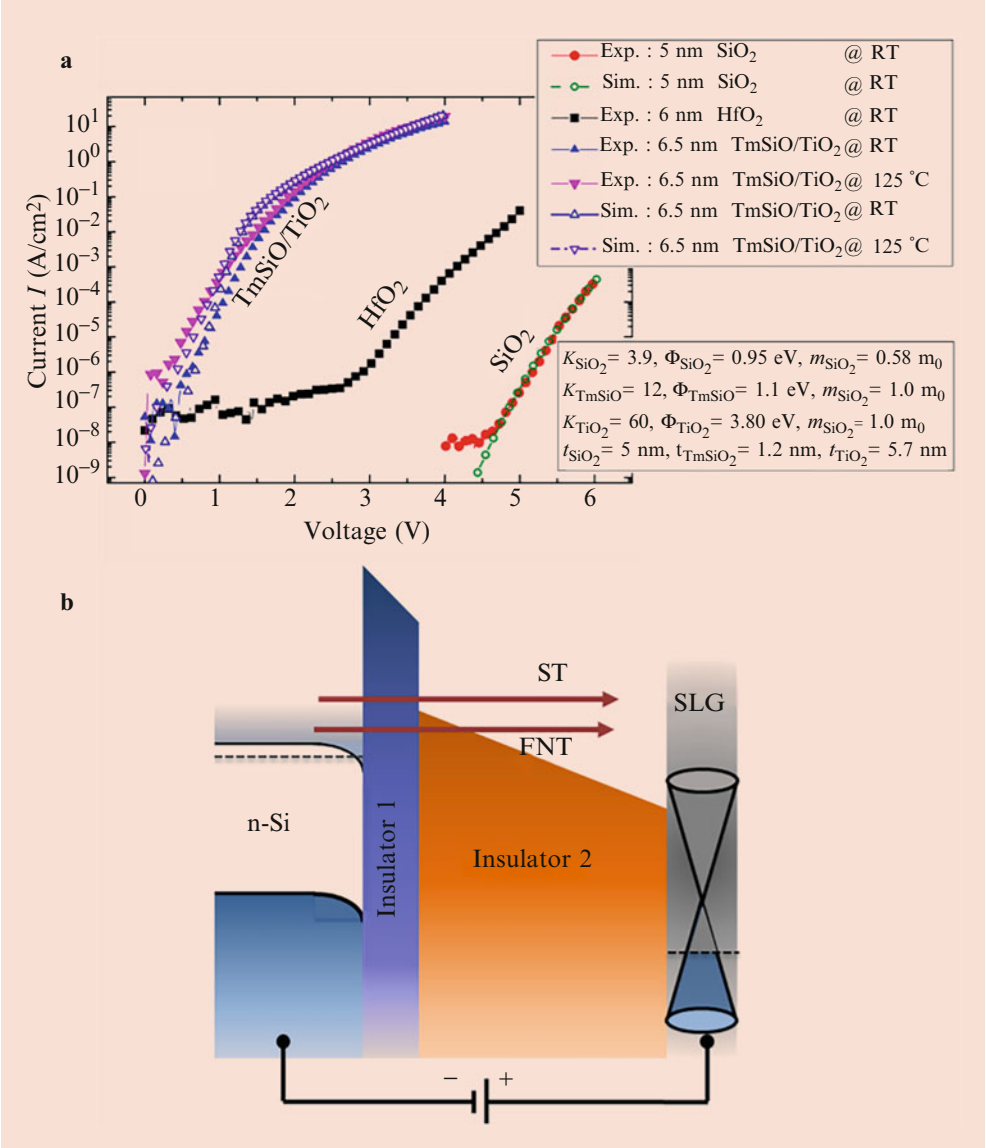

Fig. 25.13 (**a**) I–V characteristics of Si-insulator-graphene tunnel diodes with SiO_2, HfO_2, and $TmSiO/TiO_2$ tunnel barriers. The HfO_2 tunnel barrier with lower band offset with respect to Si conduction band shows improved I–V characteristics (blue triangulars) in comparison to SiO_2 (brown squares). Superior I–V characteristics have been achieved using $TmSiO/TiO_2$ bilayer tunnel barrier (red circles). The tunneling transport mechanisms in the bilayer tunnel barriers are shown in the (**b**) simplified band diagram. (Reprinted from [78], Copyright (2015), with permission from Elsevier)

So far, the entire set of conditions has not been met experimentally. Nevertheless, there are considerable efforts worldwide on GBTs or related devices. In fact, these conditions led to the theoretical prediction/invention of graphene-based heterojunction transistors (GBHTs), with low barriers made from semiconducting materials [82–84]. In addition, the RF performance potential of both GBTs and GBHTs has been predicted with multi-scale models, taking into account the limitations of process technology. Di Lecce et al. compared through numerical simulations an n-type Si GBHT with a state-of-the-art n-p-n SiGe HBT structure aggressively scaled to reach its performance limits from [85]. The study predicted that the GBHT may deliver an f_T that is two times higher compared to optimized HBTs assuming a transparent graphene/Si interface (Fig. 25.14). This is due to the monolayer thickness of the base region and the smaller emitter transit time due to the unipolar nature of the device (very few holes are present in the n-type device), another key feature which distinguishes the GBHT from the HBT.

25.2.7 Metal-Insulator-Graphene (MIG) Diodes

Metal-insulator-graphene (MIG) diodes , essentially one-half of the GBTs/GBHTs discussed in the previous section, can be

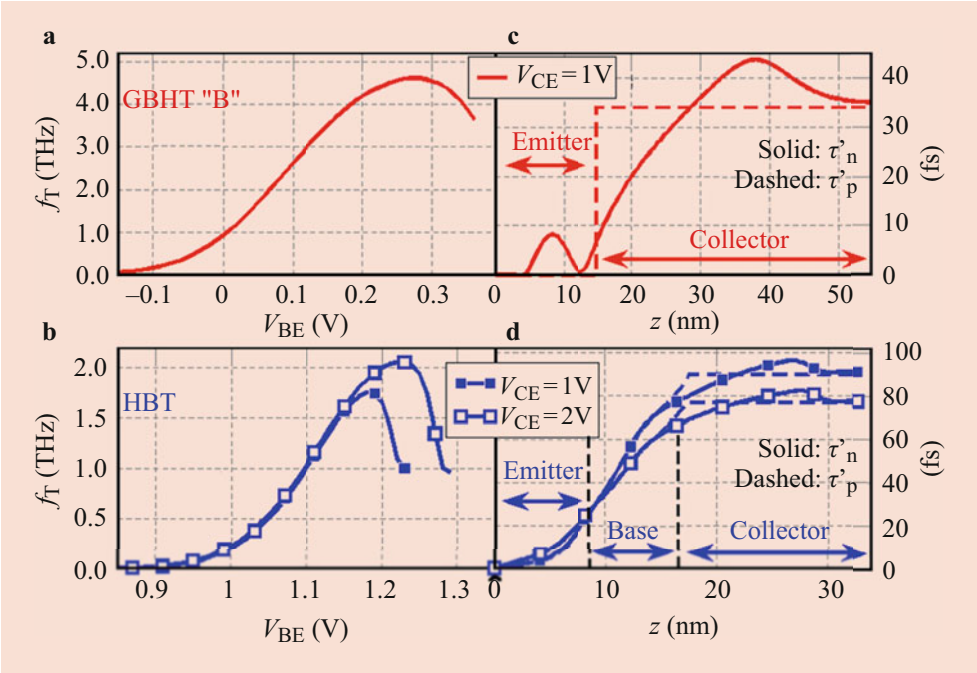

Fig. 25.14 f_T of the GBHT (**a**) and HBT (**b**), showing the capability of the former to outperform the HBT's cutoff frequency by a factor higher than 2. utilized to realize different functional circuits. We therefore consider them as alternative devices for non-transistor-based electronics. The realization of p-n diodes is not possible with graphene, because of the gapless band structure and Klein tunneling, both leading to a linear IV characteristic of p-n junctions in graphene. Hence, MIG diodes have been realized and developed for several high-frequency circuit applications.

MIG diodes consist of a layer of graphene, an insulting layer, and a metal electrode similar to metal-insulator-metal (MIM) diodes. Current can flow through the insulator from the metal to the graphene either by tunneling or by thermal emission, depending on the insulator material. Due to asymmetric work functions of the metal and graphene, the IV characteristic is nonlinear. This effect is enhanced by a biased induced barrier height modulation on the graphene side, and thus the asymmetry of these diodes is higher compared to conventional MIM diodes. In 2014, a graphene/hBN/-graphene tunneling diode with a 6-nm-thick hBN barrier was experimentally demonstrated [88]. The diode showed DC rectification, with relatively low current levels of up to 10 nA. The diode was made by exfoliation of hBN and graphene, which is not a scalable process and was not characterized at RF frequencies. In 2016, an MIG based on 2-nm TiO_2 as insulator material was demonstrated [89], where thermal emission dominated the transport over tunneling. Yet again, the current levels were rather low (tens of nA), the characterization was limited to DC operation, and the fabrication process was based on graphene flakes. This MIG concept was extended with a similar layout and materials (6-nm TiO_2 as insulator) toward a fully scalable technique in 2017 [86] (Fig. 25.15a, b). The current level in these diodes was up to 100 μA, and characterization was performed at RF frequencies. The diodes showed asymmetry up to 520, nonlinearity up to 15, and responsivity up to 26 V^{-1}. The RF bandwidth defined by the RC product was about 30 GHz, with further improvements expected. The so-called one-dimensional (1D) MIG diodes, which form the junction only at the 1D edge of graphene, are expected to increase RC bandwidth to above 1 THz (Fig. 25.15c, d). Since the MIG diodes are quite reproducible compared to the current state of GFETs, there have been more complex ICs fabricated based on MIG diodes, such as power detectors [90, 91], receivers [92], mixers [93, 94], and frequency doublers [95], with examples shown in Fig. 25.16.

MIG diodes are very competitive to MIM diodes in their key DC characteristics, namely, nonlinearity, asymmetry, and responsivity (Table 25.6). The RF bandwidth is not yet competitive to silicon and III-/V-based p-n junction or Schottky diodes, which have RC bandwidth of up to or even above 1 THz; however, for many ICs, this bandwidth is not required at the moment. Theoretical calculations predict that several THz of bandwidth should be attainable with MIG diodes through design optimization. MIG diodes are thus very promising, in particular for IoT applications and for flexible electronics, because of their reasonably high performance and compatibility with thin-film processing. Applications at higher frequencies (>100 GHz) may be explored for applications like THz imaging sensors or radar, if the RC bandwidth can be improved.

25.3 Carbon Nanotube-Based Transistors

After we have gained some insight on graphene, we will now start to discuss on CNTs, which can be considered as a one-dimensional tube rolled up from a sheet of graphene.

25.3.1 Band Structure of CNT

The structure of CNTs can be described by the circumference vector or chiral vector **C**, which represents the full circumference of the tube and is defined by

$$\mathbf{C} = n\mathbf{a}_1 + m\mathbf{a}_2 \equiv (n, m)$$

where a_1 and a_2 are the unit vectors in the two-dimensional plane and n and m are integers. This defines singe-wall CNTs, i.e., CNTs that have walls which consist of a single-graphene sheet. CNTs made up of several layers of graphene are called multiwall carbon nanotubes. They are not discussed in detail in this chapter, but are well covered in literature [98–101]. The propagation vector $\mathbf{T}_a$ is perpendicular to **C** and represents the periodicity of the tube along the tube axis (Fig. 25.17). The chiral angle θ ($0 \leq \theta \leq 30^\circ$) is defined as the angle between **C** and $\mathbf{a}_1$. As shown in Fig. 25.17, depending on different edges after rolling up, CNTs can be classified into three different groups: zigzag, armchair, and chiral types. If $n = m$, we have $\theta = 30^\circ$, and the CNT is armchair-type. If $m = 0$, we have $\theta = 0$, and the CNT is zigzag-type. For other situations with $0 < \theta < 30^\circ$, the CNTs are known as chiral-type, because they produce a mirror image of their structure upon an exchange of n and m.

For a (n, m) CNT, the circumference of the cross section L, the tube diameter d, and the chiral angle θ are defined as below, respectively [6]:

$$L = |\mathbf{C}| = \sqrt{\mathbf{C} \bullet \mathbf{C}} = a\sqrt{3\left(n^2 + nm + m^2\right)} \tag{25.11}$$

$$d = \frac{L}{\pi} = \frac{a}{\pi}\sqrt{3\left(n^2 + nm + m^2\right)} \tag{25.12}$$

$$\cos\theta = \frac{\mathbf{C} \cdot \mathbf{a}_1}{|\mathbf{C} \cdot \mathbf{a}_1|} = \frac{2n + m}{2\sqrt{n^2 + nm + m^2}} \tag{25.13}$$

Many electronic properties of CNTs are determined by the tube diameter and chiral angle, which are essentially defined by n and m.

We can derive the band structure of CNTs from that of graphene. For CNTs, a periodic boundary condition should be met along the circumference, which is

$$\mathbf{k} \cdot \mathbf{C} = 2\pi\nu \tag{25.14}$$

where ν is an integer and $\mathbf{k} = (k_x, k_y)$ is the allowed wave vector. Through the boundary condition, the allowed wave vector is now restrained to a set of lines in 2D plane. Each line with a different ν corresponds to a subband. If one of the lines intersects the K (or K') points, the resulting CNT is metallic; otherwise, they are semiconducting. Based on a geometrical analysis of Eq. 25.13, a rough conclusion can be drawn. If $n - m$ is a multiple of 3, the CNTs are metallic, while otherwise they are semiconducting with a bandgap of [6]

$$E_g \cong \frac{0.7}{d\,(\text{nm})}\text{eV}. \tag{25.15}$$

However, these considerations do not take the curvature of the tubes into account. Therefore, the conclusions are mainly valid for CNTs with relatively big diameter. For small CNTs, the curvature modifies their electronic structure. Thus, one typically observes a bandgap independent of chirality due to the quantum confinement effect [103].

Here we have two examples. In the case of an armchair tube (3,3), the periodic boundary conditions yield allowed values for the wave vector in circumferential direction according to

$$k_{y,\nu} = \frac{2\pi\nu}{3\sqrt{3a}} \tag{25.16}$$

where $\nu = 0, \pm 1, \ldots, \pm 3$. Figure 25.18a shows the projection of the allowed 1D states onto the first Brillouin

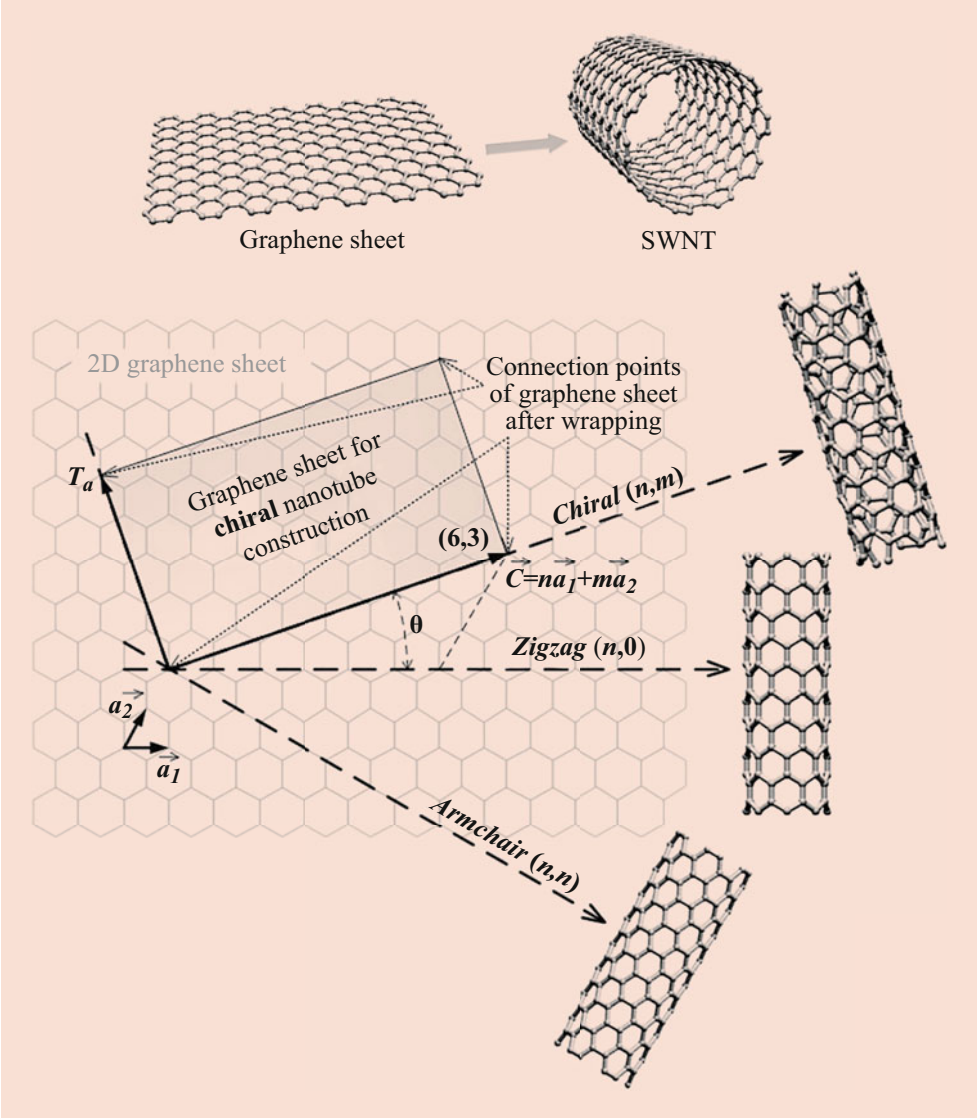

Fig. 25.17 The structure of CNT and different types of CNTs. (Republished with permission from The Royal Society of Chemistry, from [102])

zone of graphene, as well as the energy dispersion. Due to the periodic boundary condition in Eq. 25.16, the allowed states condense into lines (white lines in Fig. 25.18a). Here, there are three lines on either side of the center of the Brillouin zone and an additional line going through the center. In case of a (3,3) tube, the allowed states include the K points. The (3,3) tube and armchair tubes in general thus show metallic behavior.

As an example of a chiral tube, Fig. 25.18b shows the projection of the allowed 1D states onto the first Brillouin zone of graphene, as well as the energy dispersion for a (4,2) tube. Again, due to the periodic boundary conditions, the allowed states condense into lines (white lines in Fig. 25.18b). In contrast to the (3,3) tube, the $\mathbf{C}_h$ vector is not in parallel to the y-direction, and hence leads to a mixed quantization of k_x and k_y. The propagation of an electron along the tube axis is described by a combination of k_x and k_y components. The band structure of (4,2) tubes is determined by the fact that there are no modes which include the K points of the Brillouin zone of graphene. Therefore, a bandgap appears in the dispersion relation, and this type of tube is a semiconductor. The bandgap is of the order of a few eV.

25.3.2 CMOS and Integrated Digital Circuits Based on CNT

In order to realize simple CNT-based transistors, one approach is to place a CNT on a silicon wafer with SiO_2 as dielectric layer. After contacting two ends of the tube with appropriate metal electrodes, the device is ready to function as a back-gated transistor (Fig. 25.19). The silicon substrate

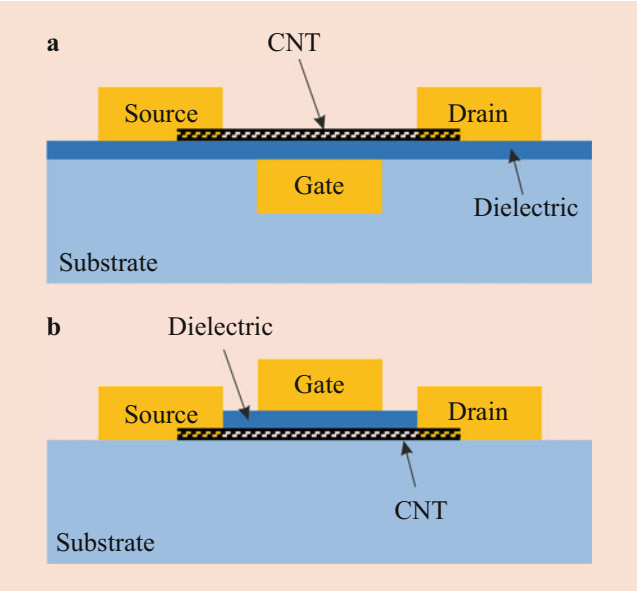

Fig. 25.19 Bottom-gate (**a**) and top-gate (**b**) CNT-based transistors

can be utilized as a gate electrode, and the contacts to the CNT serve as source and drain electrodes. Since many CNTs have a bandgap, CNT-based transistor can be switched off. In 1998, Tans et al. and Martel et al. successfully demonstrated the first back-gated CNT transistor independently by using Pt as contacting electrodes [105, 106]. These prototype transistors are not ideal due to the Schottky contact with platinum (Pt), resulting in a low on-state current. Javey et al. used palladium (Pd) contacts and obtained high-performance p-type CNT transistors [107]. This is because the contact with Pd is ohmic and the transistors showed ballistic transport. For a long time, n-type CNT transistors have been difficult to realize. In 2007, it was found that scandium can form n-type ohmic contacts with CNTs and later the same was found for yttrium [108–110]. These efforts enabled the realization of CNT CMOS circuits. A symmetrical top-gate CMOS inverter was demonstrated [111], and integrated circuits based on single CNTs have also been realized, demonstrated in Fig. 25.20 [112, 113]. Doping-free CNT transistors are of great advantage since for such an approach there is no need to modify the lattice structure of the CNTs or to use charge transfer doping at the CNT/gate dielectric interface, which typically reduces the performance of CNT transistors.

Due to the short-channel effect in traditional silicon MOSFETs, planar gates can no longer provide proper field-effect modulation for channels shorter than approximately 20 nm. Therefore, new device architectures such as FinFETs or multigate transistors were developed. CNT FETs have ultrathin channels defined by their diameter, which gives them near ideal scaling behavior. In addition, CNTs provide a nearly unperturbed inside, which allows ballistic transport over large distances and hence large potential for high on currents. CNT p- and n-type transistor with gate length of 10 nm has been demonstrated recently, with near ideal room-temperature subthreshold swing of 70 mV/dec [114].

Transistors based on a single CNT result in competing performance even compared to silicon-based technology. Yet, large-scale production is challenging since the control of the chirality and diameter of CNTs during synthesis does not yet meet semiconductor reproducibility standards. Hence, manufacturing of circuits with billions of nearly identical single CNT transistors on a wafer scale, as is the norm in silicon technology, is highly unlikely. Nevertheless, alternatives such as dense CNT arrays or CNT networks have been used for CMOS integrated circuit fabrication [115–120]. Compared to single CNTs, array- or network -based thin-film transistors can result in a fairly uniform performance over wafer scale since the CNTs can be presorted by using chemical methods [121]. Here, the device performance does not depend on single CNTs, but rather the average of many. Even in such arrays, metallic CNT components, control of CNT density, and contact resistance variations remain challenges for digital circuit applications [122].

Despite these challenges, CNT-based digital integrated circuits reached new integration levels, with a modern microprocessor with 14,000 CMOS transistors demonstrated in 2019 (Fig. 25.21) [123]. This 16-bit microprocessor is based on the RISC-V instruction set, and it runs standard 32-bit instructions on 16-bit data and addresses. In this technology demonstration, p-type and n-type transistors have

been realized through contact engineering using Pt and Ti metal contacts in combination with silicon oxide and hafnium oxide, respectively. This design and fabrication methodology for CNT technology is proposed to overcome the imperfections inherent in the materials system. This technology is also suitable for circuits made on flexible substrates [124]. Finally, a heterogeneous integration on a chiplet level may enable simple co-integration with silicon logic or memory [125].

25.4 Summary

Carbon electronics has remained a high potential candidate for future electronic applications. Although no products are on the market today, the performance and maturity of demonstrators and fabrication technologies for graphene and CNTs keep improving. At the same time, silicon technology keeps moving along at an incredible pace, driven by business demands. Hence, the investments for developing silicon technology are extraordinarily higher than for developing carbon technology. This means that carbon-based devices or circuits might become products if they found niche applications first, similar to early-stage compound semiconductor technology. Here flexible electronics may provide a suitable platform, as existing technologies cannot compete in terms of performance with carbon electronics. For example, CNT processors or graphene analog circuits can easily be manufactured on flexible substrates. In addition, 3D stacking of functional layers in conjunction with silicon CMOS may be an entry point for graphene and CNTs. This and other co-integration approaches provide further opportunities for additional functionality in silicon technology, i.e., for sensing, optoelectronics, photonics, or novel fields like neuromorphic or quantum computing. In summary, although silicon technology is still superior in integration density and overall performance, these advances show potential routes for carbon to enter the semiconductor industry.

Dr. Zhenxing Wang is the Head of the Graphene Electronics Group at AMO GmbH. He obtained his PhD degree in 2012 from Peking University in China, with the topic of carbon nanotube and graphene-based radio frequency electronics. After that, he joined the University of Erlangen-Nuremberg as a Postdoctoral Researcher, working on solution-based 2D materials-based nanodevices. From 2014, he has been with AMO, where he is responsible for development of graphene-based electronics, especially for high-frequency applications. He is leading different German national projects as well as EU international projects.

Prof. Dr. Daniel Neumaier is a Full Professor for Electrical Engineering at the Bergische Universität Wuppertal and Scientific Advisor at AMO GmbH since 2020. He studied physics and obtained his PhD degree in 2009. Afterward, he joined AMO as Head of a research group focusing on the exploitation of two-dimensional materials in microelectronics and photonics. He is or was Principal Investigator in several national and European projects on electronic and photonic devices. He is currently Leader of the Graphene Flagship's work package on electronic devices and coordinating the FET-Open Project ORIGENAL. He has been organizing several international conferences and schools (EuroCarbon 2010, Graphene Week 2013, X-Mas School on Spintronic 2014, GrapheneStudy 2015 and 2017).

Prof. Dr. Max Christian Lemme is a Full Professor at RWTH Aachen University and the Director of AMO GmbH. He obtained his PhD degree in Electrical Engineering from RWTH in 2004. He has worked on nano-CMOS devices and technology, including FinFETs and SOI-MOSFETs, high-k/metal gate stacks and graphene, and 2D materials. He received the "NanoFutur" Award from the German Ministry for Education and Research in 2006 and a Humboldt Fellowship in 2007. In 2008, he joined Harvard University in Cambridge, USA, to work on helium ion-based nanolithography and graphene photodetectors. In 2010, he became Professor at KTH Royal Institute of Technology, Sweden. He received an ERC Starting Grant and became Full Professor at the University of Siegen, Germany, with a DFG Heisenberg Professorship in 2012. He was appointed Full Professor at RWTH Aachen University and Scientific Director of AMO GmbH in 2017. He has coordinated numerous national and European research projects.

Abstract

The long-standing tug-of-war between off-state leakage power consumption and switching speed has posed severe challenges to the scaling of semiconductor devices. Deeply scaled short-channel transistors are faster but consume more off-state power. This power vs speed trade-off stems from the fundamental physical limit related to the thermionic emission that governs switching in field-effect transistors. There is a broad consensus in the semiconductor industry that future progress is impossible unless the next-generation transistors and circuits overcome the so-called Boltzmann limit associated with thermionic emission over a barrier and offer a steeper on-off switching to enable a more aggressive voltage scaling.

In this chapter, we explain the need for and suggest an intuitive classification of the emerging transistor technologies. We use two illustrative examples of next-generation transistors (i.e., negative capacitance FET (NCFET) and phase FET (PhaseFET)) to explain the relative merits of gate-controlled vs channel-controlled steep-slope switching. We explain the basic principle of device operation, summarize the experimental results reported in the literature, and highlight the speed and reliability challenges to be resolved before the devices are integrated into practical systems. In addition, the chapter includes a careful analysis of circuits based on these emerging transistor technologies with applications toward Boolean logic, memories, and non-Boolean computing. The analysis suggests relative merits of various circuit designs and application-specific opportunities for significant power-performance improvement.

26.1 Introduction

Since the early 1970s, the progress in the semiconductor industry has been dictated by the scaling of (field-effect) transistors that allow each generation of devices to have significant performance improvements over its predecessor. The tremendous growth of the computing power was driven by Moore's law from the cost/economical point of view and by Dennard scaling from the performance/physical point of view. A decisive change of course began to occur at the beginning of the twenty-first century, when transistor speed began to saturate due to self-heating and the limits of power dissipation ($\sim$100 W/cm^2) in an integrated circuit were reached.

This problem was initially solved (or circumvented) (a) from the system point of view by switching to multicore architectures and (b) from the device perspective by devising new scaling rules. These rules formed the so-called "equivalent scaling" roadmap, which relied on the introduction of new insulating materials (to limit the leakage power consumption) and of complex three-dimensional geometries (to improve electrostatic control and limit the short-channel effects). Although scaling was effectively preserved and performance could still improve, the issues brought up by new geometries in terms of self-heating (and thus temperature rise) threatened to stop transistor scaling once more. This aspect motivated researchers to focus on new device concepts with the ultimate goal of decreasing power dissipation and thus control temperature rise in transistors. The equivalent scaling rules, which are expected to be effective until around 2025 [1], will need to be replaced by next-generation transistors and computing architectures to sustain the semiconductor industry.

26.1.1 Classification of Next-Generation Transistors

It has been clear since the 1990s that next-generation transistors would have to circumvent the fundamental limits of classical Boltzmann field-effect transistors (FETs). The initial focus on tunnel FET (TFET) and resonant-tunneling transistors has now broadened to include NCFET, PhaseFET, MottFET, MEMS relay, etc. These beyond-Boltzmann FETs rely on new physical principles and device designs to overcome the fundamental limit of transistor switching. This limit is related to the energy required by electrons to overcome a potential barrier, expressed in multiples of k_BT (k_B is the Boltzmann constant, and T is the temperature), which in turn forces the minimum voltage swing required to decrease the transistor current by one order of magnitude to the value of 60 mV/dec at room temperature. This minimum voltage swing is called subthreshold swing (SS) and is expressed as follows:

$$\begin{aligned} SS &= \left(\frac{\partial \log I_D}{\partial V_{GS}}\right)^{-1} = \left(\frac{\partial \psi_s}{\partial V_{GS}} \times \frac{\partial \log I_D}{\partial \psi_s}\right)^{-1} \\ &= \left(\frac{\partial \psi_s}{\partial V_{GS}}\right)^{-1} \times \left(\frac{2.3 k_B T}{q}\right) \\ &= m \times n \approx m \times 60\ \text{mV/dec} \end{aligned} \tag{26.1}$$

where I_D is the drain current, V_{GS} is the gate-to-source bias voltage, ψ_s is the surface potential, m is the body factor (described more in detail later), n is the transport factor, and q is the elementary charge. The SS imposes a lower limit on the minimum allowable operating voltage for a target on- to off-current ratio of $V_{min} \approx SS \times \log (I_{ON}/I_{OFF})$. It is then clear than to further reduce power dissipation, SS needs to be decreased. From Eq. (26.1), it is possible to devise different strategies to reduce SS, through either m or n. The classes of transistors belonging to the family of beyond-Boltzmann devices – originating from the attempts of reducing m and/or n – can be classified as follows:

- *Non-thermionic FETs* ($m = 1$, $n < 60$) exploit physical mechanisms different from the thermionic emission to control the channel conduction. One can either reduce the electron temperature below the lattice temperature to suppress off-state conduction or use positive electrothermal feedback to enhance on-state conduction. This category includes TFETs [2, 3], impact ionization FETs (IFETs) [4], PhaseFETs [5], and MottFETs [6].
- *Landau FETs* ($m < 1$, $n = 60$) exploit the "negative capacitance" effect to lower the body factor [7, 8]. This category includes NCFET, nano-electromechanical FET (NEMFET) [9], suspended-gate FET (SGFET), etc.
- *Super FETs* ($m < 1$, $n < 60$) combine the benefits of non-thermionic FET and Landau FETs to obtain minimum subthreshold swing, such as the negative capacitance tunnel FETs (NC-TFETs) [10] or phase change tunnel FETs (PC-TFETs) (with the phase transition material (PTM) layer inserted in the gate stack [11]).

Figure 26.1 summarizes the different class of transistors in the space defined by the possible combinations of m and n, including also classical Boltzmann FETs, characterized by $m > 1$ and $n = 60$. In this chapter, we will focus on two illustrative examples of next-generation switches, namely, NCFETs and PhaseFETs. In the following, we will explain device physics, reliability limits, as well as circuit implications of these transistors.

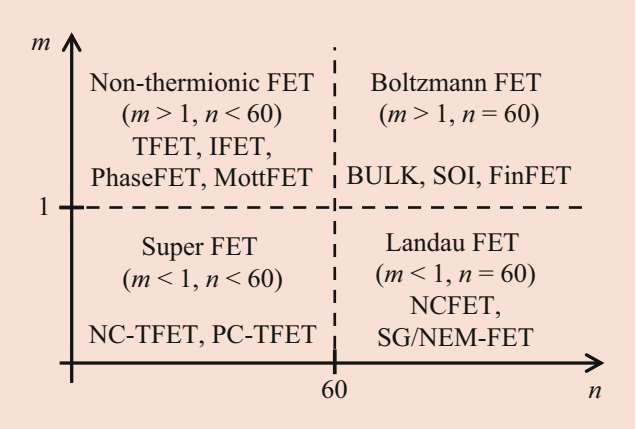

Fig. 26.1 Transistor classes in the $m \times n$ space. NCFETs belong to the Landau switch category, where m is reduced, thanks to the stabilized negative capacitance effect. PhaseFETs (and MottFETs) belong to the non-thermionic FET class as they alter the channel transport to achieve $n < 60$

26.1.2 Phase Transition and Landau Theory

We now briefly discuss some elements of phase transition and Landau theory which are at the foundation of both NCFETs and PhaseFETs operation. Phase transitions are changes occurring in a thermodynamic system when a certain order parameter of the system itself changes suddenly in response to an external stimulus. Examples of materials that undergo phase transitions are $BaTiO_3$, which experience dielectric to ferroelectric transition [12], and VO_2, which experiences insulator-to-metal transition [5]. Regardless of the physical stimulus triggering phase transition, the order of the system is disrupted from its previous state, which can be restored if the reverse process is stimulated. This interesting physical behavior is at the core of the operation of the devices discussed in this chapter.

In ferroelectric materials, the stored energy as a consequence of phase transition can trigger the so-called negative capacitance behavior [7]. This behavior occurs only if the instability associated with the negative capacitance (NC) effect can be stabilized (and this is indeed achieved by device design, as discussed in Sect. 26.2). The free energy of a ferroelectric U (in the case of uniform, mono-dimensional polarization) can be written as follows:

$$U = \alpha P^2 + \beta P^4 + \gamma P^6 - E \times P \qquad (26.2)$$

where, α, β, γ are material parameters, E is the external applied electric field, and P is the polarization of the ferroelectric. For a negative capacitor, α is always negative [7].

Although the Landau theory allows for a phenomenological interpretation of ferroelectric behavior (based on a mean-field approach [13]), it can be shown that the Gibb's free energy as written in Eq. (26.2) can be derived also starting from microscopic physics arguments [14]. In practice, this allows to connect the Landau parameters (α, β, γ) to physical properties of the ferroelectric (such as dielectric constant, temperature dependence, and so on). In Sect. 26.2, we will discuss how we can use Eq. (26.2) to deduce the NC behavior and exploit the effect for novel transistor design.

For PTMs employed in PhaseFETs, such as vanadium dioxide (VO_2), when the device temperature reaches a critical temperature (T_c), an abrupt transition occurs causing the material to switch between metal and insulator states, and vice versa. The temperature of a PhaseFET varies due to self-heating determined by the current flow as controlled by the transistor. The phase transition of VO_2 leads to the sub-thermionic switching of the transistor, as we will discuss in more details in Sect. 26.3.

26.2 Device Physics of NCFETs

In this chapter, we will describe the fundamental aspects of the physics behind NCFET operation. The discussion is built upon Landau theory introduced in Sect. 26.1.2 that allows deriving the electrostatics of the system composed by a conventional metal oxide semiconductor FET (MOSFET) and the NC layer (i.e., the ferroelectric layer).

26.2.1 Phenomenological Theory of NCFETs

Figure 26.2 shows the two typical NCFET configurations: metal-ferroelectric-insulator-semiconductor (MFIS) (Fig. 26.2a) and metal-ferroelectric-metal-insulator-semiconductor (MFMIS) (Fig. 26.2b). Regardless of the specific configuration, an appropriately designed ferroelectric layer can behave like a negative capacitor, storing energy and thus amplifying the applied gate bias [1, 7]: this phenomenon is the fundamental mechanism for the steep *SS* in NCFETs. The oxide layer between the ferroelectric and the semiconductor (either with the metal in between or not) is required in order to stabilize the ferroelectric in the NC region and to obtain sub-60 mV/dec *SS*.

Body Factor Reduction with Negative Capacitors

Before moving into the details of NCFET device physics, it is instructive to understand how the body factor m can be reduced through the negative capacitance effect. To illustrate

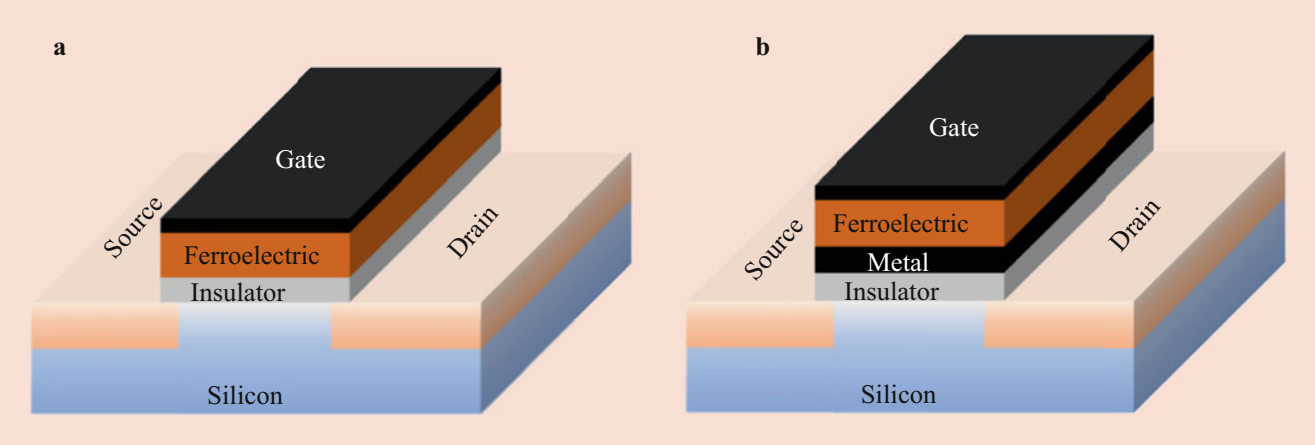

Fig. 26.2 Sketch of the NCFET configurations: (**a**) MFIS and (**b**) MFMIS. If stabilized, the ferroelectric layer in the gate stack can provide voltage amplification to reduce the subthreshold slope

the concept, we will consider a simple network of three capacitors in series, as shown in Fig. 26.3a. This network simplifies the gate stack of NCFETs composed by the NC layer, (C_{NC}), the gate oxide layer (C_{ox}) (SiO_2, normally), and the semiconductor layer (C_s). For simplicity, we will consider C_s to be a constant. Thus, the relation between ψ_s and V_{GS}, can be written as (see Fig. 26.3a)

$$m \equiv \frac{\partial V_{GS}}{\partial \psi_s} = 1 + \frac{C_s}{C} \tag{26.3}$$

where $C \equiv (C_{NC} + C_{ox})/(C_{NC}C_{ox})$. Since $C_{NC} < 0$, then $m < 1$ and $SS < 60$ mV/dec. Reducing m and SS leads to lower-power consumption, as the off-state current $I_{OFF} = I_D(V_{GS} = 0)$ is reduced. This can be simply understood from the relationship between V_{GS} and subthreshold current:

$$I_{OFF} = I_0 \times e^{\frac{q\psi_s}{kT}} \sim I_0 \times e^{\frac{-qV_T}{mkT}} \tag{26.4}$$

where V_T is the threshold voltage of the transistor and I_0 a proportionality factor (which depends on device properties). Figure 26.3b shows graphically the reduction in I_{OFF} obtained with NCFETs compared to conventional MOSFETs.

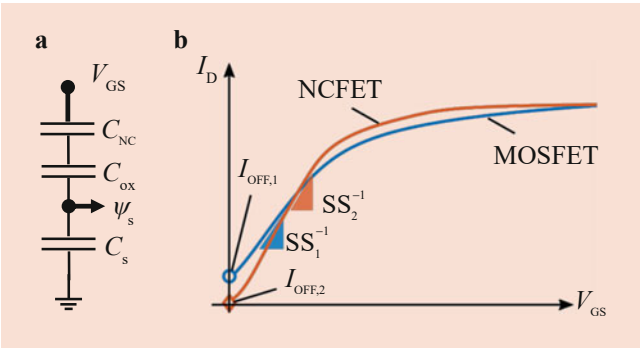

Fig. 26.3 (**a**) Simplified capacitor divider network of the gate stack to illustrate the concept of body factor m reduction. If a negative capacitance layer is used, such that $C_{NC} < 0$, then $m \equiv \partial V_{GS}/\partial \psi_s < 1$, and SS is reduced. (**b**) I_D–V_{GS} characteristics of a MOSFET (blue solid line) and NCFET (red solid line) showing that reduced SS leads to reduced I_{OFF} and thus lower-power consumption

Capacitance Matching Condition

Having clarified the role of NC in body factor reduction, we can discuss more in detail the physics of NCFETs. The discussion focuses on how to obtain effective reduction in SS by careful matching of the nonlinear C_s and C_{NC}. The NCFET analysis is presented considering a bulk MOSFET as the underlying transistor (however, it can also be adapted to encompass different kinds of transistors). The capacitance network needed to calculate the body factor reduction in an NCFET is shown in Fig. 26.4. C_{FE} is the ferroelectric (FE) layer and C_{MOS} is the MOSFET gate stack capacitance, composed by the series of the gate oxide layer, C_{ox}, and the semiconductor capacitance, C_s.

Compared to a standard MOSFET, an NCFET has an extra capacitance C_{FE} that adds an additional voltage drop, V_{FE}, to that of the gate oxide, V_{ox}. If the FE is stabilized in the NC region, then V_{FE} can become negative, thus providing voltage amplification. The constraint to guarantee the stable operation in the NC region is defined as the capacitance matching condition (CMC). We will derive the CMC starting with the ψ_s vs V_{GS} relation obtained by invoking the Kirchhoff voltage law (KVL) at the gate-to-source loop. This approach

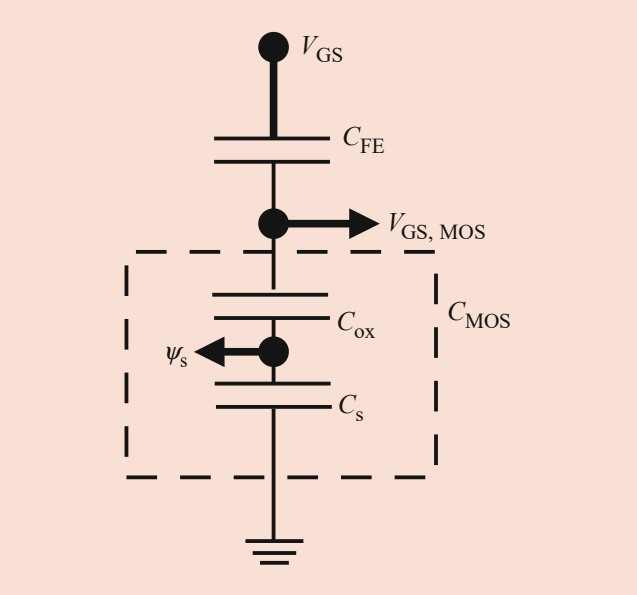

Fig. 26.4 Network capacitance for deriving the KVL at the gate-to-source loop. The voltage gain A_V between V_{GS} and $V_{GS,\,MOS}$ becomes >1 when C_{FE} is negative and with magnitude close to C_{MOS}

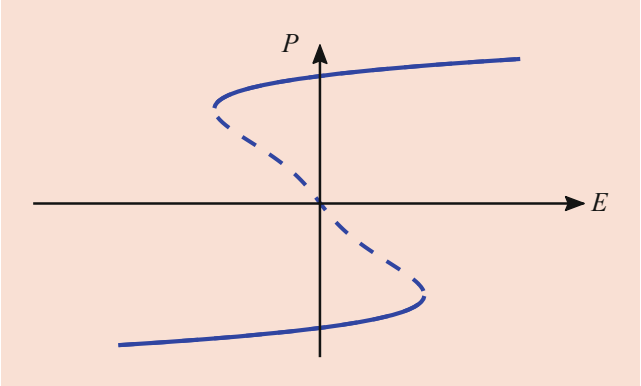

Fig. 26.5 P – E loop representing the solution of the time-independent LKE. The parameters chosen are $\alpha = -1.0 \times 10^7$ m/F, $\beta = -8.9 \times 10^8$ m^5/F/C^2, and $\gamma = 4.5 \times 10^{10}$ m^9/F/C^4 for $BaTiO_3$ [7, 17]. The dashed line represents the part of the loop for which negative capacitance occurs

is equivalent to the minimization of the Gibb's free energy of the system [15] and thus is physically sound within the limits of the validity of the theory. The KVL can be written as follows [16, 17]:

$$V_{GS} - V_{FB} = V_{FE} + V_{ox} + \psi_s \tag{26.5}$$

where V_{FB} is the flat-band voltage. V_{FE} is obtained from the phenomenological description of the FE behavior as given by the Landau-Khalatnikov equation (LKE) [7]. The LKE in the case of one-dimensional polarization component reads as follows:

$$\rho \frac{dP}{dt} + \frac{\partial U}{\partial P} = 0 \tag{26.6}$$

where U is the Gibb's free energy of the ferroelectric (see Eq. (26.2)) and ρ is the ferroelectric damping parameter (inversely related to the switching speed of the system). From Eqs. (26.2) and (26.6), it is possible to write an expression for the electric field applied to the ferroelectric as a function of the polarization, as follows:

$$E = 2\alpha P + 4\beta P^3 + 6\gamma P^5 + \rho \frac{dP}{dt} \tag{26.7}$$

By equating the polarization of the ferroelectric, P, to the semiconductor charge Q_s (i.e., the second term in $Q = P + \varepsilon E$ is considered to be negligible for simplicity, as the electric field in the ferroelectric is small [16]) and by focusing on the steady-state response (i.e., $\rho\, dP/dt = 0$ in Eq. (26.6)), then V_{FE} can be written as

$$V_{FE} = T_{FE}\left(2\alpha Q_s + 4\beta Q_s^3 + 6\gamma Q_s^5\right). \tag{26.8}$$

where T_{FE} is the ferroelectric layer thickness. From this equation, one can define the NC region that gives rise to body factor reduction, as shown in Fig. 26.5. The characteristic "S-shaped" curve between the two stable polarization branches (i.e., $-P$ and $+P$) represents the unstable NC region, where $(\partial^2 U/\partial P^2)^{-1} < 0$. This point will be discussed further in Sect. 26.2.2 for the whole class of NC systems, called Landau FETs. Thus, in the NC region, V_{FE} can assume negative values, so that the effective gate voltage seen by the MOSFET, $V_{GS,MOS}$, becomes larger than the applied bias. That is:

$$V_{FE} < 0 \Rightarrow V_{GS,MOS} = V_{GS} - V_{FE} > V_{GS} \tag{26.9}$$

We can define the internal voltage gain, A_V, as follows:

$$A_V \equiv \frac{dV_{GS,MOS}}{dV_{GS}}. \tag{26.10}$$

When the transistor is stabilized in the NC region (i.e., $A_V > 1$), the internal voltage amplification allows to achieve steep-slope operation. The capacitor divider network in Fig. 26.4 allows then to derive a simple equation for A_V through the expressions of C_{FE} and C_s. The former, C_{FE}, is derived by taking the inverse of $\partial V_{FE}/\partial Q_s$ [16]:

$$C_{FE} = \frac{1}{T_{FE}\left(2\alpha + 12\beta Q_s^2 + 30\gamma Q_s^4\right)} \tag{26.11}$$

Thus, simply

$$A_V = \frac{C_{FE}}{C_{FE} + C_{MOS}} = \frac{|C_{FE}|}{|C_{FE}| - C_{MOS}} \tag{26.12}$$

Clearly, A_V is maximized if $|C_{FE}| \rightarrow C_{MOS}$: this is the CMC. In the following, we discuss the design constraints necessary for CMC.

Design Constraints for Gain Maximization

To maximize A_V and reduce *SS*, it is crucial to design C_{FE} to match C_{MOS}. Since both C_{FE} and C_{MOS} are nonlinear and bias-dependent, CMC can only be obtained for a limited V_{GS}. Indeed, Fig. 26.6 shows that the ferroelectric thickness T_{FE} dictates the I_D–V_{GS} characteristics (Fig. 26.6a), the internal voltage amplification A_V–V_{GS} (Fig. 26.6b), and the corresponding *SS*–V_{GS} (Fig. 26.6c) ($T_{FE} = 0$ nm in Fig. 26.6 corresponds to a stand-alone MOSFET). Figure 26.6c confirms that *SS* is reduced significantly only over a limited range of V_{GS} because of the nonlinear, voltage-dependent C_{FE} and C_s. In general, transistors based on other semiconductor technologies (such as Ge, 2D metal transition dichalcogenides, compound semiconductors, and so on) will have different *SS* values for different V_{GS} range [18]; thus, each technology must be optimized based on their specific geometry and operating conditions. Section 26.2.4 summarizes the experimental results of NCFETs for different technologies, showing a relatively large scatter among the *SS* values due to different CMC conditions.

Subthreshold Swing and Hysteresis Trade-Off

From Fig. 26.6, we notice that although *SS* is reduced with increasing T_{FE}, at some critical value, T^*_{FE}, hysteresis in the I_D–V_{GS} characteristics appears. Thus, optimum design of NCFET must ensure that the *SS* reduction does not lead to excessive hysteresis. This undesirable feature arises when the total gate capacitance becomes negative, i.e., when $|C_{FE}|$ becomes smaller than C_{MOS}. During hysteretic operation, the ferroelectric starts switching between two stable states (indicated by the solid lines in Fig. 26.5) and skips the NC region. In this scenario, the *SS* might still be lower than 60 mV/dec but not due to the NC effect but rather to abrupt polarization switching [18]. It is important to avoid hysteresis in digital and, more importantly, in analog applications that would otherwise lead to larger power consumption and circuit overheads to manage the nonsymmetrical turn-on and turn-off characteristics. To summarize, maximization of A_V may lead to undesirable hysteresis; therefore, the design of a "well-tempered" NCFET must balance the two requirements of hysteresis-free and steep-slope operation.

Incidentally, we observe that a whole class of transistors called ferroelectric MOSFETs (FeFETs) using the same device structure as NCFETs [18] relies on hysteresis in the I_D–V_{GS} characteristics to enable a variety of applications. These include low-power and ultrafast nonvolatile memories, computing elements embedded with memory capability (suitable for the logic-in-memory paradigm), and cross-bar arrays for artificial neural networks [19]. Some of the possible circuit applications of FeFETs (as well as NCFETs) will be discussed more in detail in Sects. 26.4 and 26.5.

26.2.2 Tailoring Negative Capacitance by Energy Landscape Engineering

Let us now generalize the concept of NC operation to a wider range of devices. As discussed in the introduction, NCFETs belong to the family of devices called Landau FETs (or Landau switches) [8]. This class of devices achieves the $SS < 60$ mV/dec metric by reducing the body factor m below 1 (see Eq. (26.1)). The general behavior of Landau FETs can be understood in terms of their energy landscape, which determines the NC region as discussed in Sect. 26.2.1. The energy landscape for a NC system is expressed in Eq. (26.2), which is valid for any system that can switch between two stable states, such as a ferroelectric layer. Basically, an NCFET is a system that combines a positive capacitor with a negative capacitor so that the total energy U_{TOT} can be expressed by

$$U_{TOT} = \left(\alpha + \frac{1}{2\varepsilon}\right) P^2 + \beta P^4 + \gamma P^6 - E \times P. \tag{26.13}$$

The positive capacitor adds up the $1/(2\varepsilon) \times P^2$ term to the Gibb's free energy of the NC, making it possible to stabilize the NC region. The energy landscapes for a positive and negative capacitor are depicted in Fig. 26.8a, b, respectively. Unfortunately, the Landau coefficients are material-specific, and the higher-order terms, β and γ, make the body factor m, voltage gain A_V, and *SS* improvement bias-dependent making it more challenging, in turn, to reach the CMC condition with hysteresis-free operation for the whole V_{GS} range. In general, one could use various series combinations of NC layers in a Landau FET (such as FE, anti-ferroelectric layer (AFE), nano-electromechanical system (NEMS), each with their specific energy landscape) to tailor/flatten the total energy landscape so that CMC is reached for the entire bias range of interest [20, 21].

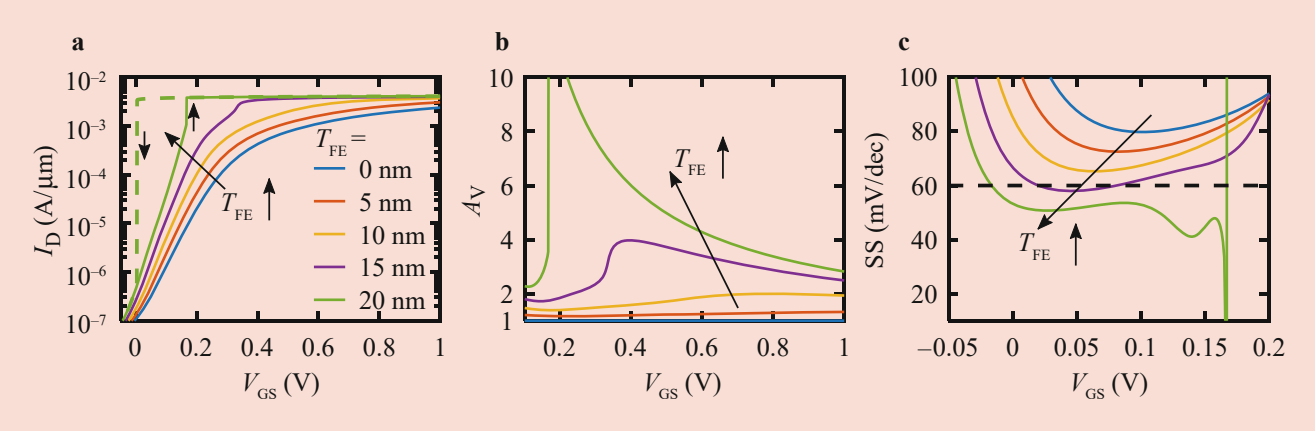

Fig. 26.6 (**a**) I_D–V_{GS} characteristic of a NCFET for different T_{FE} values (see legend). By increasing T_{FE}, (**b**) the voltage gain A_V is increased, and (**c**) at the same time the *SS* is reduced. When $|C_{FE}|$ becomes smaller than C_{MOS}, then the total gate capacitance becomes negative (i.e., unstable), and hysteresis starts to appear, as shown in panel (**a**)

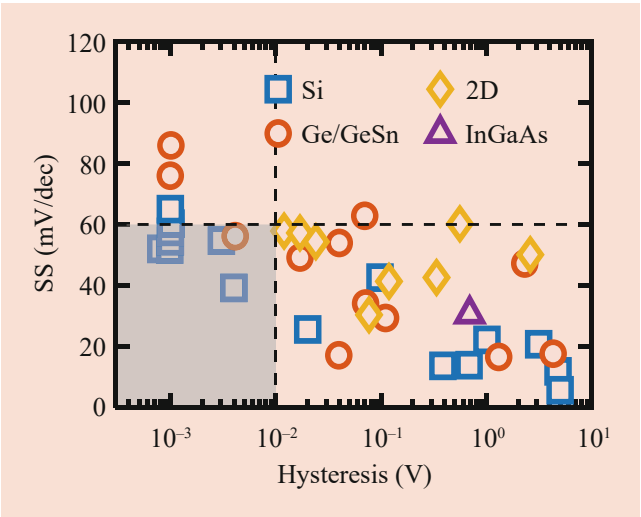

Fig. 26.7 Published experimental data of *SS* vs hysteresis for different NCFET technologies, i.e., Si, Ge/GeSn, 2D, and III–V semiconductors. The shaded area represents a "sweet spot" for an NCFET with $SS < 60$ mV/dec and moderate hysteresis. (Reproduced from [18], with permission from AIP Publishing)

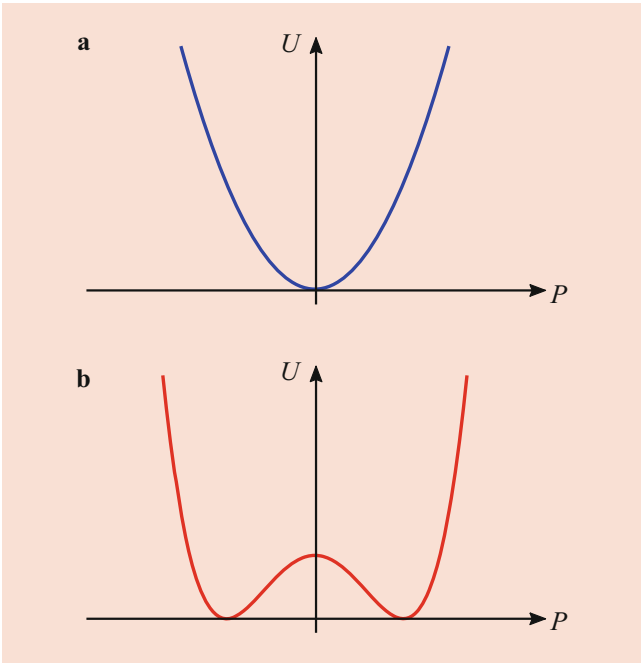

Fig. 26.8 Energy landscape plot, *U*–*P*, of (**a**) the classical positive capacitor and (**b**) the negative capacitor. The capacitance is proportional to $(\partial^2 U/\partial P^2)^{-1}$; thus, its sign is defined by the concavity (up, positive and down, negative) of the *U*–*P* plot

Prospects of Hysteresis-Free Abrupt Switching

In principle, it is possible to design Landau FETs exhibiting ideal $SS \approx 0$ mV/dec with no hysteresis [8]. This can be achieved by properly compensating for the energy barrier present in between the two wells of the energy landscape (see Fig. 26.8b). The extra energy component to compensate for the switching barrier can be provided by a nonlinear capacitor, as for example the depletion layer of a MOSFET. In this way, the intrinsic two-well energy landscape of an NC layer (be either an air gap in a SGFET or a ferroelectric in a NCFET) can be effectively flattened out, removing the switching barrier and eliminating hysteresis. In more realistic cases, however, where neither the semiconductor capacitance nor the negative capacitance is constant throughout the bias range, the *SS* cannot be arbitrarily reduced [20]. In fact, it can

be proved that depending on the particular Landau FET, there exists a minimum *SS* that is dictated by stability constraints to achieve hysteresis-free operation [20]. We conclude by observing that the theory developed in Sect. 26.2.1 can be extended to any kind of Landau FET to achieve optimum design in terms of *SS* and hysteresis.

26.2.3 Reliability Physics of NCFETs

Having discussed the general theory for NCFETs and Landau FETs, we move on with the discussion of the reliability issues of NCFETs. The reliability issues have not yet been systematically quantified [18]; thus, we will summarize the current understanding regarding the reliability issues of NCFETs in comparison with stand-alone MOSFETs:

1. Negative Bias Temperature Instability (NBTI). Negative bias temperature instability is a major reliability concern for traditional MOSFETs [22, 23]. It appears that NCFET suppresses NBTI as a consequence of two counterbalancing effects: First, the threshold voltage shift due to interface traps changes the internal potential of the transistor, thereby modifying the voltage amplification. Second, the charge balance requirement changes the range over which voltage amplification is achieved. Combined with parasitic gate-to-drain capacitance, these two effects are predicted to suppress NBTI degradation in modern Fin (or tri-gate) FETs [24].
2. Time-Dependent Dielectric Breakdown (TDDB). The amplification of internal potential induces higher fields in the oxide layer between the ferroelectric and semiconductor; thus, the TDDB reliability may be compromised if one wishes to increase drive current through voltage amplification [25]. Instead, one should design the NCFET and scale the voltage appropriately so that the interface field (and therefore I_{ON}) remains unchanged and TDDB robustness is preserved.
3. Hot Atom Damage (HAD). First analyzed for ferroelectric switching devices (such as FeFET), HAD is a novel reliability aspect of NCFETs that is associated with the polarization overshoots that might occur during switching [26]. HAD raises reliability concerns as it can lead to dielectric breakdown in FeFETs and Landau FETs. However, in NCFETs, HAD is intrinsically mitigated, thanks to the operating voltage being lower than the coercive voltage of the ferroelectric layer, which reduces the required switching energy [27].
4. Gate Leakage. The presence of a finite current discharging the negative capacitance in NCFET can destabilize the system and cause a loss of the *SS* improvement. Nevertheless, it has been suggested that for fast enough gate voltage cycles, i.e., higher than the time it takes for the leakage current to discharge all the capacitors, NCFETs can still show steep-switching operation [28].
5. Flicker Noise. Fluctuations in the number of traps and in the mobility are at the origin of the so-called flicker noise that, in turn, causes fluctuations in I_D [29]. Interestingly, NCFETs have been found to reduce flicker noise, thanks to enhanced effective gate capacitance [30], with a scaling trend of I_D power spectral density with increasing T_{FE}.

As a general remark, we observe that reliability issues in NCFETs (and Landau FETs) can be potentially mitigated by the fact that these devices reduce static and dynamic power consumption simultaneously, so that the same I_{ON} compared to a stand-alone MOSFET can be achieved at reduced V_{DD}. On the other hand, the fact that the internal potential between the ferroelectric and insulator layer has higher values than a normal MOSFET (due to voltage amplification) can lead to higher degradation in terms of TDDB, self-heating [31], and possibly also NBTI. Therefore, to ensure that NCFETs are able to meet requirements in terms of reliability, it is of paramount importance to properly design these transistors trading off the reduction of *SS* with adequate lifetime.

26.2.4 Advanced Issues

We conclude the discussion on NCFETs by outlining the advanced issues related with the technology that are yet to be fully solved or that are still debated in the community. Given the relatively recent proposal of the NCFET, it is natural that fundamental theoretical aspects and valid experimental demonstrations are still under debate. We will briefly summarize these aspects, with the goal of addressing the most pressing questions that require further investigation to consolidate the NCFET technology.

Single- vs Multi-domain Models

The analysis of NCFETs in Sect. 26.2.1 relied on the tacit assumption that the polarization is uniform across the ferroelectric layer [7]. This simplified picture derives from the adoption of the phenomenological Landau theory, neglecting the microscopic details of a ferroelectric layer. In general, a ferroelectric has multiple domains each associated with its polarization state (in the simplest case, either positive or negative) leading to an overall nonuniform polarization across the layer [32]. The models describing the spatial dependence of the polarization belong to the "multi-domain" models class compared to the "single-domain" one [18]. There are several practical implications of the nonuniform polarization. For example, it can lead to reduced [32] as well as complete loss of NC operation [33]. Further exploration of multi-domain aspects of ferroelectric layer in the NCFET is thus required to harness the negative capacitance behavior and to build

up predictive models to quantitatively characterize realistic NCFETs [34].

Quasi-Static vs Dynamic NC Operation
The steady-state analysis of NCFET in Sect. 26.2.1 neglected the dynamical effects (recall that $\rho dP/dt = 0$). However, NCFET operation (in terms of steep subthreshold switching) can also be interpreted with other models that rely on dynamic effects to explain the decrease of ferroelectric voltage with increasing applied bias. For example, in [35], the NC effect was attributed to the increase of the slope of the *P–V* characteristic near the coercive field and to the polarization lag occurring during electric field AC sweeps. Thus, in [35], the internal voltage gain was explained with the Miller theory, which did not require the ferroelectric capacitance to be negative. Besides [35], there are other works that provide alternative interpretation of the voltage amplification behavior observed in ferroelectric-dielectric (FE-DE) stacks, as summarized in [18]. In the presence of different theories for the NC effect, a single model would need to prove self-consistently a whole set of feature characteristics of these devices to convincingly explain NCFET operation.

Experimental Results on NCFETs
Ever since the seminal paper by Salahuddin and Datta in 2008 [7], researchers have come up with experimental demonstrations of the NCFET concept, either on perovskite or doped-HfO_2 ferroelectrics or on a variety of different substrates [18]. However, published data have shown hitherto a relatively broad scatter of the measured *SS* values, especially related to hysteresis. This scenario is shown in Fig. 26.7, where experimental data of NCFET realized in different device technologies (i.e., Si, Ge/GeSn, 2D, III–V semiconductors) is compared. This level of scatter is a clear indication of the relatively limited maturity of the technology and needs to be reduced in order to guarantee the adoption of NCFETs into mainstream semiconductor industry.

NCFET Models for Advanced Transistor Architectures and Technologies
While in Sect. 26.2.1 we focused the analysis on long-channel bulk MOSFETs, the NCFET concept can be applied also to other transistor technologies. Indeed, there are several attempts in the literature to couple the LKE with electrostatic and transport equations to find self-consistently the solution to advanced transistor architectures and technologies. Some examples of such modeling efforts are *(i)* dual (or double)-gate FET (DGFET) [36], *(ii)* FinFET [37], *(iii)* gate-all-around FET (GAAFET) [38, 39], and *(iv)* MoS_2 junctionless FET (JLFET) [40]. The interest in developing models for advanced transistor technologies is motivated by the scaling needs of the semiconductor industry, which require the reduction of the so-called short-channel effects as well as reduction in operating power. Indeed, NCFETs can prove instrumental in achieving these goals, provided that their distinctive features are verified in realistic devices, as discussed in the next paragraph.

Requirements to Prove the NCFET Concept
The interpretation of experimental demonstrations of NCFETs is further complicated by the debate around the theoretical aspects of the NC effect as derived from the Landau theory, as well as by the presence of other possible models explaining the observed reduction of *SS*. To unambiguously prove the NCFET concept on fabricated devices, it is not only necessary to demonstrate that *SS* is effectively reduced, but also a number of other features must be guaranteed. The necessary features to prove self-consistently the NCFET operation are [18] the following:

- Hysteresis-free steep subthreshold switching with $SS < 60$ mV/dec.
- Negative differential resistance (NDR) in the output characteristics, i.e., the reduction of I_D with increasing V_{DS}.
- Negative drain-induced barrier lowering (NDIBL), i.e., the increase in threshold voltage with increasing V_{DS}.
- Suppression of the $1/f$ flicker noise measured in I_D.

The features outlined above (e.g., NDR, NDIBL, etc.) should be proven for a combination of dielectric and ferroelectric thicknesses, for different bias sweeps, and also for a range of frequencies (to determine the speed limits of the technology). These requirements provide an operative procedure to conduct experiments to systematically prove NCFET operation.

26.3 Device Physics of PhaseFETs

In the Introduction, we mentioned that PhaseFET is a non-thermionic device that allows steep-slope switching by focusing on the channel transport and reducing channel transport factor, *n*, below 60 mV/dec. PhaseFETs are composed of the series of a MOSFET and a nonlinear variable resistor connected to the source, as sketched in Fig. 26.9a. Less commonly, some devices connect the variable resistor (also called threshold selector (TS)) to the drain, as in [41]. The variable resistor connected in series to the MOSFET is realized with a PTM that shows an abrupt switching between two stable low- and high-resistance states. Some examples of PTM are vanadium dioxide (VO_2) [5] or Ag/TiO_2 [41]. In general, the phase transition involves insulator-to-metal transition (IMT) and metal-to-insulator transition (MIT) as a response to an external stimulus (i.e., temperature, pressure, electric field), and this leads to sharp transitions in the current-voltage

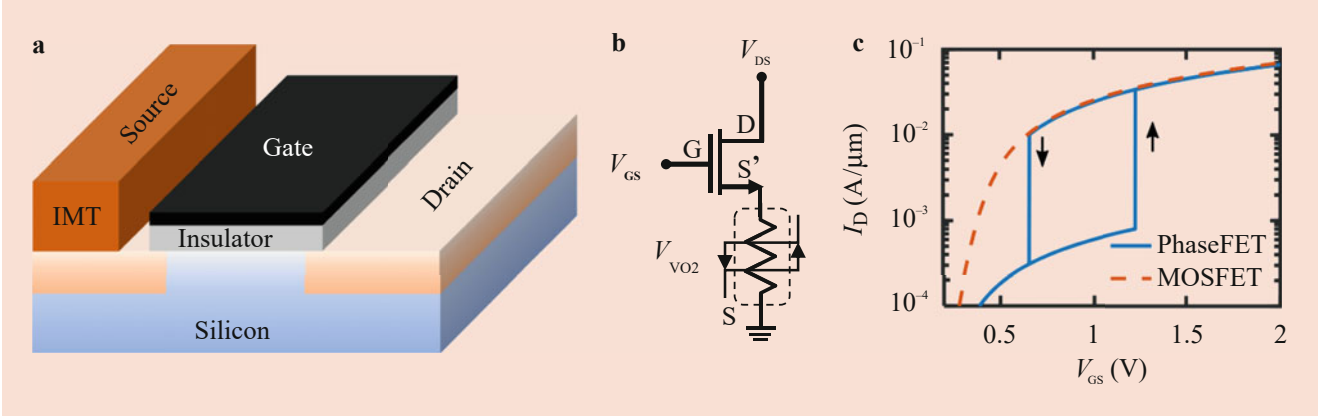

Fig. 26.9 (**a**) Sketch of the PhaseFET cross-section, which consists of an MOSFET with in series to the source a variable resistor undergoing phase transition (PTM). (**b**) Circuit schematic of the PhaseFET and (**c**) its I_D–V_{GS} characteristic (blue solid line) compared to that of the standard MOSFET (orange dashed line). The PhaseFET has much better subthreshold swing than the MOSFET though it exhibits hysteresis

characteristics of the device. The corresponding transition between on and off operation leads to steep *SS* switching.

Compared to other options (e.g., tunnel FET or MEM relay), a PhaseFET may be easier to integrate into an existing MOSFET process flow because the phase-changing element can be embedded among the interconnects within the back end. In this section, we discuss more in detail the physics of phase transition and describe the general framework of operation of the PhaseFET. The theory of PhaseFET is not as well developed as for TFETs or Landau FETs. Hence, we focus on two simple approaches (i.e., behavioral compact model and electrothermal phenomenological model) to provide a general understanding of the potential of PhaseFET-based circuits.

26.3.1 Behavioral Compact Model

To understand the operation of the PhaseFET, we can employ a simple behavioral model that captures the abrupt resistivity change in a general way and that can be coupled to a MOSFET model to obtain a self-consistent solution of the drain current vs gate-to-source voltage. The behavioral model assumes that the high- to low-resistive switching occurs at a threshold voltage, V_1, while the high-to-low switching occurs at a second threshold, V_2 [42]. Since $V_2 < V_1$, the device traces different current-voltage paths depending on the direction of voltage sweep, resulting in hysteretic switching in response to an off-on-off input pulse. This is illustrated in Fig. 26.9, where the simple circuit shown in panel (b) is simulated to obtain the I_D–V_{GS} characteristic shown in panel (c). The characteristics of PhaseFET compared to the standalone MOSFET are much steeper during turn-on and turn-off; however, hysteresis is present, as mentioned previously. In this regard, both NCFET and PhaseFET must balance clear advantage of *SS* reduction against the hysteresis inherent in the transition. We note that while an NCFET can be designed to be essentially hysteresis-free, it is difficult to completely eliminate the hysteresis in PhaseFETs. This has to do with the physics of abrupt resistive switching that inherently occurs at different thresholds depending on the previous state of the device. Nevertheless, appropriate material choice [43] can reduce the PhaseFET hysteresis to a level tolerable for a given application.

26.3.2 Physics-Based Phenomenological Model

The PhaseFET behavioral model explains device operation empirically, but it does not allow to connect the abrupt resistance change to the physical mechanism inducing phase transition (i.e., either electrical or temperature switching). An improved phenomenological PTM model should self-consistently solve for the electrical and thermal behaviors of the PhaseFET. This would allow phase transition through Joule heating in the VO_2. The abrupt resistance variation can be captured by an empirical model [44, 45]:

$$R_{PTM} = R_{LRS} + \frac{(R_{HRS} - R_{LRS})}{1 + \exp\left[(T - T_c)/T_x\right]} \tag{26.14}$$

where R_{LRS} (R_{HRS}) is the low (high)-resistance state value, T_c is the critical temperature at which transition occurs, and T_x is an empirical parameter. The temperature variation is determined by the following first-order differential equation:

$$C_{th}\frac{dT}{dt} = V_{PTM} \times I_{PTM} - \frac{T - T_0}{R_{th}} \tag{26.15}$$

where C_{th} (R_{th}) is the thermal capacitance (resistance), T_0 is the ambient temperature, and V_{PTM} (I_{PTM}) is the voltage across (current flowing in) the PTM. Notice that this equation connects the Joule heating term $V \times I$ and the thermal properties of the device, i.e., C_{th} and R_{th}.

Although this modeling approach might be good enough for circuit simulations, it is still not adequate for realistic physics-based modeling, for which the resistivity variation needs to be connected to the material properties and more fundamental theories. One possible way of to accomplish this is to rely on MottFET theory, which provides a theoretical framework to explain phase transition [6]. Materials like VO_2, in fact, belong to the class of Mott insulators, which exhibit an abrupt (but reversible) IMT when the internal temperature exceeds a critical value, T_c [6]. Although the MottFET, employing a PTM as the channel of the transistor, has not been demonstrated yet, understanding the details behind PTM in Mott insulators is instructive to harness the interesting physics associated with phase transition.

The MottFET theory allows us to model the IMT/MIT with bandgap, E_G, and thermal conductivity, κ, variations. As temperature varies in a PTM, the bandgap is modified through the following relation [6]:

$$E_G = E_{G,0} - \frac{E_{G,0}}{1 + a \exp\left[-b\left(T - T_c\right)\right]} \tag{26.16}$$

where a and b are intrinsic material parameters specific to the Mott insulator. Associated with the bandgap collapse, which determines the electrical behavior, is the variation in thermal conductivity which effectively controls the thermal behavior:

$$\kappa = \kappa_0 + \frac{(\kappa_1 - \kappa_0)}{1 + a \exp\left[-b\left(T - T_c\right)\right]} \tag{26.17}$$

where κ_0 (κ_1) is the thermal conductivity of the insulator (metal) phase, respectively. This approach of modeling bandgap and thermal conductivity variations allows for an accurate description of the observed temperature dependence of carrier concentration and resistivity, enabling predictive analysis for a variety of novel devices based on Mott insulators [6].

26.3.3 Experimental Results on PhaseFETs

Similarly to Fig. 26.7 for NCFETs, we summarize in Fig. 26.10 the data of fabricated PhaseFETs present in the literature [5, 11, 41, 46–50]. The measured data for PhaseFETs also shows a relatively broad scatter of *SS* vs hysteresis values. We note that *SS* for PhaseFET is much lower than that of NCFETs: in fact, PhaseFETs have almost ideal on-off switching, i.e., $SS \sim 0$ mV/dec. On the other hand, hysteresis is generally much larger in PhaseFETs than NCFETs (always higher than 100 mV). Thus, once again, the technology choice for a given application must be based on the trade-off between *SS* and hysteresis.

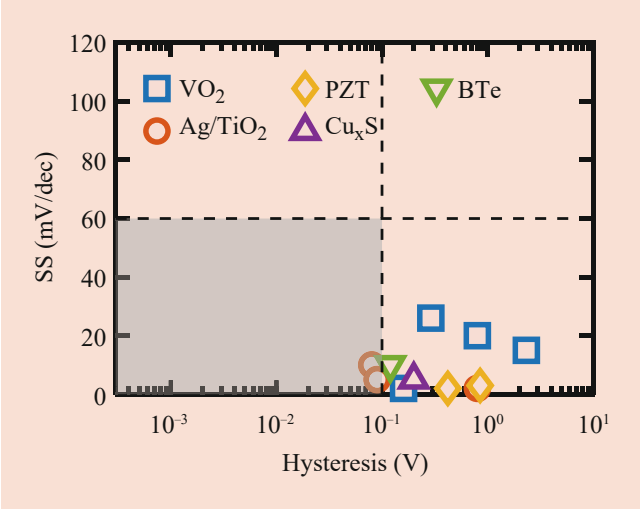

Fig. 26.10 Published data of various PhaseFET experimental data of *SS* vs hysteresis for different variable resistance materials, i.e., VO_2 [5, 11], Ag/TiO_2 [41, 46], PZT [47, 48], Cu_xS [49], and BTe [50]. The shaded area represents a "sweet spot" for a PhaseFET with $SS < 60$ mV/dec and moderate hysteresis

26.4 Boolean Computing with NCFETs, FeFETs, and PhaseFETs

With the understanding of the device operation of NCFETs and PhaseFETs, we now present their circuit implications. To complete the picture on the applications of FE-based devices, we will also discuss FeFET-based circuits which utilize the hysteretic characteristics as opposed to NCFETs that utilize steep-switching. In this section, we will focus on applications targeted toward Boolean computing in the context of both digital logic and memories. In Sect. 26.5, we will discuss the potential of using such new technologies for non-Boolean computing.

26.4.1 Logic Design

In the context of the design of digital logic primitives, NCFETs and PhaseFETs exhibit promising characteristics such as steep-switching (either due to NC effect or abrupt hysteretic switching, respectively) and therefore can potentially enable aggressive voltage scaling. The question, however, is whether or not these devices can be or should be

used as drop-in replacements of standard transistors or if new design techniques will be needed to translate the device-level benefits to optimal circuit performance. Here, we will address this question and highlight the importance of technology-circuit co-design to enable NCFET- and PhaseFET-based low-power logic. We will discuss the circuit behavior both from the perspectives of DC voltage transfer characteristics (VTC) (which dictates the gain and noise margins of the logic gates) and transient response (which determines the energy efficiency and speed).

NCFET-Based Logic

Logic gate implementation prefers non-hysteretic NCFET operation to avert polarization switching (and the associated delay/energy overheads) as well as to simplify the design of logic gates (since NCFETs can be directly used as drop-in replacements of MOSFETs). Hence, in this section, the focus of our discussion will be on logic design with non-hysteretic NCFETs.

The very NC effect that gives rise to steep-switching in NCFETs also leads to a concomitant increase in their gate capacitance [51]. Thus, for digital logic, the benefits of higher on current at iso-off current (due to steep-switching) may be offset by the increase in the fanout (gate) capacitance. Also, the viscosity coefficient of the ferroelectric, ρ, may affect circuit delay [51]. In addition, the steep-switching in NCFETs is often accompanied by NDR in the output characteristics [51, 52]. Here, we will discuss the overall effect of such unique NCFET properties on circuit behavior.

From the perspective of the DC response, steep-switching in NCFETs leads to sharper VTCs compared to complementary metal oxide semiconductor (CMOS) circuits, which implies higher gain and improved noise margins [51]. However, the story does not end here. NDR in NCFETs leads to some unique VTC attributes, especially at sufficiently large ferroelectric thickness. Specifically, the VTC becomes hysteretic due to NDR (Fig. 26.11a (see [51] for more details), even though the device is non-hysteretic. This leads to improved noise margins for Boolean applications. This unique feature can be used to design oscillators, as discussed later in Sect. 26.5.1.

Let us now come to the energy-delay analysis of NCFET-based logic. Here, we need to consider the interplay between higher on-off current ratios and larger gate capacitance (compared to CMOS) as well as the viscosity coefficient of the ferroelectric layer, ρ. While the viscosity coefficient still needs further characterization, recent experiments have indicated that ρ may be as low as 0.18 Ω.cm [53]. Nevertheless, here (in Fig. 26.11b adapted from [51]), we show the characteristics for different values of ρ to illustrate its effect. It can be observed that NCFETs show lower delay at iso-energy compared to CMOS circuits in the low-voltage regime due to higher on current. At high voltages, however, the delay associated with charging/discharging of the circuit nodes is small, and thus, the relative contribution of ρ to the overall circuit delay increases [51]. As a result, NCFET-based logic can show delay increase for large ρ. However, if ρ can be reduced, the benefits of NCFETs can be extended to a larger voltage range. In addition, NCFET circuits show higher energy-delay improvements over CMOS with the increase in the contribution of wire (back-end load) to the overall load. This is because large wire capacitance mitigates the effect of higher gate capacitance of NCFETs [51].

We will end this section by emphasizing that to maximize the benefits of NCFETs, design of devices (e.g., T_{FE} optimization) needs to be coupled with circuit design (e.g., voltage optimization, back-end and front-end fanout, etc.). With proper design, NCFET-based circuits exhibit performance benefits, especially at low voltages. Further, their unique NDR characteristics can lead to Schmitt trigger action in NCFET-based logic gates, which can be beneficial for noise immunity.

PhaseFET-Based Logic

Similar to NCFETs, PhaseFETs offer steep (in fact, abrupt) switching, which can potentially be beneficial for logic design. However, one important distinction is that unlike NCFETs, PhaseFETs cannot have non-hysteretic characteristics [43]. (The only exception to this is a very specific design point where the gate voltage associated with IMT and MIT can theoretically be matched by design; however, such a design would be impractical as a small variation can lead to the phase transition material going into the oscillatory mode [54], which is detrimental for logic operation). With hysteretic and abrupt transfer and output characteristics of PhaseFETs, logic design becomes nontrivial [55].

In order to obtain proper functionality and performance gains, the resistance ratio of the insulating and metallic state of the PTMs can neither be too high (in which case, the devices and circuits will fail to function) nor too low (in which case, PhaseFETs will not show any improvement in the on-off current ratio [43]). Moreover, the transition voltages associated with IMT and MIT need to be tailored by proper device-circuit co-design to ensure that the phase transitions in the PTM enable the required circuit functionality (for instance, complete voltage swing in the logic gates [55]).

The VTC of properly designed PhaseFET-based logic gates (obtained from DC characteristics – Fig. 26.12a) is quite unconventional, showing hysteresis in the non-transition region (which is a result of the intrinsic device hysteresis). VTCs also indicate an "apparent" reduction in the noise margins [43] due to the high insulating state

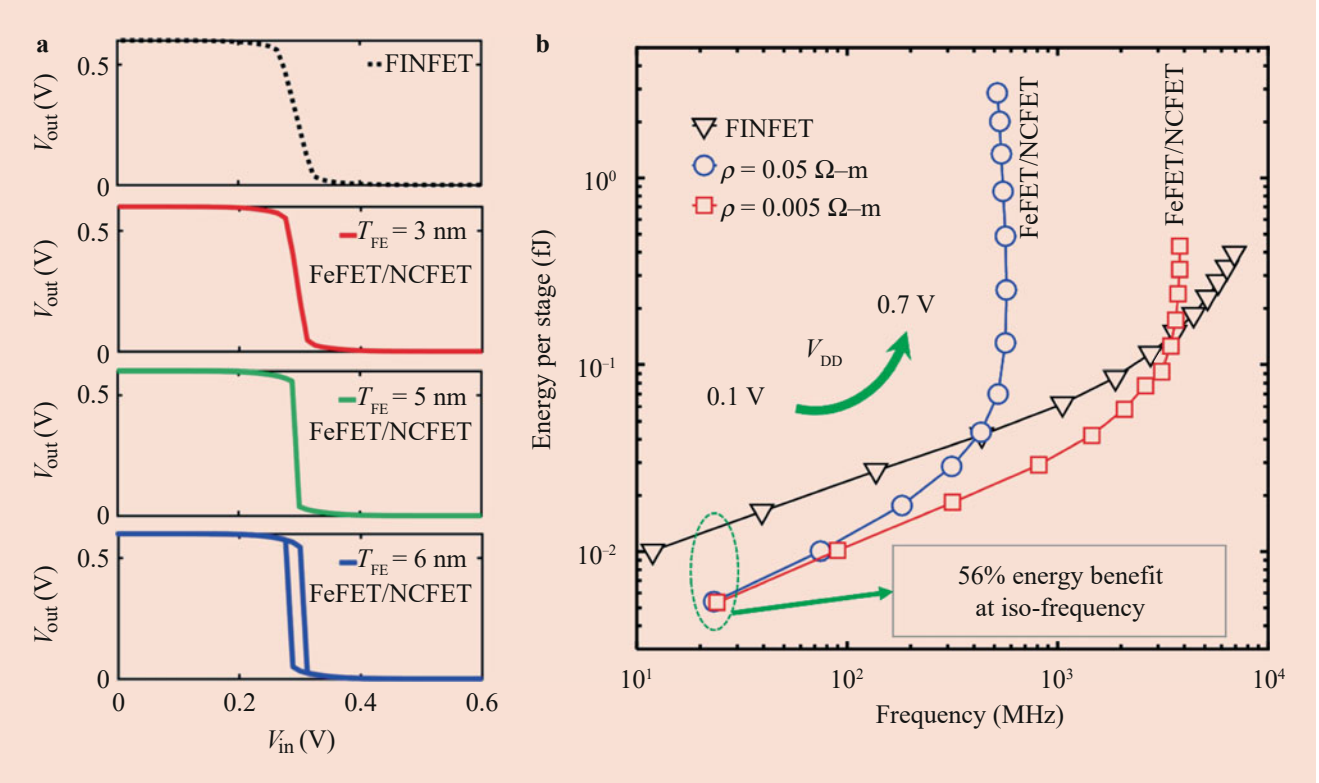

Fig. 26.11 (**a**) Voltage transfer characteristics (VTC) of NCFET inverter for different FE thickness, T_{FE}. (From [51] © 2017 IEEE). (**b**) Energy delay for NCFET-based ring oscillator for different ρ

resistance of the PTMs in the pull-up and pull-down paths. However, this effect is not as severe as predicted by the DC characteristics, and the dynamic change in the resistance of the PTMs during the circuit operation due to IMT significantly improves the noise margins by establishing a low-resistance path to either V_{DD} or ground [55].

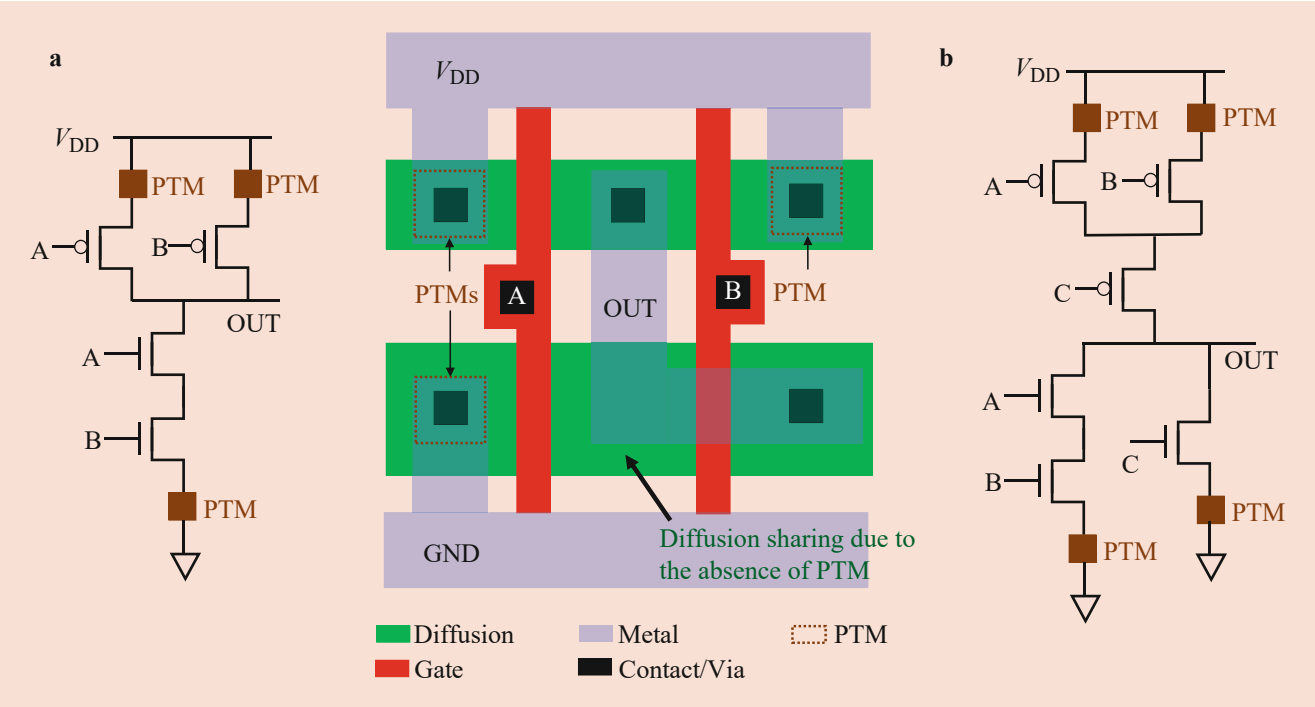

Fig. 26.13 (**a**) Schematic and layout of PhaseFET-based two-input NAND gate and (**b**) schematic of PhaseFET-based AND-OR-INVERT (AOI) gate, showing one PTM per network of series-connected transistors in the pull-up and pull-down paths

The energy-delay analysis of PhaseFETs (see Fig. 26.12b [55]) shows that PhaseFETs exhibit delay reduction at iso-energy at low voltages (similar to NCFETs) by virtue of their steep-switching and higher on-off current ratio. At high voltages, however, the transition time associated with IMT and MIT degrades the performance of PhaseFETs. Hence, novel PTMs may need to be explored that not only meet the resistance and transition voltage requirements to support the logic gate functionalities but also exhibit low transition times and high stability to enhance the benefits of PhaseFET-based logic at high operating voltages as well.

It is noteworthy that for multiple input gates, it may not be judicious to use PhaseFETs as drop-in replacements of standard MOSFETs (unlike for NCFETs). Instead, only one PTM is needed for a set of series-connected transistors in a logic gate [55]. For instance, a two-input NOT-AND (NAND) gate is shown in Fig. 26.13a. This design employs two parallel PhaseFETs in the pull-up network (PUN), but instead of using two series PhaseFETs in the pull-down network (PDN), a single PTM is placed in series with the n-type transistors. This design has the following advantages: (1) by avoiding two series PTMs, the effect of the metallic resistance of the PTM on the logic gate speed is reduced; (2) diffusion/contact-sharing between the two series n-transistors (as in standard CMOS) becomes possible, thereby averting area penalty due to PTMs (Fig. 26.13a); and (3) the regulation of IMT/MIT of a single PTM and its interactions with the network of series-connected transistors becomes easier (compared to two PTMs in series), which makes the design more robust to variations. Note, similar to an inverter, the width of the series-connected transistors and the PTM geometry need to be co-optimized, to achieve the correct functionality of the gate, sufficient noise margins, complete voltage swing, and energy-delay benefits. The idea of using a single PTM per series network of transistors can be easily extended to other complex gates. For instance, an AND-OR-INVERT (AOI) gate based on PhaseFETs is shown in Fig. 26.13b.

26.4.2 SRAM Design

Similar to the logic design, the implementation of static random access memories (SRAMs) with NCFETs and PhaseFETs requires careful co-design of devices and circuits to harness the maximum benefits. In fact, the importance of utilizing the unique attributes of the devices becomes even more critical in SRAMs because of the self-conflicting design requirements for read and write. In this section, we briefly review NCFET- and PhaseFET-based six-transistor SRAMs (6 T-SRAMs).

NCFET-Based SRAM

NCFETs, in their non-hysteretic mode, can be used as drop-in replacements of MOSFETs in a 6 T-SRAM cell (Fig. 26.14a).

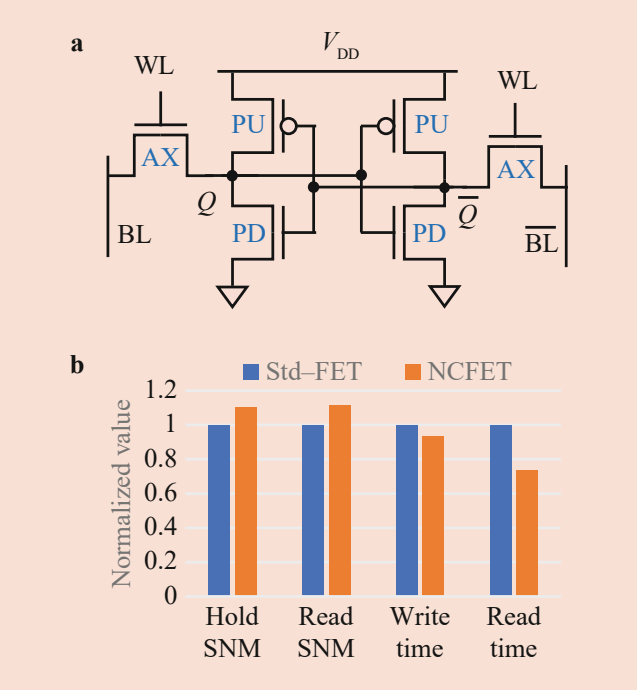

Fig. 26.14 (**a**) SRAM cell showing pull-up (PU), pull-down (PD), and access (AX) transistors. (**b**) Comparison of performances (read time and write time) and stability (hold SNM and read SNM) between Std-FET-based and NCFET-based SRAM cell. (From [56] © 2016 IEEE)

By virtue of their steep-switching, NCFETs naturally offer higher read and hold stabilities (Fig. 26.14b) [56]. However, by utilizing the NDR in their output characteristics (with proper optimization of T_{FE}), Schmitt trigger action (or hysteretic response in their DC characteristics) is achieved, which further improves the read and holds noise margins [57]. Furthermore, access time of NCFET-based SRAMs at iso-leakage and iso-area is lower due to higher I_{ON}. The overhead of higher gate capacitance in NCFETs is significantly mitigated due to the wire capacitance associated with word lines and bit lines. The write time of NCFET-based SRAMs is strongly dependent on ρ: for ρ close to 0.18 Ω.cm [53], write time improvement is observed, mainly due to higher I_{ON} in NCFETs. However, increase in ρ lessens these benefits and may even degrade write time [56]. Hence, proper device design coupled with cell optimization (including the possible use of read/write assist techniques) is needed in NCFET-based SRAMs to mitigate the design conflicts and achieve superior design solutions compared to their CMOS counterparts.

PhaseFET-Based SRAM

Unlike NCFETs, employing PhaseFETs as drop-in replacements in 6 T-SRAMs may yield a suboptimal design. As an example, the additional resistance given by the PTM in the access PhaseFET in 6 T-SRAMs may reduce the cell leakage and bit-line leakage but can lead to a significant degradation in the write-ability and read speed. Similarly, if both the pull-up and pull-down transistors of 6 T-SRAM are implemented using PhaseFETs, the stability of the cell (especially during read) may be degraded considering process variations. Therefore, it becomes important to selectively employ PhaseFETs in conjunction with standard transistors in SRAMs to utilize their unique properties (such as abrupt switching) for mitigating the read-write conflicts.

In [58], it is shown that using PhaseFETs as the pull-down transistors while using MOSFETs as pull-up and access transistors can be beneficial to simultaneously increase the read stability, hold stability, and write-ability without any increase in the area, albeit at the cost of the access time. The key idea is as follows. During read, the cell is designed to trigger IMT in the PTM of the PhaseFET driving the node storing "0" so that read current can flow. On the other hand, the other PTM remains insulating, which increases the trip point (or logic threshold voltage) of the corresponding inverter in the SRAM cell. This significantly improves the read stability. During write, two scenarios can occur depending on the design: either (1) the PTM driving node storing "0" undergoes IMT followed by MIT, while the other PTM remains insulating, or (2) both PTMs remain insulating. Irrespective of which case occurs, write-ability is significantly improved due to insulating PTMs. Thus, by triggering operation-driven phase transitions in the PTM, the read-write conflicts present in standard SRAMs can be mitigated. For the details of this design and other related aspects (such as hold stability, area, the impact on the unaccessed cells, etc.), the reader is referred to [58].

In addition to the 6 T-SRAMs, PTMs have also been shown to improve the read functionality in SRAMs and dynamic random access memory (DRAMs) with separate read-write paths at a minimal area cost [59]. Besides, PTMs have also been used as a technology assist to design nonvolatile SRAMs [60].

26.4.3 Nonvolatile Memory Design

In the following, we discuss the design of novel nonvolatile memory (NVM) technologies based on FeFET and PhaseFET and the specific constraints introduced by the integration of either the ferroelectric or PTM layer with conventional devices.

FeFET-Based NVMs

FE materials have been widely accepted as an attractive storage element for nonvolatile memories. Therefore, in addition to the applications of FE in NCFET-based logic/SRAM designs, we consider it is important to briefly review the applications of FeFETs in NVM designs.

Traditionally, NVMs based on FE capacitor RAMs (FeRAMs) have been among the most promising technologies and have been implemented in industry using their unique property of polarization retention in the absence of an external electric field [61]. They offer high endurance along with high integration densities close to DRAMs. However, they suffer from low read distinguishability. Moreover, their read operation is destructive and requires a write-back operation, leading to large energy overheads [62].

More recently, the possibility of direct integration of FE layer in the gate stack of MOSFETs, as schematically depicted in Fig. 26.15a, has led to the realization of nonvolatile FeFETs [63]. Moreover, the HfO_2-based FE enables a scalable (and CMOS-compatible) emerging NVM that keeps up the pace with the scaling demands of leading-edge logic technologies [63]. In this memory device, the binary states are encoded in the form of the FE polarization (P). The direction (and value) of P determines the resistance state, either low-resistive state (LRS) or high-resistive state (HRS), of the underlying transistor [64] (see Fig. 26.15b). For storing the memory state in the FE layer (and to switch between LRS and HRS), a V_{GS} of appropriate polarity and value greater than the coercive voltage of the FE is applied. To sense the memory state, I_D of the FeFET is used, thus separating the read and write paths. Moreover, the read operation (in FeFETs with MFIS gate stack – see Fig. 26.2a) is no longer destructive, and the distinguishability is significantly improved by virtue of the gain of the transistor coupled with polarization switching [64].

Although FeFETs are immensely promising due to their electric field-driven write, read-write path separation, and CMOS compatibility of HfO_2-based ferroelectrics, the variability associated with the domain nucleation and propagation as well as traps in FeFETs (especially with MFIS gate stack [65]) needs to be tackled. FeFETs with MFMIS mitigate these issues and other challenges related to hysteresis optimization [66]. However, gate leakage can adversely affect such devices, resulting in the need for more advanced read schemes, which may incur in energy overheads [67].

For FeFETs with dominant single-domain behavior, especially for MFMIS gate stacks [68] or those at highly scaled technology nodes, the design of NVM arrays is fairly distinct compared to FeFETs with explicit multi-domain characteristics [66]. Here, we will briefly review both.

For the former category, various designs spanning highly compact 1T NVM to a more robust 4 T NVM have been explored, as shown in Fig. 26.16 [62, 69–71]. To design the NVM arrays, selective access of the FeFET NVM cells needs to be facilitated. In the 1T design [69], this is achieved by utilizing the drain coupling with the ferroelectric layer in the FeFET. While highly compact, the design margins of this cell need further exploration. Other designs [62, 70, 71] achieve

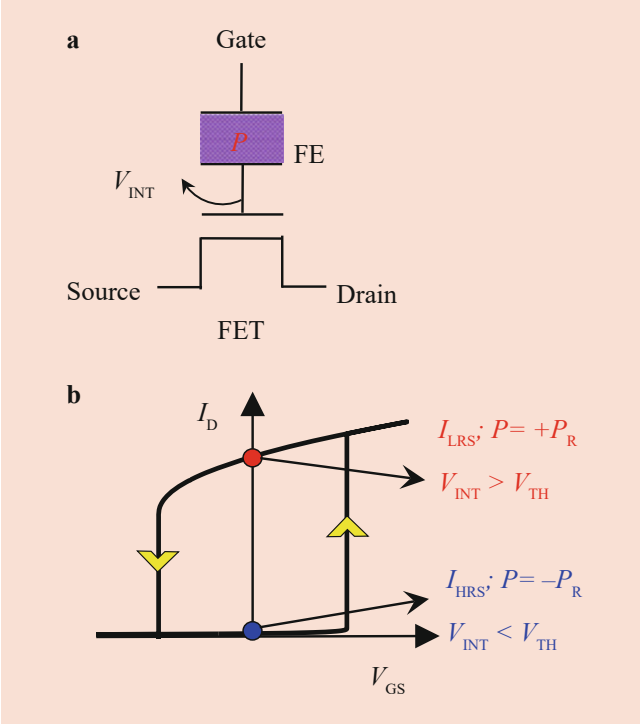

Fig. 26.15 (**a**) Schematic of FeFET with FE integrated in the gate stack of a FET. (**b**) I_D–V_{GS} characteristics of FeFET illustrating the bistability of polarization, P at $V_{GS} = 0$ V

selective access in the array by employing access transistors. In all these designs, a write access CMOS transistor is required to isolate the write paths of the unaccessed cells from that of the accessed cell. In the 2T (one MOSFET and one FeFET) design proposed in [62], an unconventional read scheme is adopted to minimize the flow of the read current through the unaccessed cell. To circumvent the overheads of the complex read scheme, 3T (two MOSFETs and one FeFET) design uses a read access transistor, albeit at the cost of area. The write operation of 1T, 2T, and 3T designs needs both positive and negative voltages [69, 62, 70]. To avert the use of negative write voltages (thereby, reducing the associated energy overheads), 4T (three MOSFETs and one FeFET) design [71] uses a third-access transistor. The other design option for all-positive write voltages is to use a two-phase write operation, as explored in [72]. The features common to all designs include (a) the application of write voltages on bit lines so that positive or negative V_{GS} greater than the coercive gate voltage appears across the FeFET of the accessed cell and (b) the application of read voltages on the sense lines to facilitate drain current flow through the accessed transistor, which can then be sensed by the sense amplifier.

Recently, multi-domain FeFETs (MD-FeFET) (with MFIS gate stack) have been explored for memory applications [66]. Their unique characteristics of polarization-

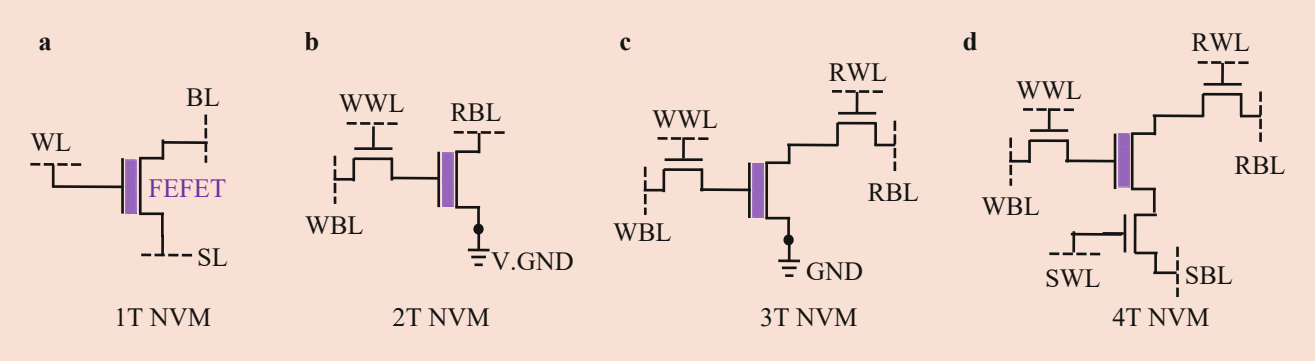

Fig. 26.16 (**a**) 1T, (**b**) 2T, (**c**) 3T, and (**d**) 4T FeFET-based nonvolatile memory (NVM) designs

dependent threshold voltage shifting (similar to NAND flash memories) have enabled the possibility of an ultrahigh-density 1T FeFET NVM [66]. Moreover, the same multi-domain characteristics have also been extensively proposed for multilevel memory cells as synapses in neuromorphic applications [73], as we will discuss later. However, the scalability of multi-domain ferroelectrics needs further exploration, and the techniques to engineer the domain sizes and distributions can potentially pave the path for MD-FeFET-based NVM designs.

In addition to standard memories, FeFETs have been utilized to design content-addressable memories (CAMs) showing promise of high-energy efficiency [74]. In addition, novel device structures such as reconfigurable FeFETs (R-FeFETs) have been proposed that dynamically change their operation between nonvolatile and volatile modes. These devices lower the power consumption of NVMs, mitigate the issues associated with gate leakage [75], and achieve differential memory designs [76]. In addition, the run-time modulation of hysteresis in R-FeFETs enables efficient logic-memory coupling for new applications such as logic in memory [76] as well as memory in logic [77].

PhaseFET-Augmented MRAMs

Unlike FEs in FeFETs, PTMs employed for the design of PhaseFETs do not offer nonvolatile characteristics. Hence, they cannot be directly utilized to design NVMs. However, by virtue of the large resistance ratio between their insulating and metallic states, PhaseFETs can be harnessed to augment the design of NVMs that inherently have low distinguishability (such as spin-based memories [78]). In [79], magnetic random access memories (MRAMs) have been designed with PhaseFETs (Fig. 26.17a, b) by coupling the nonvolatility of magnetic tunnel junction (MTJ) memories with the high ratio of insulating resistance and metallic resistance of the PTMs. The key idea behind MRAMs is to trigger operation-driven phase transitions in the PTM depending on the data stored in the MTJ. During the hold operation, the PTM remains in the insulating state. During the write operation, the PTM operates in its metallic state by design. This minimizes the adverse effect of PTM resistance on the write speed. During the read operation, PTM undergoes data-dependent selective phase transition.

First, on the assertion of the word line, IMT is triggered in the PTM. The cell is designed such that if the MTJ is in the low-resistance parallel state, cell current is high enough to keep the PTM metallic. However, if the MTJ is in the high-resistance antiparallel state, low cell current triggers MIT, thus significantly increasing the resistance of the cell. In this manner, the distinguishability of the spin memories can be enhanced by synergistically utilizing the nonvolatility of MTJs with orders of magnitude resistance difference between insulating and metallic phases of the PTMs. Results from [80] (Fig. 26.17c) show that in addition to a large increase in the sense margin, a simultaneous increase in read disturb margin and a moderate write power reduction are achieved with this technique without any area penalty but with a negligible write time increase. In [79], read improvements under process variations are also established.

In addition to this technique (with series MTJ-PTM connection), PhaseFETs can be used in spin memories with separate read-write paths such that the PTM is connected in parallel with the MTJ [81]. This design also considerably improves the read operation without affecting the write operation (due to the separation of read-write path). Moreover, instead of amplifying the distinguishability at the cell level (as in the aforementioned techniques), this design principle can be extended to the array level, wherein PhaseFETs are utilized to design compact low-power sense amplifiers, in which the core amplification occurs in the PTM (see [82] for details).

Furthermore, PTMs (without transistors) have also been explored to design cross-point NVM architectures, wherein the abrupt switching of the PTMs is utilized to design selectors with high nonlinearity [83].

26.5 Non-boolean Computing with NCFETs, FeFETs, and PhaseFETs

In the previous section, we presented the potential applications of NCFETs, FeFETs, and PhaseFETs for standard Boolean computing and storage. In this section, we will extend our discussion to non-Boolean computing, wherein we will highlight how the unique attributes of these technologies enable circuits that can cater to the demands of emerging applications. Before we dive into the discussion, let us understand the application perspective for non-Boolean computing. Traditional computing based on Boolean logic and von Neumann architectures has been immensely successful in the era of predominant compute-intensive tasks. However, with the advent of data-intensive applications such as recognition, machine learning, etc., the standard architectures prove to be inadequate to meet efficiency demands. Hence, new computing approaches are being explored that mitigate the limitations of Boolean computing by customizing the architectures, circuits, and technologies to meet the demands of the new applications. Here, we will focus on two non-Boolean computing approaches: (1) coupled oscillator-based computing and (2) neuromorphic computing.

26.5.1 Coupled Oscillator-Based Computing

For certain tasks involving associative computing (e.g., pattern matching) or solving optimization problems (e.g., graph coloring), coupled oscillator-based processing has emerged as a promising computing paradigm. The key idea is to couple multiple oscillators whose oscillation frequency is controlled by the inputs. If the degree of matching of the inputs is high or other interactions are strong, the oscillators get frequency- or phase-locked. Otherwise, they show asynchronous oscillations. This working principle is utilized to find the minima in optimization problems or perform recognition/matching tasks. While CMOS-based oscillators have been utilized for this purpose, it has been shown that emerging technologies can potentially offer higher-energy efficiency [84–86]. Here, we will discuss how NCFETs, FeFETs, and PhaseFETs enable the design of energy-efficient coupled oscillators.

NCFET-/FeFET-Based Coupled Oscillators

FE-based transistors, namely, (a) NCFET which shows steep-switching and NDR and (b) FeFET with hysteretic transfer characteristics, have emerged as promising candidates for compact and low-power beyond-von Neumann architectures powered by their unique device features. An example application based on these architectures is associative computing, for which oscillator-based networks have been a subject of recent study [85, 86]. By leveraging special device-circuit capabilities of NCFET/FeFET, oscillators with significantly reduced transistor count compared to their CMOS-based counterparts are realizable [85, 86].

In [85], an oscillator with one FET and one FeFET (Fig. 26.18a) was proposed. The design utilized abrupt polarization switching and hysteretic transfer characteristics of FeFETs. The key idea is illustrated in the load-line plot of Fig. 26.18c. This circuit would show stable solution if the load line (corresponding to the FET) intersected with the transfer characteristics of the FeFET. With proper design, it can be ensured that the load does not intersect in the flat (solid line) regions of the FeFET characteristics, ensuring that (as

a result of the lack of a stable DC solution) oscillations build up as shown in Fig. 26.18d. This technique is similar to the approach explored for other technologies such as PTMs that we will discuss later on. The design proposed in [85] shows relaxation-type oscillations. Synchronization between two oscillators has also been shown, which can be useful for non-Boolean applications. The oscillatory behavior has also been experimentally demonstrated in [87] utilizing a perovskite-based (e.g., $BaTiO_3$) FeFET. However, since this oscillator design relies on abruptness of polarization switching, it needs to be further explored in the context of CMOS-compatible HZO-based ferroelectrics, which are polycrystalline and hence are expected to have smoother polarization switching due to multi-domain effects [88].

In [86], NCFET-/FeFET-based oscillators (Fig. 26.19a) utilize a different mechanism to achieve oscillations. They rely on Schmitt trigger action or hysteretic VTC of inverters (see Fig. 26.11a). In contrast to the 6 T CMOS-based Schmitt trigger, NCFETs and FeFETs lead to hysteretic VTC with just two transistors by virtue of (a) NDR in NCFETs (discussed in Sect. 26.4, Fig. 26.11a) or (b) hysteretic transfer characteristics ($I_D - V_{GS}$) of FeFETs (discussed in Sect. 26.4, Fig. 26.15b). Hysteretic VTC is translated to voltage-controlled oscillations by a feedback, R_f, from output to input of the inverter. Depending on whether R_f is realized as a pass transistor (PT) or transmission gate (TG), the oscillator outputs a variety of oscillations, viz., (a) relaxation-type with PT in both NCFET (Fig. 26.19b) and FeFET (Fig. 26.19d) implementations, (b) "sinusoid-like" with TG in NCFET-based design (Fig. 26.19c), and (c) "pulse-like" with TG in FeFET design (Fig. 26.19e). Moreover, dynamic reconfiguration between relaxation and "sinusoid-/pulse-like characteristics" is achievable by tuning the bias of P-transistor in TG. Their coupled dynamics have also been analyzed, which show a promise for non-Boolean computing ([86]).

Each of the aforementioned designs has their own benefits and trade-offs. While the design in [85] offers a highly compact solution, the oscillator in [86] has been shown to achieve higher oscillator frequencies in simulations and can be implemented even if the polarization switching dynamics is not abrupt. Moreover, the latter design can be realized by both NCFETs and FeFETs.

PhaseFET-Based Oscillators

Phase transition materials (PTMs) and PhaseFETs offer intrinsic abrupt characteristics and therefore are highly suitable for the realization of relaxation oscillators. In [84], VO_2 has been used in the design of nano-oscillators (Fig. 26.18b). The working principle is based on using a series-connected resistor (or transistor) to prevent the system to stabilize in a particular phase (or find an intersection point in the load-line plot (Fig. 26.18c) by leveraging the abruptness in the current-voltage characteristics. Recall that a similar principle was used in FeFET-based oscillators [85] discussed before. Here, we describe this mechanism in a greater detail.

Let us consider in Fig. 26.18c that the PTM is in the insulating state initially. Hence, the resistor (or transistor) will charge the output node (V_0 – Fig. 26.18c). As the output voltage (or voltage across PTM) increases, IMT is triggered in the PTM. This establishes a low-resistance path from the output to ground, and the output starts discharging. As the output (and hence PTM) voltage decreases, PTM undergoes MIT. This breaks the path to ground, and the resistor (or transistor) again begins to charge the output. This keeps repeating, leading to sustained oscillations as shown in Fig. 26.18d. The gate voltage of the series transistors (not shown in Fig. 26.18b) can be used to tune the oscillation frequency, thus achieving voltage-controlled oscillations.

Further, the coupled dynamics of PTM-based oscillators have also been analyzed in [89] suggesting that the dynamics can be tuned by modulating the resistance of the series transistor, effective capacitance of PTM devices (dependent on PTM dimensions), and coupling capacitance.

26.5.2 Neuromorphic Computing

Neuromorphic computing is yet another form of non-Boolean computing that draws its inspiration from the way our brain processes data (or at least the little that we understand of it). Like for the human brain, the primitives of neuromorphic computing are neurons (or thresholding elements that fire when their weighted sums of inputs exceed a certain value) and synapses (or weights that determine the strengths between different neurons) [90]. Among the many challenges of neuromorphic computing, low-power hardware implementation of neurons and synapses remains one of the key areas of exploration.

While several existing neuromorphic architectures [91] employ CMOS technology, their energy efficiency is nowhere close to our brain. To bridge (or at least narrow) this gap, post-CMOS technologies that are intrinsically more amenable to the functionalities of the neuromorphic primitives are being actively investigated. Here, we review how FeFETs and PhaseFETs can enable low-power neurons and synapses by virtue of their unique attributes.

FeFET-Based Synapses

In FeFETs, under certain conditions [92], the FE can form multi-domains with alternating polarization directions (see Fig. 26.20a). In this multiple domain (MD) scenario, the average macroscopic polarization, $\overline{P}$, depends on the relative size of the $+P$ and $-P$ domains, which can be tuned by applying a gate voltage pulse, V_{PULSE}, as shown in Fig. 26.20b and thereby inducing a domain wall motion. Such changes in $\overline{P}$ modify the channel carrier concentrations due to the

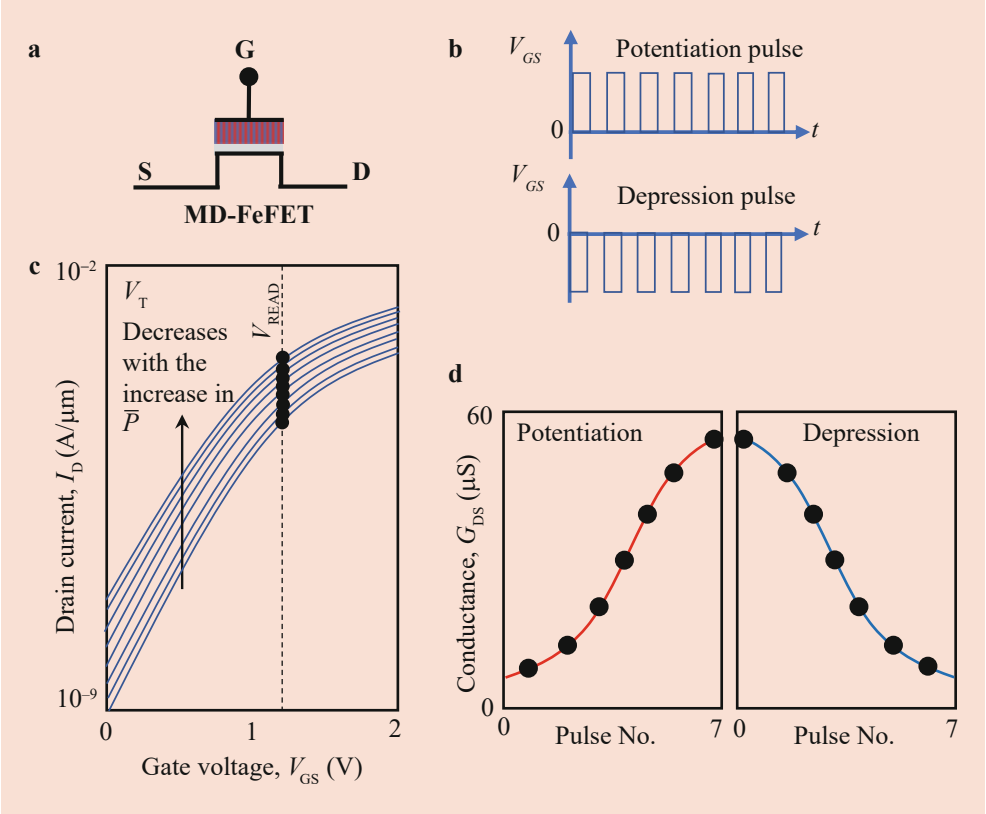

Fig. 26.20 (**a**) FeFET with multiple domains (MDs) in FE. (**b**) Voltage pulse scheme for synaptic potentiation and depression. (**c**) I_D–V_{GS} characteristics of MD-FeFET for different $\overline{P}$ that corresponds to the change in V_T. (**d**) Synaptic potentiation and depression characteristics of MD-FeFET

electrostatic coupling between the FE and the semiconductor. Alternately, the V_T of FeFET changes due to the change in $\overline{P}$ (see Fig. 26.20c), which is analogous to the dependency of V_T on the fixed oxide charge in MOSFETs. Moreover, the change in $\overline{P}$ is dependent on the magnitude and time duration of V_{PULSE} [88]. Therefore, by modulating V_{PULSE}, the V_T of the FeFET can be tuned, and thus the channel conductivity ($G_{DS} = I_D/V_{DS}$) can be modified gradually. This gradual change in G_{DS} in MD-FeFETs (see Fig. 26.20d) can readily be exploited to mimic multilevel synaptic behavior.

FeFET-based multilevel analog synaptic devices have been experimentally demonstrated in [93], where the G_{DS} potentiation and depression via a gradual V_T tuning were obtained by applying a voltage pulse at the gate terminal. However, in case of identical voltage pulses, the observed potentiation and depression characteristics are highly nonlinear and asymmetric with respect to the number of pulses. To overcome such nonidealities, different nonidentical pulsing schemes were proposed in [93]. These schemes utilize a gradual modulation of pulse amplitude or duration to improve the potentiation/depression linearity and symmetry. However, if pulses are not identical throughout the programming process, an additional step of accessing the synaptic weight (G_{DS} value) is needed every time an update takes place so that an appropriate pulse can be applied. This leads to design overheads and may increase the energy consumption of the network during training. In this regard, by using identical pulses, improved linearity and asymmetry were experimentally demonstrated in a ferroelectric germanium nanowire FET (Fe-GNWFET) [94].

In addition, an FeFET synapse featuring spike timing-dependent plasticity (STDP)-based update scheme has been demonstrated in [73] for spiking neural networks (SNNs). The proposed circuit design is shown in Fig. 26.21a, where a resistor is connected between the gate and the drain terminals of the FeFET to enable the two-terminal operation of the synapse. With this circuit design and the spiking waveform proposed in [73], the relative spike timing between the pre- and the post-neuron can be converted into a voltage drop across the FeFET. As a consequence, the closer the pre- and post-neuron spiking in the time domain, the higher is the voltage drop across the FeFET, and the larger is the change in G_{DS}. The STDP pattern considering the synaptic potentiation and depression is qualitatively depicted in Fig. 26.21b.

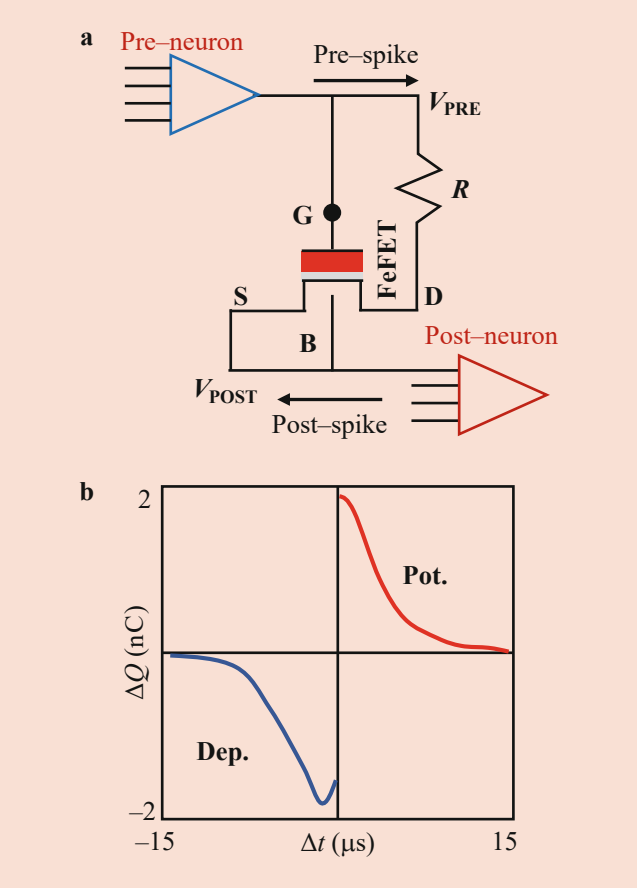

Fig. 26.21 (**a**) Schematic of FeFET-based synapse and the corresponding (**b**) spike timing-dependent plasticity (STDP) pattern

FeFET-Based Neurons

In a spiking neural network, the basic functionality of a spiking neuron is to integrate the voltage spikes fed to its excitatory input over a period of time and to generate an output spike (called fire) when the integrated quantity becomes higher than a threshold value. In addition to these integrate and fire (IF) behaviors, a neuron may also feature a leaky property while integrating spikes and is referred to as leaky integrate and fire (LIF) neuron. So far, different flavors of FeFET-based spiking neurons have been experimentally demonstrated, which we briefly discuss in this section.

The FeFET spiking neuron demonstrated in [87] comprises of 1T-1FeFET structure, where the FE layer, made out of lead zirconium titanate (PZT), is separately connected at the gate of the underline transistor with a metal (Fig. 26.22a). In this design, the "leaky" and "integration" functionalities of the neuron have been implemented in the external RC circuit, whereas the abrupt "firing" event has been mimicked through the abrupt polarization switching of FE in response to the input spikes at the gate of the FeFET (Fig. 26.22a).

The FeFET neuron demonstrated in [95] (comprising of 1R-1FeFET as shown in Fig. 26.22b) does not need an RC network and can mimic the leaky integration behavior by utilizing the inherent polarization switching dynamics of FE. In this design, an M-FE-M capacitor is connected to the gate of the underlying transistor to form the FeFET structure. A thin partially crystallized zirconium-doped hafnium oxide (HZO) layer is used so that the tunneling current can induce the leaky behavior in M-FE-M capacitor. For integration functionality, multi-domain polarization switching behavior is utilized (described earlier in the context of MD-FeFET synapse), so that the spiking inputs at the FeFET gate terminal gradually modulate the channel conductivity and hence change the output voltage of the 1R-1FeFET circuit to generate a voltage spike (Fig. 26.22b).

The FeFET-based neuronal dynamics demonstrated in [96] utilizes the polarization accumulation of FeFETs. Unlike the previous designs [95, 87], the FE layer (HZO) is directly integrated in the gate stack of FeFET. When a voltage pulse is applied to the FeFET gate for a limited time duration (typically less than the writing time of FeFET NVM), the polarization does not switch completely but merely changes incrementally. However, after a certain number of pulses are received, the FeFET abruptly switches to the LRS. Such phenomenon can be understood as the initial nucleation of nano-domains followed by an abrupt polarization reversal of the entire FE layer. Now, the applied pulses prior to the latching of the LRS can be regarded as the process of "integration" of excitatory inputs, whereas the subsequent abrupt transition from HRS to LRS can be regarded as the "firing event." To obtain the leaky behavior, a proposed option is the insertion of a negative inhibitory voltage in the intervals between consecutive excitatory pulses.

Apart from this externally emulated leaky feature (by applying an additional inhibitory signal), the possibilities for an intrinsically leaky process have been theoretically predicted in [88], which originates from the domain wall instability leading to spontaneous relaxation in average polarization. Such leaky characteristics have been experimentally demonstrated in an HZO thin film [97]. Moreover, the polarization leak rate exhibits a dependence on the initial polarization value, which is distinct from the conventional leak rate of first-order system (i.e., RC network). Utilizing such quasi-leaky (QL) behavior along with the IF characteristics, a quasi-leaky-integration-fire (QLIF)-type FeFET-based neuron was realized [97]. QLIF analysis predicted a reduction in firing rate in SNNs compared to traditional LIF neuron at iso-accuracy.

PhaseFET-Based Neurons

By virtue of their abrupt phase transitions, PTMs (and hence PhaseFETs) can potentially be ideal candidates for the implementation of the thresholding function of neurons. In

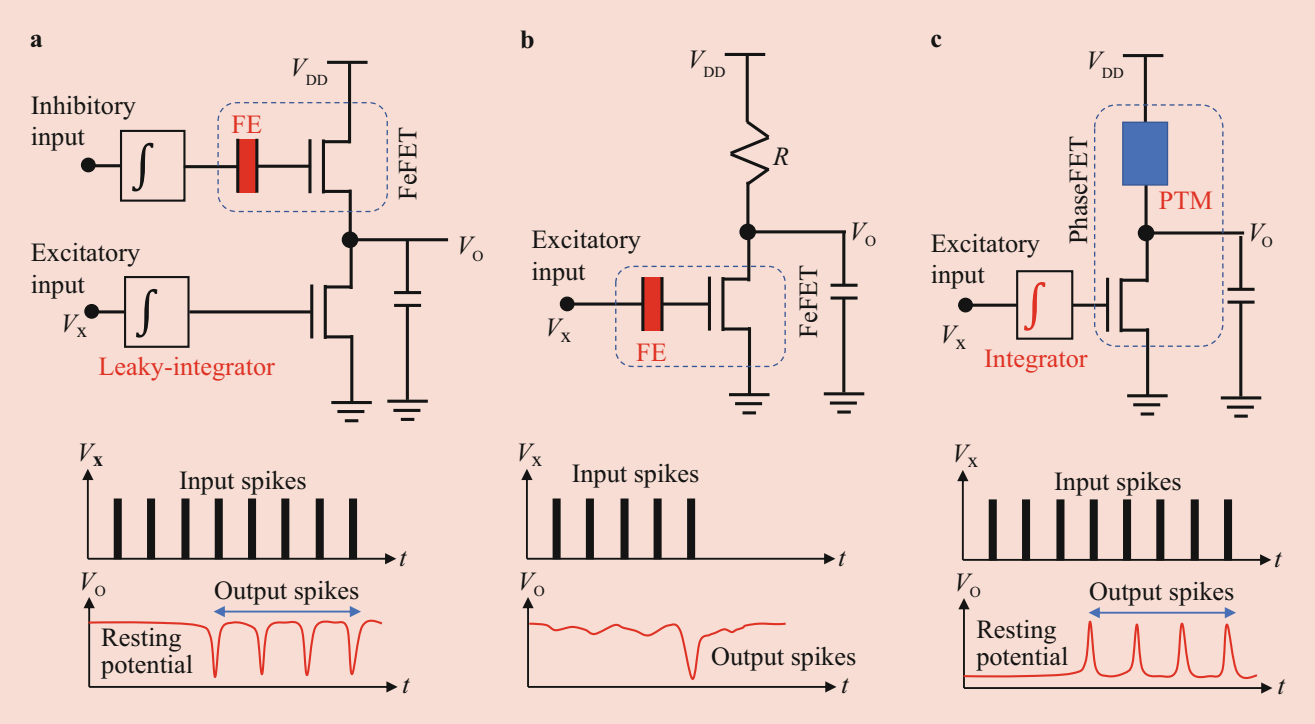

Fig. 26.22 Schematics and input-output spiking waveform for (**a**) 1T-1FeFET neuron, (**b**) 1R-1FeFET neuron, and (**c**) PhaseFET (1T-1PTM) neuron

addition, the ability of PTMs to oscillate (see Sect. 26.5.1) offers an elegant method of generating a train of output spikes where the spiking frequency can be used to encode the data. These features have been used in [54] to design a spiking neuron, as shown in Fig. 26.22c. Moreover, by biasing the neuron close to the critical voltage for IMT and leveraging the inherent randomness of the phase transition in PTMs, stochasticity in the neuron firing can be achieved. Stochastic neurons have been known to facilitate better generalization by preventing over-fitting of data during training [54]. PhaseFETs offer an ultralow-power hardware solution to design stochastic neurons. It is noteworthy that the PhaseFET only provides the thresholding (or fire) functionality; the leaky integrate functionality is obtained using additional circuitry. In contrast, FeFETs have been shown to exhibit a wide range of unique characteristics that can potentially achieve the LIF with a minimal number of transistors.

26.6 Summary and Conclusions

In this chapter, we presented a systematic overview of the fundamental device physics and the applications of NCFETs and PhaseFETs, given their immense potential to outperform MOSFETs in specific applications where low-power consumption is of paramount importance. These devices were first conceptualized to overcome the fundamental physical limits dictated by the Boltzmann tyranny that lead to the unbearable power dissipation in standard MOSFETs, especially at deeply scaled technology nodes.

We presented a theoretical analysis of NCFETs based on the phenomenological Landau theory that describes the negative capacitors as special capacitors with double-well energy landscape. Their unique properties enable a voltage step-up action in the gate stack that, in turn, leads to steep-switching. We described the conditions to achieve subthermionic switching (i.e., subthreshold swing lower than the Boltzmann limit of 60 mV/dec at room temperature) for a particular class of NCFETs employing ferroelectrics as a negative capacitance layer. We also provided a comparison of the reliability physics of NCFETs with conventional MOSFETs to outline the advantages and drawbacks of the technology. We additionally discussed the advanced issues along with open questions that need to be answered to fully harness the potential of NCFETs. Similarly, we discussed the theoretical aspects of PhaseFETs, which utilize a phase transition material in series with a conventional transistor to obtain steep-switching. We also outlined their current stage of development (presenting experimental data from the literature).

We also discussed various circuit applications of NCFETs and PhaseFETs. We began by presenting the implications of steep-switching and other unique features of NCFETs and PhaseFETs on the performance of Boolean logic and

SRAMs, showing delay reduction at iso-energy at low voltages and improvements in stability/noise immunity. In addition to steep-switching, ferroelectric-based transistors offer hysteretic characteristics, which can be highly beneficial for low-power nonvolatile memory (NVM) designs. In contrast, PhaseFETs cannot be used as NVMs; however, they can be employed to augment MRAMs to improve their read stability and distinguishability. Furthermore, the unique characteristics of FeFETs, NCFETs, and PhaseFETs enable low-power hardware for non-Boolean computing such as coupled oscillators and neuromorphic primitives. Our discussion points to the importance of understanding the unique device-circuit interactions in these technologies to translate their rich physics into useful circuit functionalities.

Every couple of years or so, new predictions about the demise (and confirmation) of Moore's law are discussed in conferences as well as in the general media. Although we cannot predict with certainty when the final chapter of this very fortunate roadmap will be written, newer devices like NCFETs and PhaseFETs provide researchers with confidence that the ability of mastering new challenges and overcoming the limits of current technology will never completely falter. In this sense, steep-switching devices belong to an exciting novel class of transistors that not only can potentially improve conventional logic switches and semiconductor memories but also offer advantages to novel applications, as for example to realize super-Nernstian nano-biosensors [98, 99]. In general, both NCFETs and PhaseFETs pave the way for a brand-new design space for a variety of applications that are yet to be explored and that we expect will continue to grow in the decades to come.

Muhammad Ashraful Alam Professor Alam is the Jai. N. Gupta Endowed Chair. Professor at Purdue University, where his research focuses on fundamental limits and end-to-end modeling of classical (transistors and solar cells) and emerging (biosensors, flexible electronics) electronic devices. His research has been recognized by the fellowships in multiple professional organizations (IEEE, APS, and AAAS) as well as by the 2006 IEEE Kiyo Tomiyasu Award, 2015 SRC Technical Excellence Award, and 2018 IEEE EDS Education Award. His web-enabled courses posted at nanohub.org on solid-state devices, reliability physics, nano-biosensors, and solar cells are used by hundreds of thousands of users in industry and academia across the world.

Nicolö Zagni earned his Doctoral degree in 2021 in Information and Communication Technologies (ICT) at the University of Modena and Reggio Emilia, Italy. His research interests are into modeling, simulation, and characterization of emerging semiconductor devices for low-/high-power, logic, and memory applications. In 2018 and 2019, he was a Visiting Scholar at Purdue University where he worked on ferroelectric negative capacitance transistors and their applications.

Atanu Kumar Saha is pursuing his Ph.D. in Electrical Engineering at Purdue University, USA. Prior to this, he served as a Lecturer in BRAC University, Bangladesh, from 2013 to 2016. His current research interests include advanced multi-scale modeling of emerging materials and devices, developing simulation framework for post-CMOS technologies, compact modeling, and device-circuit co-design for Boolean and neuromorphic computing.

Niharika Thakuria is a Ph.D. Student in the Integrated Circuits & Devices Laboratory (ICDL), Purdue University. Her current research interests are in compact modeling and device-circuit co-design of post-CMOS technologies, post-CMOS device-based logic and memory design (including nonvolatile memory), and circuits for non-Boolean computing.

Sandeep Thirumala earned his Doctoral degree in the School of Electrical and Computer Engineering at Purdue University, IN. He received his Bachelor's degree in Engineering Physics from the Indian Institute of Technology, Madras, and Master's degree in Electrical Engineering from the Pennsylvania State University, PA. He is currently an MTX Product Engineer at Micron. His research interests are focused toward device-circuit co-design, near/in-memory computing architectures, emerging technologies for memory design, and nonvolatile logic and systems.

Sumeet Kumar Gupta is an Associate Professor of Electrical and Computer Engineering at Purdue University. Prior to this, he was an Assistant Professor of Electric Engineering at the Pennsylvania State University from 2014 to 2017 and a Senior Engineer at Qualcomm Inc. from 2012 to 2014. His research interests include low-power variation aware VLSI circuit design, neuromorphic computing, nanoelectronics, spintronics, device-circuit co-design, and nano-scale device modeling and simulations. He has published over 100 articles in refereed journals and conferences and is a Senior Member of IEEE and EDS. He was the recipient of DARPA Young Faculty Award in 2016, an Early Career Professorship by Penn State in 2014, and the 6th TSMC Outstanding Student Research Bronze Award in 2012. He has also received Magoon Award and the Outstanding Teaching Assistant Award from Purdue University in 2007 and Intel Ph.D. Fellowship in 2009.

Abstract

Thin-film transistors (TFTs) have been successfully used as the key electronic components in today's displays in mobile electronic devices and televisions, as well as in a new realm of biomedical imagers and related applications. The requirement for mechanical flexibility and stretchability, needed in a new generation of displays and wearable devices, poses new process integration challenges for TFTs, particularly for some materials families. This chapter is focused on the flexible TFTs and their biomedical applications, in which the materials presented are drawn from several doctoral theses. We begin with a comparison of TFT technologies based on different material families in terms of their electrical performance and flexibility. The general methods for TFT fabrication are introduced, along with a special focus on printable and flexible TFTs. Subsequent discussions are focused on introducing concepts underlying modelling and simulation of flexible TFTs, addressing circuit design considerations and compensation for spatial and temporal device variations and related instabilities. Here, we review the different TFT compact models that have been reported along with small signal models and techniques for parameter extraction. Finally, we focus on the applications of flexible electronics and biomedical applications, addressing the challenges and benefits of using flexible sensors and sensor interfaces, related system design, and integration considerations, along with different use cases.

27.1 Flexible Electronic Devices and Fabrication

27.1.1 Key Materials

Typical TFT technologies are broadly based on four types of materials and structures. These include amorphous silicon, low-temperature polycrystalline silicon, amorphous oxide

Table 27.1 Basic performance and fabrication specification comparison for TFT technologies

TFT technologies	a-Si	LTPS	IGZO	Organics
Material				
Band gap (eV)	~1.8	~1.1	>3	1–3
Density of deep states (cm^{-3} eV^{-1})	$\sim 10^{18}$	$\sim 10^{18}$	$\sim 10^{17}$	$>10^{14}$
Device

semiconductors, and organic families, all of which have different electrical and mechanical properties [1] (Table 27.1).

Amorphous Silicon

Amorphous silicon (a-Si) is the non-crystalline form of silicon and was used in the first commercialized TFTs (Fig. 27.1). Before the 1960s, a-Si was formed by sputtering or by thermal evaporation, and the material had a very high defect density, which prevented doping, photoconductivity, and the other desirable characteristics of a useful semiconductor [2]. To reduce the defects, in 1974, Lewis et al. introduced hydrogen to the sputtering system and improved the material properties with high photoconductivity, a low defect density, and low doping [3]. A similar improvement was achieved actually 5 years earlier by Chittick et al. using radiofrequency (RF) glow discharge to deposit a-Si thin films from silane (SiH_4) gas [4], but the effect of Si-H bonds in improving material quality had not been found. Since the findings by Chittick et al. and Lewis et al., hydrogenated a-Si has been intensively developed using SiH_4 through plasma-enhanced chemical vapour deposition (PECVD) and has been widely used in solar cells and TFTs for display pixel circuits. Despite this success, a-Si TFTs demonstrate a mobility of around $1\,cm^2V^{-1}s^{-1}$, which is far lower than that of single-crystalline silicon in metal-oxide-semiconductor field-effect transistors (MOSFETs) ($1400\,cm^2V^{-1}s^{-1}$ and $450\,cm^2V^{-1}s^{-1}$ for electron and hole mobility, respectively) [5]. The main factor that limits the mobility of a-Si films is the nature of disordered

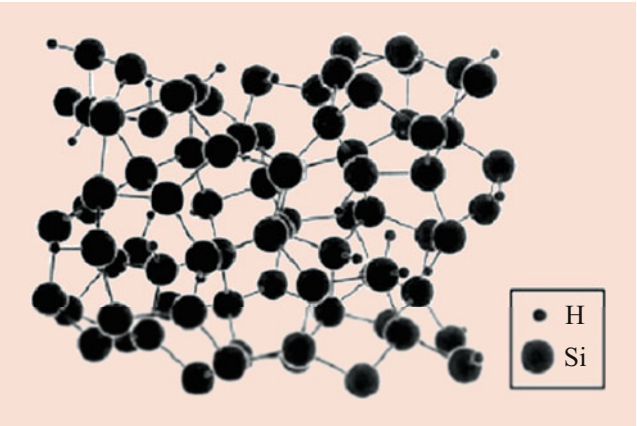

Fig. 27.1 Structure of hydrogenated amorphous silicon. (Adapted from [2])

crystalline structure that causes scattering at the grain boundaries. To reduce scattering and increase material mobility, a better ordered form of silicon is necessary, giving rise to polycrystalline silicon. In addition, a-Si TFTs are manufactured with vacuum systems, i.e. PECVD, sputtering, and reactive-ion etching. Thus, the manufacturing cost still needs to be reduced.

Low-Temperature Polycrystalline Silicon

Polycrystalline silicon (poly-Si) is a form of silicon whose crystalline order is between that of single-crystal silicon and a-Si, with grain sizes in the range of 1–100 μm. However, the

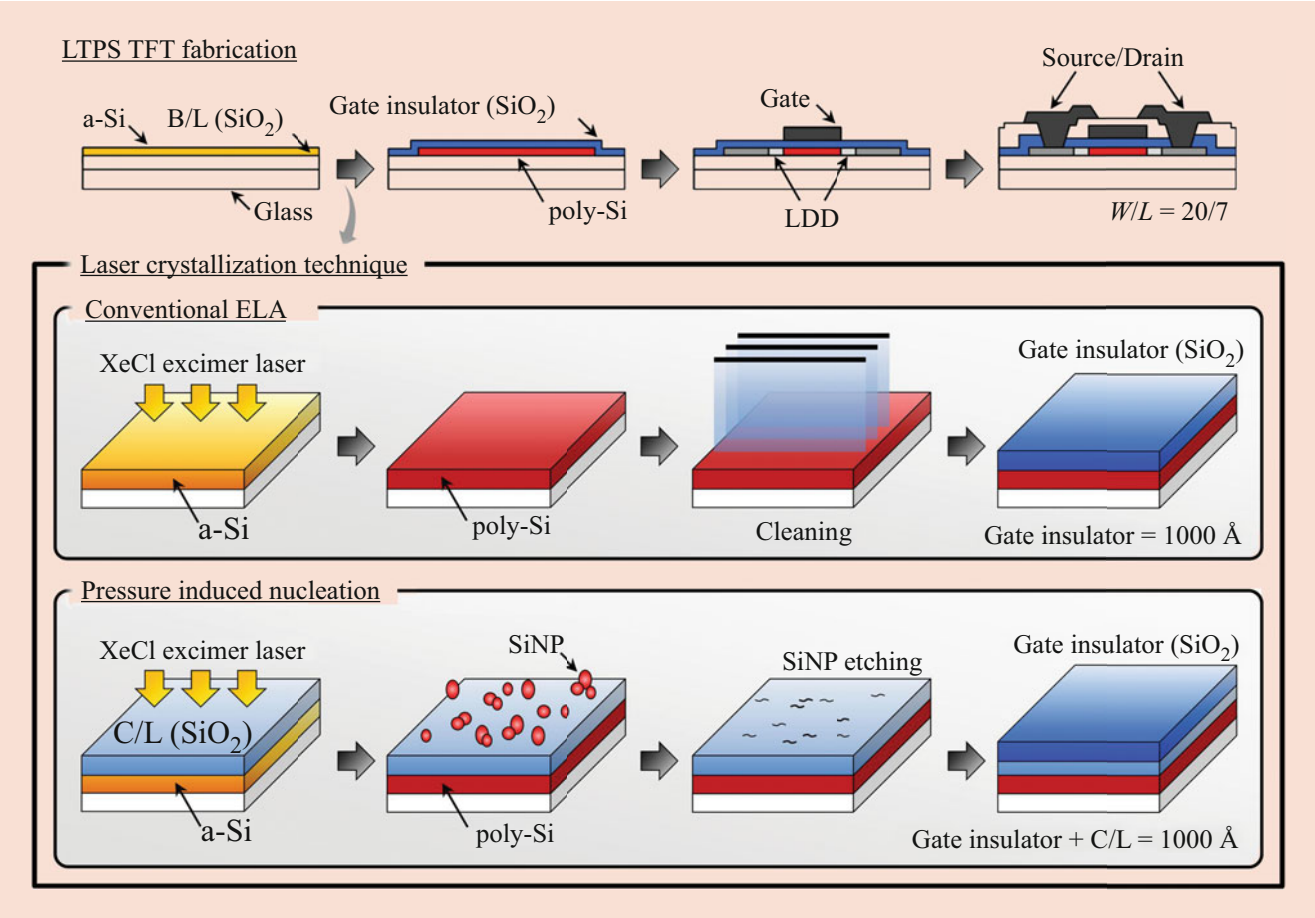

Fig. 27.2 Schematic illustration of the LTPS TFT fabrication scheme. (Adapted from [10])

conventional poly-Si process requires a high temperature of over 900 °C. Due to the requirements for display manufacturing at low temperatures on glass substrates, low-temperature polycrystalline silicon (LTPS) was invented by using XeCl excimer laser annealing (ELA) to produce poly-Si by melting a-Si material through laser irradiation (Fig. 27.2). The ELA temperature is relatively low (i.e. ~500 °C) compared to the conventional process. However, the additional poly-crystallization process from a-Si increases both process temperature and time [6]. To tackle these problems, pulsed rapid thermal annealing was developed [7, 8]. Due to larger grain sizes, LTPS TFTs generally show a high mobility of ~100 $cm^2V^{-1}s^{-1}$, and reports have demonstrated their use in logic circuits, memories, and CPUs [9]. However, there is a lack of reliable large-area production processes for LTPS TFTs with good mobilities [6], and scaling up LTPS TFTs significantly increases the cost for delicate and complex XeCl excimer lasers, therefore necessitating alternative methods for producing poly-Si.

In addition to poly-crystallization from a-Si, poly-Si films can be solution processed. Shimoda et al. reported spin-coated and inkjet-printed poly-Si TFTs through ultraviolet (UV) irradiation of cyclopentasilane (which is a liquid silicon material), demonstrating a high mobility of 108 $cm^2V^{-1}s^{-1}$ and 6.5 $cm^2V^{-1}s^{-1}$, respectively [11]. With solution-processed poly-Si, the process temperature was further reduced to 300–400 °C, compared to ELA. However, for flexible TFTs, their substrates require mechanic flexibility. Good substrate candidates are polymers, such as polyethylene terephthalate (PET), polyethylene naphthalate (PEN), and polyimide (PI), but their glass transition temperatures are <200 °C. Therefore, the process temperatures for silicon-based TFTs are still too high, and low-temperature (i.e. <200 °C) processable semiconductor alternatives are demanded.

Amorphous Oxide Semiconductors

Metal oxide semiconductors are a class of TFT materials, including binary oxides (ZnO, In_2O_3, SnO_2, Ga_2O_3) and ternary and quaternary compounds from the binary materials. In the past decade, amorphous indium gallium zinc oxide (a-IGZO) has been intensively studied, demonstrating a high mobility of >10 $cm^2V^{-1}s^{-1}$ while balancing several issues in the binary systems, including instability [12], low

mobility [13], and low current on/off ratio [14]. The reason that amorphous oxide semiconductors (AOS) possess high electron mobilities is that AOS are ionically bonded by oxygen sp^3-orbitals with metal s-orbitals, of which the shape is a sphere [15] (see Fig. 27.3). Therefore, metal s-orbitals are insensitive to bonding angles, resulting in high electron mobilities even in an amorphous phase. This is a key advantage of AOS over a-Si, in which the covalent bonds formed by silicon tetrahedral-shape sp^3-orbitals are sensitive to bonding angles, significantly degrading carrier mobility in an amorphous phase.

The high electron mobilities of AOS enable low-temperature sputtering AOS, which can greatly reduce the manufacturing cost compared to using PECVD. In addition, the wide band gaps (>3 eV) of most AOS make them suitable for transparent electronics [16] and more importantly ultra-low-power electronics [17, 18] for flexible electronics. However, ZnO-based TFTs fabricated at a low temperature lack operational stability unless annealed at 400 °C [19], since Zn-containing AOS are sensitive to moisture in the ambient environment [20]. This limitation motivated the development of Zn-free AOS TFTs. In_2O_3 is a good base material due to its wide band gap of 2.9 eV, but the issue of In_2O_3-based AOS is their stability due to excessive oxygen vacancies (V_O). Suppressing V_O can be achieved by adding gallium, as well as silicon, titanium, and tungsten, to enhance TFT operational stability [21–23]. Since the increasing usage of indium as a key material in the solar cell and display industry resulted in the shortage of indium, indium-free AOS became popular, such as gallium tin zinc oxide (GSZO) [24], tungsten-doped ZnSnO (WZTO) [25], and zinc oxynitride (ZnON) [26–28]. Despite these, a-IGZO is still the most popular material among AOS.

Apart from n-type AOS, some oxide semiconductors are p-type, such as tin oxide (SnO) [29] and copper oxide (CuO) [30]. These materials can also be deposited by sputtering. With both n-type and p-type semiconductors, complementary metal oxide semiconductor (CMOS) based on AOS was reported by Martins et al., demonstrating ultra-low-power circuits on flexible paper substrates [31, 32].

Since sputtered AOS TFTs require vacuum systems to further reduce manufacturing cost, solution-processed AOS have also been investigated. The soluble precursors are important. Common precursor solutions include acetate-, nitride-, and chloride-based precursors, among which the former two require lower process temperatures. The reactions from precursors to AOS generally take three steps: decomposition of metal ions and acetates/nitrides, hydrolysis of metal ions to form metal-OH bonding, and dehydroxylation to form metal-oxygen bonding. The maximum process temperatures are in the range of 200–300 °C. Based on soluble metal oxide precursors, AOS TFTs have been demonstrated by spin coating [33], spray coating [34], and inkjet printing [35–37], depicting high ($>10\,cm^2V^{-1}s^{-1}$) electron mobilities. In comparison to sputtered AOS, solution-processed AOS requires relatively high (>200 °C) process/annealing temperatures. There have been reports of solution-processed AOS TFTs under 200 °C [38], but the device performance is generally not as good as those annealed at higher temperatures (e.g. >250 °C) [39]. Although improvements are evident compared to the process temperatures for silicon-based solution-processable semiconductors, further developments in low-temperature AOS are required to meet the requirements of flexible plastic substrates.

Organic Semiconductors

Organic semiconductor materials are carbon-based compounds that consist of π-conjugation systems, which contribute to electron/hole charge transport. Depending on their molecular structures, organic semiconductor materials can be categorized into small molecules and polymers depending on their molecular structures. The most common small molecules include rubrene [40], pentacene (and its derivatives) [41], anthradithiophene (ADT) derivatives [42], and benzothieno[3,2-b] [1], benzothiophene (BTBT) derivatives [43]. Most polymer semiconductors are thiophene-based, such as region-regular poly-(3-hexylthiophene-2,5-diyl) (P3HT) [44] and indacenodithiophene-co-benzothiadiazole (IDT-BT) [45]. In general, small molecules can form well-ordered crystalline phases and thus demonstrate higher mobilities; however, mobilities of small molecules depend on the stacking directions of molecules [46], which are randomly distributed by most deposition methods (e.g. spin coating, inkjet printing), resulting in large variation of mobility values. In contrast, polymers are normally in amorphous phases, which yield better uniformities but lower mobilities ($<1\,cm^2V^{-1}s^{-1}$). The first organic TFT was invented by Koezuka et al. using polymer semiconductor, polythiophene in 1987, but the mobility was only $2\times10^{-5}\,cm^2V^{-1}s^{-1}$ [47]. In the past three decades, significant developments in organic semiconductors have been achieved, with a high mobility of $>10\,cm^2V^{-1}s^{-1}$ in both small molecules and polymers [48].

The most striking advantage of organics is their solution processability. Although silicon and AOS are also solution-processable, they need high process temperatures for precursors to react and form the desired materials and structures. In contrast, organics can easily dissolve in compatible organic liquids, which simplifies the processes of ink formulation and post-deposition reactions/treatments. This feature of organics enables organic TFTs and circuits printable on plastics with process temperatures of lower than 130 °C [50]. In addition, all-printed organic TFTs have been reported [51–53]. However, conventional solution-processed organic TFTs require high operating voltages of several tens of volt,

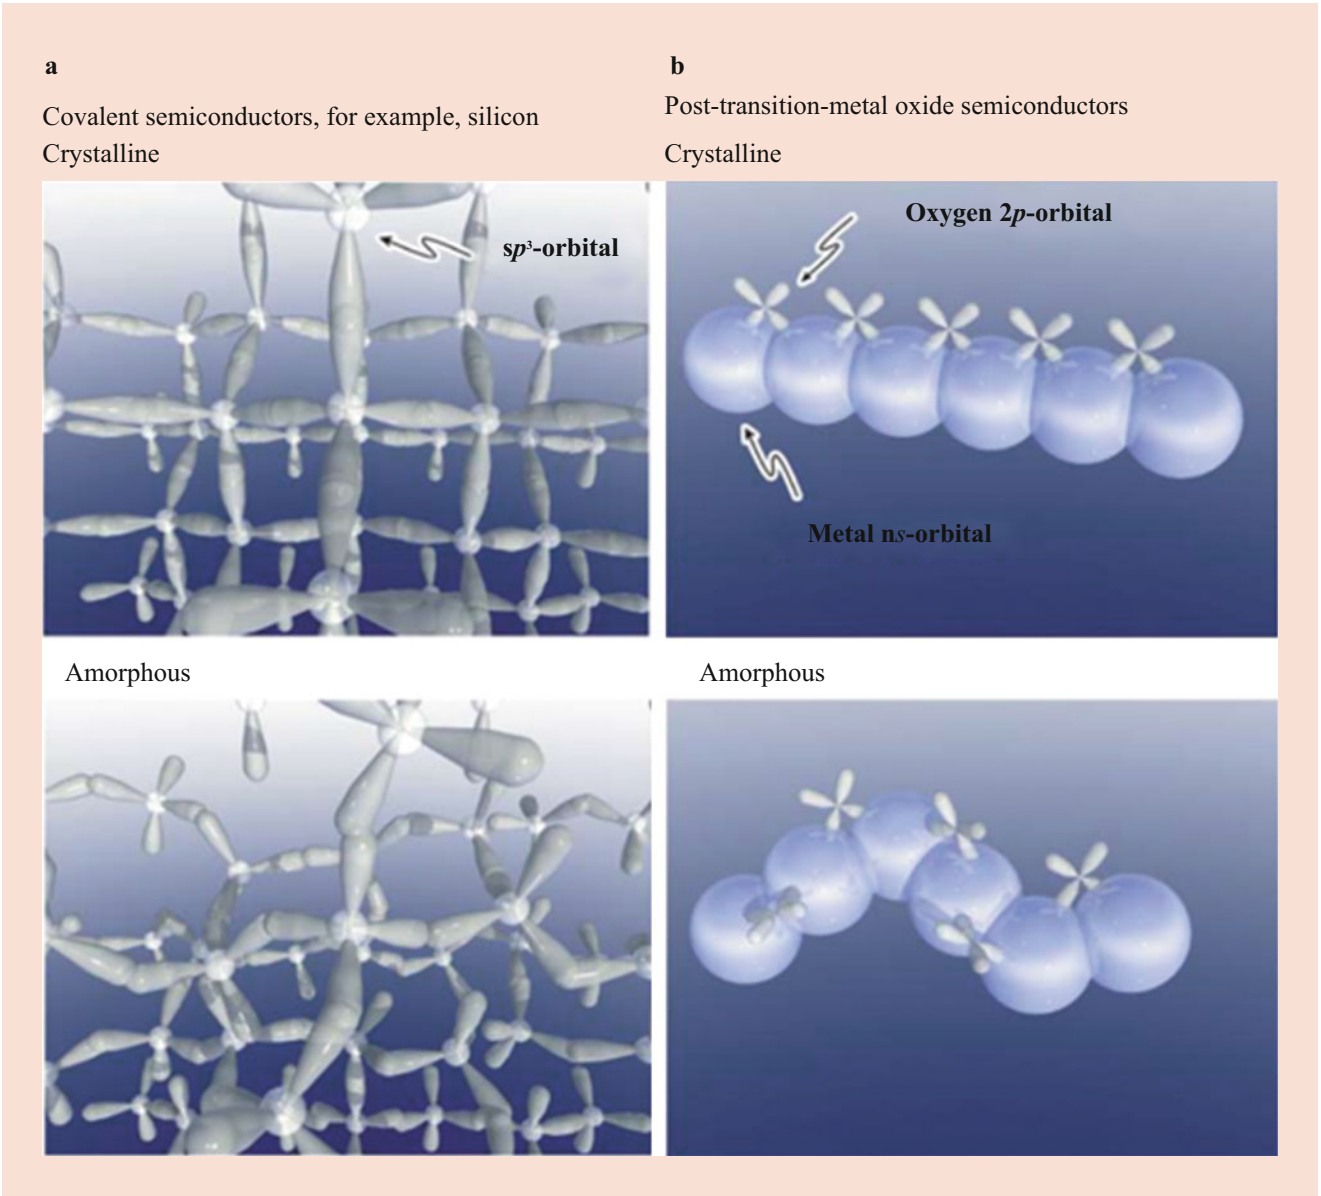

Fig. 27.3 Schematic orbital drawings for charge transport paths in the conduction band of crystalline and amorphous covalent (**a**) semiconductors (e.g. silicon) and (**b**) metal oxides. (Adapted from [15])

which contradicts the idea of low power. To tackle this issue, considerable effort has been made to lower the operating voltage of organic TFTs, and reports have demonstrated low an operating voltage of less 1 V, which has greatly reduced the power consumption for TFT operation [54–56].

Another advantage of organics is their mechanic flexibility. In contrast to silicon and metal oxides that are covalently bonded, organic molecules are van der Waals bonded and therefore can restore themselves from certain bending deformations. Someya and his coworkers have developed organic TFTs with both n-type and p-type devices and integrated them into circuits, demonstrating extreme bending stability [57, 58]. The same research group has reported ultra-flexible and ultra-lightweight organic TFTs, which are potential candidates for imperceptible electronics to be employed on the skin [59]. In recent years, intrinsically stretchable organic semiconducting materials have been achieved by Bao and her coworkers through the nanoconfinement of polymers into nanometer-scale dimensions (see Fig. 27.4), which can alter many polymer physical properties, including lowering the mechanical modulus and glass transition temperature and increasing the mechanical ductility [49, 60]. In addition to flexibility and stretchability, organic TFTs have also been developed as essential components for sensors [61], radiofrequency identification (RFID) tags [62], smart memories [63], point-of-care diagnostic systems [64], and wearable systems

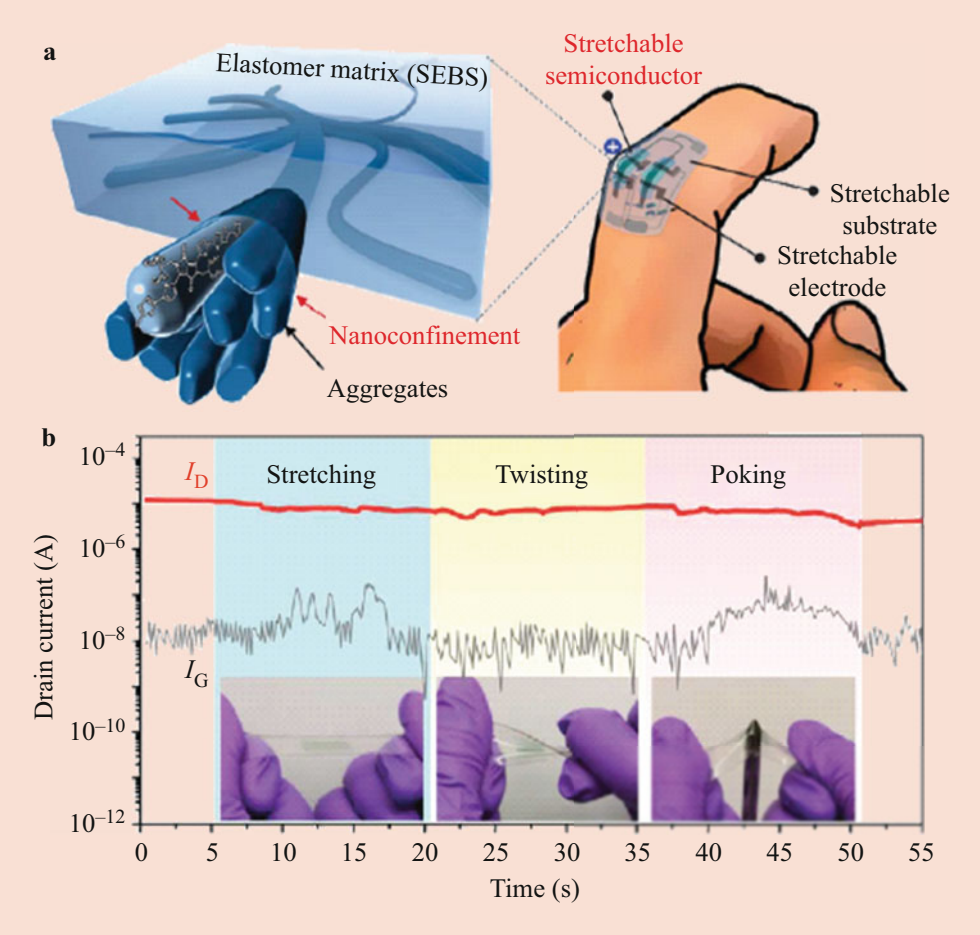

Fig. 27.4 Nanoconfinement effect for enhancing the stretchability of polymer semiconducting film and organic TFT. (**a**) A 3D schematic of the desired morphology composed of embedded nanoscale networks of polymer semiconductor to achieve high stretchability, which can be used to construct a highly stretchable and wearable TFT. [65]. With good compatibility to the skin, the organic TFT-based flexible e-skin has been proposed and developed [66].

27.1.2 Fabrication Methods

Vacuum Depositions

Thermal Evaporation

Thermal evaporation is a popular technique for thin metallic layer deposition such as aluminium and chrome due to their simplicity (see Fig. 27.5). It can be also used for organic semiconductor deposition. The source material is placed on a conductive carrier (normally tungsten or molybdenum with a much higher melting point), a filament, or a boat. A current is passed through the carrier to heat the source material to an evaporation point. The substrate is placed above the evaporating material, and any molecules that hit the substrate will condense. The distance between source and substrate should be large enough to grant the thin film uniformity but also small compared with the mean free path in the vacuum. The evaporation generally produces amorphous layers. The poor step edge coverage and non-uniformity over large areas are the main disadvantages of this process.

Sputtering

Sputtering employs a large source target, which is normally a block of metal [67, 68]. A bigger source metal will contribute better uniformity relative to evaporation with a point metal source see Fig. 27.6. Sputtering also provides good step coverage. However, sputtering is a more costly process to implement, as an inert gas is required to fire at the target under a vacuum. The basic principle behind sputter coating is that the inert gas ion passes its kinetic energy to the atoms at or near the target surface, allowing them to escape into the vacuum. The released atoms will condense when they hit the substrate. Argon is most commonly used for a sputtering system, but it may also be incorporated into the substrate

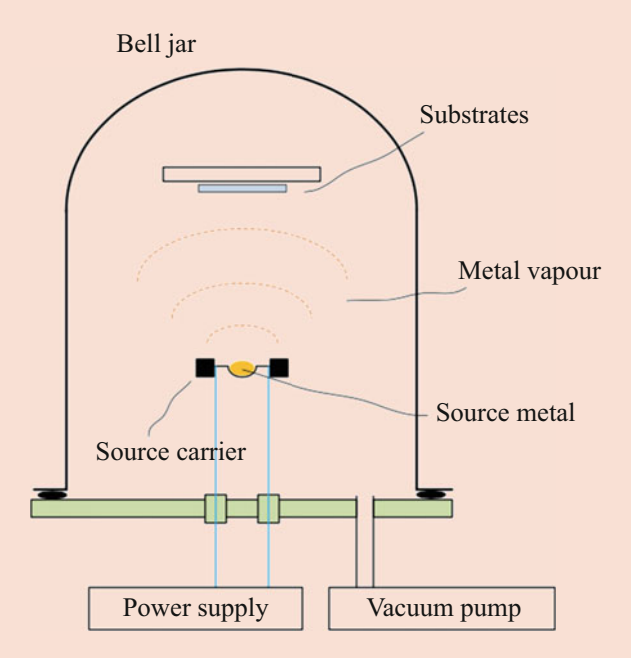

Fig. 27.5 A typical bell jar thermal evaporation system

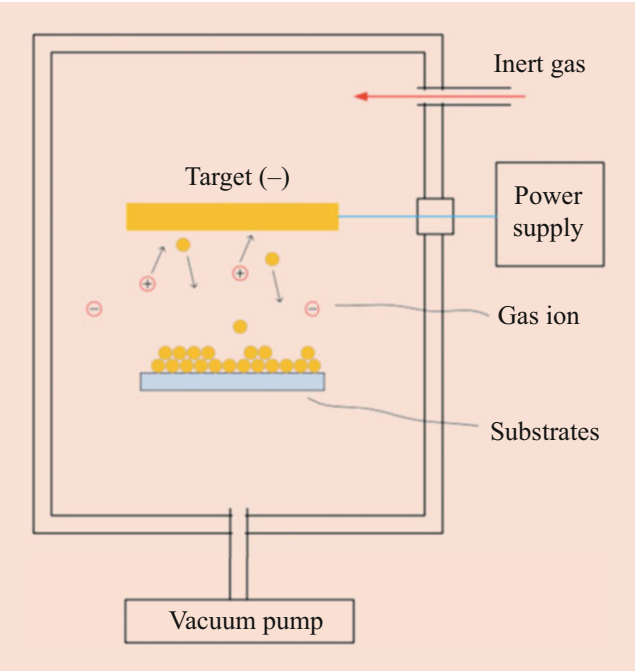

Fig. 27.6 A typical sputtering system

which is leading a porous sample. The gas used can also include some reactive gas, such as oxygen and nitrogen, and therefore sputtering can be used for amorphous metal oxide semiconductor deposition.

Chemical Vapour Deposition

Chemical vapour deposition (CVD) is a process in which films of materials are deposited from the vapour phase by the decomposition of chemicals on the surface of a substrate [69]. Contrary to thermal evaporation and sputtering, chemical vapour deposition involves chemical reactions, which can be enhanced by photo or plasma. For plasma-enhanced CVD (PECVD), the plasma is generated by radiofrequency or direct current discharge between two electrodes. The two electrodes are generally two metal plates, by which the substrate is sandwiched for material depositions. For PECVD system, it is essential that the distance between the two electrode plates is well-controlled to maintain a constant electrical field and therefore the plasma intensity. In addition, the flow rates of gases feeding into the vacuum chamber needs to be controlled by mass flow controllers to achieve a good gas environment and a constant mixture of gases if more than one gas is used. For TFTs, CVD is widely used for the deposition of several inorganic materials, such as amorphous silicon, silicon oxide, and silicon nitride.

Atomic Layer Deposition

Atomic layer deposition is a subclass of CVD. Different from conventional CVD that all the precursors are filled into the chamber simultaneously, only one gas precursor is present at each cycle of ALD to deposit materials atomically, as shown in Fig. 27.7. Generally, ALD involves at least two precursors. For example, the deposition of aluminium oxide (AlO_x), one of the most widely used materials by ALD, generally uses trimethylaluminium (TMA) and water (H_2O). During the TMA cycle, TMA gas is filled in the vacuum chamber, and some of the ethyl groups in TMA are dissociated so that the surface of substrate is covered by $Al(CH_3)_2$. During the H_2O cycle, the ethyl groups react with the H_2O molecules, leaving the surface of substrate covered by hydroxyl groups that can react with TMA for the next cycle. It is important that between each of the two gas cycles, the chamber is purged with an inert gas, such as argon, to avoid undesired reaction in the chamber and exhaustion gas line. Due to the nature of ALD, the coverage and the uniformity of deposited films are good, but the process is slow. To increase the deposition speed, a spatial ALD system with inert gas curtains was invented [70]. In this spatial ALD system, two precursors are always present in the chamber but separated by an inert gas curtain, and the substrate swings between the two spaces that contain different gases. Since the substrate can swing faster than the purge cycles in the conventional ALD systems, the deposition speed can be greatly enhanced.

Printing Techniques

In the past, printing was a method that was used to transfer a layer of ink from a stamp to a substrate [71]. In contrast to

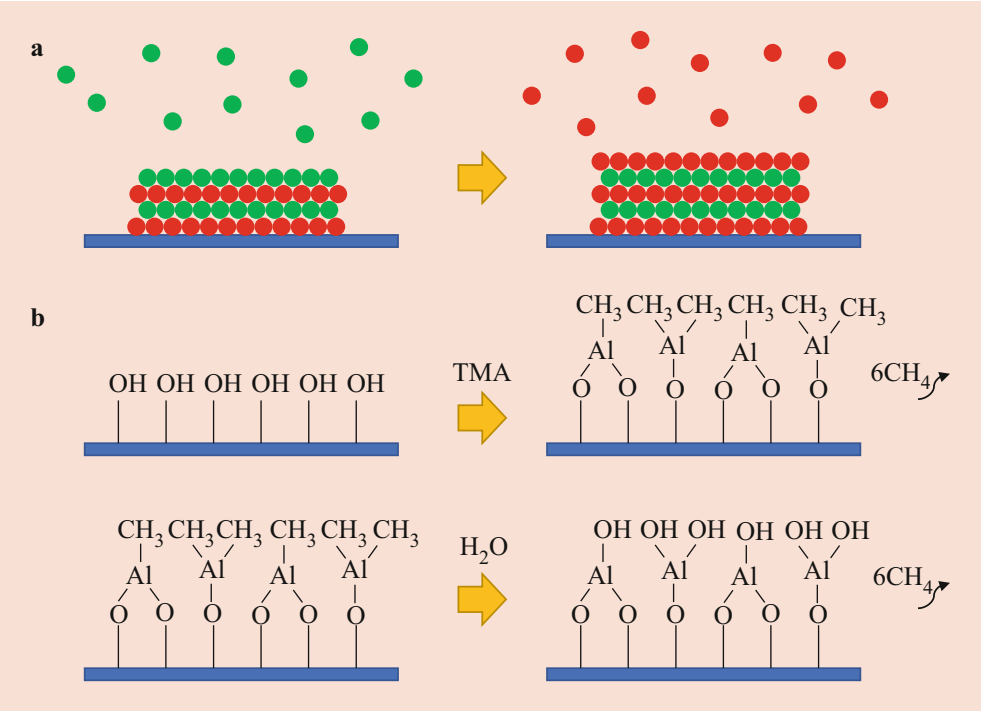

Fig. 27.7 (**a**) A schematic of ALD. (**b**) An example of the ALD of aluminium oxide

coating techniques, which simply involve pouring or casting materials over a surface, printing can provide more complex patterns (see Fig. 27.8). For the fabrication of electronic devices, patterning electronic materials is important to achieve integrated films and patterns that can function as an electronic device. For conventional fabrication of electronic devices, i.e. silicon MOSFETs, the wastage of materials is huge, since all the material deposition processes involve photolithography. In a typical photolithography process, a layer of a material is deposited and covers the whole substrate, and the unwanted areas are removed afterwards to form the desired patterns. Compared to photolithography, printing is more straightforward, and the patterning of materials can be achieved by the so-called direct patterning, i.e. depositing materials only on the wanted areas. In this way, material wastage can be greatly reduced. Therefore, printing techniques are suitable to meet the low-cost requirements of TFT fabrication for bio-applications, where low fabrication cost and negligible material waste are important criteria. Regarding TFT technologies, here we focus on printable organic TFTs, which have better compatibility with printing technologies and better mechanical flexibility as previously mentioned.

Inkjet Printing

Inkjet printing is the most promising printing technique which can produce high-resolution two-dimensional patterns. An inkjet printer consists of a cartridge and a printhead [72]. The cartridge contains ink and supplies the ink to the printhead. The printhead is a sophisticated micro-scale system which pumps the ink through nozzles to form jetted droplets, as shown in Fig. 27.9a. The printhead is designed to be resistant to organic solvents, which allows a wide range of solvents for ink formulation, and therefore the inkjet printing technique is compatible with various printable materials. Inkjet printing has several advantages, including good resolution, little material waste, the potential for customization, and no contact between the printhead and substrate [73]. These advantages are highly beneficial for printed electronics. Currently, inkjet printing for commercial electronics is still very limited, and most of the work is at the research and development or prototype level.

Screen Printing

Screen printing consists of a screen of woven material and a squeegee, as shown in Fig. 27.9b. The pattern of screen is obtained by partially filling the screen with an emulsion, which prevents ink from contacting the substrate. The open area without emulsion allows ink to go through, by which the deposited material is patterned. During printing, the screen is filled with ink, and the squeegee then forces the screen to contact the substrate to produce the pattern. Screen printing is currently widely used in industry for simple patterns, such as printing etch resists, and for complex patterns such as printing conductors for flexible electronics [71]. It can also be fully adapted to a roll-to-roll process with a rotary screen.

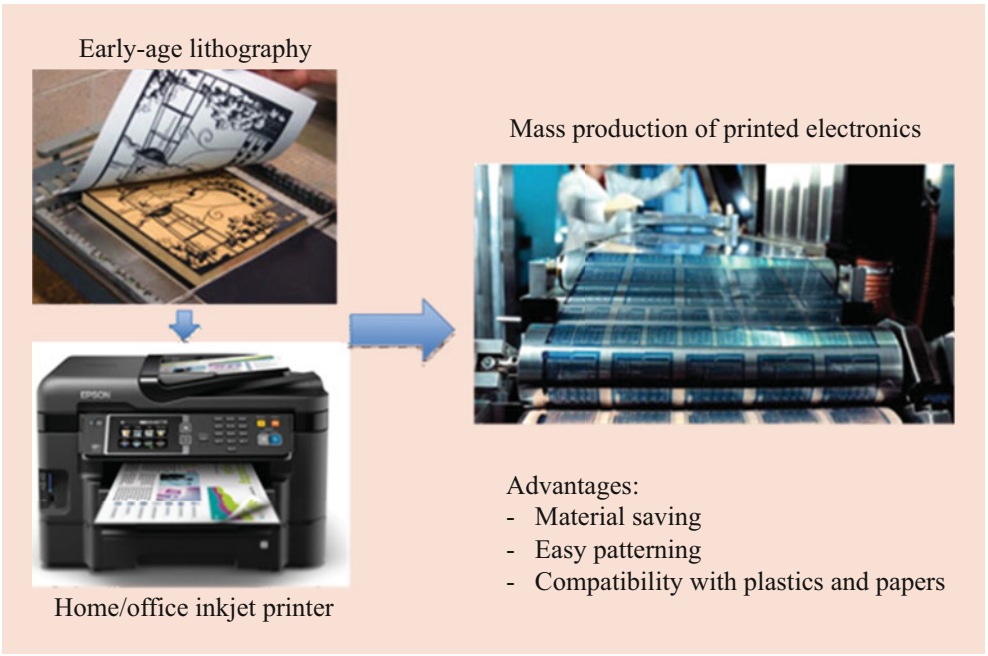

Fig. 27.8 From printing documents to printing electronics. (Adapted from [1])

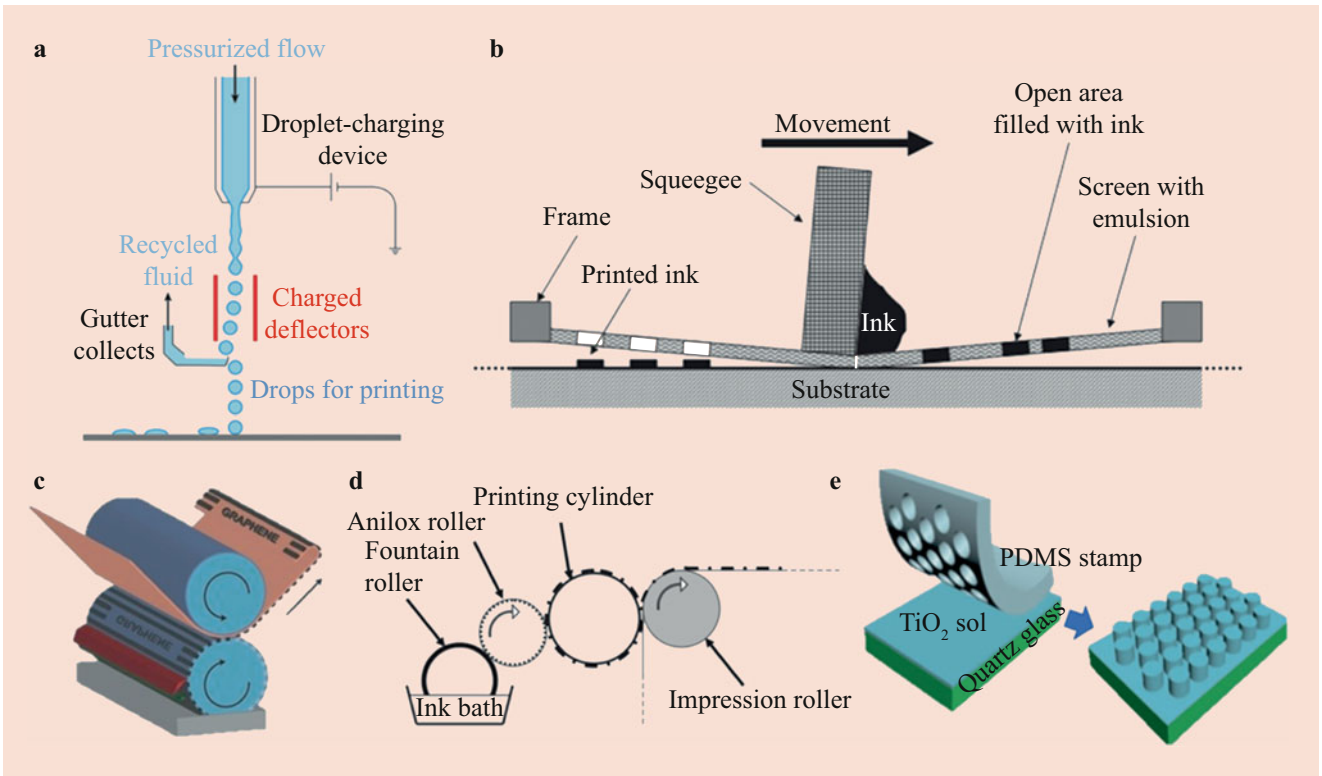

Fig. 27.9 Schematics of different printing techniques: (**a**) inkjet printing. (Adapted from [72]); (**b**) screen printing. (Adapted from [71]); (**c**) gravure printing. (Adapted from [74]); (**d**) flexographic printing. (Adapted from [71]); (**e**) nano-imprinting. (Adapted from [75])

Gravure Printing

The gravure printing technique is increasingly complex as it offers high-speed, roll-to-roll deposition of functional materials at high resolution [76]. The process consists of a two-roller system, where the printing roller has engraved patterns [74], as shown in Fig. 27.9c. The printing roller is partly immersed in the ink bath, so that the ink can be continuously refilled. The excess ink is doctored off the

printing roller to prevent accumulation in undesired areas. Since the printing roller makes strong enough contact with the rubber supporting roller, the ink in the gravure is transferred from the substrate to form patterns. The disadvantage of gravure printing is that it requires a new costly engraved roller to change new patterns. The advantage is that the web speed can be 1–10 m/s, which meets the requirement of the roll-to-roll process [71]. Gravure printing has been used in printing organic and inorganic photovoltaics [77, 78], and it has potential in conductive inks, RFID tags, and logic and memory circuits [71].

Flexographic Printing

Flexographic printing is similar to gravure printing, except that the ink is on the convex area of the printing cylinder/roller rather than in the concave area. In this case, in order to avoid excess ink, an anilox roller is used to refill a measured amount of ink into the printing cylinder, as shown in Fig. 27.9d. Therefore, a typical flexographic printing system is a four-roller system, containing a fountain roller, an anilox roller, a printing cylinder, and an impression roller. The process is simple, and the only requirement is that the inks should be less volatile. Flexographic printing has potential in smart packaging [79], transparent conductive films [80], logic circuits [81], etc.

Imprint and Nano-imprint

Imprint achieves patterning by physically deforming a deposited thin-film resist material through a micro-/nanostructured mould [75, 82]. The resist material can be thermal or UV-curable [81]. For example, as shown in Fig. 27.9e, a UV-curable material is deposited on a quartz substrate and then deformed by the mould. After UV exposure, the deformed layer is fixed with a pattern formed by the mould. Though the process is simple, it can produce patterns with good definition and high resolution, which are determined by the mould. The disadvantages of imprinting are air bubbles and ink sticking [83]. When the mould imprints the resist film, some areas make contact at the end, which can induce some air bubbles within these areas. The de-moulding process may also cause damage to the patterned layer, since the material though cured can still stick to the mould.

Comparison Among Different Printing Techniques

Due to different printing principles, these printing techniques can result in various qualities and features of printed patterns. Table 27.2 shows the comparison of the features of the printing methods. Among these printing techniques, imprint yields the highest resolution of <1 μm, which is attributed to the high-resolution mould used in imprinting. In addition, imprint does not have requirements for ink viscosity, thus allowing a wide range of choices for ink formulation.

Table 27.2 Comparison of the features of different printing methods

Printing method	Ink viscosity (mN m^{-1})	Line width (μm)	Line thickness (μm)	Speed (m min^{-1})
Screen	500–100,000	30–50	5–100	50–150
Inkjet	1–100	30–50	0.1–1	1–500
Gravure	100–1000	10–50	0.1–1	1000
Flexographic	50–500	45–100	<1	500
Imprint	–	0.01	0.1	Slow

However, the drawback of imprint is its slow printing speed. Flexographic and gravure printing techniques can provide similar feature sizes of several tens of microns and have similar requirements for ink viscosity, due to their similar printing principles. Screen printing requires very high viscosity of inks (>500 mN m^{-1}), and thus the selection of inks is limited. In addition, screen-printed features are very thick, i.e. >5 μm, which is not appropriate for printed dielectrics whose thickness is around 100 nm. As for inkjet printing, it can produce a similar resolution to most printing techniques (except imprint), and it does not require inks to be highly viscous. Therefore, inkjet printing is a good choice as a printing technique for TFT fabrication. In addition, inkjet printing has the crucial advantage that its customization capacity is high. The research and development of organic TFTs in laboratories or startups use trial and empirical patterns of devices, so it is important that the printing technique provides flexibility in pattern designs. This flexibility enabled by inkjet printing can save a considerable amount of time and money, compared to other thin-film deposition techniques which need masks, moulds, or gravures.

Ink Formulation and Printability

For inkjet printing technology, the critical part is the ink. The quality of the ink can greatly affect the reliability of the jetting droplets and the printed patterns. In this section, the chemistry and physics of inks are reviewed. Different types of ink and the compositions of ink are introduced, including the differences between different types of ink and how the composition of ink affects the properties of the inks. The fluid physical properties of ink are also reviewed, indicating how different physical parameters of ink can influence its printability.

Ink Types

In general, according to the liquid carrier medium, inks can be classified into two systems: aqueous-based inks and non-aqueous-based inks. The liquid carrier medium determines the basic properties of inks, including viscosity, density, and surface energy [84] (see Fig. 27.10). These three properties influence the printability of inks, and therefore, it is important to understand the differences between these two ink systems.

Aqueous-based or water-based inks are typically composed of 60–90% deionized water [85], which serves as the

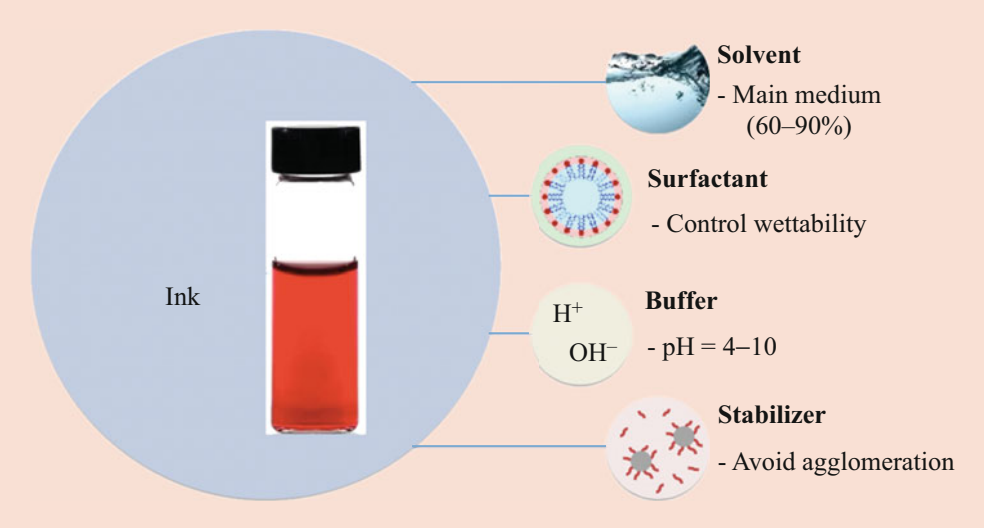

Fig. 27.10 Compositions of ink. (Adapted from [1])

carrier medium. According to the nature of water, aqueous-based inks have lower viscosities and higher surface energies compared to non-aqueous-based inks [86]. In aqueous-based inks, these properties can be engineered to meet the requirements through the addition of co-solvents, such as glycol, glycerin, and alcohols [84]. Since deionized water and co-solvents take up approximately 90% of the compositions [85], aqueous-based inks generally have many advantages, such as the use of easy-to-handle and cheaper source materials, as well as low flammability and low toxicity of the waste materials [87]. However, the drying mechanism of aqueous-based inks on non-paper substrates (e.g. glass) is based on the evaporation of water, which results in a relatively low drying rate. In addition, the high surface energies of the aqueous-based inks can cause less effective wetting on substrates.

Non-aqueous-based or solvent-based inks are based on organic solvents, which can be ketones (e.g. toluene), glycol ethers (e.g. diethylene glycol monoethyl ether acetate), and a mixture of alcohols (e.g. ethanol, isopropanol, ethylene glycol) [84,88]. These groups of organic solvents are volatile, so they can readily evaporate even at room temperature. Therefore, non-aqueous-based inks are widely used in industrial fabrication. However, although a fast drying rate is desired to obtain quick fixation of the inks and to print multilayer materials, it is somewhat undesirable that these inks evaporate so rapidly at the printheads, causing the nozzles to possibly clog [84]. Therefore, during ink formulation, organic solvents with higher boiling points may be preferred to avoid clogging of the nozzles.

Compositions of Ink

In order to improve the printability and reliability of inks, some additives are added into the inks, including humectants, viscosity modifiers, surfactants, pH buffers, stabilizers, etc. [85, 88].

Among the additives mentioned above, humectants, viscosity modifiers, and surfactants contribute to modifying the physical properties of inks. Humectants can lower the drying rate of inks; thus, inks do not dry at nozzle/air interface, and the clogging of nozzles can be avoided. The viscosity modifiers are co-solvents whose viscosities are different from the liquid carrier medium, so the viscosity of inks can be modified to meet the requirements of printing processes. Surfactants are additives that can change the surface energy of inks. The surface energy of inks not only affects the printability and the reliability of inks, but it can also influence the wetting of inks on the printed substrates [89]. In general, for a piezoelectric inkjet printer system, the surface energy and the viscosity of inks at operating temperature should be between 28–70 mN/m and 1–12 cPs, respectively [85, 90]. Buffers serve to adjust the pH of inks, which is preferred to be in a range of 4–9 to prevent printhead from corrosion and damage. These buffers can be organic or inorganic acids and bases, depending on the ink types and the pH of the original inks [88].

Stabilizers are additives that can enhance dispersion and storage time of inks. In general, for nanoparticles, stabilizers can enhance dispersion or prevent agglomeration through two approaches: electrostatic repulsion and steric repulsion [91]. Steric repulsion stems from the interaction between the capping ligands that are bound to the nanoparticles surfaces, while electrostatic repulsion results from the repulsion of charged stabilizer molecules that are chemisorbed on the surfaces of nanoparticle [91, 92]. There are different groups of stabilizers, including thiols [93, 94], citrates [95–97], carboxylic acids [98, 99], polymers [96, 97], etc. For printed

Table 27.3 Boiling point, surface energy, and viscosity of common solvents

	Boiling point (°C)	Surface energy (mN/m)	Viscosity (cPs)	Density (g/cm^3)
Deionized water	100	72.8	0.1	1.000
Ethanol	78	20.6	1.26	0.789
2-methoxyethanol	125	27.2	0.16	0.965
Glycerol	182	64	853.1	1.26
Ethylene glycol	198	48.5	1.9	1.11
Diethylene glycol	244	44.8	35.7	1.12
Toluene	110	27.9	0.06	0.867
Hexane	69	18.4	0.03	0.655
Tetradecane	253	26.6	0.22	0.765
Anisole	155	35	1.52	0.996
PGMEA	146	30.4	1.1	0.969

TFTs, however, additives may become impurities, in particular in dielectrics and semiconductors. Therefore, during ink formulation for printed TFTs, additives need to be carefully chosen and even avoided.

Fluid Physical Properties of Inks

Fluid physical properties of functional inks are essential for the stable and reliable performance of an inkjet printing system, including viscosity, density, and surface energy. Among these three parameters, viscosity and surface energy can strongly influence the fluid dynamics during jetting droplets [84]. Highly viscous inks are difficult to jet out of the nozzles, and thus the solutes of the inks may aggregate or agglomerate at the nozzles. In an advanced inkjet printer, the temperature of inks at the nozzles can be heated up to lower the working viscosity of the inks. In terms of surface energy, if it is too high, drops are more difficult to generate, and satellite droplets may form; if it is too low, droplets are easier to generate, but the tails of the droplets are long. The long tails are undesirable, since they may connect nozzles to the substrate and affect the precision of the droplet landing positions [100]. The physical properties of some commonly used solvents are shown in Table 27.3. Comparing these solvents, it can be seen that ethanol, ethylene glycol, anisole, and propylene glycol monomethyl ether acetate (PGMEA) meet the surface energy and viscosity requirements. Though these three properties influence inks differently, they have a combined effect on the printability of inks [101]. The behaviour of fluids can be evaluated by the Reynolds number (*Re*) and the Weber number (*We*), which are the ratio of inertial to viscous forces and the balance between inertial and capillary forces, respectively [102]:

$$Re = \frac{\upsilon\rho\alpha}{\eta} \tag{27.1}$$

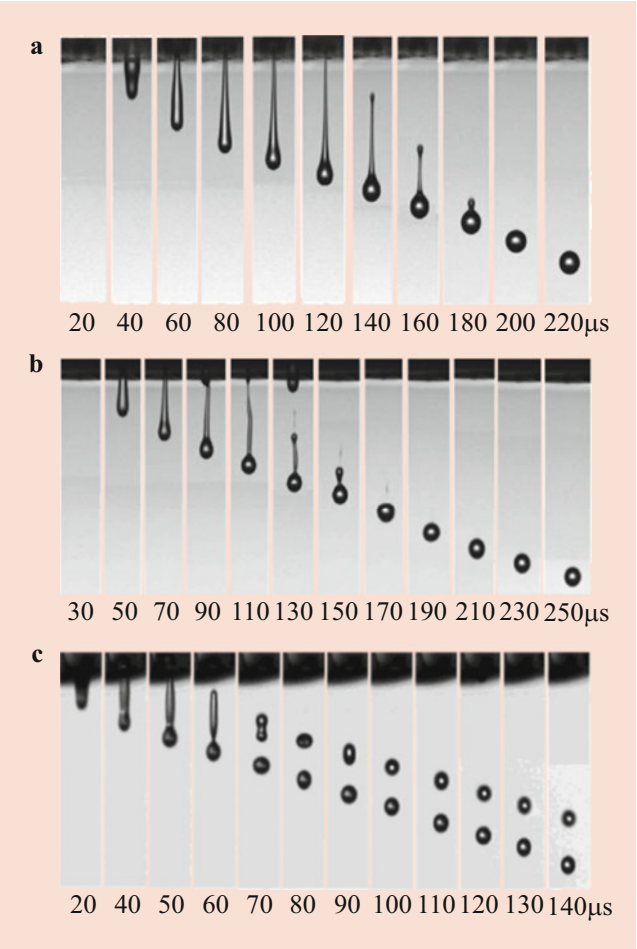

Fig. 27.11 Representative photo sequence of drop formation for fluids with values of (**a**) $Z = 2.17$, (**b**) $Z = 4.08$, and (**c**) $Z = 17.32$. (Adapted from [100])

$$We = \frac{\upsilon^2\rho\alpha}{\gamma} \tag{27.2}$$

where υ is the fluid velocity, α is the drop diameter, ρ is the drop density, γ is the surface energy of ink, and η is the viscosity of ink. The Ohnesorge number (Oh) is another useful dimensionless number to predict the printability of inks. The Ohnesorge number is independent of fluid velocity and defined as follows:

$$\mathrm{Oh} = \frac{\sqrt{We}}{Re} = \frac{\eta}{\sqrt{\gamma\rho\alpha}} \tag{27.3}$$

Therefore, the Ohnesorge number can be determined without the actual printing conditions, while the Reynolds and Weber numbers cannot be determined without the actual printing conditions.

The inverse of the Ohnesorge number, known as Z number, is widely used to evaluate the printability of inks [84]. Based on a simple model of fluid flow and numerical anal-

ysis, Fromm proposed that the requirement to form stable droplets is $Z > 2$ [103]. Reis and Derby improved this result by computational fluid dynamics simulations and pointed out that the Z value should be in a range of between 1 and 10 [104]. Later, Jang et al. experimentally defined a printable range as $4 \leqslant Z \leqslant 14$, by mixing water and different alcohols with different ratios and then characterizing the single droplet formability, positional accuracy, and maximum allowable jetting frequency of different mixtures of solvents [100].

Figure 27.11 shows the droplet formation for fluids with different Z values. As seen in the figure, when $Z < 4$, the droplet tends to generate a long tail; when $Z > 14$, the droplet tends to generate a satellite [100]. However, neither the tail nor the satellite is desirable for a droplet to be printed on the substrate, since they could distort the printed pattern in comparison to the design. Therefore, in order to achieve a printable ink, these physical properties of inks require investigation.

27.1.3 Printable and Flexible Transistors

TFT Device Architectures

In general, there are four possible TFT device architectures, including bottom-gate bottom-contact (coplanar), bottom-gate top-contact (staggered), top-gate bottom-contact (inverted staggered), and top-gate top-contact (inverted coplanar) structures, as seen in Fig. 27.12.

For flexible electronics with ultra-low-power consumption, the operating voltages of organic TFTs should be low, which can be achieved by reducing defects/traps in TFTs. For low-voltage TFTs, the semiconductors should be crystallized, and the semiconductor/dielectric interfaces should be smooth. These factors need to be taken into consideration when selecting TFT device architectures. For organic semiconductors, small molecules are much more likely to crystallize compared to polymer semiconducting materials, thereby reducing the density of defects or traps in the bulk of the semiconductor. However, the issue of using a small-molecule semiconducting material is that it tends to generate a rough surface, on which, if a gate dielectric is deposited, the semiconductor/dielectric interface trap density is significant. In contrast, polymers normally demonstrate smooth surfaces, which can be used as a base for the semiconductor/dielectric interface to reduce the interface trap density. As a result, it is preferred if the semiconductor is deposited on top of a smooth polymer gate dielectric. In other words, a bottom-gate structure is preferred. In addition, small-molecule semiconductors are more vulnerable to heat with regard to the reorganization of crystals and even evaporation. The source/drain electrodes (which need high-temperature annealing) should be deposited prior to the deposition of the semiconductor. Therefore, to achieve printable low-voltage organic TFTs, the bottom-gate bottom-contact structure is preferred, while regarding materials, small-molecule semiconductors and polymer gate insulators are preferred.

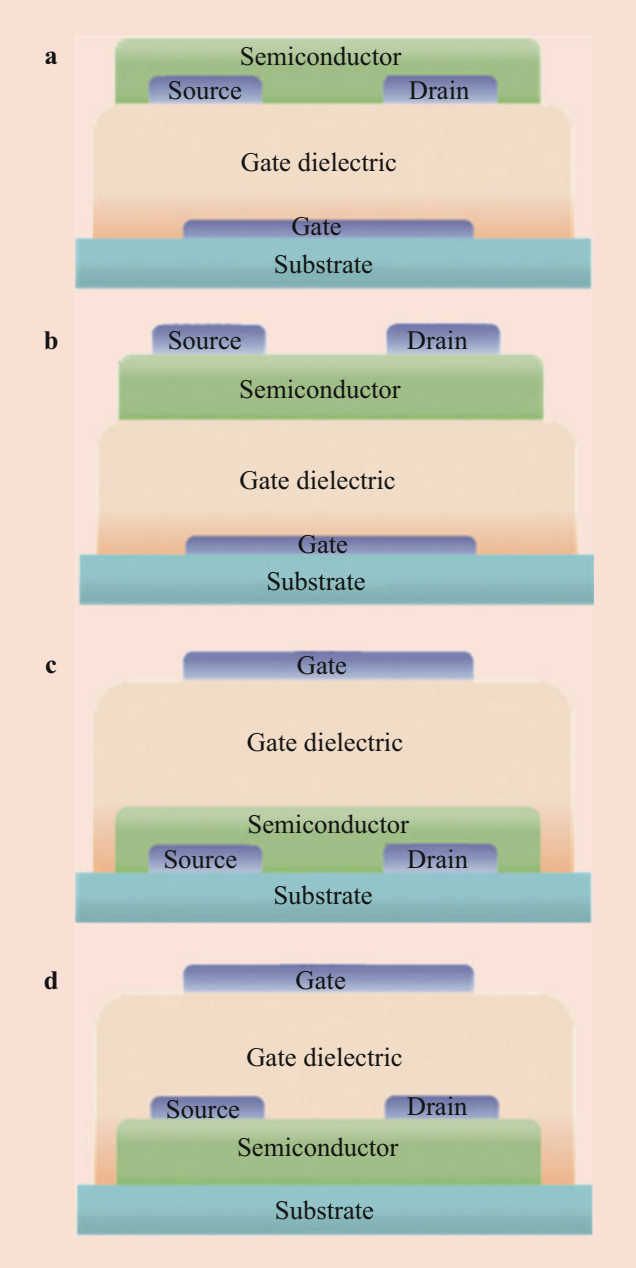

Fig. 27.12 Schematic diagram of the four TFT device architectures: (**a**) bottom-gate bottom-contact, (**b**) bottom-gate top-contact, (**c**) top-gate bottom-contact, and (**d**) top-gate top-contact. (Adapted from [1])

In fact, other device architectures also have advantages. Staggered and inverted staggered architectures can greatly reduce contact resistance between the semiconductor and source/drain electrodes [105]. In these two architectures, charge carriers are not only injected from the edge of the source electrode but also from the area of the electrode that

is overlapped with the gate electrode. Top-gate architectures allow self-aligned TFTs, which use source/drain patterns to define gate pattern [106] or vice versa [107]. In self-aligned TFTs, the overlap between source/drain electrodes and gate electrode is small, and therefore, parasitic capacitance is reduced. Noh et al. demonstrated self-aligned all-printed polymer TFTs with parasitic overlap capacitance to values as low as 0.2–0.6 pF/mm and cutoff frequencies of f_T = 1.6 MHz [106].

Issues of Printed Organic TFTs

The main issues in organic TFTs (either vacuum- or solution-processed) are the high operating voltage and poor stability, specifically short shelf-life time and significant threshold voltage shift under bias stress. The most straightforward way to lower the operating voltage is to increase unit-area gate capacitance, which can be achieved by an ultra-thin dielectric layer [59] or a high-k dielectric material [108]. However, a thin gate dielectric can result in large gate leakage in all-printed organic TFTs, while organic TFTs based on a high-k gate dielectric could suffer from the interface dipole disorder [109], inducing instability. Alternatively, operating voltages can be lowered by reducing semiconductor/dielectric interface traps. This method offers another advantage that due to the reduced traps, organic TFTs can be more stable with regard to shelf-life and bias stress [110]. However, printed thin films are not as good as vacuum-processed thin films, with regard to the defects and surface roughness of the films. These can significantly generate a considerable number of traps and are the key challenges that need to be tackled.

Instability prevails in most organic TFTs, either vacuum-processed or solution-processed. The instability of organic TFTs can be attributed to intrinsic (e.g. structural and energetic disorder in the semiconductor) and extrinsic (e.g. oxidation, presence of moisture, and chemical impurities) factors [111, 112]. These can induce degradation of device performance during storage in the ambient environment and a threshold voltage shift of the organic TFTs under electrical bias stress [113]. During bias stress, trapped charged can be created in the dielectric (which holds the high electric field) and at the semiconductor/dielectric interface (where charge carriers transport). In order to achieve highly stable all-printed organic TFTs, it is important that:

- there are few defects in the organic TFTs, in particular, in the bulk semiconductor, in the dielectric, and at the semiconductor-dielectric interface;
- organic TFTs are encapsulated to avoid material oxidation;
- materials used are water-proof but organic solvent-like, which avoid moisture while making printing possible.

Besides challenges regarding organic TFTs, there are particular issues associated with the inkjet printing technique and all-printed organic TFTs. Among all the electronic components, transistors have the most complex structure, compared to resistors, capacitors, and diodes. For a typical organic TFT, there are at least four layers stacked together, and each of these layers should be of good quality in order to form a functional device. In previously reported all-inkjet-printed organic TFTs, only one piece of work provides statistical analysis of the fabricated devices, depicting a low proportion of functional devices (34%) as compared to defective devices (Fig. 27.13) [52]. The defective organic TFTs depict atypical

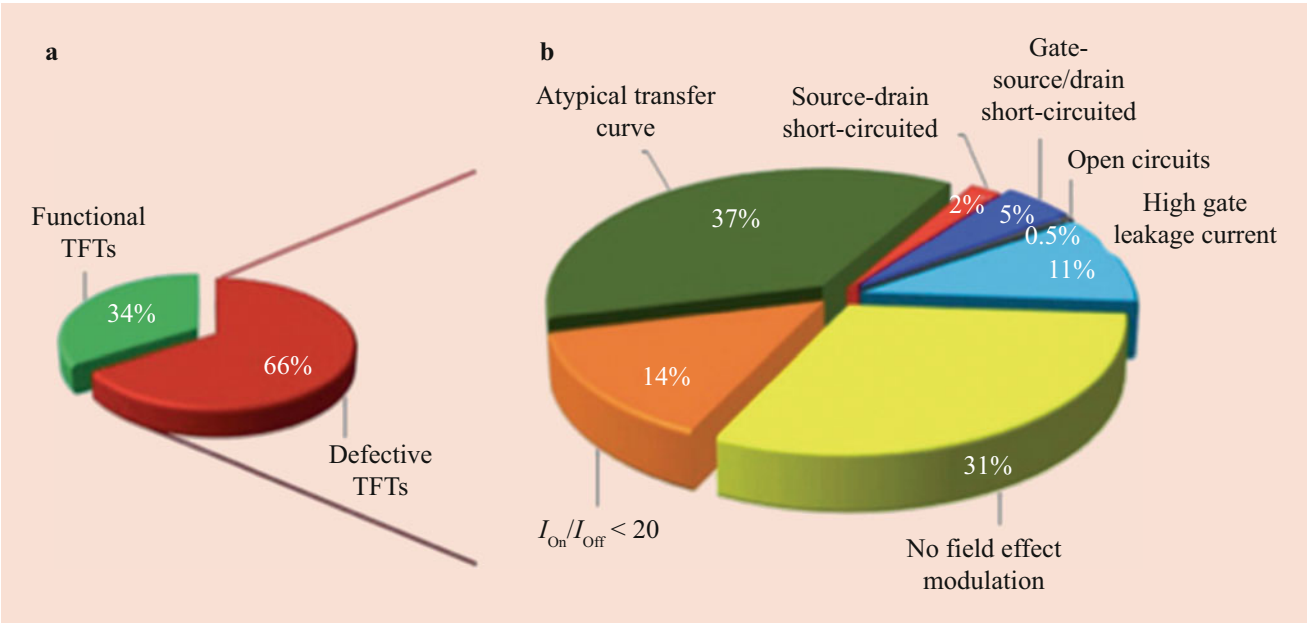

Fig. 27.13 The proportion of functional TFTs to defective OTFTs. (Adapted from [52])

transfer curves, source/drain short circuits, gate-source/drain short circuits, open circuits, high gate leakage current, no field-effect modulation, and a low on/off ratio. The reasons for the failures can be categorized into wetting, satellite drops, droplet jetting oddness, dirt and dust particles, as well as missing droplets [114]. Therefore, in order to improve the yield and device performance of all-inkjet-printed organic TFTs, it is essential to ensure that:

- the jetting properties of inks are in good condition, e.g. without satellites;
- the materials used have adequate compatibility, with regard to wetting;
- the quantities of dirt and dust are as small as possible.

Developments in Printable Organic TFTs

Methods of Organic Semiconductor Deposition

In previous work on solution-processed/printable organic TFTs, most interest has centred on semiconductor materials. In the early years (2000s) of developing solution-processed organic TFTs, most work used silicon wafers as the substrate, utilizing highly doped silicon as the conductive gate and thermally grown SiO_2 as the gate dielectric layer [115–117]. However, due to the poor interface between SiO_2 and the organic semiconductor materials, self-assembled monolayers (SAMs) were grown on the SiO_2 to facilitate charge transport at the semiconductor/dielectric interface [118], such as octadecyl-, decyl-, and butyltrichlorosilane (OTS, DTS, and BTS). At that time, typical solution-processable organic semiconductor materials were P3HT (polymer) [111, 119] and TIPS-pentacene (small molecule) [41, 120], and the mobility of the fabricated organic TFTs was low, generally less than 0.1 $cm^2V^{-1}s^{-1}$.

Since polymer semiconductor materials are amorphous, it is not easy to control the crystallization of the materials. In contrast, small-molecule materials can crystallize, and therefore, in the past decade, significant effort has been made to grow highly crystallized organic semiconductor materials, using drop casting [110, 123] and blade coating [118, 122, 124]. Optical polarized photos of TIPS-pentacene thin films deposited through these techniques are shown in Fig. 27.14. Compared to spin-coated TIPS-pentacene thin films, where crystals are randomly distributed [121], the crystallization of TIPS-pentacene in these advanced techniques is well aligned. In terms of drop casting, by using a tilted angle to guide the flow of the semiconductor solution, the crystallization direction of TIPS-pentacene also follows the flow direction, so

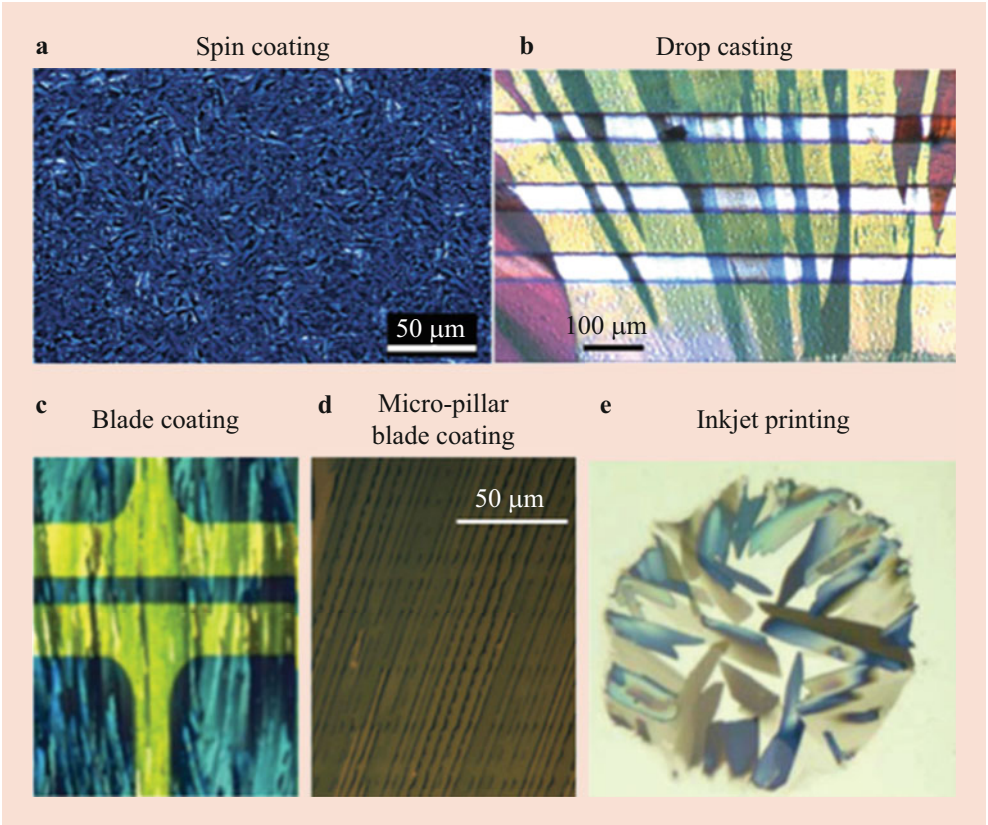

Fig. 27.14 Optical microscopy images of TIPS-pentacene thin films with various morphologies deposited by different techniques: (**a**) spin coating. (Adapted from [121]); (**b**) drop casting. (Adapted from [110]); (**c**) blade coating. (Adapted from [118]); (**d**) solution coating (micro-pillar blade coating). (Adapted from [122]); (**e**) inkjet printing. (Adapted from [117])

that the mobility of the fabricated organic TFTs is improved to around 1 $cm^2V^{-1}s^{-1}$ [125]. However, in most of cases, drop casting is a manual process, so repeatability and precise controlling of this process are the main challenges. For blade coating, the crystallization direction is also defined by the movement of the blade, and the mobility of the organic TFTs is over 3 $cm^2V^{-1}s^{-1}$ [118]. In addition, using a micropillar-patterned blade, an approach termed fluid-enhanced crystal engineering (FLUENCE), highly aligned single crystals of TIPS-pentacene can be achieved, resulting in a high mobility of 11 $cm^2V^{-1}s^{-1}$ [122]. However, the issue of blade coating is that this process does not allow patterning at the same time, so a further subtractive process is required.

In order to achieve better material usage and direct patternability, the inkjet printing of TIPS-pentacene has also been reported [53, 62, 115–117, 125–128]. Though highly crystallized TIPS-pentacene thin films can be achieved, the alignment is hard to control (Fig. 27.14e) [117]. To solve this issue, off-centre printing has been proposed [128]. Due to the better crystallinity of TIPS-pentacene at the off-centre area compared to the centre area (as seen in Fig. 27.14), the channel area can be covered by well-aligned TIPS-pentacene crystals by using the off-centre printing technique [128]. However, this technique depends on good control of the off-centre positions. To enhance the crystallinity of TIPS-pentacene thin films, polymer binders have been blended into the semiconductor ink, such as polystyrene (PS), poly(α-methyl-styrene) (PαMS), and amorphous polycarbonate (APC) [62, 116, 126]. In comparison to the work solely using TIPS-pentacene [53, 115, 117, 125, 129], the TIPS-pentacene/polymer blends facilitate TIPS-pentacene crystallization, and the fabricated organic TFTs exhibit a higher mobility, a higher on/off ratio, and a lower operating voltage.

Solution-Processable Organic Semiconductors

In addition to significant developments in semiconductor deposition processes, considerable attention has been focused on new solution-processable semiconductor materials. TIPS-pentacene is a derivative of pentacene. In the family of acenes, there are many derivatives that are solution-processable and printable, such as 6,13-bis-(triethylsilylethynyl)pentacene (TES-pentacene) [130] and 2,8-difluoro-5,11-bis(triethylsilylethynyl) anthradithiophene (diF-TES-ADT) [118]. These semiconductor materials, when highly crystallized and well aligned, generally exhibit a mobility of around 1 $cm^2V^{-1}s^{-1}$. In addition to the functionalized acenes, in the recent years, small-molecule thiophene-based materials have been popular, such as 2,7-alkyl [1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT) and 2,9-alkyl-dinaphtho [2,3-b:2′,3′-f]thieno[3,2-b]thiophene (C10-DNTT). Based on these advanced materials, organic TFTs with a high mobility have been achieved, with a mobility of around 10 $cm^2V^{-1}s^{-1}$ [131, 132] and even as high as 43 $cm^2V^{-1}s^{-1}$ [133]. More recently, a band-like charge transporting material has been developed, 3,11-didecyldinaphtho[2,3-d:2′,3′-d’]benzo[1,2-b:4,5-b’]dithiophene (C10-DNBDT), and nanowire-based organic TFTs exhibit a high mobility of >17 $cm^2V^{-1}s^{-1}$ [134].

Organic Dielectrics

Compared to the significant development of organic semiconductor materials, there has been less interest in advancing organic dielectric materials. In general, organic dielectric materials are polymers. Among polymer dielectrics, the most popular one used in solution-processed organic TFTs is poly(4-vinylphenol) (PVP) [53, 115, 135, 136], due to the straightforward processes of PVP deposition and annealing. CYTOP is another widely used dielectric material, due to its hydrophobicity that prevents water molecules from being polarized or trapped in the dielectric, thus enhancing the stability of organic TFTs [132, 137, 138]. Though good for stability, CYTOP is rarely used in all-solution-processed organic TFTs, since the hydrophobicity of CYTOP eliminates the possibility of depositing functional materials on top of it through solution-based processes. For all-inkjet-printed organic TFTs, all previous work used PVP as the dielectric, and the mobility of the printed devices was consistently <0.1 $cm^2V^{-1}s^{-1}$. However, PVP is not a good dielectric material for organic TFTs due to its hydrophilicity that can result in instability. Recently, monopolar dielectrics were proposed as good candidates for all-printed organic TFTs [50]. In particular, Lewis-acid monopolar dielectrics are hydrophobic, thus preventing water molecules from being trapped in the dielectrics while also allowing good wetting of most organic solvents (Fig. 27.15).

All-Printed Organic TFTs

To further reduce the cost and improve the efficiency of organic TFT manufacturing, an all-printed organic TFT device platform is needed. The pioneering work on all-printed organic TFT circuits was reported by Sirringhaus et al. using all polymer materials in 2000. However, the transistors demonstrated a low field-effect mobility of 0.02 $cm^2V^{-1}s^{-1}$ and a high operating voltage of 20 V. To improve mobility, researchers replaced the polymer semiconductor by a small-molecule semiconductor, typically TIPS-pentacene, which tended to demonstrate a higher mobility [53, 62, 115–117, 125, 126, 128, 139]. However, most works on all-printed organic TFTs based on small molecules also demonstrated low mobilities of ~0.01 $cm^2V^{-1}s^{-1}$ and high operating voltages of >20 V.

In 2016, Feng et al. controlled the printing processes to reduce semiconductor/dielectric interface trap density and achieved low-voltage all-inkjet-printed organic TFTs, with a mobility of 0.26 $cm^2V^{-1}s^{-1}$ and an operating voltage of 3 V (see Fig. 27.16) [51]. However, the organic TFTs used hy-

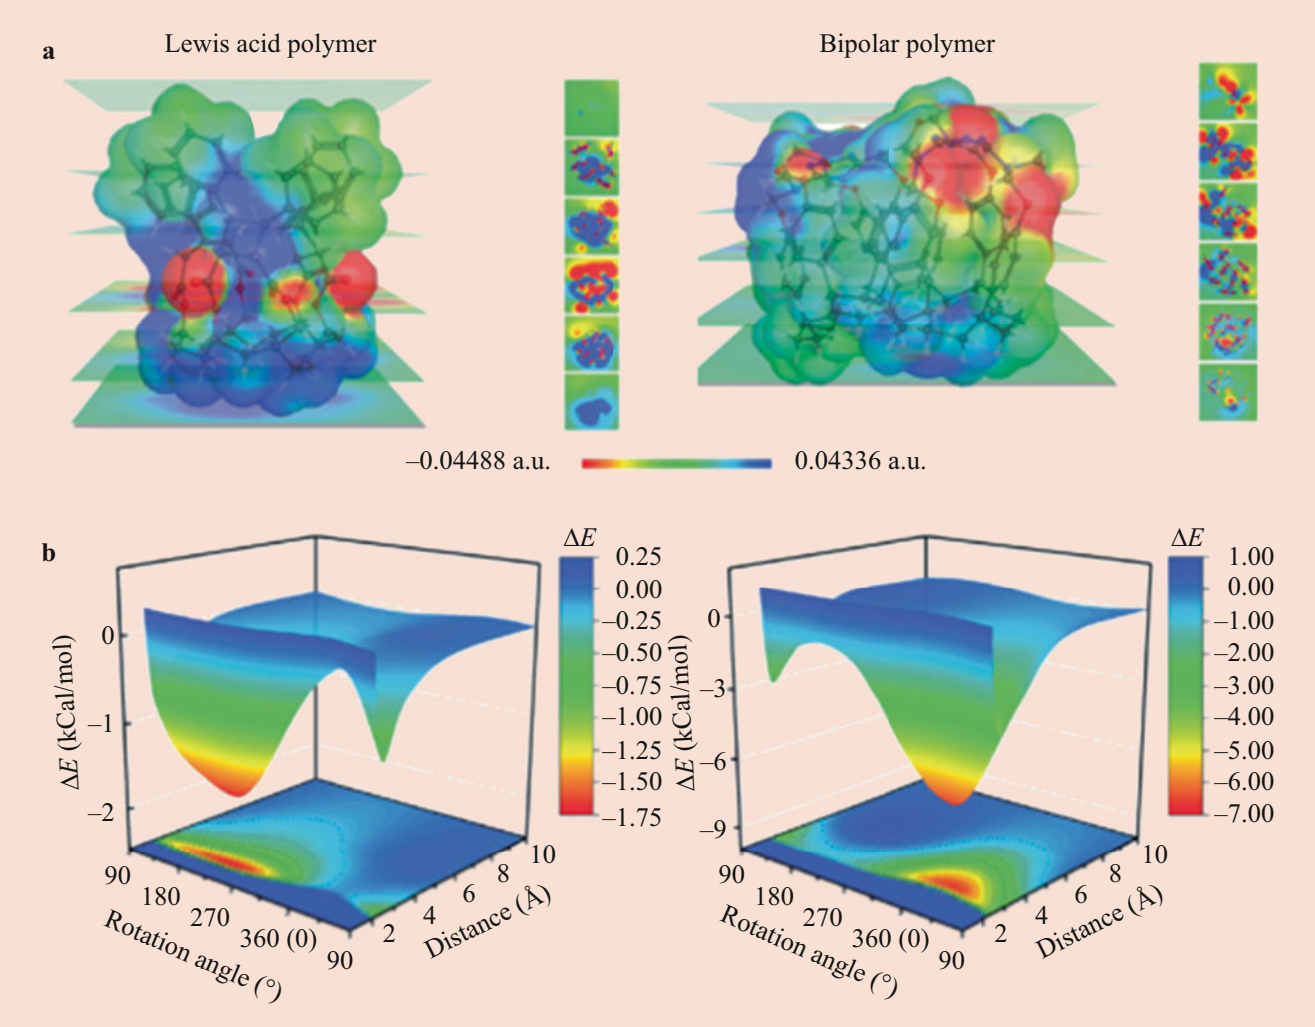

Fig. 27.15 (**a**) 3D tomographic comparison of electron densities between a Lewis-acid monopolar polymer, PVC, and a bipolar polymer, PVP. The isosurfaces and tomographic sections are coloured red (electron-rich), green (neutral), and blue (electron-poor). Different atoms in the 3D molecular structures are coloured grey (carbon), white (hydrogen), red (oxygen), and blue (nitrogen). (**b**) The interaction energy (ΔE) when a water molecule approaches PVC and PVP at different rotation angles (from 0° to 360°). (Adapted from [50])

drophilic PVP as the dielectric, which resulted in significant threshold voltage shift during bias stress [140]. To enhance all-printed organic TFT bias stress stability, Jiang et al. used a Lewis-acid monopolar dielectric, i.e. polyvinyl cinnamate (PVC), and the threshold voltage shifts were greatly reduced to 0.11 V under both positive and negative bias stress for 1 h. More recently, they used C8-BTBT as the semiconductor for all-printed organic TFTs. The printed C8-BTBT films possessed large crystals (of which grain sizes were >50 μm), and the density of states of the TFTs was reduced (i.e. deep state density was $\sim 10^{14}\,\mathrm{cm^{-3}eV^{-1}}$). Due to the large semiconductor crystals and reduced traps, the all-printed organic TFTs demonstrated a high mobility of $>1.0\,\mathrm{cm^2V^{-1}s^{-1}}$ and a low operating voltage of 1 V. In addition, the transistors exhibited good stability under ambient environment storage with threshold voltage shift of <1 mV over 3 months as well as under bias stress.

27.2 Modelling of Flexible TFTs and Circuit Design Considerations

27.2.1 TFT Compact Modelling

Computer-Aided Design

The growing maturity of thin-film transistor (TFT) technology coupled with newly emerging materials and processes is enabling integration of circuits and systems for a new family of applications ranging from biosensing systems to areas augmenting displays and imaging [28, 141–143]. The design of systems places great demand for fast computer-aided design (CAD) tools to accurately and reliably predict system behaviour [144].

CAD always requires accuracy, high speed, and reliable convergence of device models. In order to achieve high

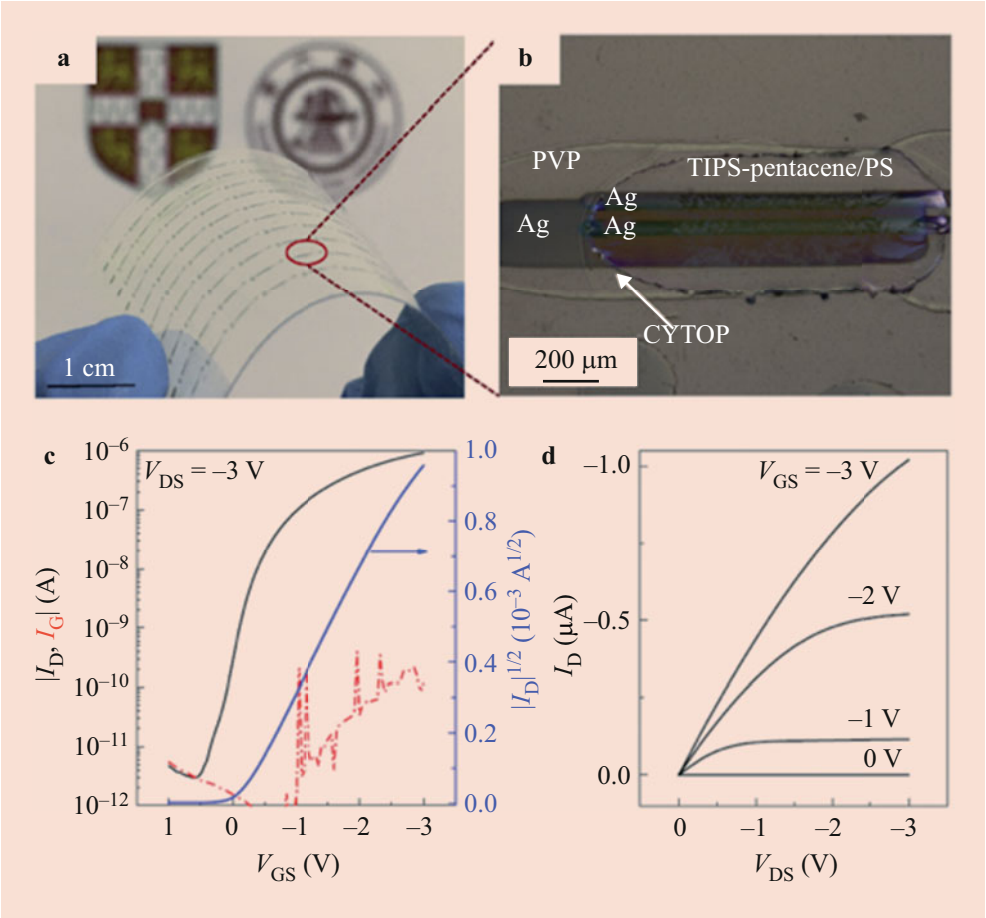

Fig. 27.16 (**a**) Photograph of the low-voltage all-inkjet-printed organic TFTs. (**b**) Polarized optical micrograph of the fabricated device. (**c**, **d**) Measured electrical characteristics of the fabricated device: (**c**) transfer characteristics (I_D–V_{GS}) and (**d**) output characteristics (I_D–V_{DS}). (Adapted from [51])

accuracy in all working regions without the use of many fitting parameters, a good understanding of device physics is needed. However, physical models are not necessarily sufficient for good CAD in the sense that the equations could be complex, which can lead to slow execution or convergence problems. Therefore, simplification of the model equations without sacrificing accuracy is one of the major requirements for a good CAD model. In addition, the model should be adaptive to a wide range of technological/process parameters through simple extraction procedures.

During the past 30 years, a great amount of effort has been made in the TFT modelling area for various semiconductor technologies, including amorphous silicon [145–151], polysilicon [150], organics [152–156], and metal oxides [157–163]. For a-Si TFTs, several SPICE models have been developed. Specifically, the model developed by Rensselaer Polytechnic Institute, also known as the RPI model [150], has become a commercial standard supported by many simulation platforms including SmartSpice, HSPICE, Spectre, etc. However, no CAD tool for organic and metal-oxide TFTs has yet become a standard due to the rapid evolution of materials and device structures.

In this chapter, we will review the major contributions to the TFT modelling area and compare the differences between Verilog-AMS and SPICE from the standpoint of compact device modelling. Finally, we present the implementation of the Cambridge TFT compact model [161] for oxide TFTs in Verilog-AMS for Spectre simulation. The major goal of this review is to give the reader guidelines for implementing device models for the CAD of circuits and systems.

Physical and Empirical Modelling

Physical and empirical modelling approaches are generally aimed at providing an accurate model for a given transistor or transistor family, which covers all working regions of the device. While the major consideration is accuracy, the developed model is not necessarily physical. In this sense, it is theoretically possible to use polynomial approximation or other empirical ways to fit any kind of transistor behaviour with acceptable accuracy. However, without a proper un-

derstanding of the underlying device physics, the resulting number of fitting parameters could be large and difficult to extract from measurements since the model should cover a wide range of different bias conditions and transistor scales. Therefore, the transistor models used in a simulator are often a combination of terms and coefficients that are physically and empirically based.

Recent efforts have primarily focused on physically based approaches in an attempt to develop simple and accurate models. The most well-studied material for TFTs is amorphous silicon (a-Si:H). Several models have been developed based on different distributions of deep states and tail states of the semiconductor to describe static and dynamic behaviour for the above and subthreshold regions [149–151]. Other properties include trap-related V_T shift [164] and the off/leakage currents [146]. The RPI model [150] captures most of the device properties leading to satisfactory simulation results and thus has been widely used.

For organic TFTs, researchers have developed models based on multiple trapping and release (i.e. trap-limited conduction) [165] and variable range hopping (VRH) [153, 166, 167]. However, due to the diverse use of materials in the TFT, the underlying physics differs, and therefore a trend has emerged to develop a model that is unified but less physical [154].

As for metal-oxide TFTs, modelling efforts are still in their infancy, although there are growing interests in the area for implementation of circuits and systems. In what follows, early efforts in compact models for CAD of oxide TFTs are reviewed.

Cambridge's TFT Model

Compared with a-Si TFTs, the oxide system has unique properties, which need to be captured. For example, localized traps or band tail states in oxides do not exist to the same extent as a-Si [160]. Their tail state density is much lower, and hence, trap-limited conduction is generally insignificant [158, 160]. In addition, more complex systems such as amorphous indium gallium zinc oxide (a-IGZO) can have compositional disorder due to the random distribution of metal constituents [158, 168]. This gives rise to potential barriers above the conduction band minima (E_m), suggesting the presence of percolation conduction [158, 160, 168].

In the following, compact models for the terminal current-voltage behaviour are presented, taking into account the different transport mechanisms in the device for the above- and subthreshold regions of TFT operation. The former is based on a mobility model that combines trap-limited conduction (TLC) with percolation conduction. The latter takes into account diffusion and drift current components [159]. A unified model is then presented that covers both regions based on a single expression that uses a reference turn-on voltage V_{on} rather than V_T [161]. Good agreement with measured terminal characteristics is obtained over the entire range of gate-source voltage (V_{GS}) > V_{on} for the test TFTs with an a-IGZO channel.

Above-Threshold Model

As illustrated in Fig. 27.17, oxide TFTs have potential barriers above E_m due to compositional disorder, suggesting percolation conduction when electrons are released into the conduction band. Moreover, there are localized tail states within the gap states, implying trap-limited conduction. In particular, oxide semiconductors can have a shallow slope of the tail states (kT_t) ~20 meV, smaller than the thermal energy (kT) at 300 K, leading to different mobility behaviour. This suggests that the field-effect mobility (μ_{FE}) model needs to be modelled based on TLC and percolation conduction, although the former is not as significant as compared to a-Si.

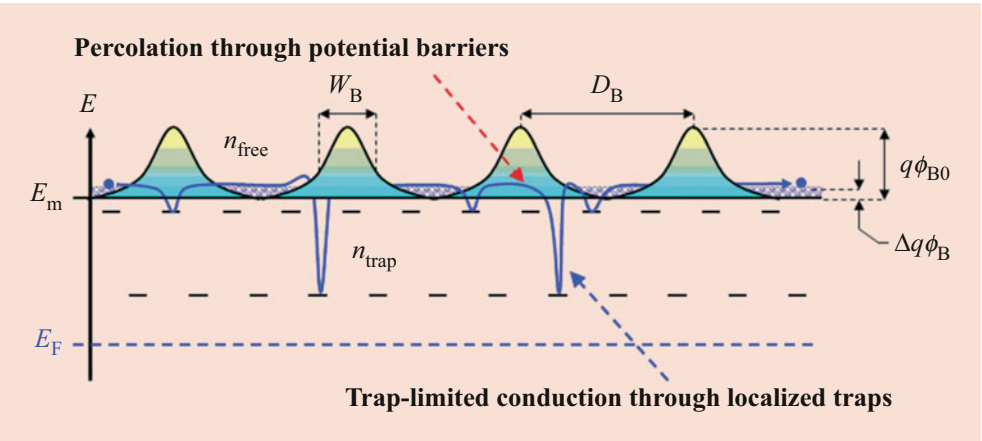

Fig. 27.17 Carrier transport combining percolation with trap-limited conduction (TLC) for oxide semiconductor TFTs (here, D_B and W_B denote spatial distance and width of potential barriers, respectively)

1. Trap-Limited Conduction (TLC)
Effect of trap-limited conduction (TLC) can be considered as μ_{FE} being proportional to ratio (γ_{TLC}) of free carrier density (n_{free}) and trapped carrier density (n_{trap}), yielding $\gamma_{TLC} = n_{free}/(n_{free} + n_{trap})$. Here, $n_{free} = N_C \exp[(E_F - E_m)/kT]$, where N_C is effective density of states in conduction band and kT the thermal energy. And the expression for n_{trap} is approximated with $kT_t < kT$ using exponential distribution of tail states. This yields $n_{trap} = N_{tc}kT_t\exp[(E_F - E_m)/kT]$, where N_{tc} is the density of trap states at conduction band edge. Now, we have γ_{TLC} as just a constant:

$$\gamma_{TLC} \equiv \frac{n_{free}}{(n_{free} + n_{tail})} \approx \frac{N_C}{N_C + N_{tc}kT_t} \tag{27.4}$$

2. Percolation Conduction
Percolation conduction associated with potential barriers above E_m can be considered as mobility scaled from band mobility (μ_0), assuming Gaussian random distribution of potential barriers with the mean (ϕ_{B0}) and the variance (σ_{B0}). This yields $\mu_0^* = \mu_0 \exp[-q\phi_{B0}/kT + (q\sigma_{B0})^2/(kT)^2]$. Here, ϕ_{B0} can be reduced by $\Delta\phi_{B0}$ due to thermally released electrons, depending on Fermi level change (ΔE_F), as described in Fig. 27.4. The thermally reduced barrier height can be expressed as $\phi_{B0}\exp(-\gamma_B \Delta E_F/kT)$, where $\gamma_B \equiv (D_B - W_B)/D_B$, which can be approximated as $\phi_{B0}(1 - \gamma_B \Delta E_F/kT)$ when $\gamma_B \Delta E_F/kT << 1$ by Taylor expansion. Thus, $\Delta\phi_{B0}$ is defined as $\gamma_B \Delta E_F/kT\phi_{B0}$. These conditions yield the percolation mobility (μ_{Per}) as follows:

$$\begin{aligned}\mu_{Per} &\equiv \mu_0 \exp\left(-\frac{q(\phi_{B0} - \Delta\phi_B)}{kT} + \frac{(q\sigma_{B0})^2}{2(kT)^2}\right) \\ &= \mu_0^* \exp\left(\frac{\gamma_B \Delta E_F}{kT}\phi_{B0}\right)\end{aligned} \tag{27.5}$$

where $\mu_0^* = \mu_0 \exp[-q\phi_{B0}/kT + (q\sigma_{B0})^2/2(kT)^2]$ considered as an effective band mobility.

3. Combined Mobility Model with V_{GS} Dependence
In Eq. (27.5), the ΔE_F is controlled by gate voltage (V_{GS}). The relationship between them can be derived by solving Poisson's equation, yielding $\Delta E_F = 2(kT/q)\ln[C_{ox}(V_{GS} - V_T)/Q_{ref}]$, where C_{ox} is gate-insulator capacitance, V_T threshold voltage, and $Q_{ref} \equiv \{2\epsilon_S N_C kT \exp[(E_{F0} - E_m)/kT]\}^{0.5}$. Combining TLC with percolation from Eqs. (27.4)–(27.5), we now have the V_{GS}-dependent mobility relation:

$$\mu_{FE} \equiv \mu_{Per}\gamma_{TLC} = \mu_0^* \left(\frac{N_C}{N_C + N_{tc}kT_t}\right)\left(\frac{C_{ox}}{Q_{ref}}\right)^{\alpha_p} (V_{GS} - V_T)^{\alpha_p} \tag{27.6}$$

As can be seen, Eq. (27.6) follows a power law. Here, $\alpha_p \equiv 2q\phi_{B0}\gamma_B/kT$, related to percolation. In Eq. (27.6), TLC affects the constant term, while the exponent is determined by percolation.

4. Current-Voltage Relation
With Eq. (27.6) and the definition of drift current, $I_{DS} = \mu_{FE}C_{ox}(V_{GS} - V_T - V_{ch})\mathrm{d}V_{ch}/\mathrm{d}x$, current-voltage relation $I_{DS}(V_{GS})$ can be derived with the integral ranges, $x = 0$ to L and channel potential $(V_{ch}) = 0$ to V_{DS}:

$$I_{DS} \equiv \mu_0^* \left(\frac{N_C}{N_C + N_{tc}kT_t}\right)\frac{W}{L'}\frac{C_{ox}^{\alpha_p+1}}{Q_{ref}^{\alpha_p}}(V_{GS} - V_T)^{\alpha_p+1}V'_{DS} \tag{27.7}$$

In Eq. (27.7), L' is defined as $L - \Delta L$, where ΔL is effective channel length reduction, and effective drain voltage $V'_{DS} = V_{DS} - 2R_C I_{DS}$, where R_C is contact resistance. For saturation region expression, Eq. (27.7) can be reformed with a saturation parameter (β_{sat}), replacing V'_{DS} by $\beta_{sat}(V_{GS} - V_T)$. Figure 27.18a shows a comparison between measured and modelled transfer characteristics

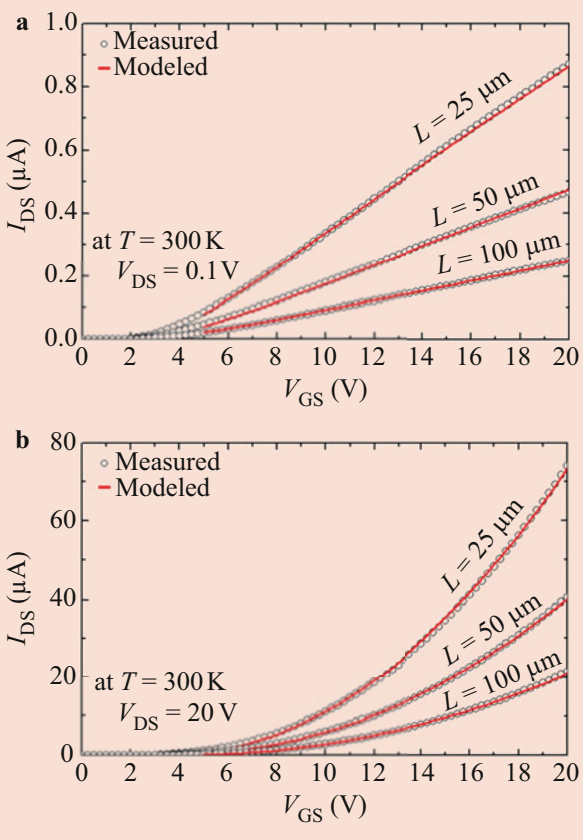

Fig. 27.18 Comparison between measured and modelled transfer characteristics (I_{DS} vs. V_{GS}) for the above-threshold region. For each region, a good agreement between measurement and modelling is achieved (**a**) Linear region with a small drain voltage (V_{DS}) of 0.1 V. (**b**) Saturation region with a high V_{DS} of 20 V

(I_{DS} vs. V_{GS}) at $V_{DS} = 0.1$ V, providing a good agreement. The measured saturation characteristics at V_{DS} =20 V is also well matched with the modelled results, as seen in Fig. 27.18b.

To check the model validity for temperature dependency, we measured and simulated the drain current as a function of gate bias for different temperatures, e.g. 100 K, 200 K, and 300 K, respectively. As seen in Fig. 27.19a, there is a good agreement between the measurements and the model (Eq. 27.7). For the purposes of validation, the modelled values of exponent (α_p) in the power law, Eq. (27.7), are compared with the extracted values from the best fit since it has a unique signature of percolation conduction, i.e. $a = \alpha_p + 1 \equiv 2q\phi_{B0} \cdot \gamma_B/kT + 1$. As seen in Fig. 27.19b, the proposed percolation model for $\phi_{B0} \cdot \gamma_B = 2.5$ meV shows better agreement compared to the conventional model (e.g. trap-limited conduction model with $a = 2kT_t/kT - 1$ for $kT_t = 30$ meV).

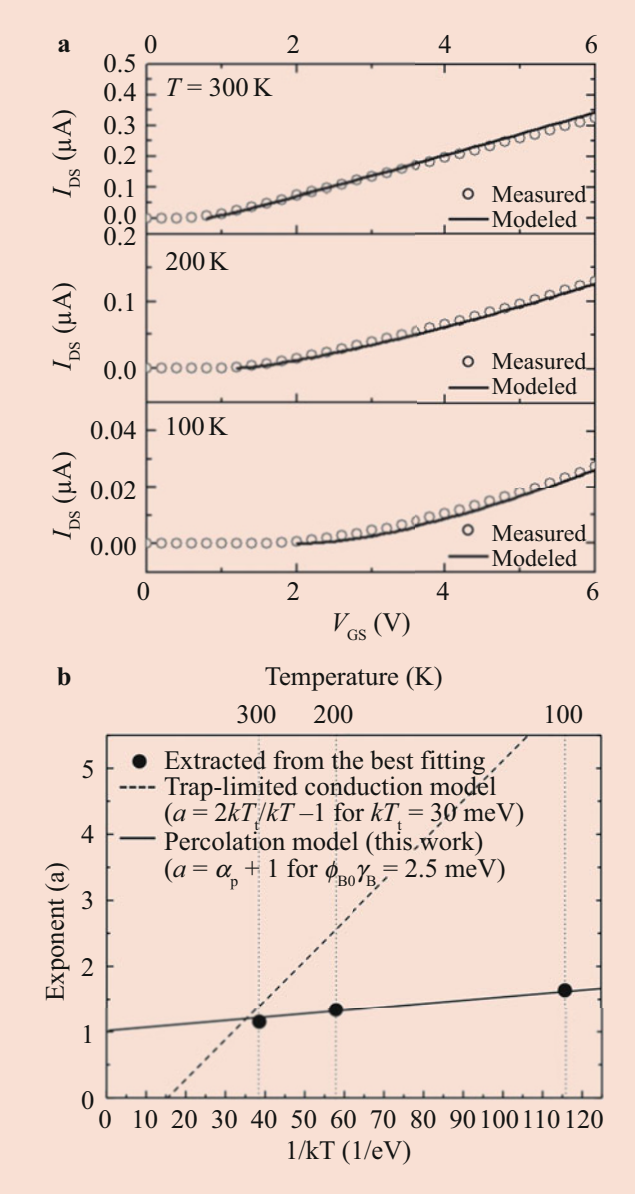

Fig. 27.19 Comparison between measured and modelled transfer characteristics at different temperatures. Here, the proposed model shows a better agreement compared to the conventional model (e.g. trap-limited conduction model) (**a**) Measured and modeled I_{DS}-V_{GS} for above-threshold region at $V_{DS} = 0.1$ V for different temperatures (100 K, 200 K, 300 K, respectively). (**b**) Retrieved exponent (**a**) vs. temperature

Subthreshold Model

The subthreshold current in the limit of low V_{GS} shows a linear dependence on V_{GS} in a semi-log plot, as illustrated in Fig. 27.22, suggesting diffusion current, as follows:

$$I_{Diff} \approx \mu_0 \frac{kT}{q} \frac{W}{L'} Q_{fi} \exp\left(\frac{q}{kT}\left(\frac{V_{GS} - V_{FB}}{1 + q^2 D_{it}/C_{ox}}\right)\right) \left(1 - \exp\left(-\frac{qV'_{DS}}{kT}\right)\right) \tag{27.8}$$

where μ_0 is the band mobility for electrons. Note that the subthreshold slope (SS) can be derived from Eq. (27.8) with the definition $dV_{GS}/d\log I_{DS}$,

$$S \equiv \ln 10 \frac{kT}{q}\left(1 + \frac{q^2 D_{it}}{C_{ox}}\right) \tag{27.9}$$

As described in Fig. 27.20, interface states are occupied first, followed by filling deep states located in the bulk at higher V_{GS}. So, as the E_F moves to the location of deep states for increasing V_{GS}, the drain current can be defined as a drift current (I_{Drift}):

$$I_{Drift} \approx \mu_0 \frac{W}{L'} \frac{C_{ox}^{\alpha_d+1}}{Q_d^{\alpha_d}} (V_{GS} - V_{FB})^{\alpha_d+1} V'_{DS} \tag{27.10}$$

where Q_d is a reference charge density associated with deep states, α_d is a power law exponent defined as $2(T_d/T - 1)$, and T_d is the characteristic temperature of deep states.

We now have the current-voltage relations for both diffusion and drift components as given by Eqs. (27.8) and (27.10). These equations can be combined as a total drain current (I_{sub}) in the subthreshold region using a harmonic average:

$$I_{sub} \equiv (I_{Diff}^{-m} + I_{Drift}^{-m})^{-1/m} \tag{27.11}$$

The examined TFT to verify this model, which is the same as that used in the previous sections, has the following geometrical and physical parameters (extracted in the previous sections): $W = 100\,\mu$m, $L = 100\,\mu$m, channel thickness $t_S = 40$ nm, channel permittivity $\epsilon_S = 11.5\epsilon_0$ (where ϵ_0

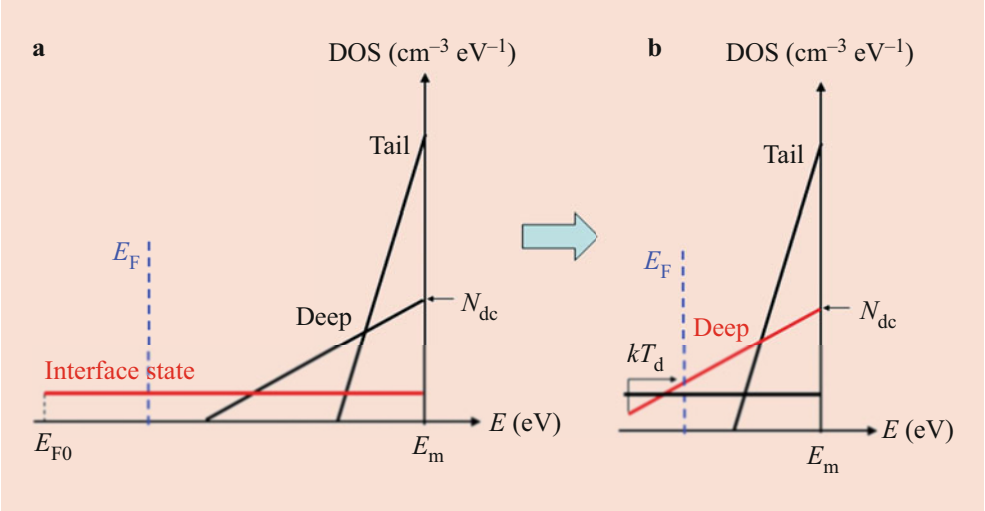

Fig. 27.20 Density of states profile with (**a**) Fermi level within interface states at low gate voltage and (**b**) the case of deep states dominant with increasing gate voltage corresponding Fermi level now within deep states

Table 27.4 Extracted subthreshold parameters at $T = 300$ K

Parameters	Value
SS	0.19 V/dec
D_{it}	1.64×10^{11} cm^{-2}eV^{-1}
I_{off}	2×10^{-14}A
Q_{fi}	7.05×10^{-14} C/cm^2
α_d	2.26
T_d	639 K
Q_d	7.8×10^{-8} C/cm^2

is vacuum permittivity), $V_{FB} \sim 0.6$ V, $V_T \sim 4$ V, $C_{ox} = 11.5$ nF/cm^2, $\mu_0 = 15$ cm^2/V · s, and $N_C = 5 \times 10^{18}$ cm^{-3} at 300 K. $2R_C \equiv R_{SD} = 9637\ \Omega$ for $W = 100\ \mu$m (equivalent to $R_{SD}W = 96.37\ \Omega \cdot$ cm), and $\Delta L = -3.5m$ ($L' = L - \Delta L = L + 3.5\ \mu$m). Other extracted model parameters are summarized in Table 27.4. Figure 27.21 shows the measured subthreshold characteristics for a different V_{DS}, providing a good agreement with each other.

To validate the subthreshold model in terms of the diffusion component in the examined transistors, we measured the drain current for small $V_{DS} = 0.01$, 0.1, and 1 V. Comparing to the model, we get good agreement as seen in Fig. 27.22. In particular, as shown in the inset of Fig. 27.22, the measured I_{DS} vs. V_{DS} at the diffusion dominant region of V_{GS} (e.g. $V_{GS} = 0.5$ V) is compared with Eq. (27.8). Here, the dependence of the drain current on V_{DS} is found to follow the law of $(1 - \exp(-qV_{DS}/kT))$ of Eq. (27.8), which is a signature of the presence of the diffusion current.

Regarding continuity and symmetry of the compact model where above- and sub-threshold models are combined, the model was subject to the Gummel symmetry test (GST)

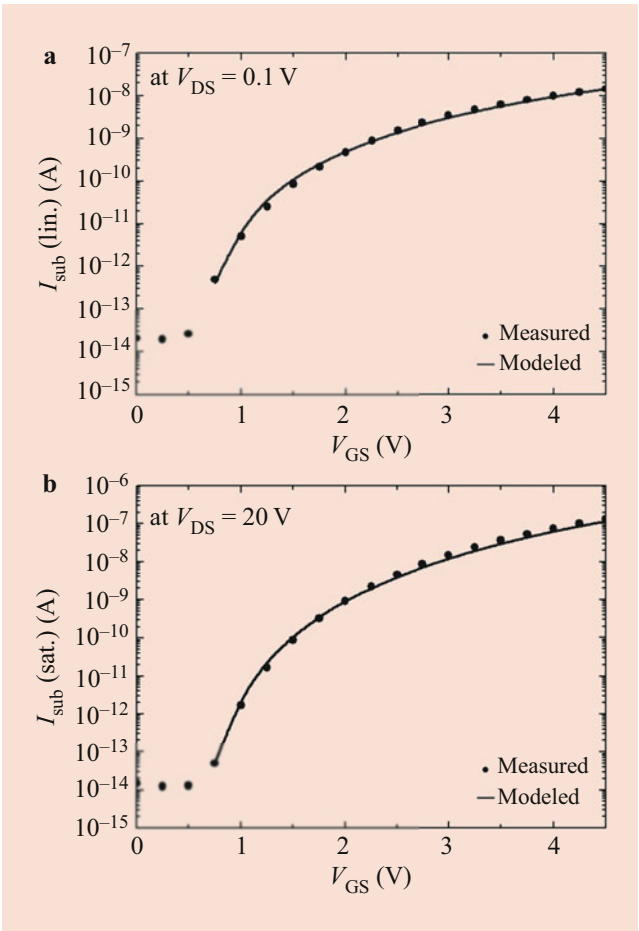

Fig. 27.21 Measured and modelled subthreshold current (I_{sub}) as a function of V_{GS}. (**a**) Linear region with $V_{DS} = 0.1$ V. (**b**) Saturation region with $V_{DS} = 20$ V

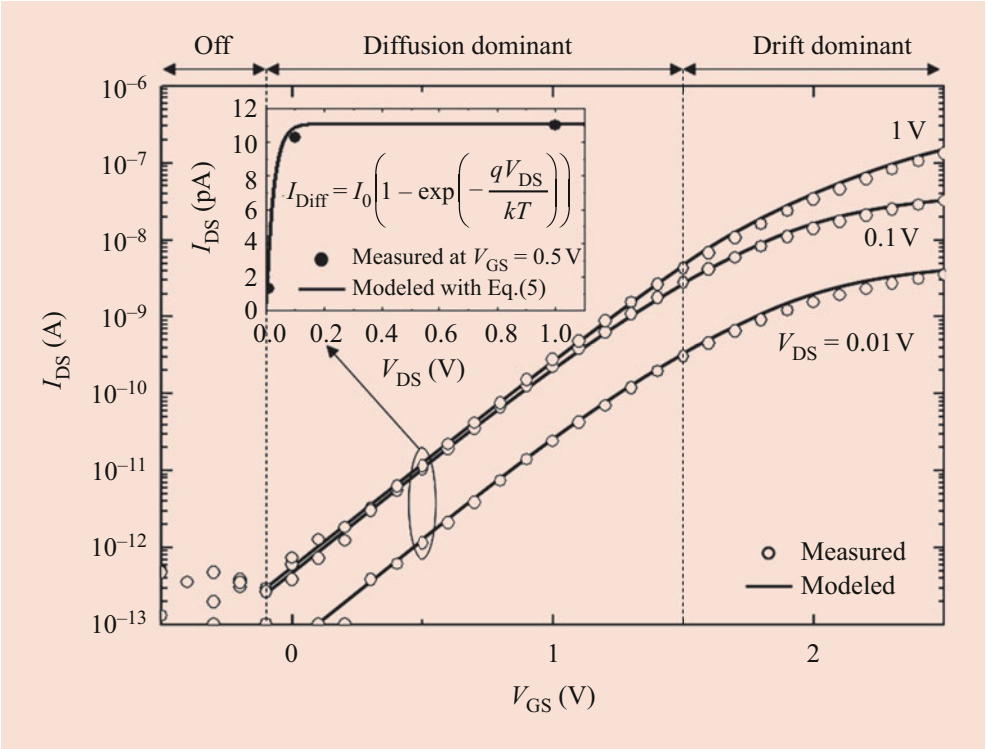

Fig. 27.22 Measured and modelled I_{DS} vs. V_{GS} at subthreshold region for a different V_{DS}. Inset: Measured and modelled I_{DS} vs. V_{DS} for $V_{GS} = 0.5$ V. Here, the equation is simplified from Eq. (27.8) introducing the pre-constant I_0 which is around 10 pA at $V_{GS} = 0.5$ V

[162, 169]. As seen in the inset of Fig. 27.23a, V_X represents a symmetrical voltage applied on source and drain sides, respectively. Figure 27.23 demonstrates perfect continuity and symmetry as a function of V_X even for the fourth derivative of I_{DS} with respect to V_X, suggesting it has successfully passed the GST. For this, we employed smoothness and continuity functions for the effective drain voltage and threshold voltage terms [170].

Off Region Model

The off current can defined according to [159] at $V_{GS} = V_{FB}$:

$$I_{off} \approx \mu_0 \frac{kT}{q} \frac{W}{L} Q_{fi} \left(1 - \exp\left(-\frac{qV'_{DS}}{kT}\right)\right) \tag{27.12}$$

Unified Model

As seen in previous Sects. 27.2.1 and 27.2.1, the current-voltage relation needs to be derived separately to describe the subthreshold and above-threshold characteristics. Here, we need separate expressions for the subthreshold and above-threshold regions, implying two different equation systems to describe total current (see Fig. 27.24). Moreover, in this case, threshold voltage (V_T) is not immediately apparent from the I-V plot and needs to be extracted from above-threshold region of the characteristic as a fitting parameter. However, the extracted value of V_T can be quite different depending on the extraction method and the I-V data range chosen for the fit. In contrast, turn-on voltage (V_{on}) is the gate voltage (V_{GS}) at which drain current (I_{DS}) starts increasing rapidly; thus, it is easy to identify V_{on} on a semi-log plot of I_{DS} vs. V_{GS}.

We can unify this to cover both subthreshold and above-threshold characteristics. The proposed unified model is a single expression with a reference voltage level V_{on} rather than V_T, providing good agreement with measured terminal characteristics over the entire range of $V_{GS} > V_{on}$ for the test TFTs with an amorphous InGaZnO (a-IGZO) channel, which is the same TFT used in the previous sections. The derived equation for this model is as follows:

$$I_{DS} = G_0 \frac{W}{L'} \exp\left(\kappa (V_{GS} - V_{on})^{\alpha}\right) V'_{DS} + I_{off} \tag{27.13}$$

where $G_0 = \mu_0 (\epsilon_S kTN_C)^{1/2}$, $\kappa = \zeta/2kT$, and ζ & α are related to trap states. To extract the values of κ and α, we can rewrite Eq. (27.13) as,

$$U \equiv \frac{I'_{DS}/V'_{DS}}{\mathrm{d}(I'_{DS}/V'_{DS})/\mathrm{d}V_{GS}} = \frac{1}{\alpha\kappa}(V_{GS} - V_{on})^{1-\alpha} \tag{27.14}$$

Here, $I'_{DS} \equiv I_{DS} - I_{off}$. Therefore, $1-\alpha$ and $1/(\alpha\kappa)$ can be extracted from the plot of $\ln U$ vs. $\ln(V_{GS} - V_{on})$ as the slope and the intercept, respectively (as illustrated in Fig. 27.25a). The extracted model parameters are summarized in Table 27.5.

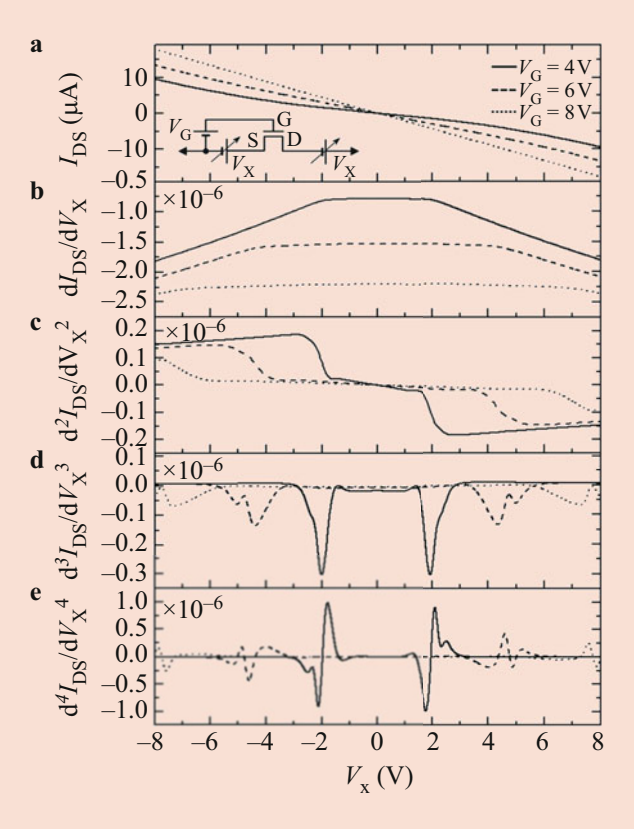

Fig. 27.23 (**a**) Calculated I_{DS} vs. V_X of the combined above- and sub-threshold model for different V_G (4, 6, 8 V). (**b**) First, (**c**) second, (**d**) third, and (**e**) fourth derivatives of I_{DS} with respect to V_X. The inset of (**a**): test circuit configuration of the GST

Figure 27.25b shows modelled results for different L (=25, 50, and 100 μm), providing good agreements with the measured characteristics. Also, they exhibit small average errors <5% over a wide range of V_{GS} from 5 to 20 V. Interestingly, the proposed model using only one equation covers both the sub- and above-threshold regions at the same time. This is mainly due to a combination of the exponential function and power law. Additional advantage of this unified model is that it just needs a few model parameters to be implemented in model code description, e.g. Verilog-A, thus providing a higher-speed simulation.

Computer Interpretation of Device Model

After having established an accurate analytical model for the TFT, computer implementation for circuit simulation is not always easy. Several considerations including speed, convergence, and even the way of translating different forms of equations into computer language should be taken into consideration in this step.

For a-Si TFTs, several SPICE models have been developed. Specifically the model developed by Rensselaer Polytechnic Institute, also known as the RPI model [150], has become a commercialized standard supported by many simulation platforms including SmartSpice, HSPICE, Spectre, etc. However, CAD of organic and metal-oxide TFTs is yet to become a standard due to the rapid and ongoing evolution in materials and device structures. In fact, and as mentioned previously, there is a quest for unifying the TFT model to meet simulation requirements of TFTs with ever-changing structures and materials.

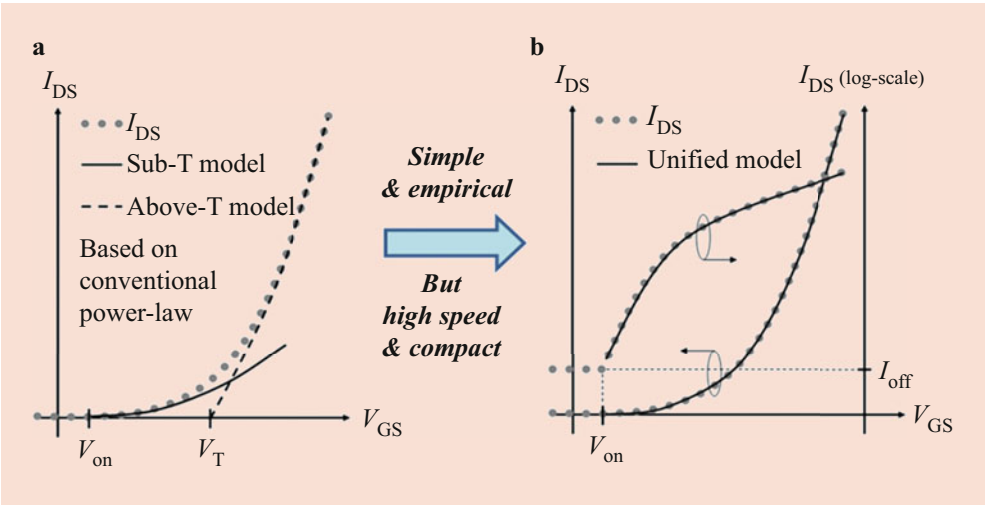

Fig. 27.24 (**a**) Schematic I_{DS} vs. V_{GS} curves (grey circles) with the conventional power law models for subthreshold (Sub-T, solid line) and above-threshold (Above-T, dot line) characteristics. In this case, we need two models for these two different operational regions. Here, V_{on} and V_T are on-voltage and threshold voltage, respectively. (**b**) Schematic I_{DS} vs. V_{GS} curves (grey circles) with only one model: unified model which can cover subthreshold as well as above-threshold regions at the same time

It is important to understand the benefits and drawbacks of SPICE and Verilog-A while developing a device model to be used in further circuit simulation and system design.

SPICE

SPICE is an open-source analogue circuit simulation software firstly developed at the University of California, Berkeley [171]. The first two versions of this simulator were written in Fortran. SPICE2 included several elements widely used in circuit simulation at that time, including the diode, MOSFET, JFET, BJT, etc. In 1989, a version of the simulator SPICE3 was rewritten in C. This version includes the well-known BSIM model [172].

Many commercial circuit simulators today are based on the aforementioned software, including PSPICE, HSPICE, SmartSpice, Spectre, etc. The fast simulation speed, high accuracy, and ease of use make the SPICE simulator extremely popular in the area of circuit design. However, SPICE is written in a low-level computer language (Fortran or C) and so are the models used in it. Therefore, researchers should not only have a good understanding of device physics but also need enough knowledge of the algorithms and limitations of the simulator. The procedure for developing a standalone SPICE model (not by combining existing elements) always takes time and resources. Due to the complexity of model development in SPICE, currently only well-developed and widely used devices are having SPICE models.

It is worth noting that modern circuit simulators use a heavily modified original SPICE model, but they separate as much as possible the simulation algorithm from the device model. For example, the Spectre simulator provides a Spectre Compiled Model Interface (CMI) for Spectre developers and others to use C code directly for device modelling.

Verilog

The Verilog Hardware Description Language (Verilog HDL) was designed in 1984 to meet the design demands of VLSI engineers working in the higher abstractive level to increase the number of transistors in simulating digital circuits. Subsequently adopted by Cadence Design Systems and Open Verilog International, VHDL has become an IEEE standard in 1995, i.e. IEEE Std 1364-1995 [173].

Since the original Verilog language did not support analogue systems, the extensive use of HDL languages led to a growing demand for high-level behavioural model for systems and components for use in analogue and mixed signal system design. Thus, Verilog-AMS standard was then developed by Accellera to include Verilog-A, a previously standalone behavioural language used for analogue modelling in Spectre, and extending both the digital part of the IEEE Std 1364 and the analogue part of Verilog-A [174].

In the early days of Verilog-A and Verilog-AMS, the behaviour model was limited in terms of accuracy for analogue devices. The language was first developed for design of systems, and thus the behavioural language was at that time not intended for complex physical equations at the device level. Figure 27.26 illustrates the mixed signal simulation environment in early days. In addition, device modelling often led to long execution times compared with SPICE models. Even so, the capability of behavioural modelling started to attract the attention of device modellers struggling with low-level implementation.

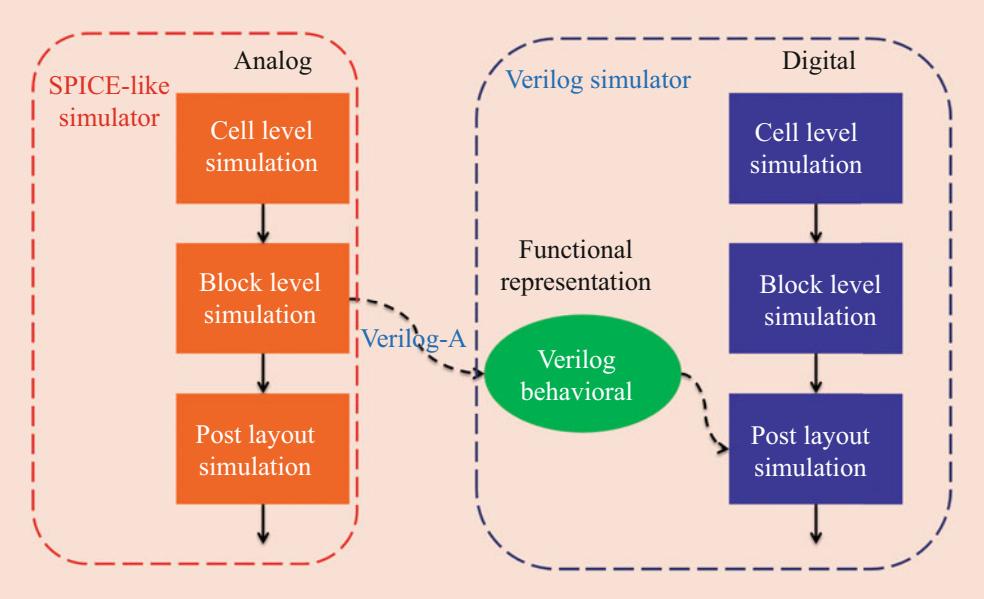

Fig. 27.26 Verilog-A behaviour model in early mixed signal simulation environment

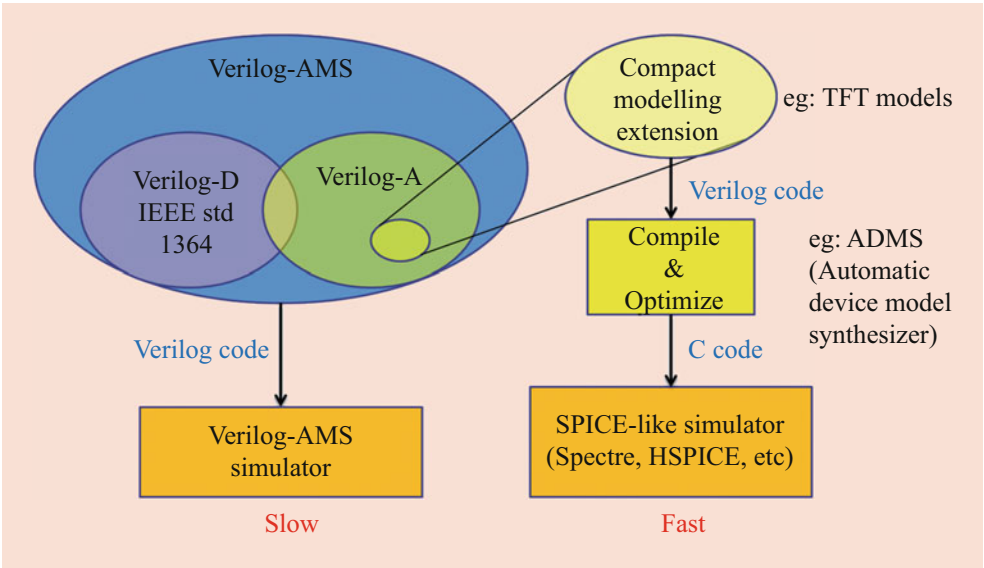

Fig. 27.27 Verilog-A(MS) extension for compact modelling with SPICE-like simulator integration

In 2002, the open-source tool supporting automatic conversion [175] of Verilog-AMS models to C codes was introduced. Since then, several proposals have been made to use Verilog-AMS to efficiently develop compact device models [176,177] to integrate with SPICE-like simulators. The report in 2010 [178] showed comparable performance of their Verilog-AMS device model against SPICE. The language has now become a major tool for device model developers. Figure 27.27 illustrates the relation between different Verilog languages and the simulation flow in two types of simulators.

Short Summary of Comparison

Table 27.6 summarizes the comparison of different model languages. The SPICE model development based on a low-level language is only used by model developers of components, which are not likely to change (due to heavy usage or technology maturity) in view of resource requirements. In the meantime, the Verilog approach is ideally suited to meet the modelling demands of ever-changing TFT or other device structures without requiring a mature physical understanding of the devices or underlying material system. The direct

implementation of physical equations in Verilog-AMS will dramatically reduce the time between development of new devices and subsequent circuit simulation.

Despite all the benefits of Verilog-AMS, the model is still slower and less efficient than a well-developed SPICE model, due to the fact that the Verilog-AMS model should be converted to a lower-level language form. The converted form although automatically optimized by the synthesizer (e.g. ADMS [175]) cannot be as efficient as a SPICE model because the latter is optimized directly in a lower-level language. Therefore, it is recommended to use SPICE for circuit simulation whenever it could offer sufficient accuracy. On the other hand, Verilog-AMS is suited for devices that are new or under development.

Table 27.6 Comparison between different model languages

	SPICE	Spectre CMI	Verilog-AMS
Language	C/Fortran	C	Verilog
Language level	Low	Low	High
Easy to use	No	No	Yes
Efficiency and speed	High	High	Low
Complexity	High	High	Low
Information needed	Algorithm and limitations	Equation limitations	None
Users	SPICE developers	CAD engineers, Cadence programmers	End users

CAMCAS Model in Simulation Environment

As discussed before, we implement the Cambridge's TFT compact model (i.e. CAMCAS model) directly into Verilog-A language for use in a Cadence Design Environment so as to focus on developing a more accurate model for circuit simulations. The simulation flow in the Cadence Design Environment is shown in Fig. 27.28.

The user extracts processing parameters based on the measurement results of their own devices and incorporates them into the CAMCAS Verilog-AMS model. In addition, the user can change the form of equations for better fitting to measurement results. Thus, circuit designers can use the usual route of circuit design by simulating their TFT circuits before fabrication analogous to using the SPICE model in Cadence Spectre.

Figure 27.29 shows an example of an IGZO TFT circuit simulated using the CAMCAS model in Cadence Spectre. The simulation results show a voltage gain of 12 dB in both transient and AC simulation as shown in Fig. 27.30a and b, respectively.

27.2.2 Small-Signal Modelling

General Small Models

Small-signal model is used for linear approximation of many nonlinear electronic devices including diodes, MOSFET, BJT, etc. when the signal under processing is reasonably small compared with the DC bias of devices [179]. The use of small-signal model significantly simplifies the design procedure of many analogue circuits, especially amplifiers. Different small-signal models exist for different electronic devices; for example, MOSFET and BJT are having different small-signal models due to their different structure and working principles. However, researchers in the area of TFT circuit design are using the same small-signal model as MOSFET. In spite of the similarity of their structures, TFTs are having a much bigger contact resistance between different materials, more significant parasitic capacitance, and a severe instability problem. Therefore, it is helpful to re-evaluate the small-signal model specifically for TFTs.

Midband Small-Signal Model

First, we review how a midband small signal model was developed. As linear systems are to be designed out of nonlinear devices, the straightforward solution is to use a small part of the nonlinear behaviour (I-V curves) to approximate a linear response (small-signal model). Therefore, under the assumption that the signal is sufficiently small, the linear approximation would be equal to the derivative of the none linear device at the bias point. For a general three-terminal device with terminals G, S, and D (terminal names can be arbitrarily chosen; here they are chosen in consistency with TFTs), the I-V formula can be written as:

$$\begin{cases} I_D = f_1(V_{GS}, V_{DS}) \\ I_G = f_2(V_{GS}, V_{DS}) \end{cases} \tag{27.15}$$

Here, V_{GS} and V_{DS} are the voltage drops between G-S terminals and D-S terminals, respectively. As V_{GD} can be calculated from $V_{GS} - V_{DS}$ and $I_S = -I_D - I_G$, Eq. (27.15) is enough to represent the I-V of an arbitrary three-terminal device.

For small changes of V_{GS} and V_{DS}, the current differences would approximately follow the derivative of the I_D and I_G functions in Eq. (27.15).

$$\begin{cases} dI_D = \frac{\partial f_1}{\partial V_{GS}} dV_{GS} + \frac{\partial f_1}{\partial V_{DS}} dV_{DS} \\ dI_G = \frac{\partial f_2}{\partial V_{GS}} dV_{GS} + \frac{\partial f_2}{\partial V_{DS}} dV_{DS} \end{cases} \tag{27.16}$$

For sufficiently small signals and sufficiently good linearities at the bias point, the partial derivatives can be treated as a constant. The small-signal relations should follow:

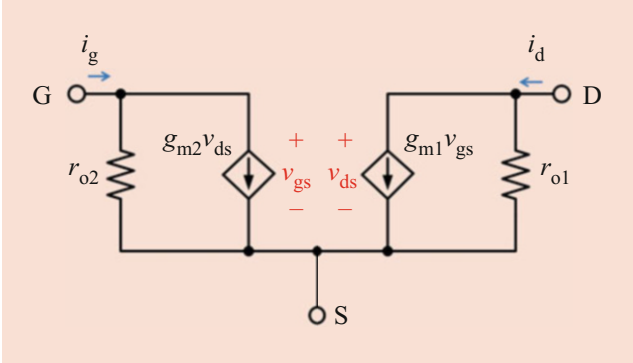

Fig. 27.31 Small signal model for a general three-terminal device

$$\begin{cases} i_d = g_{m1} v_{gs} + \frac{v_{ds}}{r_{o1}} \\ i_g = \frac{v_{gs}}{r_{o2}} + g_{m2} v_{ds} \end{cases} \tag{27.17}$$

where i and v in small cases represent the small change in current and voltage of the corresponding terminals, respectively. The coefficient of v_{ds} for i_d or v_{gs} for i_g can be represented as passive components (a resistor connection), while the coefficient of v_{gs} for i_d or v_{ds} for i_g can only be represented by active components, a voltage-controlled current source (VCCS). Therefore, resistance is used to represent passive components (i.e. r_{o1} and r_{o2}), and transconductance is used to represent active components (i.e. g_{m1} and g_{m2}).

Now, from Eq. (27.17), we have the linear approximation of the device at a fixed bias point of V_{GS} and V_{DS} (note that the coefficients in Eq. (27.17) can be a function of V_{GS} and V_{DS}, but not a function of v_{gs} and v_{ds} under the small-signal assumption.) The corresponding small-signal model of the equation can be drawn as Fig. 27.31. This is a general form of a hybrid-pi model which is consistent with both BJT and MOSFET. In the case of most transistors, V_{DS} does not affect I_G. Thus, $g_{m2} = 0$. And for the case of MOSFET, the gate resistance is huge and normally treated as open circuit. Therefore, the corresponding components can be removed.

The analysis reviewed above is a general approach for all three terminal devices. Thus, it should also be valid for TFTs at midband frequencies. However, as the parameters are derived from the derivative of I-V curves, a more physical representation of those parameters can be complicated, and some of the parameters should be represented as separate components.

High-Frequency Small-Signal Model

An accurate calculation of the circuit response at midband frequency is not enough for circuit designers as the bandwidth and phase margin should also be predicted when designing circuits. This is especially crucial for amplifiers and active filters to prevent self-oscillation. While midband

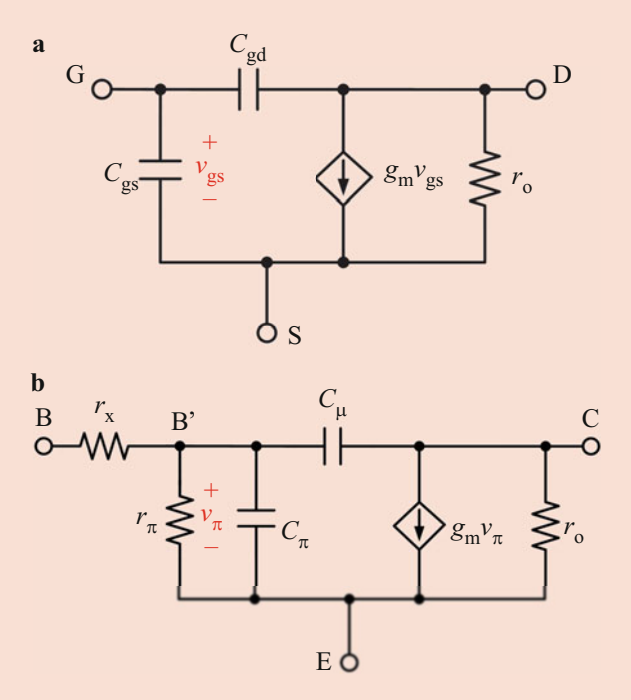

Fig. 27.32 High-frequency small-signal models for CMOS and BJT. (**a**) CMOS model. (**b**) BJT model

small-signal models can be developed through a general way from I-V curves, the high-frequency small-signal model can only be developed by considering I-V, C-V, and physical meanings of different components. This is why the high-frequency small-signal models are very different for CMOS and BJT despite the similarities on their midband models.

The comparison of CMOS and BJT models is shown in Fig. 27.32 [180]. The CMOS high-frequency model (Fig. 27.32a) is more consistent with the midband model that the parasitic capacitors are added to the midband model while keeping the original connections. In comparison, the BJT model (Fig. 27.32b) is less so as node B' is added between r_x and r_π (which are the same resistance in the midband model). The separation of r_x is due to the physical representation of a base spreading resistance, which is the resistance of the connection to the base inside the device. The contribution of this resistor becomes more significant at high frequency because of the reduced impedance of the parasitic capacitors, namely, C_μ and C_π.

The review of CMOS and BJT high-frequency small-signal models suggests that physical structure should be considered while developing high-frequency models as the connections of parasitic capacitances may vary and affect the overall performance of the model. Therefore, it is imperative to evaluate the TFT structure to include physical resistance, capacitance, and their connections correctly.

TFT Small-Signal Model

As discussed in the introduction section, an accurate TFT small-signal model needs to consider the physical representations and modelling not only for the sake of a simpler expression of each component in the midband model but also for an accurate modelling in the high-frequency model. In this section, we will discuss the concerns at the stage of model developing and report the developed models.

Midband TFT Model

As discussed in Sect. 27.2.2, the midband model can be developed using the general approach. Therefore, the small-signal behaviour can be represented by a VCCS and an output resistor in parallel. The major concern of this approach is the expression of the two components, g_m and r_o. As the two components come from the derivative of $I_{DS} - V_{GS}$ and $I_{DS} - V_{DS}$ curves, the static characteristic of TFTs should be considered first before deriving the expressions of g_m and r_o.

The major concern here comes from the big contact resistance (R_C) [161, 181–185] and the threshold voltage shift (V_T shift) [164, 186–190] in TFTs which include TFTs from different material families such as amorphous silicon, organic, and metal oxide semiconductors. Although TFTs are having a similar working principle with MOSFET, the contact resistance (R_C) is so dominant that even the static model should consider R_C as independent components. Most of the static models are developed based on a structure shown in Fig. 27.33 where the I-V characteristics are modelled for the internal transistor and the $R_C s$ (R_S and R_D here) are accounted for separately.

In this section, we will consider the effect of contact resistance and V_T shift in the midband TFT model.

The Effect of Contact Resistance

As the overall I-V expression is complicated when considering R_S, R_D, and the ideal TFT as a whole, it is more convenient to derive the small-signal model of the ideal TFT and then consider the circuit as a linear network. Therefore, by using the I-V expression, we can easily derive a small-signal model shown in Fig. 27.34a. As reviewed in Sect. 27.2.1, the general I-V expression for a TFT can be written as:

$$I_{DS} = \frac{1}{\alpha_p + 2} K \frac{W}{L'} (V_{GS'} - V_T)^{\alpha_p + 2} \tag{27.18}$$

where $K = (\alpha_p + 2)\mu_0^* (\frac{N_C}{N_C + N_{tc} kT_t}) \frac{C_{ox}^{\alpha_p + 1}}{Q_{ref}^{\alpha_p}} \beta_{sat}$. The transconductance g_{mi} in in Fig. 27.34a can then be calculated directly as:

$$g_{mi} = K \frac{W}{L'} (V_{GS'} - V_T)^{\alpha_p + 1} \tag{27.19}$$

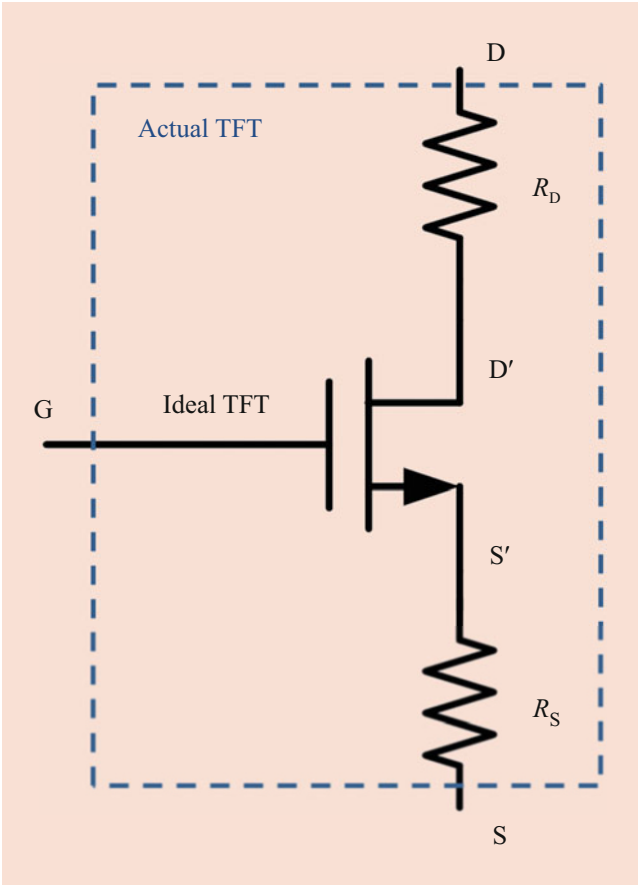

Fig. 27.33 The inner structure based on which static TFT models are developed

The r_{oi} in the figure, however, is harder to express in physical parameters. As the slope of the output characteristics are normally modeled using an empirical Early voltage (V_A), TFTs do not have the same short channel effect as CMOS does. But the output characteristics have similar trend of having an Early voltage. Thus, it is usually modeled by an empirical Early voltage. r_{oi} is then calculated using:

$$r_{oi} = \frac{V_A}{I_{DS}} \tag{27.20}$$

With the above equations, we can easily get an accurate midband small-signal model for the TFT of concern and design suitable g_{mi} and r_{oi} by choosing W/L ratio, given that the TFT technology and processing parameters are already modeled with known R_S, R_D, and V_A. However, it is not so convenient in terms of measurements as the results will be overall I-V curves directly. The derivatives of the overall I-V curves can capture the overall g_m and r_o in an equivalent midband model shown in Fig. 27.34b (the general approach).

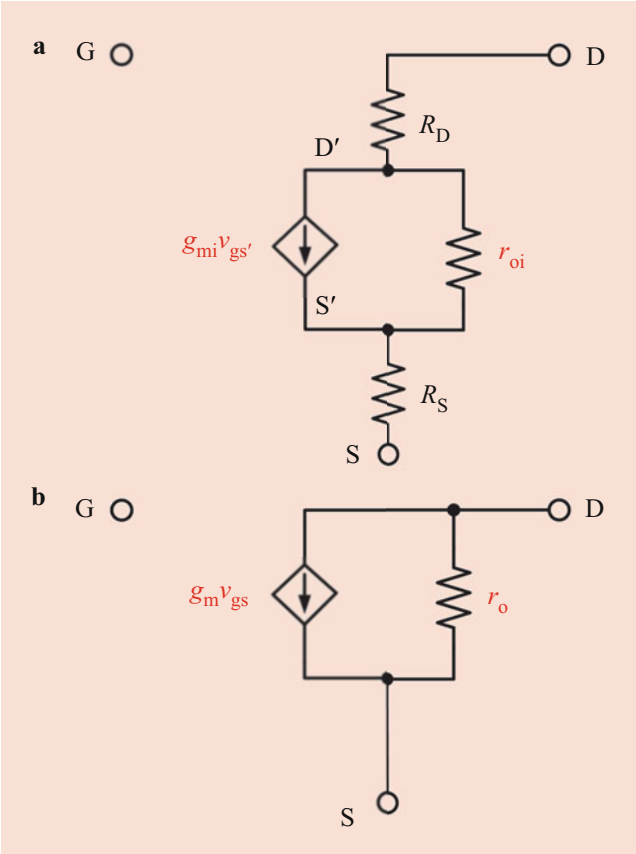

Fig. 27.34 Midband small-signal models. (**a**) R_C as separate component. (**b**) Overall midband model

It is worth finding the relations between the two models shown in Fig. 27.34.

As the circuits only consist of linear components, in this case only VCCS and resistors, the circuit in Fig. 27.34a should be equivalent to the one in Fig. 27.34b according to Thevenin' theorem [191, 192]. From Fig. 27.34a, we have:

$$\begin{cases} i_d = \frac{v_{s's}}{R_S} \\ i_d = g_{mi}(v_{gs} - v_{s's}) + \frac{v_{ds} - i_d R_D - v_{s's}}{r_{oi}} \end{cases} \tag{27.21}$$

Substituting $v_{s's}$ and considering. As the semiconductor layer and source/drain contacts are made of the same material and have identical geometries and similar properties, the contact resistances are considered to be equal at both sides for convenience. $R_S = R_D = R_C$, we get:

$$i_d = \left(\frac{g_{mi}r_{oi}}{g_{mi}r_{oi}R_C + 2R_C + r_{oi}}\right)v_{gs} + \left(\frac{1}{g_{mi}r_{oi}R_C + 2R_C + r_{oi}}\right)v_{ds} \tag{27.22}$$

Compared with Fig. 27.34b, we have:

$$i_d = g_m v_{gs} + \frac{v_{ds}}{r_o} \tag{27.23}$$

As both models should capture the same derivatives of the overall I-V curves (i.e. g_m and r_o), the relations should follow:

$$\begin{cases} g_m = \frac{g_{mi}r_{oi}}{g_{mi}r_{oi}R_C + 2R_C + r_{oi}} \\ r_o = g_{mi}r_{oi}R_C + 2R_C + r_{oi} \end{cases} \tag{27.24}$$

Here, we can derive the overall g_m and r_o out of the theoretical prediction of our transistor models. While designing real circuit applications, this will be the equations to use to estimate the circuit behavior. By solving Eq. (27.24), we can also get the values of internal components from measurement results:

$$\begin{cases} g_{mi} = \frac{g_m r_o}{r_o - g_m r_o R_C - 2R_C} \\ r_{oi} = r_o - g_m r_o R_C - 2R_C \end{cases} \tag{27.25}$$

This equation is very useful when the values of internal components are to be extracted out of measurement results. It also provides a convenient way of checking the validity of the model, which will be discussed later.

Equations (27.24) and (27.25) not only show the relation between the static model parameters and the overall parameters from measurements but also reveal some insights of the parameters:

1. The intrinsic gain $g_m r_o$ of both the overall performance and the ideal internal TFT is the same. As the overall g_m is reduced due to the contact resistance (in comparison with g_{mi}), the r_o increases at the same rate, making $g_m r_o = g_{mi} r_{oi}$. This also means that the contact properties of the semiconductor layer and the electrodes do not affect the intrinsic gain of the overall transistor. The measurement of $g_m r_o$ directly shows the maximum achievable single-stage gain of the semiconductor technology.
2. The term $g_{mi}R_C$ can be used to evaluate how different the measurement results will be from the ideal TFT in the model. As $g_{mi}r_{oi}R_C$ cannot be dominant over r_{oi}, the overall $g_m \approx \frac{1}{R_C}$ (which is impractical as there's no dependence on bias), and $R_C \ll r_{oi}$, the value of $g_{mi}R_C$ should be around 0 1 (might be a bit higher than 1 but should be around the order of magnitude).

The Effect of V_T Shift

Another property that might affect the midband model is the V_T shift under bias condition. As the implementation of TFTs in AMOLED display proves that bias-induced V_T shift must be compensated especially when the analogue properties are to be used (i.e. the output current needs to be actually controlled), the TFT small-signal model should capture the behaviour to help design and evaluate TFT analogue circuits.

The major concern of V_T shift is that it would change the bias condition in effect, as in the static models, the V_T terms always appear in $V_{GS} - V_T$. Therefore, considering V_T shift,

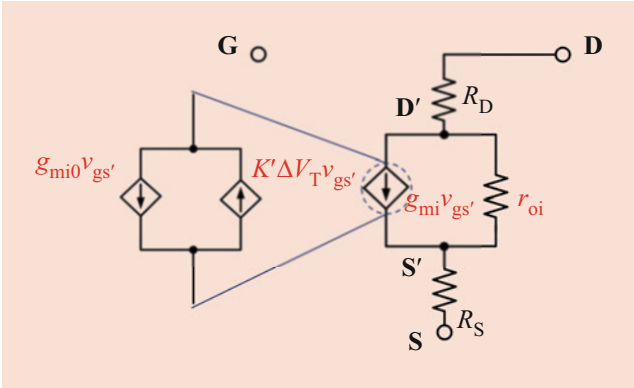

Fig. 27.35 Midband TFT model considering V_T shift

the expression of Eq. (27.19) can be rewritten as:

$$\begin{aligned} g_{mi} &= K\frac{W}{L'}(V_{GS'} - V_T - \Delta V_T)^{\alpha_p+1} \\ &= K\frac{W}{L'}(V_{GS'} - V_T)^{\alpha_p+1}\left(1 - \frac{\Delta V_T}{V_{GS'} - V_T}\right) \\ &= K\frac{W}{L'}(V_{GS'} - V_T)^{\alpha_p+1} - K\frac{W}{L'}(\alpha_p + 1) \\ &\quad \times (V_{GS'} - V_T)^{\alpha_p}\Delta V_T + O\left(\frac{\Delta V_T}{V_{GS'} - V_T}\right) \end{aligned} \tag{27.26}$$

Typically, $\Delta V_T << V_{GS'} - V_T$, as the experiments show that the V_T shift does not turn the transistor off (i.e. $\Delta V_T \sim V_{GS'} - V_T$) at least not within a reasonable time period. Hence, the higher-order terms can be omitted in the above Taylor expansion. The first-order approximation of $g_m i$ can then be written as follows:

$$g_{mi} \approx g_{mi0} - K'\Delta V_T \tag{27.27}$$

where $g_{mi0} = K\frac{W}{L'}(V_{GS'} - V_T)^{\alpha_p+1}$ is the initial value where there's no V_T shift, and $K' = K\frac{W}{L'}(\alpha_p + 1)(V_{GS'} - V_T)^{\alpha_p}$ is the coefficient of the g_{mi} change per ΔV_T change. Here, as α_p is a constant value close to zero, K' can normally be treated as a constant coefficient.

This means that the V_T shift effect can be represented by a separate component. The corresponding modification of small-signal model is shown in Fig. 27.35.

High-Frequency TFT Model

Device structure and physical meanings of all components need to be considered in high-frequency small-signal model, especially when capacitances come into the picture, as discussed in Sect. 27.2.2 of the BJT model. The connection of contact resistances in TFTs plays a similar role as the base spread resistance of BJT, which is connected in series with a parasitic capacitance. Here, as illustrated in Fig. 27.36, the contact resistance at source side (R_S) separates the overlap

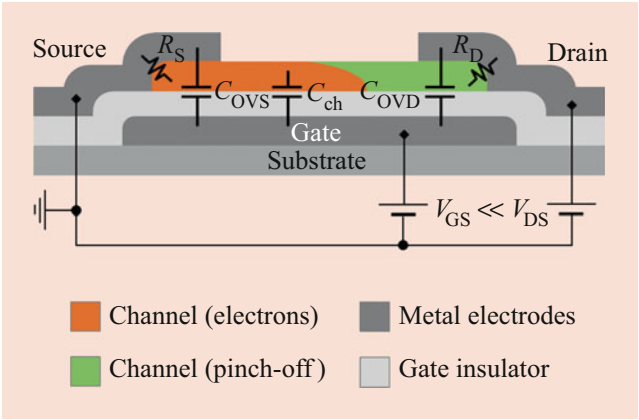

Fig. 27.36 Bottom-gate TFT structure considering passive components of the small-signal equivalent circuit. C_{OVS} and C_{OVD} are the overlap capacitance at source and drain side; C_{ch} is the channel capacitance; R_S and R_D are the contact resistances at source and drain side

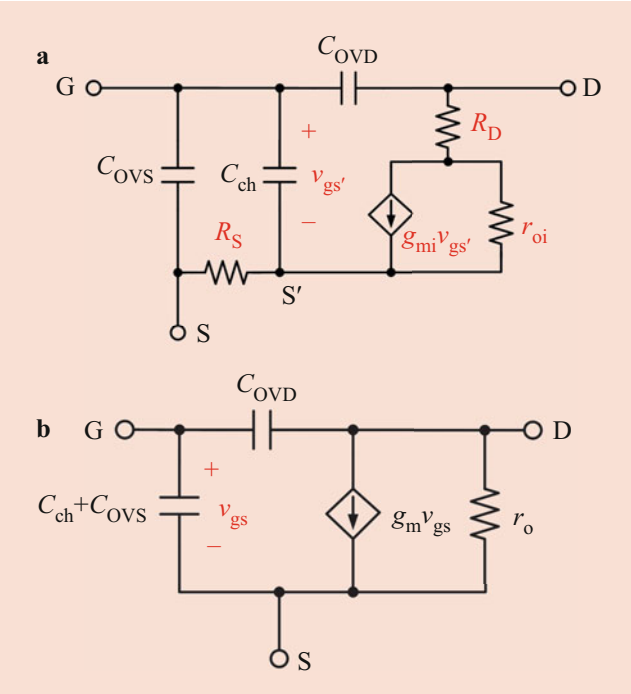

Fig. 27.37 High-frequency small-signal models. (**a**) TFT model. (**b**) CMOS model adapted to TFTs

capacitance (C_{OVS}) and channel capacitance(C_{ch}). Hence, R_S might not be negligible nor included in overall components (i.e. g_m and r_o) especially at high frequencies. Combining the analysis of the midband model, the high-frequency small-signal model for TFT can be drawn as Fig. 27.37a. In comparison, the CMOS model adapted to TFT parameters is shown in Fig. 27.37b. Here, C_{OVS} and C_{ch} are considered to be the same capacitor between source and gate terminals, and the contact resistances are included in the overall g_m and r_o.

In order to evaluate the difference between the developed model and the CMOS model, we compare the expressions of

the short-circuit current gain (A_i) and the cutoff frequency of the two different circuits.

For CMOS model, A_i can be calculated as:

$$A_i = \frac{sC_{OVD} - g_m}{s(C_{OVD} + C_{OVS} + C_{ch})} \tag{27.28}$$

which contains one pole (at 0) and one zero (at g_m/C_{OVD}). Assuming the zero is far from the point of cutoff frequency. The unit-gain cutoff frequency can be calculated as:

$$f_T = \frac{g_m}{2\pi(C_{OVD} + C_{OVS} + C_{ch})} = \frac{g_m}{2\pi C_{tot}} \tag{27.29}$$

where C_{tot} is the sum of all capacitances of the TFT.

In contrast, the current gain calculated for the TFT small-signal model seen in Fig. 27.37a is:

$$A_i = \frac{-g_{mi}r_{oi} + ((2R_C + r_{oi} + g_{mi}R_C r_{oi})C_{OVD} + C_{ch}R_C)\,s + C_{OVD}C_{ch}R_C(R_C + r_{oi})s^2}{s\,(g_{mi}C_{OV}R_C r_{oi} + (2R_C + r_{oi})(C_{OV} + C_{ch}) + C_{OV}(R_C + r_{oi})R_C C_{ch}s)} \tag{27.30}$$

where $C_{OV} = C_{OVS} + C_{OVD}$ is the total overlap capacitance. The equation shows two zeros and two poles for this model. Assuming the poles and zeros are far from the cutoff point (for linear assumption at the point in Bode plot), the cutoff frequency expression is derived as:

$$f_T = \frac{g_{mi}r_{oi}}{2\pi\,(g_{mi}C_{OV}R_C r_{oi} + (2R_C + r_{oi})(C_{OV} + C_{ch}))} = \frac{g_m}{2\pi(C_{tot} - g_m R_C C_{ch})} \tag{27.31}$$

The simplification of the above equation shows that the major difference between Fig. 27.37a, b comes from the term $g_m R_C C_{ch}$. As g_m is a term that already contains the R_C, it is preferable to consider this term as a function of independent variables. Thus, by substituting the g_m term, the expression of $g_m R_C$ is:

$$g_m R_C = \frac{g_{mi}r_{oi}R_C}{g_{mi}r_{oi}R_C + 2R_C + r_{oi}} \tag{27.32}$$

As g_{mi}, r_{oi} and R_C are independent values depending on semiconductor and interface properties with positive values, the whole term should be smaller than one. This indicates that the fraction C_{ch} is of the total capacitance that plays an important role in determining whether the two models become identical. In the case when C_{OV} is dominant over C_{ch} or when the value of R_C is very small or close to zero, the $g_m R_C C_{ch}$ term can then be omitted, and thus Eq. (27.31) becomes the same as Eq. (27.29). The CMOS model can be used despite the connection of $R_C s$ as in these cases the two high-frequency models are equivalent.

In the case when the value of C_{ch} is at least of the same order of magnitude as C_{OV} or higher, the $g_m R_C C_{ch}$ term can reduce around 50% of the total capacitance (for the case when $g_{mi}R_C \approx 1$), making the two models very different in terms of modelling of the cutoff frequency. This also indicates that the CMOS model can be inaccurate especially when the contact resistance and overlap capacitance are big and small, respectively. As the contact resistance is known to be big in TFTs (from a few kΩ to several 100 kΩ) and the reduction of overlap capacitance is preferable at the processing side for the sake of making faster TFTs, the inaccuracy of CMOS model might exist in most TFTs and may become more significant as processing technique becoming mature (e.g. for self-aligned TFTs, the overlap capacitance is close to zero).

The other point to notice is that the assumptions used to derive Eq. (27.31) is supported by calculating the actual values of zeros and poles of the transfer function. As the extra zeros and poles are at way higher frequency compared with the cutoff frequency, they are not of concern as the transistor is dominated by capacitor effects and is not working properly at the frequency range.

Model Validation

From the theoretical analysis of small-signal modelling, we know that the TFT small-signal model can be very different from CMOS model when the contact resistance and overlap capacitance are big and small, respectively. In this section, we will evaluate the amount of difference by measurement of IGZO TFTs' cutoff frequency and the dominating s-parameters.

Measurement Setup

In order to evaluate the small-signal model, we need to measure the current gain of the TFT and compare the cutoff frequency to see the model difference quantitatively. The common way of measuring the cutoff frequency of a transistor is to use a network analyser to measure the s-parameters and convert them to h-parameters. The calculated h_{21} directly reflects the short-circuit current gain of the device. Here, we use Keysight E5061B network analyser (ENA) calibrated by CS-11 calibration substrate provided by GGB Industries, Inc. The standard measurement setup is shown in Fig. 27.38. The bias-T provides DC bias to the TFT under test and separates the small signal input and output from the DC circuitry. The TFT is then connected to the ENA ports for s-parameter measurement.

The main reason for choosing the analyser is that it can provide low-frequency measurement down to 5 Hz. In contrast, most of the network analysers on the market are targeted above 100 kHz range, which is already a range close to TFT's cutoff. In the next section, we will see that even with the network analyser, low-frequency measurement is still hard, as the TFTs are more resistive at low frequencies.

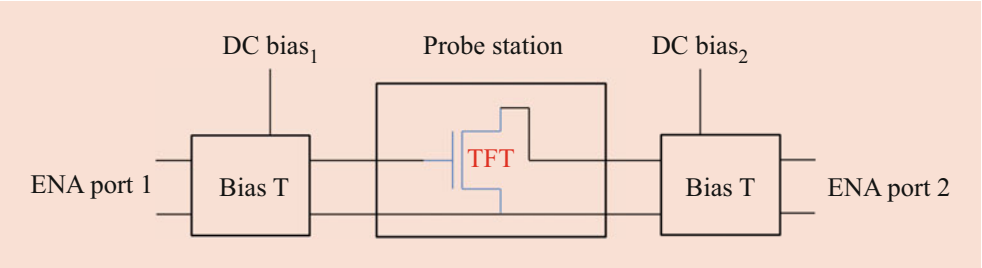

Fig. 27.38 Measurement setup for f_T and s-parameters

The ENA in use can only provide DC bias at port 1. Therefore, the bias-T at port 1 is already included inside the ENA. We still need to find a bias-T for port 2. As low frequency is important for our measurement, we choose Picosecond 5546 bias-T for this purpose. The low 3 dB frequency is 3.5 kHz, the lowest we managed to find on the market. We choose CS-11 calibration substrate and model 10 high-frequency probe (from DC to 6 GHz) from GGB Industries, Inc. for the purpose of calibration, as the parasitics on the wires and the probes, etc. should be calibrated out before s-parameter measurement.

The DC bias conditions are chosen to be $V_{GS} = 8\,V$ $V_{DS} = 15\,V$ to make sure the TFT is working in the saturation region. It is to be noted that from the output characteristic, (Fig. 27.39) the TFT saturates later than $V_{GS} - V_T$, which is the saturating point for CMOS. This is explained as the voltage drop on the contact resistance effectively reduced the $V_{D'S'}$ on the internal TFT (Fig. 27.33). The device under test has following physical and geometrical parameters: $t_s = 50\,nm$, $V_T = 1.6\,V$, $C_{ox} = 30\,nF/cm^2$, $\mu_0^* = 8.6\,cm^2/V{\cdot}s$. The device with *W/L* ratio of 100 µm/10 µm is used for model validation, and 50 µm/10 µm is used for stress measurement.

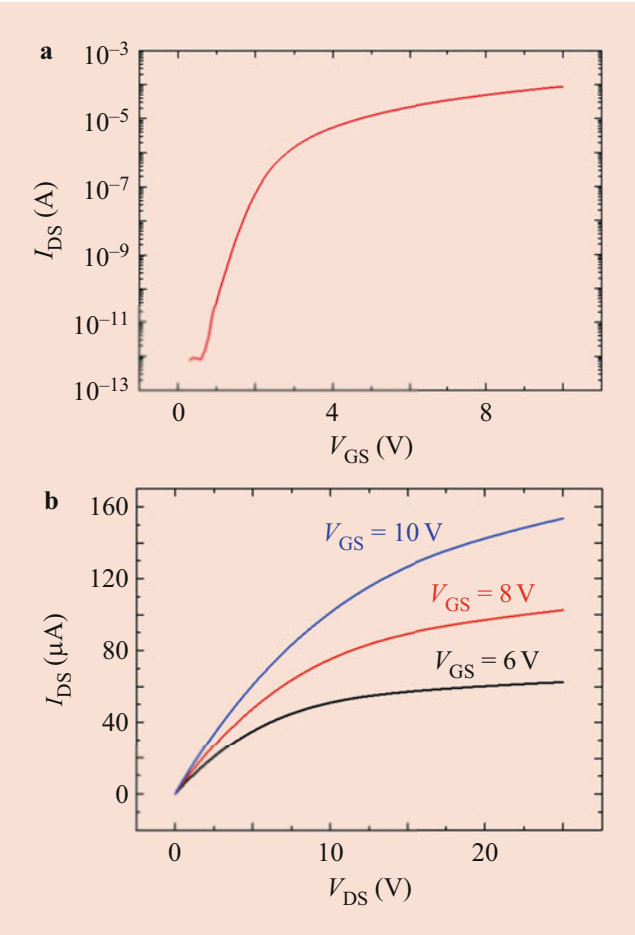

Fig. 27.39 I-V characteristic of the TFT under test. (**a**) Transfer characteristic. (**b**) Output characteristic

s-Parameters and f_T Measurement

As f_T is calculated through s-parameter measurements, it is essential to understand how it is calculated and evaluate the measurement procedure as TFTs might have specific properties which may make the measurement very different from standard CMOS.

The most significant difference for TFTs is that the devices are very resistive. As TFTs are normally biased with a few volts to 20 V level and the output current is normally around a few or a few tens µA, the corresponding resistances are around 100 kΩ or even a few MΩ level. Resistance at this level is huge, particularly in s-parameter measurement, as s-parameters are usually normalized with a characteristic resistance of 50 Ω or 75 Ω. For single-port measurement such as S_{11} and S_{22}, the relation between corresponding impedance(Z_L) and $S_{xx}(S_{11}/S_{22})$ is:

$$S_{xx} = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{27.33}$$

where $Z_0 = 50\,\Omega$ is the characteristic resistance. Here, as Z_L is much larger than Z_0, the S_{11} *or* S_{22} values should be very close to 1 (or very close to 0 dB). This fact only changes at higher frequencies when the impedance of the capacitors drops significantly. As discussed before, the frequency range of concern is the range below the cutoff frequency. The

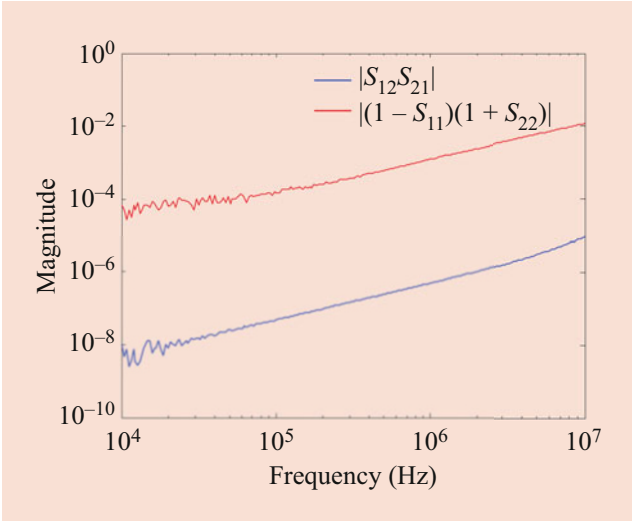

Fig. 27.40 Comparison between terms of $(1-S_{11})(1+S_{22})$ and $S_{12}S_{21}$

impedance of the capacitor at the frequency range should be comparable with the internal components; otherwise, the circuit performance will be dominated by the capacitors. Therefore, the assumption will be valid in the whole frequency range of concern.

S_{11} and S_{22} are also called reflection coefficient. It expresses the ratio of the reflected power to the incident power of an electromagnetic wave. As the reflection coefficient is close to 1, the transmission coefficients (S_{12} and S_{21}) should be small as most of the power are reflected rather than transmitted. The experiment shows these two parameters are very close to 0.

Now as we know the estimated value of the four parameters, we need to evaluate the equation of h_{21} Eq. (27.34).

$$h_{21} = -\frac{2S_{21}}{(1-S_{11})(1+S_{22}) + S_{12}S_{21}} \tag{27.34}$$

Here, the major complexity comes from the denominator. Therefore, the next question is whether the denominator is dominated by some part of the terms or not. It is pretty hard to tell which part of the denominator is more dominant intuitively, as both terms of $(1-S_{11})(1+S_{22})$ and $S_{12}S_{21}$ are close to 0. One could estimate from the assumption that $1-S_{11}$ has a similar order of magnitude compared with S_{12} or S_{21} to conclude that $(1-S_{11})(1+S_{22})$ term dominates over $S_{12}S_{21}$. A further check from experiment based on the IGZO TFTs shows that the former term is four orders bigger than the latter term as shown in Fig. 27.40. Therefore, the $S_{12}S_{21}$ term can be omitted when calculating the current gain.

Further, as S_{22} is very close to 1, the product of $1-S_{11}$ and $1+S_{22}$ is much more sensitive to the change of S_{11} than S_{22}. The final approximation of the equation is then as follows:

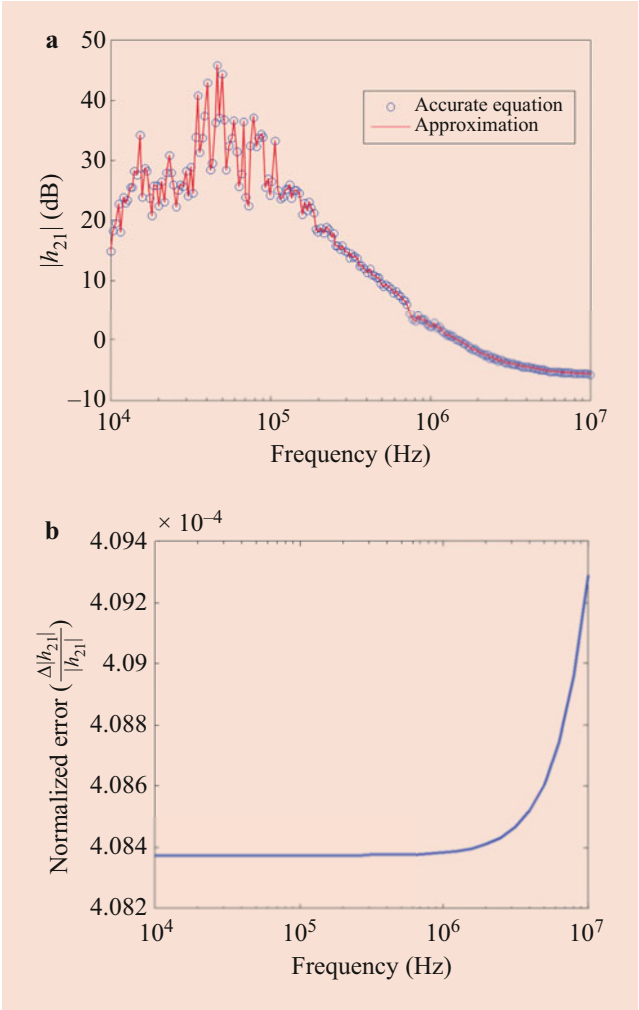

Fig. 27.41 Comparison between Eq. (27.34) and its approximation Eq. (27.35). (**a**) Calculated h_{21}. (**b**) Normalized error

$$A_i = |h_{21}| \approx |\frac{S_{21}}{S_{11}-1}| \tag{27.35}$$

Note that the approximation above is very accurate as the dominance of parameters is so significant. A comparison based on experiment result is shown in Fig. 27.41. The estimation gives 0.04% error in calculating the current gain of TFT within the frequency of concern. Therefore, Eq. (27.35) can be used in the measurement of current gain or f_T of TFTs without the measurements of S_{12} and S_{22}.

Now from the derivation and verification above, we know the dominating parameters for TFT f_T measurement are S_{11} and S_{21}. Thus, to evaluate the difference of TFT model and CMOS model, we need to evaluate and analyse the two parameters in both models. As both the two measurements need to connect a matched load at port 2 of the network, the equivalent circuit for the measurements is identical as shown in Fig. 27.42. The modelling of each parameter based

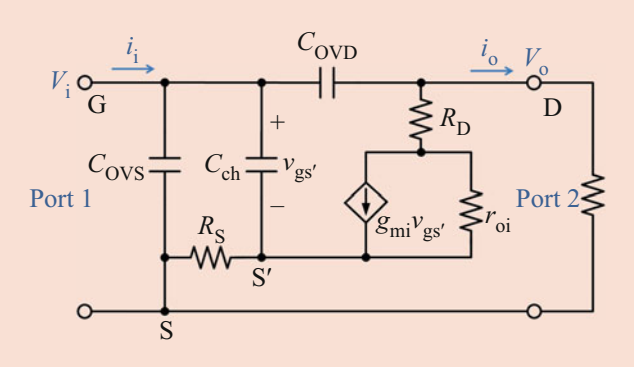

Fig. 27.42 Equivalent circuit for S_{11} and S_{21} measurement

on the equivalent circuit will be discussed in the following subsections. And the simulation will be based on the static and dynamic parameters extracted in Sect. 27.2.1.

S_{11} Measurement and Analysis

Figures 27.40 and 27.41 shows that the measurement at lower frequencies is very noisy especially when S_{11} is involved. The main reason is the contribution of the $1 - S_{11}$ term. As discussed before, the S_{11} parameter is very close to 1 due to the near open-circuit characteristic of capacitors at low frequencies. Therefore, the value of $1-S_{11}$ highly depends on the measurement accuracy of S_{11}. According to the datasheet of the network analyser E5061B, the measurement accuracy for S_{11} with different calibration kit is around 0.03 and 2 degree for magnitude and phase measurement respectively, when average factor equals to 1 and 10 Hz bandwidth is selected. However, in order to measure the parameters for the device under test (DUT), the accuracy is not enough, as the values of the S_{11} magnitude and phase are one order smaller than the corresponding accuracies.

Further, after checking the measurement results, we noticed that the major uncertainty comes from the shift of the machine property over time. As this shift is rather slow compared with one cycle of a frequency sweep, we choose to do two quick sweeps with and without the device connected to measure the S_{11} value. The open-circuit values are then subtracted from the measurement results to cancel the property shift of the machine.

The measurement and simulation results are shown in Fig. 27.43. As can be seen, TFT model fits much better compared with adapted CMOS model. The major difference comes from the magnitude measurement as the measured curve drops, which suggests that there's at least an extra pole for the S_{11} expression of TFT model higher but close to the frequency of concern. The calculation based on CMOS model gives the S_{11} model below:

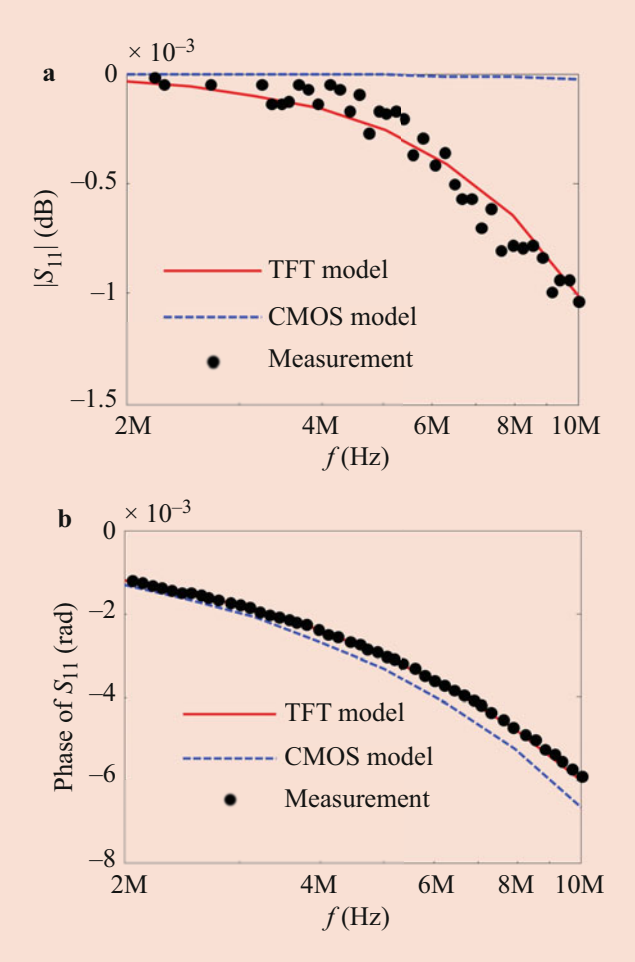

Fig. 27.43 Magnitude and phase measurement and simulation for S_{11} parameter based on TFT model and adapted CMOS model. (**a**) Magnitude. (**b**) Phase

$$S_{11_{CMOS}} \approx -\frac{-g_0^2+(C_{OVS}+C_{ch})g_0 s+C_{OVD}(C_{OVS}+C_{ch})s^2}{g_0^2+(2g_0C_{OVD}+g_0(C_{OVS}+C_{ch}))s+C_{OVD}(C_{OVS}+C_{ch})s^2} \tag{27.36}$$

where $g_x = \frac{1}{r_x}$ is the conductance of the corresponding resistor. The conductance terms are used to make the equation look simpler. An approximation is also used to simplify the equation based on the assumption that $g_0 \gg g_m$ and $g_0 \gg g_o$. This is particularly true in the case of TFT because of the high resistance of TFT devices. For example, $1/g_m$ is normally around a few kΩ to a few 100 kΩ, and r_o is around a few MΩ. However, the characteristic resistance is 50 Ω. Therefore, the conductance of the characteristic resistance g_0 should be more dominant compared with all other resistances and conductances in the small-signal model of TFT (or the

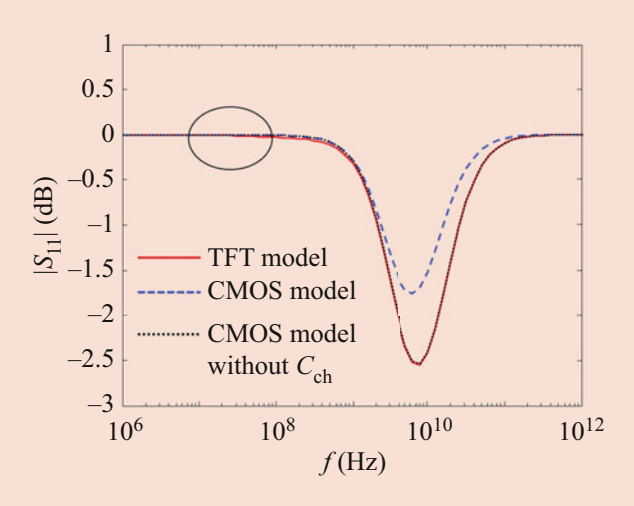

Fig. 27.44 S_{11} simulation of the TFT and CMOS models

adapted CMOS one). The assumption is also used in the derivation of S_{11} of TFT model. This model suggests that the equation has two zeros and two poles. Calculation based on Eq. (27.36) shows that the two zeros are at 3.4462 GHz and 10.853 GHz and the 2 poles at 2.4898 GHz and 15.022 GHz. As the zeros and poles are all far above the frequency of concern (i.e. below 10 MHz), the S_{11} modelled by the CMOS model would remain at 1 at the frequency range as suggested in Fig. 27.43a (which suggests a very close to open-circuit behaviour).

The calculation based on the equivalent circuit shown in Fig. 27.42 gives the S_{11} expression as follows:

$$S_{11_{\mathrm{TFT}}} = -\frac{-g_{\mathrm{tot}}g_{\mathrm{c}}g_0^2+a_1s+a_2s^2+(g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}C_{\mathrm{OVS}}C_{\mathrm{OVD}}s^3}{g_{\mathrm{tot}}g_{\mathrm{c}}g_0^2+b_1s+b_2s^2+(g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}C_{\mathrm{OVS}}C_{\mathrm{OVD}}s^3}, \tag{27.37}$$

where $g_{\mathrm{tot}} = g_{\mathrm{mi}} + g_{\mathrm{c}} + 2g_{\mathrm{oi}}$

$$a_1 = \left[g_{\mathrm{c}}g_{\mathrm{tot}}C_{\mathrm{OVS}} + g_{\mathrm{c}}(g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}\right]g_0 - (g_{\mathrm{c}}+g_{\mathrm{oi}})g_0^2C_{\mathrm{ch}},$$

$$a_2 = (g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}C_{\mathrm{OVS}}g_0,$$

$$b_1 = \left[g_{\mathrm{c}}g_{\mathrm{tot}}C_{\mathrm{OVS}} + 2g_{\mathrm{tot}}g_{\mathrm{c}}C_{\mathrm{OVD}} + (g_{\mathrm{c}}+3g_{\mathrm{oi}})g_{\mathrm{c}}C_{\mathrm{ch}}\right]g_0 + (g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}g_0^2,$$

$$b_2 = (g_{\mathrm{c}}+g_{\mathrm{oi}})g_0C_{\mathrm{ch}}(C_{\mathrm{OVS}}+2C_{\mathrm{OVD}}).$$

Here, the equation has three zeros and three poles. To further evaluate the difference between the two models, we simulated their S_{11} parameters. The simulation results are shown in Fig. 27.44. Just as the figure suggests, two zeros lie between two poles to make a valley of the magnitude curves for both models. However, these poles and zeros are at much higher frequencies compared to the cutoff of the transistor. Therefore, the simulation results only show a flat line below 10 MHz for CMOS model. As for the TFT model, the numeric calculation shows that there are three poles at 54.755 MHz, 2.8314 GHz, and 19.389 GHz. The zeros are at 54.947 MHz, 4.5660 GHz, and 11.981 GHz. The two zeros and two poles at GHz level have similar values compared with the CMOS model to make a similar shape of the curve at very high frequency. However, they would not create much difference at the low-frequency range of our concern either. The major difference we've noticed is the extra zero and pole at 54.947 MHz and 54.755 MHz, respectively. These two points are pretty close to the cutoff frequency and the frequency of concern. From further inspection of Figs. 27.43 and 27.44, we notice that it is these pole and zero that cause a slight drop of the S_{11} magnitude. As the pole is slightly smaller than the zero (although only by less than 1%), the magnitude starts to drop a little before the effect is cancelled by the zero. This drop distinguishes the two models at around 10 MHz range as the measurement in Fig. 27.43 suggests. This also suggests that the TFT model (with the contact resistance and the separation of the channel and overlap capacitance) captures an extra pole and zero, which results in better accuracy than the CMOS model.

It can be noted that $|S_{11}|$ equals to 0 dB (or 1) at both very low frequencies and very high frequencies. This can be explained by the connection of the C_{OVS} as it acts as open circuit at low frequencies ($S_{11} = 1$) and short circuit ($S_{11} = -1$) at high frequencies.

Here, as the major accuracy improvement comes from the extra zero and pole, it is worth finding the exact expression of their analytic form. The accurate expressions can be directly extracted from Eq. (27.37) by solving the cubic equations. However, the expressions become too long for the purpose of estimating the positions of the extra zero and pole. Alternatively, we discovered that by taking out the C_{ch} in CMOS model, the simulation results of the two models become very similar at high frequencies (shown in Fig. 27.44). Therefore, we could compare the coefficients of Eqs. (27.37) and (27.36) (taken out the C_{ch} term) to find the estimated expression of the extra zero and pole, assuming that the CMOS model contains all the poles and zeros except the extra ones.

Considering the matching of coefficients, we found the estimated expressions as:

$$\begin{cases} f_{\mathrm{pe}} = -\dfrac{g_{\mathrm{tot}}g_{\mathrm{c}}g_0}{2\pi(g_0+g_{\mathrm{c}})(g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}} \\ f_{\mathrm{ze}} = -\dfrac{g_{\mathrm{tot}}g_{\mathrm{c}}g_0}{2\pi(g_0-g_{\mathrm{c}})(g_{\mathrm{c}}+g_{\mathrm{oi}})C_{\mathrm{ch}}} \end{cases} \tag{27.38}$$

where f_{pe} is the frequency of the extra pole and f_{ze} is the frequency of the extra zero. Here, the expressions give a rather accurate estimation of the extra pole and zero of 54.763 MHz

and 54.946 MHz, respectively, while the numeric calculation gives 54.755 MHz and 54.947 MHz. Here, with the approximation of the extra zero and pole, one can easily draw the S_{11} curves without simulating the more complicated equivalent circuit. It also provides support for the possibility of fitting a S_{11} measurement with one pole and one zero.

S_{21} Measurement and Analysis

As for S_{21}, the simulation and measurement results are shown in Fig. 27.45. The results show that the difference of S_{21} between models is less significant compared with S_{11}. This is because the parameter varies much in a log scale axis (dB), and, therefore, the difference is not visibly prominent in comparison with that of S_{11}. For example, the measurement value at 8 MHz is $|S_{21}| = 2.85 \times 10^{-3}$. The modelled value are $|S_{21_{\text{TFT}}}| = 2.88 \times 10^{-3}$ (yielding 1.1% error) and $|S_{21_{\text{COMS}}}| = 2.69 \times 10^{-3}$ (yielding 5.6% error).

The analytic expression of S_{21} in CMOS model is shown as Eq. (27.39):

$$S_{21_{\text{CMOS}}} = \frac{2g_0(sC_{\text{OVD}} - g_{\text{m}})}{g_0^2 + (2C_{\text{OVD}} + C_{\text{OVS}} + C_{\text{ch}})g_0 s + C_{\text{OVD}}(C_{\text{OVS}} + C_{\text{ch}})s^2} \tag{27.39}$$

The equation shows that there are two poles and one zero in the model. Calculation based on the equation shows that the zero is at 6.107 MHz and the two poles are at 2.490 GHz and 15.02 GHz. Again, as the poles are all far above the frequency of concern, they would not affect the measurement results below 10 MHz. The result is that there's only one dominant zero within the frequency range. The other point that should be noticed is that at very low frequencies, Eq. (27.39) yields to:

$$S_{21_{\text{CMOS}}} = -\frac{2g_{\text{m}}}{g_0} \tag{27.40}$$

Here, the $g_0 = 1/50\,\Omega^{-1}$ is a known value. Therefore, the S_{21} measurement can directly reflect the small signal g_{m} for the CMOS model. As discussed in Sect. 27.2.2, the TFT and CMOS models are equivalent at low frequencies as the capacitances can be ignored. Therefore, this g_{m} can also be used to extract the g_{mi} for TFT model at lower frequencies.

As for TFT model, the equivalent circuit for the S_{21} calculation is the same as the one used for S_{11} as the equivalent connection for the measurements is the same (Fig. 27.42). Hence, we could derive the equation of S_{21} as below:

$$S_{21_{\text{TFT}}} = 2g_0 \frac{-g_{\text{c}}^2 g_{\text{mi}} + (g_{\text{c}} g_{\text{tot}} C_{\text{OVD}} + g_{\text{oi}} g_{\text{c}} C_{\text{ch}})s + (g_{\text{c}} + g_{\text{oi}})C_{\text{OVD}} C_{\text{ch}} s^2}{g_{\text{tot}} g_{\text{c}} g_0^2 + c_1 s + c_2 s^2 + (g_{\text{c}} + g_o)C_{\text{ch}} C_{\text{OVS}} C_{\text{OVD}} s^3}, \tag{27.41}$$

where,

$$c_1 = (g_{\text{c}} + g_{\text{oi}})C_{\text{ch}} g_0^2,$$
$$c_2 = (g_{\text{c}} + g_{\text{oi}})C_{\text{ch}}(C_{\text{OVS}} + 2C_{\text{OVD}})g_0.$$

Here, the equation shows two zeros and three poles for TFT model. Based on the parameters of the device under test, we have that the zeros are at 5.501 MHz and 60.90 MHz and that the poles are at 54.76 MHz, 2.831 GHz, and 19.39 GHz. Similar to the case for S_{11}, there's one extra zero and one extra pole at 60.90 MHz and 54.76 MHz, respectively. These extra zero and pole would also contribute a slight drop on the magnitude of S_{21} as they are very close together, just as the case for S_{11}. The difference here is that there's a dominant zero at 5.501 MHz, which is different to the 6.107 MHz zero for the CMOS model. Hence, the difference of the dominant zero contributes to the major difference between the CMOS and TFT model. And the difference caused by the extra zero and pole becomes less prominent. Here, the dominant zero for S_{21} can be expressed as:

$$f_{z0_{\text{TFT}}} = \frac{g_{\text{c}}\left(\sqrt{(g_{\text{oi}}C_{\text{ch}} + g_{\text{tot}}C_{\text{OVD}})^2 + 4g_{\text{mi}}(g_{\text{c}} + g_{\text{oi}})C_{\text{ch}}C_{\text{OVD}}} - g_{\text{oi}}C_{\text{ch}} + g_{\text{tot}}C_{\text{OVD}}\right)}{4\pi C_{\text{ch}}C_{\text{OVD}}(g_{\text{c}} + g_{\text{oi}})} \tag{27.42}$$

whereas the dominant zero for CMOS model can be express as:

$$f_{z0_{\text{CMOS}}} = \frac{g_{\text{m}}}{2\pi C_{\text{OVD}}} \tag{27.43}$$

While CMOS model gives a simpler solution for the dominant zero for the S_{21} parameter, it does not count the contribution of the channel capacitance (C_{ch}). The TFT model, however, accurately models the dominant zero with the contribution of C_{ch} but yields a much more complicated equation.

Again, at low frequencies, Eq. (27.41) yields to:

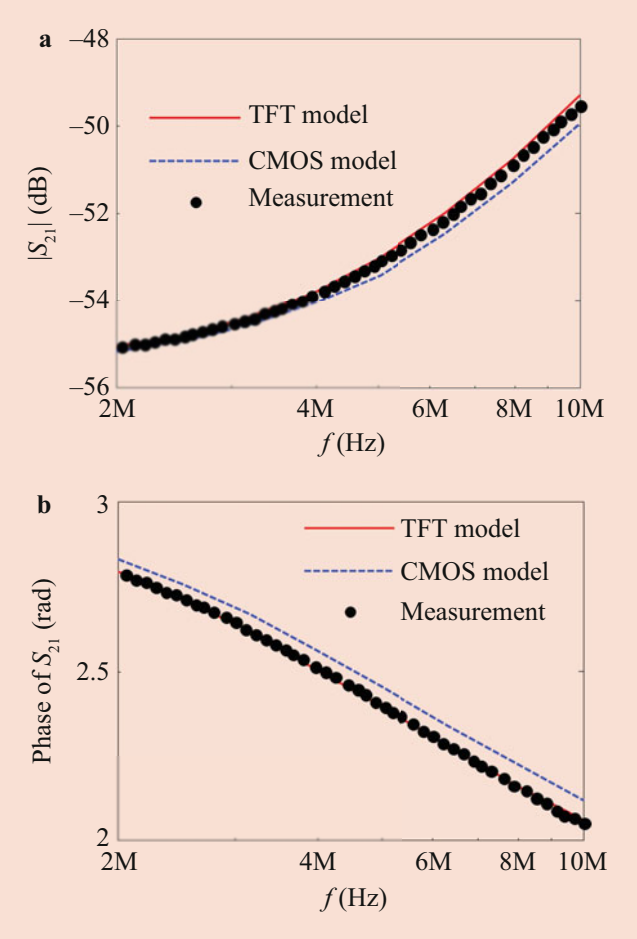

Fig. 27.45 Magnitude and phase measurement and simulation for S_{21} parameter based on TFT model and adapted CMOS model. (**a**) Magnitude. (**b**) Phase

$$S_{21_{TFT}} = \frac{-2g_c g_{mi}}{g_{tot} g_0} \tag{27.44}$$

Changing the conductance terms into resistance terms and combining Eq. (27.24), we have:

$$S_{21_{TFT}} = \frac{-2g_{mi} r_{oi}}{(g_{mi} r_{oi} R_C + 2R_C + r_{oi}) g_0} = -\frac{2g_m}{g_0} \tag{27.45}$$

This is exactly Eq. (27.40). This confirms that the CMOS and TFT model can be equivalent at low frequencies.

f_T Measurement and Analysis

As discussed, we can use Eq. (27.35) to calculate the short-circuit current gain of the TFT with enough accuracy. Therefore, we used the measured S_{11} and S_{21} to derive the current gain of the TFT under test and then use a linear fitting to get the value of the f_T.

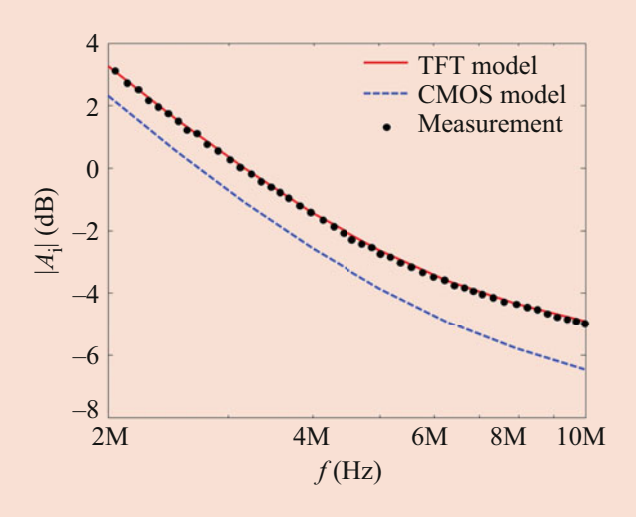

Fig. 27.46 S_{11} simulation of the TFT and CMOS models

The measurement results of f_T along with simulations based on the TFT and CMOS model are shown in Fig. 27.46. The measurement results show a cutoff frequency of 3.11 MHz, while the proposed TFT and CMOS models predict cutoff frequencies of 3.14 MHz and 2.72 MHz, respectively. This yields an error of 1% and 12.5%, respectively.

Here, we proved that the TFT model presented here is more accurate to predict the f_T compared with the CMOS counterpart. However, the measurement results of $|h_{21}|$ or $|A_i|$ only became consistent with the model at frequencies around MHz level. At lower frequencies, the measurement became very noisy as illustrated in Fig. 27.41. However, as shown in the analysis of Eq. (27.30), the $|A_i|$ curve should be a straight line at lower frequencies as it is dominated by a single pole at 0 Hz. The main reason for the discrepancy is the measurement accuracy of S_{11}, especially at low frequencies. As the value of $|S_{11}|$ is very close to, if not exactly equal to, 0 dB at very low frequencies, the noise of the measurement becomes the major contribution to its value. Therefore, as Eq. (27.35) suggested that the accuracy of $|A_i|$ depends on the subtraction of S_{11} and 1 (0 dB), the noise of the measurement at this frequency range would dominate the results of $|A_i|$ and make them unreliable. This brings a concern for the measurement of other TFTs with lower cutoff frequency, which means the frequency of concern is lower, or with smaller size, which means that the capacitances are smaller, making the gate-source port behave even closer to open circuit. Therefore, we should use a fitting method to fit the S_{11} parameter before using its value to calculate $|A_i|$ for the cases described above. More detailed discussion regarding S_{11} fitting will be discussed in the next subsection and also be used to measure the V_T shift effect in f_T measurement.

f_T and V_T Shift

In this subsection, we will discuss the effect of the V_T shift. As the accuracy of TFT model is proved in the s-parameter and f_T measurements, we would focus on the TFT model.

V_T shift is another important factor for TFTs, as this is one of the major concerns in TFT-based circuit designs, especially where TFTs' analogue properties are of concern, for example, in RFID tags. For the case of the small-signal model, the TFT is used as a voltage-controlled current source for the input of the small signal. Therefore, it is imperative to consider the impact of V_T shift on small-signal model.

In order to examine its influence on the small-signal behaviour, a constant bias stress measurement is needed to measure both f_T and V_T of the transistor. However, simultaneous measurement of the two parameters is not practical as the measurements of them need two different connections, i.e. f_T measurement needs network analyser and isolation for DC bias and small-signal input and output; however, the V_T measurement needs I-V sweep to measure the transfer characteristics (which we use KEITHLEY 4200 to measure). Therefore, we need to find an alternative way to measure both parameters other than keep switching between different measurement platforms.

Here, we decided to use two different constant bias measurements and connect the two parameters through g_m as a bridge. The basic idea is that although f_T and V_T cannot be obtained simultaneously, the g_m value can be obtained together in the measurements of both. In specific, g_m can be obtained through the derivative of transfer characteristics as discussed in Sect. 27.2.2. It can also be obtained through low-frequency S_{21} measurement as discussed in Sect. 27.2.2. Also, as V_T directly affects the value of g_m (g_{mi} is considered to be near linearly related to the overdrive voltage ($V_{GS}-V_T$)) and g_m also relates with f_T, g_m can be a perfect link between the two measurements.

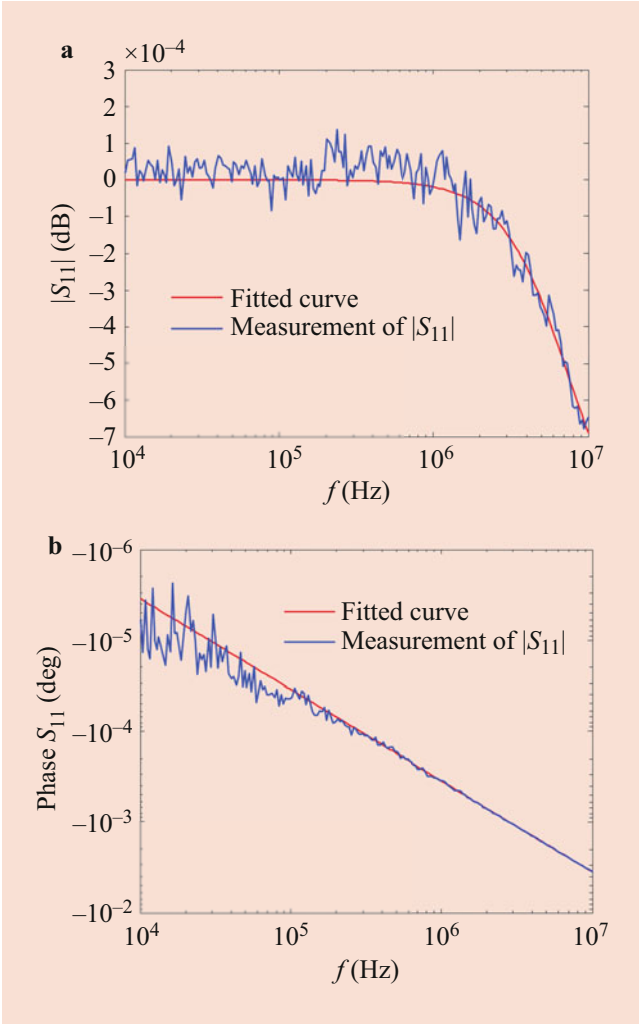

Fig. 27.47 Magnitude and phase measurement and fitting for S_{11} parameter based on single pole and zero approximation. (**a**) Magnitude. (**b**) Phase

f_T and g_m

As discussed in Sect. 27.2.2, a fitting method should be applied to the S_{11} data to obtain a better low-frequency response for the current gain result. Here, as the device under test is smaller in channel width and the cutoff frequency is lower, it is necessary to use the method for better accuracy. The measurement result of S_{11} is shown in Fig. 27.47. The results are fitted using one zero and one pole approximation following Eq. (27.46):

$$S_{11} \approx \frac{1+as}{1+bs} \tag{27.46}$$

where a and b are fitting parameters. The measurement results are fitted using MATLAB. Here, as illustrated in Fig. 27.47, the measurement results are not reliable below 1 MHz for magnitude measurement and below 100 kHz for phase measurement. The major cause of the unreliable results is that the value of $|S_{11}|$ or its phase drops below the noise level at low-frequency range. Therefore, the fitting method is imperative to obtain a reasonable low-frequency response. In addition, as the cutoff frequency for the device under test in this subsection is around 1.5 MHz, which is close to the unreliable range of $|S_{11}|$ (below 1 MHz), fitting method is even more important for a better accuracy, especially for capturing the small change of f_T caused by V_T shift.

In order to capture the f_T change under stress measurement, we kept the bias stress for 8 hours and measure the corresponding s-parameters. The converted $|h_{21}|$ with and without the fitting of S_{11} are shown in Fig. 27.48. As illustrated, the $|h_{21}|$ values without fitting are rather random at lower frequencies, which cannot reliably capture the change of the curves versus stress time. However, with fitted S_{11},

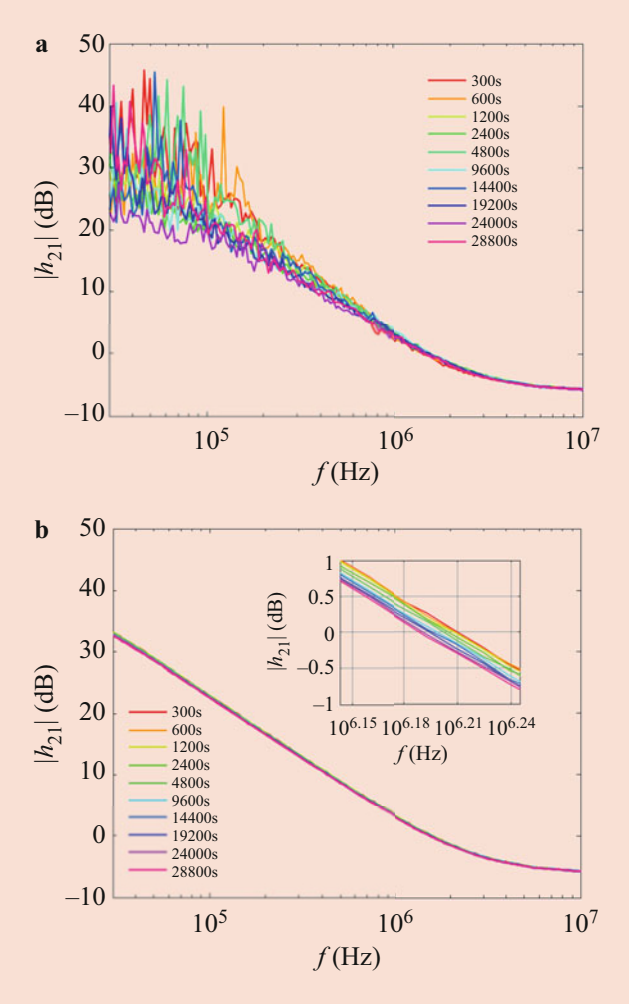

Fig. 27.48 h_{21} results with and without S_{11} fitting. (**a**) with S_{11} fitting. (**b**) without S_{11} fitting

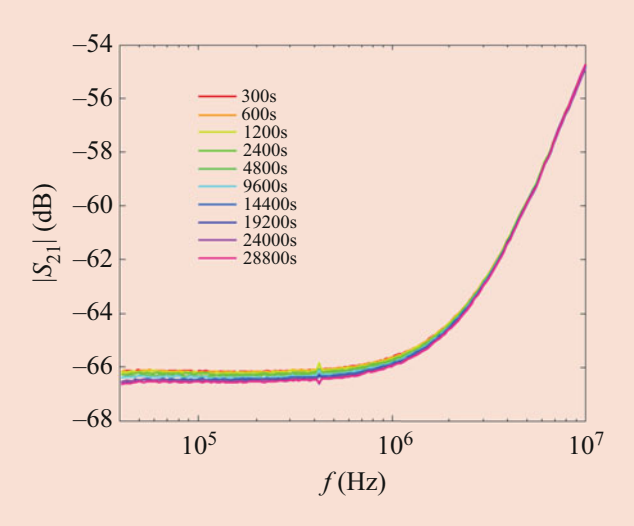

Fig. 27.49 S_{21} measurement showing low-frequency range for g_m extraction

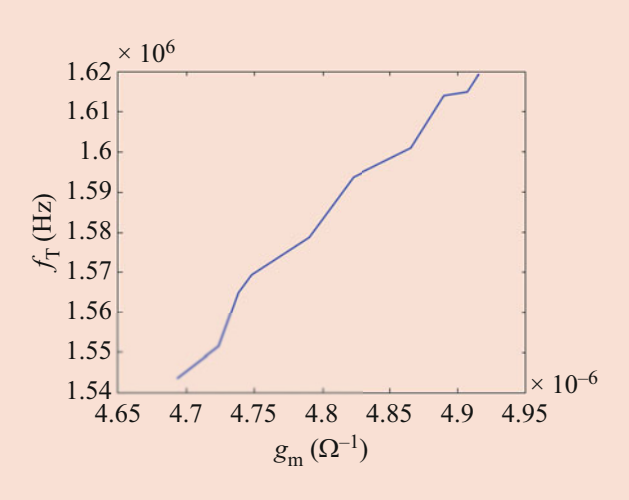

Fig. 27.50 f_T vs. g_m relation through s-parameter measurement

we can clearly capture the drop of the cutoff frequency when the stress time increases, as illustrated in the inset of Fig. 27.48b.

The low-frequency measurement of S_{21} can be used to extract g_m following a derivation from Eq. (27.45):

$$g_m = \frac{g_0|S_{21}|}{2} \tag{27.47}$$

Here, we can use the flat part of the $|S_{21}|$ measurement and calculate the average of $|S_{21}|$ as shown in Fig. 27.49. The value of $|S_{21}|$ drops when bias time increases, which is consistent with the drop of g_m caused by the V_T shift.

By extracting g_m through Fig. 27.49 and the corresponding f_T through Fig. 27.48b, we can get the f_T vs. g_m relation as shown in Fig. 27.50. The results show a linear approximation to Eq. (27.31).

g_m and V_T

The g_m vs. V_T relation can be measured through I-V measurement of the device. The TFT under test was biased at $V_{GS} = 8$ V and $V_{DS} = 15$ V, and I-V sweep was done every logarithmic time interval in order to extract the g_m and V_T. The constant stress bias is disrupted for a short time due to the measurement. However, because the sweep time (V_T measurement) is much shorter compared with the bias time, we assume that the short pause for the constant stress can be omitted. Notwithstanding this, the results showed that V_T continued rising after the sweep and the extracted value is then used to extract the relation between g_m and ΔV_T. The extracted results are illustrated in Fig. 27.51.

Combining the results of Figs. 27.50 and 27.51, we can get the f_T vs. ΔV_T relation as illustrated in Fig. 27.52. The

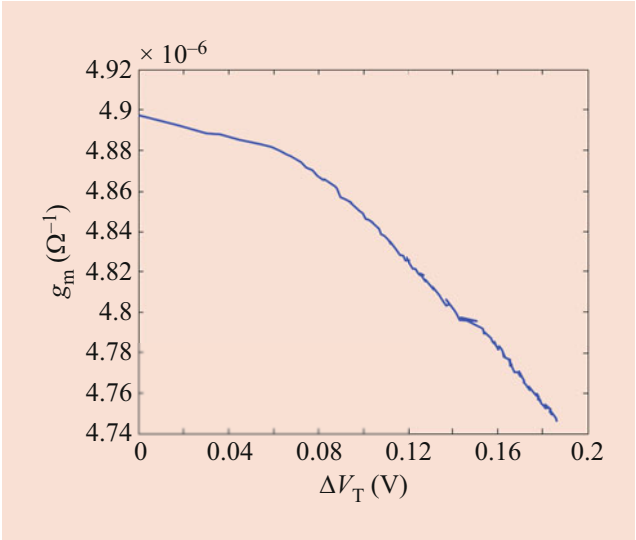

Fig. 27.51 g_m vs. V_T shift relation through stress measurement with I-V sweep

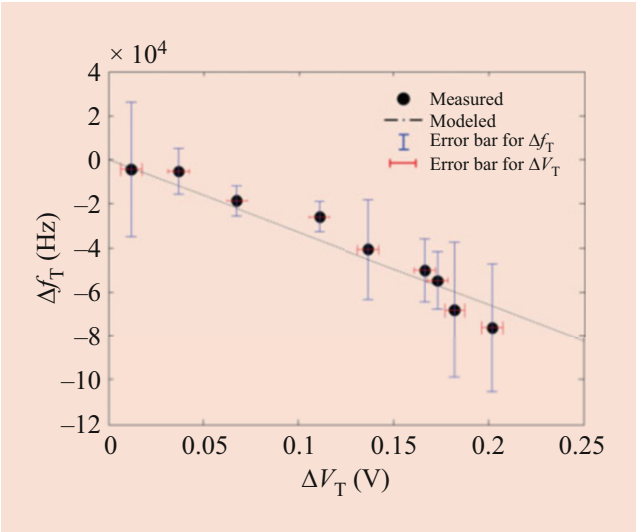

Fig. 27.52 Extracted Δf_T vs. V_T shift relation. The error bar here is the standard deviation of the fitting to obtain the corresponding result

corresponding V_T was obtained through cubic polynomial fitting of the curve in Fig. 27.51. The error bar here is the standard deviation of the fitting to obtain the corresponding result. In specific, the standard deviation of Δf_T was obtained from the linear fitting to obtain the corresponding f_T. The standard deviation of ΔV_T was obtained from the polynomial fitting of the curve in Fig. 27.51.

The ΔV_T increased to +0.2 V in total after the 10 h bias stress, and the respective Δf_T drops to 0.08 MHz almost linearly. This is due to the relatively small ΔV_T compared with V_{GS}, which leads to a first-order approximation of Eq. (27.31). From Eqs. (27.27) and (27.31), we have:

$$\Delta f_T \approx -\frac{r_{oi}(2R_C + r_{oi})(C_{OV} + C_{ch})}{2\pi\,(g_{mi}C_{OV}R_C r_{oi} + (2R_C + r_{oi})(C_{OV} + C_{ch}))}$$

$$K'\Delta V_T = \beta \Delta V_T \tag{27.48}$$

where β is the constant found to be about -3.2×106[Hz/V] for the examined TFT. Equation (27.48) allows estimating the shift in unity gain frequency with threshold voltage shift. Here, the coefficient β will be different for different material- and process-based TFTs.

27.2.3 Subthreshold Operation for Schottky Barrier TFTs

Introduction

Recent research has shown that biasing IGZO TFTs in deep-subthreshold region could improve the small-signal gain and significantly reduce the power consumption [18]. This is specifically useful in low-power applications such as sensor networks, biomedical sensing, etc. [193, 194].

While subthreshold operation in silicon-based CMOS devices had been intensively researched in the 1970s with great success in Swiss watch industry [195–198], the same in TFTs was only investigated until 2018 [1, 199].

Due to the low effective carrier mobility of TFTs (perhaps with polysilicon as an exception), TFT devices are generally working in a lower current level [57, 200]. Although this could limit the speed of the device, TFTs can be naturally suitable for low-speed and low-power applications. Biasing TFTs in subthreshold region could further reduce the power consumption to sub-nano-watt. This is particularly appealing as battery-less operation could be possible with this level of power consumption. However, as the subthreshold region is generally very narrow and current level is very sensitive to bias [201]. If a TFT has a steeper subthreshold slope (SS), a sensitivity of current variation is higher. The circuit design for this kind of devices could be challenging, although a steep SS provides a high intrinsic gain. Here, a high intrinsic gain is an important property for circuit design, so many approaches to get it have been introduced for the above-threshold operation [202–205]. For the subthreshold operation, it is known that a TFT with a Schottky contact source/drain have a steeper SS compared to an Ohmic contact TFT [18, 49, 206]; thus, a Schottky contact TFT provides a higher intrinsic gain within the subthreshold regime with a difficulty in a circuit design.

In this chapter, we will analyse several figures of merit for deep-subthreshold operating TFTs in analogue circuit design with the aim of providing a guideline of analogue circuit design capability of TFT devices using general architectures.

Subthreshold Model for IGZO TFTs

DC Model

The transfer curve of SB-TFTs in deep-subthreshold is reported to be linear in log scale, which is similar to CMOS devices. Here, we convert the model reported in [18] to a more macroscopic form to help analyse the performance. The equation for drain voltage (V_{DS}) > saturation voltage (v_{sat}) is derived as follows [18, 201]:

$$I_{ds} = I'_0 \exp\left(\frac{V_{GS} - V_T}{SS/\ln 10}\right)\left(1 + \frac{V_{DS}}{V_A}\right) \tag{27.49}$$

where I'_0 is the effective subthreshold reference current at V_T normalized by W and SS is the subthreshold slope. V_T is the threshold voltage, and V_A is the effective early voltage. The effective values can be derived as:

$$I'_0 \equiv A_J J_0 \exp\left(\frac{V_T - V_{ref}}{SS/\ln 10}\right) \tag{27.50}$$

where J_0 is the reference current density at V_{ref} and A_J is the junction area of the Schottky contact at the source and drain. In a Schottky contact TFT, A_J is proportional to the channel width (W) [18].

$$V_A \equiv n \cdot v_{th} \exp\left(\frac{v_{sat}}{n v_{th}}\right) \tag{27.51}$$

where n is the ideality factor of the junction and v_{th} is the thermal voltage.

With the above equations, we can easily connect the DC parameters to several important small-signal parameters, such as gm and ro.

Small-Signal Model

Although in previous publications [17, 18] we analysed the small-signal mode for TFTs and figured out that contact resistance can cause big errors using CMOS small-signal models, small-signal behaviour in subthreshold region can still be correctly modelled by CMOS model. This is due to the fact that channel capacitance in subthreshold is very small and normally negligible compared with overlap capacitance in TFTs.

Here, we consider C_{gs} and C_{gd} are mainly the overlap capacitance at source and drain side [17]. The tranconductance and output resistance can be calculated as:

$$\begin{aligned} g_m &= \frac{\ln 10}{SS} I'_0 \exp\left(\frac{V_{GS}-V_T}{SS/\ln 10}\right)\left(1 + \frac{V_{DS}}{V_A}\right) \\ &= \frac{\ln 10}{SS} I_{DS} \end{aligned} \tag{27.52}$$

$$r_o = \frac{I_{DS}}{V_A} \tag{27.53}$$

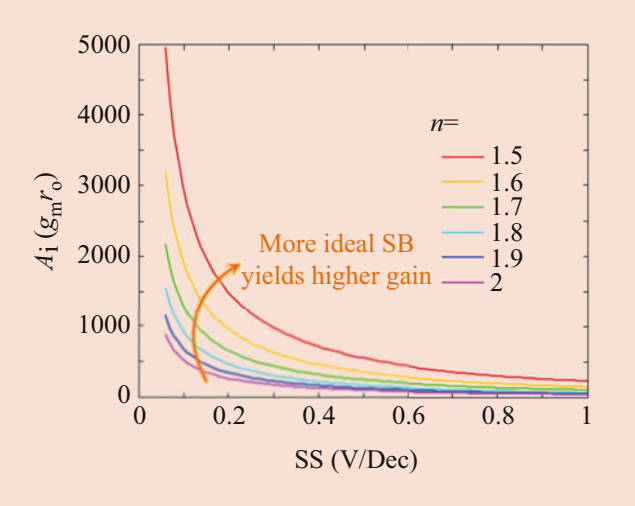

Fig. 27.53 Simulation result for the intrinsic gain (A_i) of the Schottky-Barrier IGZO TFT (SB-TFT). The parameter n is the ideality factor of the source-semiconductor junction

These equations take exactly the same form as the CMOS counterpart.

Figures of Merit

In this section, we consider several figures of merit for TFTs with emphasis in the subthreshold region. The model used for the simulation is based on the [18], and parameter values are extracted using the same samples. The W/L of the TFT under test is 50 μm/20 μm.

Intrinsic Gain

Intrinsic gain is an important figure of merit for analogue amplifier as it reflects the highest achievable single-stage gain for an amplifier. The simulation based on the model developed earlier is shown in Fig. 27.53. As seen, the intrinsic gain in subthreshold region is related with subthreshold slope and the ideality factor n of the Schottky junction.

The expression of the intrinsic gain can be approximated as:

$$A_i = g_m r_o = \frac{\ln 10}{V_A \cdot SS} \tag{27.54}$$

This suggests that intrinsic gain is reverse proportional to the SS of the TFT. By pushing the SS to its theoretical limit (60 mV), one could get over 1000 intrinsic gain with even less ideal Schottky-Barrier at source-semiconductor contact (smaller n). The expression also suggests that the value of intrinsic gain is rather independent on the bias of the transistor as long as it is working in subthreshold region.

Ideality factor n contributes to the intrinsic gain of the transistor because it controls the effective Early voltage (V_A) and thus influences the output resistance of the TFT.

Transconductance Efficiency

Transconductance efficiency (g_m/I_{DS}) is another important figure of merit for electron devices. It represents the efficiency of converting the bias current into an equivalent transconductance. For analogue TFT circuits, as the voltage bias is normally limited by the driving circuitry and the application, reducing the current bias while maintaining a high g_m also means reducing the power consumption while keeping the circuit performance.

As can be seen from Fig. 27.54, the highest g_m/I_{DS} can be obtained only at deep-subthreshold region for a TFT before it enters a transition region to above-threshold. This value remains a constant at deep-subthreshold due to the exponential nature of the TFT subthreshold behaviour. The simulation result also suggests that this value would increase if the TFT has a steeper subthreshold slope.

The expression of the g_m/I_{DS} value can be estimated as:

$$\frac{g_m}{I_{DS}} = \frac{\ln 10}{SS} \tag{27.55}$$

For above-threshold region, the g_m/I_{DS} value drops as the TFT enters above-threshold region, where the expression is:

$$\frac{g_m}{I_{DS}} = \frac{2+\alpha}{V_{GS} - V_T} \tag{27.56}$$

where α is the coefficient on the power law of TFT model and $\alpha = 0$ for the case of MOSFET [17–19]. Therefore, biasing a TFT at a high gate voltage would result in a less efficient g_m conversion and thus higher power consumption.

Cutoff Frequency

Cutoff frequency (f_T) is also considered as the current gain bandwidth product as the current gain at f_T is equal to 1 [17]. This value will limit the actual gain bandwidth product of amplifiers designed by the device. The simulation result of f_T is shown in Fig. 27.55. Here, f_T is small as the overlap capacitance of the TFT under test is quite big. The overlap length here is 50 μm, which is even bigger than the channel length of the device. Practically, this value can be reduced to a few μm or even lower with self-aligned process.

Figure 27.55 suggests that this product rolls off pretty quickly in subthreshold region. The expression of f_T can be derived as follows:

$$f_T = \frac{g_m}{2\pi C_{ov}} = \frac{I_{DS} \cdot \ln 10}{SS \cdot 2\pi C_{ov}} \tag{27.57}$$

The expression shows that the value of f_T is proportional to I_{DS}; thus, the quick roll of at subthreshold is explained by the current roll off in subthreshold region. As I_{DS} and C_{ov} are both proportional to the channel width of the TFT, f_T would be independent of channel width. In addition, by reducing the overlap length, one could further reduce the overlap capacitance (C_{ov}) to increase the frequency response.

The expression also suggests that biasing the TFT in a deeper-subthreshold region would at the same time push the frequency response lower proportionally. Therefore, it's maybe desirable to have a less steep subthreshold slope in terms of speed when considering subthreshold operation.

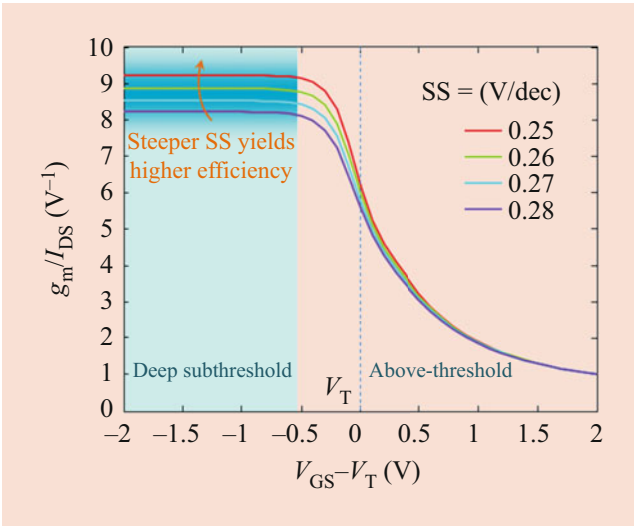

Fig. 27.54 g_m/I_{DS} from deep-subthreshold to above threshold region. The value reaches maximum at deep-subthreshold and increases with steeper SS

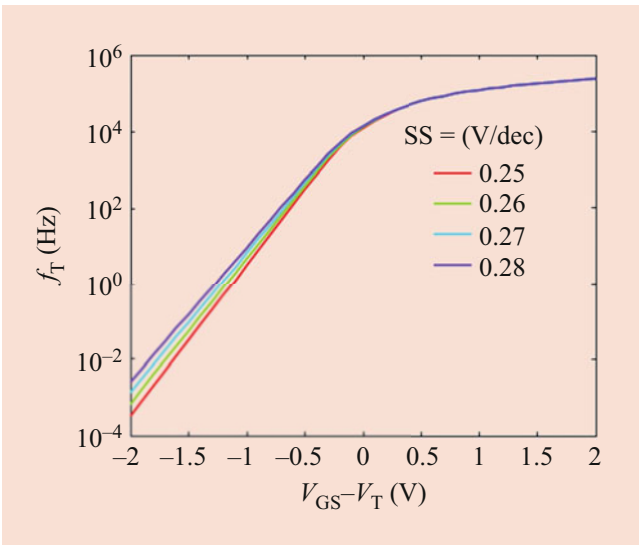

Fig. 27.55 Cutoff frequency vs. voltage bias for different SS

Sensitivity to Variations and Bias

Current Sensitivity to Variations

Here, we assume the threshold voltage shift is also a uniform shift in subthreshold. A non-uniform shift in subthreshold would mean a change in subthreshold slope, which will be discussed later. Therefore, the V_T shift at above-threshold is the same as a reference voltage shift at subthreshold, as the reference voltage shift is equivalent to a bias voltage shift. This curve can also be used for testing the sensitivity of bias voltage inaccuracy.

Figure 27.56 shows that at deep-subthreshold region, the normalized current sensitivity to V_T shift is a constant. The sensitivity becomes lower when the TFT is approaching and enters above-threshold region. As V_T shift is equivalent to bias shift, the sensitivity expression can be the same as the g_m/I_{DS} curve (as $g_m = dI_{DS}/dV_{GS}$ is also a sensitivity to bias) just with an opposite sign. For deep-subthreshold:

$$\frac{dI_{DS}}{dV_{GS}}/I_{DS} = -\frac{\ln 10}{SS} \tag{27.58}$$

For above-threshold:

$$\frac{dI_{DS}}{dV_{GS}}/I_{DS} = -\frac{2+\alpha}{V_{GS}-V_T} \tag{27.59}$$

Now we assume the change in SS would not affect V_T of the above-threshold region. Therefore, the subthreshold current of different SS would meet at around V_T. This yields the results shown in Fig. 27.57, where the normalized current sensitivity would drop when the TFT is biased closer to V_T. In above threshold region, the parameter SS do not contribute to the equation of I_{DS}. The sensitivity is therefore zero. The curve also shows that a steeper SS would increase the current sensitivity.

The expression for the current sensitivity in subthreshold is shown below:

$$\frac{dI_{DS}}{dSS}/I_{DS} = -\frac{(V_{GS}-V_T)\cdot \ln 10}{SS^2} \tag{27.60}$$

The above equation suggests that the sensitivity is reverse proportional to SS^2. Therefore, a steeper SS would yield a high current sensitivity on the variations of SS. In summary, although steeper SS would give rise to g_m/I_{DS} and potentially further reduce the power consumption, the sensitivity on process variations of SS and V_T would increase, possibly narrowing the design window for analogue circuits.

Accuracy Requirement for Biasing Circuitry

Here, we take a common source amplifier with depletion load as example (Fig. 27.58b). The load line and bias conditions are shown in Fig. 27.58a. As can be seen, bias conditions should keep both transistors working in saturated region, i.e. the V_{GS} for the green line in Fig. 27.58a. The blue lines show either of the two TFTs is working in a not saturated region.

Therefore, to maintain a high gain, V_{DS} for both TFTs should follow $V_{DS} > v_{sat}$. As the value of v_{sat} for different V_{GS} stays the same in subthreshold, the input voltage range can be calculated as:

$$V_{range} = \frac{2\cdot SS\,(V_{DD}-2v_{sat})}{V_A \ln 10} \tag{27.61}$$

27.3 Applications of Flexible Electronics in Biological Sensing

A complete biological sensing system includes samples under testing, a sensing interface, and signal processing units [207,208]. Samples (analytes) can potentially be anything biologically related, such as ions, molecules, proteins, viruses, cells, and even entire organisms. A sensing interface is a key element which offers the possibility of converting biological information into a recognizable signal. A processor is, therefore, used to amplify and process the corresponding signals. By integrating the sensing interface and signal processing unit, the analytical devices which are able to sense a certain analyte or analytes are called biological sensors or biosensors [209] and are considered the most powerful instrumentation in modern laboratories or hospitals. In this chapter, we will first introduce the current mainstream biosensing technologies, then discuss the important role of semiconductor technology in biosensing, and finally review some of the state-of-the-art flexible electronics biosensing systems.

27.3.1 Current Mainstream Biosensing Technologies

Biological sensors can be classified by the working principles, i.e. magnetic sensors, optical sensors, mechanical sensors, electrochemical sensors, etc. Figure 27.59 depicts the working mechanisms of mainstream biological sensing technologies which have been developed in recent decades.

Magnetic sensors use magnetic carriers in biological assays and molecular identification. The magnetic particles mainly perform as markers or labels to identify the analyte from the background [211].

Similar to magnetic sensors, most optical or photoabsorption-based biosensors require (fluorescent) labels to recognize the target. The optical signal (brightness) is directly related to the analyte concentration [212,213].

For biosensors which require labels, the label readout has to be converted to electrical signals and then passed to the processing unit. This has increased the system complexity and the sensor cost significantly. In order to bypass the converting step, label-free mechanical biosensors have been developed, which do not require any form of marks or label (i.e. microcantilever sensors and surface acoustic wave sensors) [210,214,215].

Electrochemical sensors could also perform label-free detection by directly converting the biosample's properties into electrical signals. A fast measurement can be carried out by a single device with a zero sample premeasured treatment. This unique advantage has made the electrochemical biosensors become one of the most successful commercial products family for in vitro diagnostics. One example is Clark's glucose sensors which was first reported in 1962 [216]. Quantitative blood glucose measurement can be performed with the glucose sensors and disposable Clark electrodes. The Clark electrode is also known as an oxygen electrode with a glucose-oxidase enzymatic membrane coating to convert the glucose concentration into electric current [217, 218]. The glucose sensor became commercially available in 1975 [219], and billions of diabetics have benefited from this technology until today.

27.3.2 Semiconductor Technologies for Biosensing

Both the sensing interface and the signal processor in a biological sensing system greatly rely on the development of semiconductor technologies. Figure 27.60 illustrates the contributions of semiconductor technologies for biological sensing, which covers materials level, single device level, and system level.

Most semiconductor materials deliver unique properties on the nanoscale. Nano-crystal quantum dots have been used to replace conventional markers to boost the biosensing performance (Fig. 27.60a). Nanowires and nanotubes are widely used for biological detection (Fig. 27.60b, d).

At device level (Fig. 27.60c), ion sensitive field-effect transistor (ISFET) is one of the major applications for biochemical sensing. A typical ISFET does not have a metal

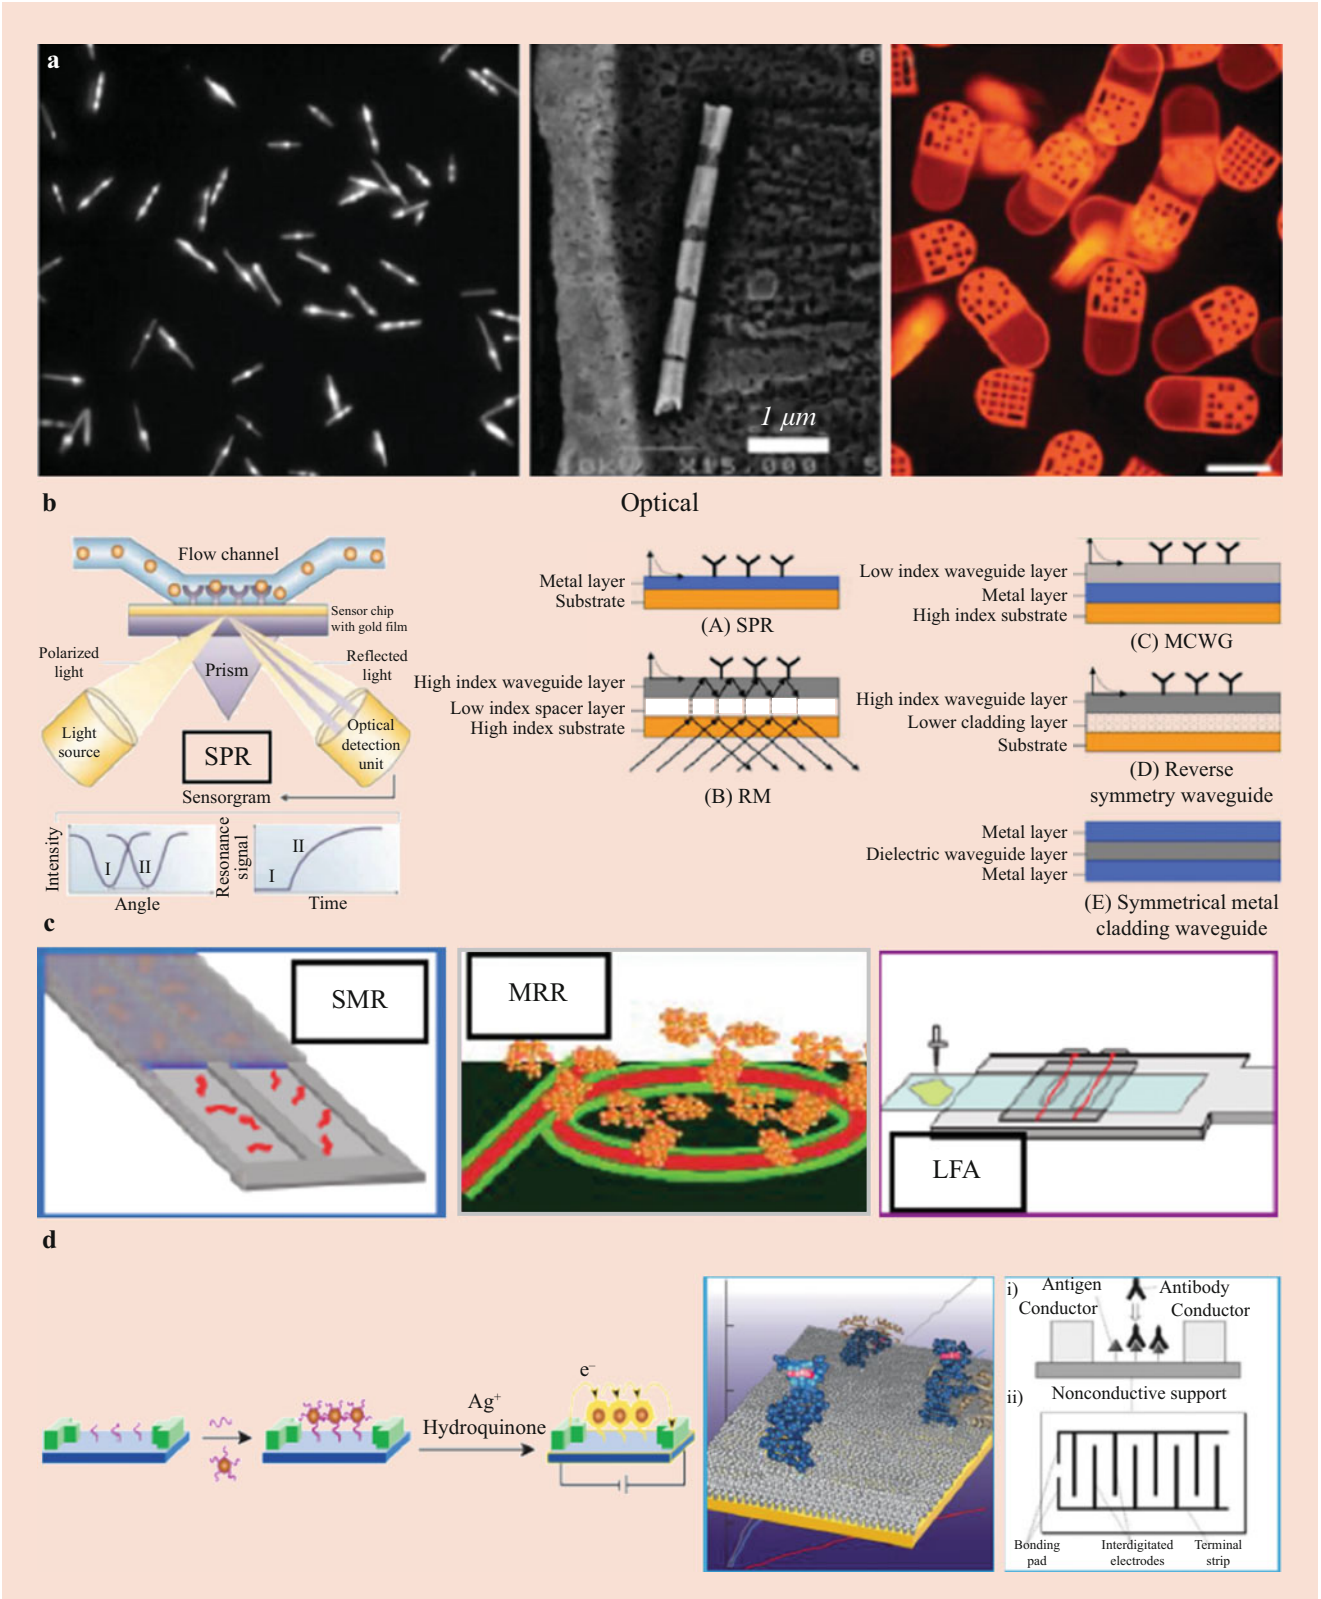

Fig. 27.59 Mainstream biological sensing technology. (**a**) Magnetic-based sensor; (**b**) optical-based sensor, including surface plasmon resonance (SPR), reflection mode (RM), micro-channel wave guide (MCWG), etc.; (**c**) mechanical sensor, including suspended micro-channel resonator (SMR), micro-ring resonator (MRR), lateral flow assay (LFA), etc.; (**d**) electrochemical-based sensor, including potentiometric sensor, voltammetric sensor, etc. (Adapted from [208, 210–213])

Material level: (**a**) quantum confinement in semiconductors and new biological labels; and (**b**) nanowire arrays for biosensing; single device level, (**c**) MEMS cantilever and suspended micro-channel resonator; and (**d**) label-free immunodetection with CMOS-compatible semiconducting nanowires; system level, (**e**) an amorphous-silicon image sensor for X-ray diagnostics; and (**f**) an integrated chip for non-optical genome sequencing. (Adapted from [210, 220–224])

gate, and a special membrane directly coats on the top of dielectric layer. This artificial membrane is designed to capture certain ions, such as Na+ or K+. A fixed charge is provided to the channel after a certain amount of ions accumulate in the membrane. In addition, the performance of the field-effect transistor (FET) changes due to this fixed charge, and the result is used to estimate the ion concentration [225].

Apart from ion detection, conventional FET could be adopted to detect biological molecules, such as DNA, RNA, and proteins. Biological capture probes can be immobilized on metal gate or other electrodes that are connected to the gate, which involves a similar process to optical assays. The probe-analyte bonds will change the electrical properties of the gate or electrodes. This charge would then be amplified and output by the readout circuit. The biological detection and signal processing are fully integrated into one chip. The sample-to-result rate is increased significantly by this approach. Different electrochemical measurement methodologies have been reported for electronic biochips, such as an ISFET-based DNA sensor [226], capacitive-based dopamine sensor [227], and a DNA sensor [228], as well as a range of impedance-based sensors [229–232].

All the works presented above are achieved by complementary metal-oxide-semiconductor (CMOS) technology. At a system level (Fig. 27.60e, f), the advantages include high processing speed, low cost, high stability, and low power consumption. However, a series of common disadvantages for CMOS biosensors have been revealed as well. First of all, standard CMOS processing only support copper and aluminium as metal layers, which none of them is biocom-

patible. A bidirectional compatibility is a key consideration for a biosensing interface. The sensing interface (electrode) materials should be highly stable when immersed for a long time in a biological solution, and it should not release any toxic ions into the samples to generate any undesired interferences. Furthermore, the cost of standard CMOS technology is directly related to the area of silicon die, which makes it difficult to be scale up to be used for high-throughput applications.

27.3.3 Fully Integrated CMOS Biosensor

We presented an integrated biosensor that is capable of preforming impedance spectroscopy with biological samples [193]. By detecting the impedance, this novel system is capable of characterizing DNA samples based on their concentration and fragment length. All the label-free experiments were performed using suspended biomolecule solutions without any surface immobilization to probes or bio-functionalization. No further post-fabrication processes are required before taking biological measurements with the integrated CMOS chip. Therefore, the sensor chip system is entirely reusable, which enhances uniformity and reduces the cost of each measurement (Fig. 27.61).

Biological samples can be very precious or scarce, and thus, minimizing waste is a key consideration in biosensor design. This micro-array-based design integrates hundreds of micro electrodes and driving circuits into a 5 mm × 5 mm area. Each measurement requires only 20 μl of sample, as this volume is sufficient to cover the electrodes. Two of the major advantages of this method allow the reuse of the analyte. First, the integrated chip utilizes a noninvasive electrochemical method, dielectric spectroscopy, to analyse the samples. The typical AC stimulus of 500 mVpp is negligible compared with that of gel electrophoresis, which typically requires a supply voltage of more than 100 V DC. Second, the biochip detects the electrical properties of the biological molecules without the need for chemical reactions. The analysed biological samples are unchanged and can be reused for further analysis.

We investigated the impedances of ssDNA samples with different concentrations using the integrated biosensing system. Current applications of DNA concentration detection systems include the quantification of samples, such as libraries, prior to next-generation sequencing and quantitative PCR. Identical measurements were performed using BSA samples for comparison. Both sets of results show that the solution impedance is related to the biomolecule concentration. Concentrated solutions had lower impedance, indicating higher conductivity. This behaviour can be explained by the role of counter-ions that are attracted by the DNA backbone charges, which are in turn proportional to the concentration. More mobile counter-ions in the vicinity of the DNA result in higher solution conductivity [233]. On a log-log scale, the solution impedance showed a linear relationship with the sample concentration. This feature makes it possible to use the biochip to determine the concentrations of different samples. In general, the DNA data were clearer and more convincing than the data for the BSA samples. This difference in data quality is most likely due to the molecular structures of the samples. We used short fragments of single-stranded DNA with a length of several hundred base pairs [234]. Although ssDNA may have some secondary structure due to interactions between its own bases and interactions with other fragments, BSA, as a protein, is expected to have a considerably more complicated structure [235, 236].

Optical sensors, such as spectrophotometers, which measure the reflection or transmission properties of an analyte as a function of wavelength [237], currently dominate the DNA (and other biomolecules) detection sensor market. Most systems employ photometers to convert light signals into electrical signals for further analysis. The complex structure of the optical-electrical system results in reduced accuracy and higher costs. In this work, we report an alternative method for the quantitative analysis of biological samples. Our method significantly reduces the cost by utilizing an integrated sensor. We performed impedance spectroscopy, which measures a sample's ability to conduct electricity as a function of frequency. Furthermore, our system is purely electrical, which reduces the system's complexity and minimizes external interference.

In addition to the DNA concentration, other parameters can be measured using this impedance-based integrated biochip system. We performed a series of impedance measurements for digested ssDNA samples. DNase I was used in this experiment. This enzyme is suitable for eliminating DNA from RNA preparations prior to sensitive applications, such as RT-PCR. The DNase was able to completely digest the ssDNA into oligo- and mononucleotides in a 15-min reaction at room temperature. We divided the samples into eight groups, and the reaction time was precisely controlled. Our results showed that the reaction progress was related to the sample's impedance. The constant solution impedance after 15 min indicated that the digestion reaction had reached completion. During the DNA digestion, DNase I randomly cut the DNA strands into smaller pieces. Longer reaction times were expected to result in a shorter average DNA length. The shorter fragments act as charge carriers with higher mobility and thus provide higher solution conductivity. The solution impedance decreased as the digestion reaction progressed until the digestion reached completion at 15 min. This experiment demonstrated that the integrated biochip is capable of monitoring the progress of DNA digestion by measuring the impedance.

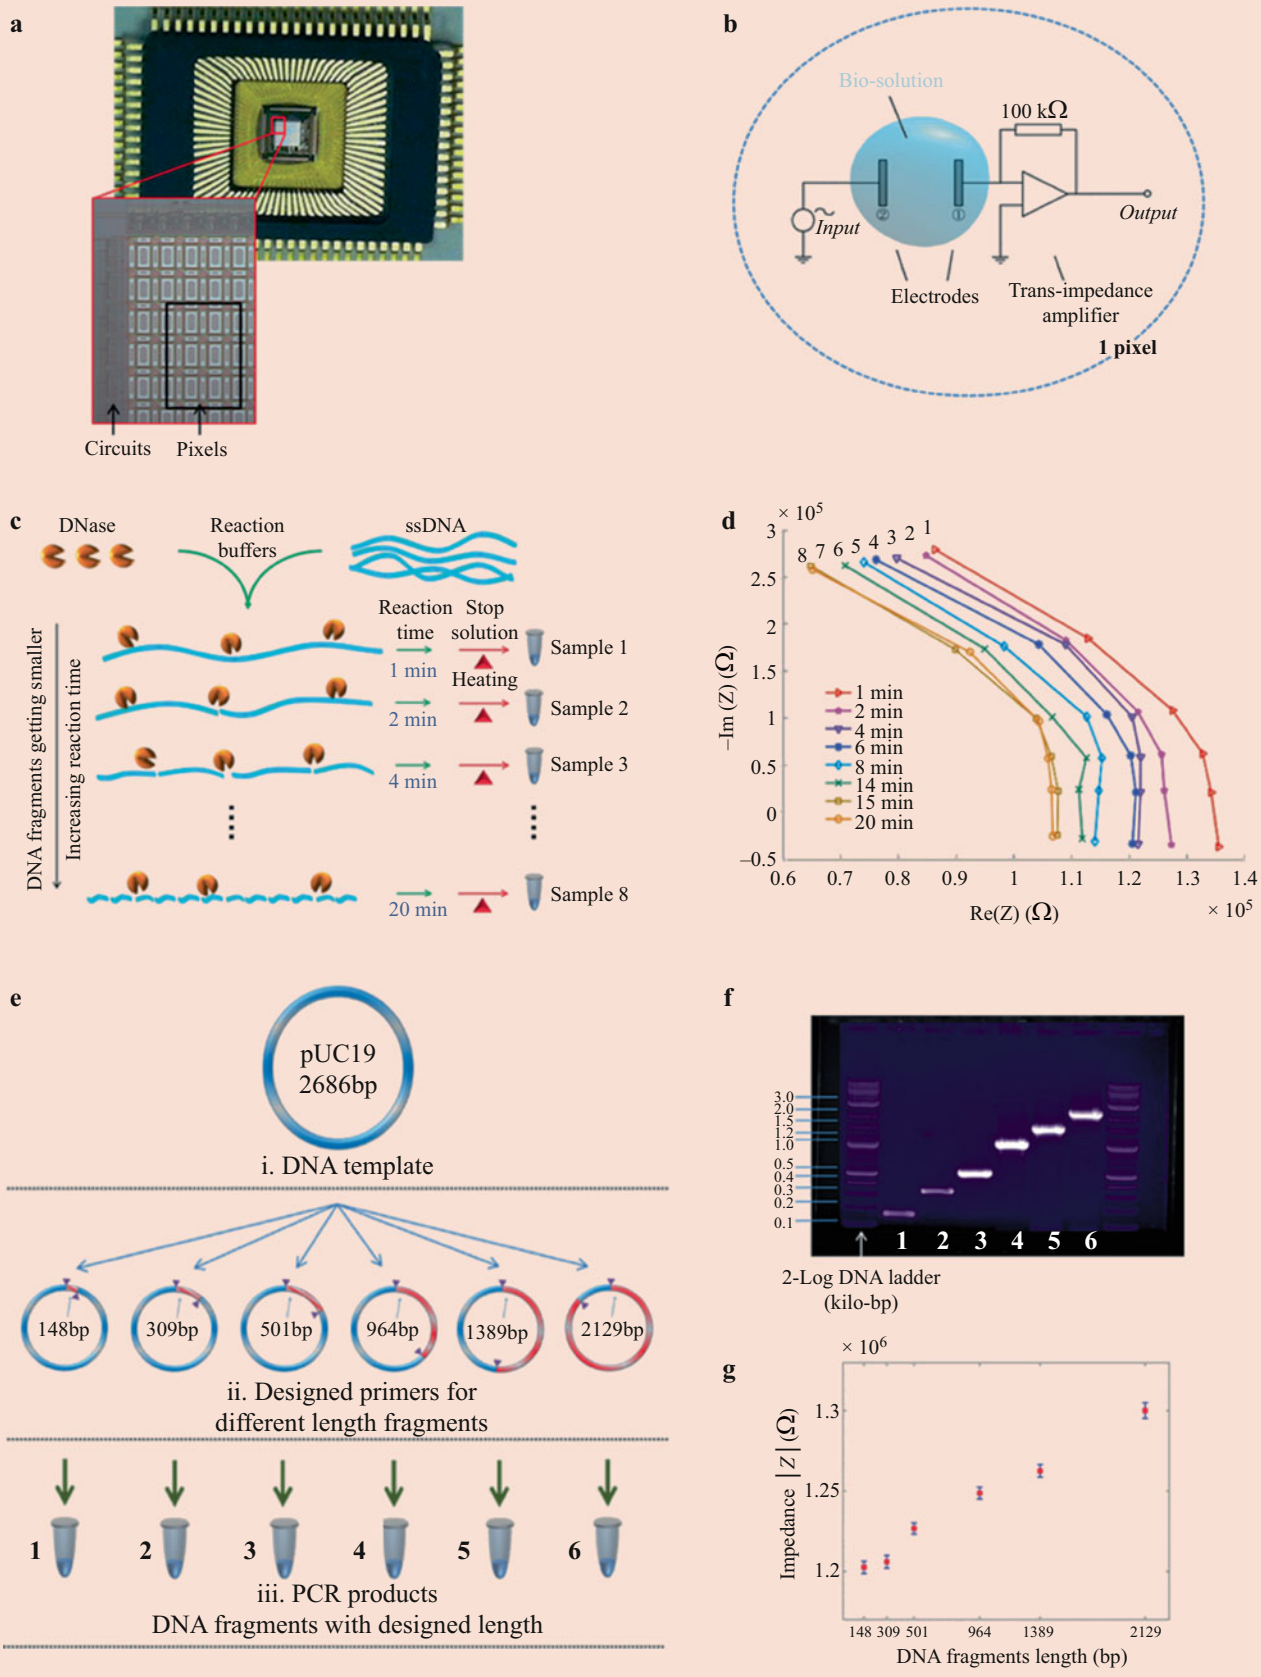

Fig. 27.61 (continued)

The DNA digestion experiment also suggested that the length of the DNA fragments is strongly correlated with the solution's conductivity. To validate this relationship, we designed an experiment that used PCR to generate various DNA fragments of known length. We amplified dsDNA, whereas the digestion test used ssDNA. Double-stranded DNA generally has less secondary structure than single-stranded DNA. In addition, the PCR products for each fragment size all had the same DNA sequence, whereas the herring ssDNA would contain a very heterogeneous mixture of DNA sequences. All of these factors minimize the interference in the impedance measurements. As expected, longer fragments were less conductive than shorter fragments. These results indicate that this system is capable of overcoming interference from other molecules in the solution, thus allowing the rapid yet precise quantitative analysis of unpurified PCR products.

The fragment length is one of the most important features of DNA for a wide range of genetic analyses [238,239]. The correlation between impedance and DNA fragment length observed in this study raises the possibility of using this purely electrical system to validate and characterize PCR products. Gel electrophoresis has dominated this area for more than 40 years. The conventional technique involves imaging the DNA using UV light after the intercalation of ethidium bromide, a highly carcinogenic compound that can also potentially damage the DNA's structure and induce mutations [240]. Our impedance system is capable of replacing this time-consuming and potentially dangerous technique. The rapid characterization of restriction fragment profiles could potentially be applied to genome assembly, in a manner similar to that of optical mapping [241]. We present a method for the label-free analysis of suspended samples, and we demonstrated that this method can detect differences in the impedance of different PCR products within a few minutes. The samples can even be reused without any further treatment.

27.3.4 Heterogeneously Integrated Biosensor with Disposable Electrodes

In this section, we developed a heterogeneous impedance measurement system with a reusable CMOS chip for signal processing and an active thin-film electrode disposable system as an electronics-biological interface (as shown in Fig. 27.62a) [242]. The disposable chip enables large-area fabrication technologies, which provide great freedom for the selection of electrode materials and electrode configurations. In addition, the design of the electrodes is separated from the CMOS chip, which can be customized for different applications. With the use of disposable electrodes, it can be used as a powerful platform for multifunctional impedance-based measurements.

The system consists of two parts, including a disposable glass chip and a reusable part. Eight Cr/Au (20 nm/80 nm) double-layer metal electrodes were fabricated by a thermal evaporator with a shadow mask on a glass substrate. Both the width of each electrode and the separation between the electrodes are 500 μm. After the metal deposition, the electrodes were then attached to connection pins by silver paste. A 5-mm-diameter metal cap was used to cover the centre part of the electrodes. The rest of the glass chip was covered by liquid PDMS to passivate and hold the connection pins. After the PDMS solidified, the cap was removed to leave a 5-mm-diameter well on top of the electrodes. This well was used to contain the sample solution during the measurement. The fabrication of the electrode chip is low-cost and highly reproducible. The glass chip is the interface between sensor and the sample, which can be disposed after each measurement.

The impedance measurement chip was designed in a Cadence analogue IC design suite, and the prototype was fabricated using AMS 0.18 um CMOS process. The design was an extended work to our previous impedance-based CMOS chip, but here sensing electrodes are extracted from the silicon chip on to a disposable glass substrate.

The DNA sample concentration tests were performed with five groups of herring sperm DNA samples at different concentrations. The measurements were carried out at frequencies from 100 Hz to 1 MHz. Figure 27.62b, c shows the results in both Cole-Cole and Bode plots. The former yields the general impedance behaviour of the samples. At low DNA concentrations (37.5 μg/ml, 75 μg/ml, and 150 μg/ml), each dataset forms a semicircle with a tail, which is a classic pattern for biosolutions [243]. The semicircle is formed by the double-layer capacitance between the electrode-electrolyte interfaces. The DNA solutions were prepared using DI water, and hence, the main charge carriers within the solution are the DNA with each base pair containing two negative charges. Higher concentration DNA meant more base pairs per volume and, hence, more charges per unit volume. Therefore, the concentrated DNA solutions were much conductive, and

as the solution concentrates, the radius of the semicircle starts to shrink. This indicates that highly conductive solutions are more resistive than capacitive. As shown in the Cole-Cole plot, a purely resistive sample manifests as a straight line parallel to the imaginary axis, which implies that the complex impedance only contains the real part. This is particularly true for the most concentrated sample (600 μg/ml), which comes up a straight line and is almost parallel to the imaginary axis.

The Bode plot shows the magnitude and the phase of the impedance for different samples. The impedance values are well spread over the frequency range from 100 Hz to 1 MHz, which indicates the clear differences in electrical properties of the samples. Each set of impedance data was fitted to a same equivalent circuit, and the results are shown in grey lines. The Randles circuit model was selected in this work, which is the classic model for depicting the electrode-electrolyte interface and the bulk solution.

From the Bode plot shown in Fig. 27.62, the magnitude of impedance for each DNA sample is relatively constant at mid-band frequencies (1 kHz–100 kHz). Higher sample concentration results lower sample impedance. This work shows almost doubled sensitivity over the previous work, where the slope of this work is 0.85 and the previous one is 0.44. The specific thin-film electrodes design in this work contributes to this sensitivity enhancement. In a DC electrolyte sensing system, cell constant κ (cm^{-1}) is defined as:

$$\kappa = \frac{R}{\rho} \tag{27.62}$$

where R represents the measured resistance and ρ is the specific resistivity. This factor also can be used to determine the performance of an impedance-based sensing system. For most biomeasurement, the solution concentration (c) is a function of the solution conductivity (reciprocal of the solution resistivity). From Eq. (27.1), we can conclude that the sensing output voltage (V_{out}) is inversely proportional to the measured impedance. We can then rewrite Eq. (27.62) as:

$$\frac{V_{out}}{c} \propto \frac{1}{\kappa} \tag{27.63}$$

where c represents the solution concentration. Equation 27.63 indicates that smaller cell constant will result better detection sensitivity; therefore, to design a small cell constant system is a key route to enhance the sensor's performance. Olthuis's work [243] suggests that the cell constant can be reduced effectively by increasing the electrodes modulus k. In a two-electrode system, k is defined as:

$$k = \frac{W}{W+S} \tag{27.64}$$

where W is the electrode width and S is the separation between the electrode pair. Thus, a better W over S ratio can give better detection sensitivity. The W over S ratio is 1:2 in previous work, and the ratio is 1:1 in this work. In the previous work, on-chip electrodes are used, and the electrode dimensions are limited by both chip area and CMOS design rules. However, by using thin-film-based electrodes, the electrode design is more flexible, and hence the sensing performance can be further enhanced. It is worth to mention that bare gold electrodes are used in this work for characterization of suspended DNA samples. This is different from the reported affinity-based sensors in which electrodes are functionalized with probes to capture target analytes. Immobilized probes are typically used to examine the presence of known analytes. However, both limit of detection and accuracy are restricted by unspecific binding and binding failure. In our work, the electrical properties of the bulk solution are measured from 100 Hz to 1 MHz. This method can be used as an effective DNA concentration sensor. It also provides the capabilities to distinguish the length of DNA fragments and can be applied to validate PCR products. Indeed, sensors without immobilization lack selectivity compared to the conventional affinity-based approaches. However, this can be solved by introducing micro-fluidic sample sorting and/or sieving technique on top of electrodes. Moreover, this heterogeneously measuring system is fully compatible with biofunctionalization on the electrodes, which can be used for different specific applications.

27.3.5 Impedance-Based Immunosensor [244]

Immunoassay is a standard technique for a wide range of applications, which is frequently applied to detect cancer biomarkers, virus, and other antigens [242, 245, 246] due to the specificity of antigen-antibody interaction. The conventional immunoassay methods include the enzyme-linked immunosorbent assay (ELISA) [247, 248], immunofluorescence techniques [249], radioimmunoassay (RIA) [250,251], mass spectrometric immunoassay [252,253], chemiluminescence assay [254, 255], immunologic colloidal gold signature (ICS) [256, 257], electrophoretic immunoassay [258], immune-polymerase chain reaction assay [259], etc. In clinical laboratories, the ELISA immunoassay method has been widely used, but the process of ELISA test is complicated, and the microplate readers are expensive and bulky, which no longer meets the current needs of immunoassays. The next-generation immunoassay techniques should have simplified operation, high specificity, and high sensitivity and should be label-free and low cost [260–262].

Compared to the complicated process of ELISA test, electrochemical sensors provide a simpler method for immunoassay [263, 264]. The electrochemical immunosensor provide the possibilities for label-free detection, detecting electrical signals instead of optical signals. They have been widely applied in biological detections at different scales, including but not limited to organs, tissues, cells, and biomolecules

[193]. A standard electrochemical cell [208] consists of conductive electrodes and sample under test (SUT). In the biological world, the majority of SUT is solution based, and the properties of the electrode-electrolyte interface are as important as those of the bulk sample itself in such electrochemical detection systems [243]. Impedance-based measurement, also known as electrical impedance spectroscopy, is emerging as a powerful tool for biomolecule detection. The electrical properties of the SUT can be depicted by equivalent circuits consisting of basic electrical components. The values of the components are directly linked to certain properties of the SUT. By extracting the parameters of the equivalent circuit, both the electro-electrolyte interface and the bulk solution can be characterized in one measurement. In addition, with suitable electrode functionalization techniques, the functionalized impedance electrodes can perform label-free detection for DNA [193, 224] or proteins [265] with high selectivity and sensitivity.

Figure 27.63 shows the system diagram of a disposable immunosensor platform. The system consists of a gold-coated glass slide and a plastic sheet with sample wells. After standard substrate cleaning procedures, a layer of 50 nm gold was deposited with thermal evaporation technique. Two designs were characterized in this work, U-shaped electrodes and W-shaped electrodes. The effective channel lengths of the two designs were 8.71 mm (U-shaped) and 9.36 mm (W-shaped).

Poly(methyl methacrylate) (PMMA, also known as acrylic) was chosen to create the sample wells. Acrylic is nontoxic, corrosion-resistant, and low-cost. Acrylic sheets (2 mm thick) were purchased from Mitsubishi, Japan. A 2-by-5 array was fabricated with a pitch of 9 mm, and the diameter of the sample well is 6 mm. The geometry of the wells matches the mainstream 96-well assay plate, making it compatible with all standard biochemistry liquid sample handling tools.

Laser processing is a standard material processing technique (for both metals and non-metals) by utilizing a high-power-density laser beam. Among different types of lasers, the CO_2 laser is the most commonly used, which can be used for cutting, welding, surface treatment, drilling, and micromachine [266].

Figure 27.63 shows the impedance-based immunosensing experiment which was carried out in a single sample well with U-shaped electrodes. The impedance of 5 mM $K_3Fe(CN)_6/K_4Fe(CN)_6$ redox solution was measured between each electrode bio-functionalization step. Figure 27.63 depicts the steps for IgG electrode functionalization, including 11-MUA modification (a type of self-assembled monolayer, SAM), IgG bonding, and blocking process. From the Cole-Cole plot in Fig. 27.63, the impedance characteristics have clearly shown that the electrode surface has been successfully modified. The bare gold electrode measurement is inserted as a subplot in Fig. 27.63 due to the different scales. After the electrode functionalization, different concentrated anti-IgG samples were added into the well to trigger the reactions. 0.025 μg/ml, 0.25 μg/ml, 2.5 μg/ml, and 25 μg/ml anti-IgG samples (in PBS) were added in sequence and held for one hour each. Impedance measurements were carried out with $K_3Fe(CN)_6/K_4Fe(CN)_6$ between each reaction. The Cole-Cole plots for four reactions are shown in Fig. 27.63, where the overall impedance raises up as the anti-IgG concentration increases. The dot data points are taken from the measurements, and the solid lines are the equivalent circuit model-fitted results. The equivalent circuit used here is shown in the subplot of Fig. 27.63. The Ret indicates the Faradic current strength, which is directly related to the numbers of antibody-antigen bonding. The value of Ret is also the indicator of the detected concentration of anti-IgG in this experiment. Figure 27.63 plots the model-fitted Ret versus the anti-IgG concentration, and a good linearity is observed. The linear relationship between the measured impedance and analyte concentration can be obtained from Fig. 27.63.

27.3.6 TFT-Based Biosensors

The most important functions for human-machine interfaces include pressure mapping, heartbeat monitoring, temperature capturing, electrophysiology recording, and ion detection. The following are TFT-based biosensors for these applications [1].

Pressure mapping can be implemented by using a pressure-sensitive film integrated with TFT arrays. Someya and his coworkers demonstrated an ultra-lightweight imperceptible pressure sensor array using ultra-thin flexible organic TFTs together with a resistive tactile sensing foil, as seen in Fig. 27.64a [59]. In this type of configuration, the pressure sensor array produced a current change when touched by an object, with a magnitude of ∼150 μA, which was a relatively small signal due to the low mobilities of organic TFTs. In contrast, also based on a resistive strain sensor, Wang et al. demonstrated a heartbeat monitor with an intrinsically stretchable organic TFT amplifier while using a potential divider configuration to generate voltage signals to achieve a large amplitude of >0.2 V (Fig. 27.64b) [60]. Similar to the pressure sensor array, Ren et al. demonstrated a low-operating-power and flexible active-matrix organic TFT temperature sensor array, by using a thermistor in series with a TFT (Fig. 27.64c) [267]. The temperature sensor array exhibited good mapping to a wide range of temperatures, i.e. from 20 to 100 °C, but the current change was less than 1 μA. For this small current signal, a low-noise trans-impedance amplifier (TIA) close to the sensor is needed for real application; otherwise, the small current

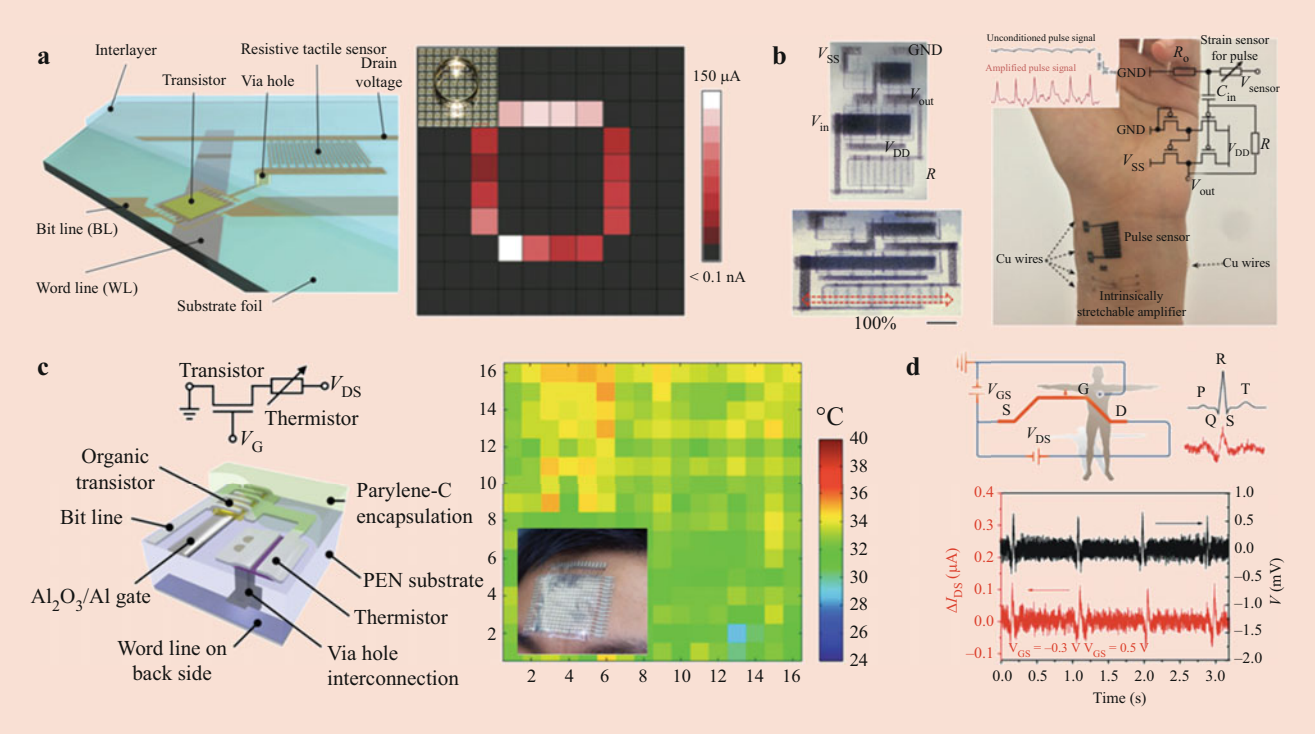

Fig. 27.64 Examples of flexible TFT-based biosensors. (**a**) An ultra-lightweight imperceptible pressure sensor array using ultra-thin flexible organic TFTs for pressure mapping. (Adapted from [59]). (**b**) An intrinsically stretchable organic TFT amplifier integrated with a resistive sensor for heartbeat monitoring. (Adapted from [60]). (**c**) A low-operating-power and flexible active-matrix organic TFT temperature sensor array with a thermistor for temperature capturing. (Adapted from [267]). (**d**) Electrocardiogram (ECG) recording using an organic electrochemical transistor. (Adapted from [268])

Table 27.7 Signal types and circuit requirements for different sensors

Sensor type	Signal type	Signal range	Frequency (Hz)	Interface circuits
Pressure	Current/ resistance	<1 mA	<10	TIA/VA
Temperature	Current	<1 μA	<1	TIA
Electrophysiology	Voltage	<1 mV	<100	VA
Ion	Voltage/ capacitance	<60 mV/dec	<1	ISFET+TIA

N.B.: *TIA* transconductance amplifier, *VA* voltage amplifier

may easily spread out and/or be affected by the noise when transmitting through a long wire (Table 27.7).

In terms of electrophysiology recording, the signals can be directly captured by thin-film amplifiers, in contrast to that of pressure mapping and temperature capturing, which require tactile sensors. Electrophysiological signals are essentially voltage signals of which the amplitudes are less than 1 mV, and therefore high-gain amplifiers are required for capturing these signals with a high sensitivity. Campana et al. used an organic electrochemical transistor that provided larger transconductance for electrocardiogram (ECG) recording (Fig. 27.64d) [268]. However, the recorded current signals were very noisy. Rather than using transconductance amplifier, Sekitani et al. demonstrated ECG recording on a rat's heart using a high-gain voltage amplifier, providing clear output signals [269]. Besides ECG to record signals from the hearts, one can also capture electrophysiological signals from the brain (electroencephalography, EEG), eyes (electrooculography, EOG), muscles (electromyography, EMG), etc., which are also very useful for e-skin or other human/humanoid applications.

Ion detection on e-skin is useful to analyse sweat compositions and their concentrations. There is a specific family of electronic devices for ion detection known as ion-sensitive field-effect transistors (ISFETs). Different from the aforementioned biosensors, ISFETs require a gate or a gate dielectric that is ion sensitive. A common example is pH sensors, which are proton sensitive. In combination with a functionalized material on the gate or gate dielectric, ISFETs can be selective towards other ions, such as sodium and potassium. The mechanism of an ISFET is that an interface potential is established by the solid/electrolyte interface ions and is modulated by the different concentrations of ions, with a theoretical maximum sensitivity of 60 mV per pH change or per decade of ion concentration change. Due to the nature of the transistor as a current device, a TIA is also required for ion detection.

For these examples of biosensors, the frequency requirement is not demanding. It is obvious that activity based on human touch, body temperature change, and ion-level change in sweat are slow, i.e. less than 10 Hz. In addition, electrophysiology signals are also in low frequencies of <100 Hz [270]. Therefore, for sensor interfaces, a relatively small bandwidth of 100 Hz is enough for most interfacing analogue front-end circuits.

Dr. Chen Jiang is currently an assistant professor, with the Department of Electronic Engineering, Tsinghua University. He received the BS degree in engineering from the Department of Electronic Engineering, Shanghai Jiao Tong University, China, and the Ph.D. degree in Engineering from University of Cambridge, UK. From 2018 to 2021, he was supported by the Wellcome Trust as a Junior Interdisciplinary Fellow at the Department of Clinical Neurosciences, University of Cambridge, UK. His research focuses on novel electronic device architectures, large-area flexible transparent electronics, low-power circuits, and their applications to bioelectronics. Dr Jiang was a recipient of the IEEE Electron Devices Society PhD Student Fellowship 2018.

Dr. Xiang Cheng received the bachelor's degree in electronic engineering from Shanghai Jiao Tong University (SJTU), Shanghai, China, in 2013, and the Ph.D. degree from the University of Cambridge, Cambridge, U.K., in 2017, with a focus on active-matrix organic light-emitting diode (AMOLED) pixel circuit design and device simulation seeking compensation solutions and new circuit architectures. He held a post-doctoral position at the University of Cambridge. He joined Cambridge Touch Technologies Ltd., Cambridge, as a System Architect Engineer. His current research interests include fundamental device physics and system integration of emerging touch technology.

Dr. Hanbin Ma received his Ph.D. degree in Engineering from University of Cambridge, UK. From 2014 to 2018, he was supported by Isaac Newton Trust and other projects at the University of Cambridge as a Research Fellow. In 2018, he joined the Chinese Academy of Sciences as a Hundred Talent Professor in CAS Key Laboratory of Bio-Medical Diagnostics, Suzhou Institute of Biomedical Engineering and Technology. He has authored or co-authored more than 30 peer-reviewed articles. He holds more than 40 awarded and pending patents. His current research is focused on large-area electronics-based biosensing systems and active-matrix biochips.

Arokia Nathan (Fellow, IEEE) received the Ph.D. degree in electrical engineering from the University of Alberta, Canada, in 1988. He is a leading pioneer in the development and application of thin-film transistor technologies to flexible electronics, display, and sensor systems. He joined LSI Logic, USA, and subsequently the Institute of Quantum Electronics, ETH Zürich, Switzerland, before joining the Electrical and Computer Engineering Department, University of Waterloo, Canada. In 2006, he joined the London Centre for Nanotechnology, University College London as the Sumitomo Chair of Nanotechnology. He moved to Cambridge University in 2011 as the Chair of Photonic Systems and Displays. He is currently a Bye-Fellow and a Tutor with Darwin College. He has over 600 publications, including four books, and more than 120 patents and four spin-off companies. He is an IEEE/EDS Distinguished Lecturer, a Chartered Engineer (U.K.), a Fellow of the Institution of Engineering and Technology, U.K., and recipient of the 2020 IEEE EDS JJ Ebers Award.

Abstract

A general goal in the development of any electronic component is to achieve high-performance operation and mechanical robustness which undergo negligible change over time. Recent advancements in materials science, thin film processing, and nanotechnology have, however, prospected the possibility of devices which can bend and stretch and provide the desired performance for a prescribed timeframe and, then, dissolve, resorb, or physically disintegrate upon the end of their functional time. Degradable or "transient" forms of electronics that disappear via hydrolysis or biochemical reactions, disintegration, and depolymerization could instill intelligence into resorbable implants, "green" environmental sensors, and biodegradable food packaging and lead to new compostable consumer electronic devices or printed boards so as to alleviate the problem of the electronic waste. Research has been driven by questions such as the following: Can we realize soft electronic implants which deliver diagnostics or therapeutic functions and then safely resorb in the body avoiding any additional surgery intervention? Can we realize compliant environmental sensors which harmlessly decompose to eliminate the need for their retrieval?

This chapter starts from reviewing the materials that have demonstrated degradable behavior in various aqueous solutions. The emphasis is on those that are key ingredients to realize active electronic devices and circuits: semiconductors, dielectrics, and conductors. Another important class of materials is the polymers which have been used mostly for encapsulation and substrates. The attention then moves to devices especially on sensors, field effect transistors, LEDs, batteries, and solar cells. The chapter also provides an insight into the dissolution mechanisms and offers some examples of the fabrication methods adopted so far to build the devices. Finally, it ends by listing some of the challenges faced by this technology.

ingredients to build electronic and optoelectronic devices. While polymers have been well studied for a long time, much less has been done on semiconductors and dielectrics. Nowadays, thanks to the progress in synthetic chemistry and materials engineering, chemical properties can be tailored to specific applications. Materials which undergo degradation by dissolution, resorption, disintegration, depolymerization, or biological processes are used for food packaging [1, 2], drug delivery [3–6], tissue engineering [3, 7–9], microfluidics [10], medical tools, and implantable devices [11–13].

28.1.1 Terminology

It is worth mentioning that terms such as "degradable," "biodegradable," and "compostable" can assume different meanings. Such ambiguity reflects the ongoing developments of insights into how biomaterials interact with living organisms. For example, a material is considered "biocompatible" if it does not produce an adverse effect when in contact with a living organism. However, since the immune response and repair function of living organisms are so complicated, it is not adequate to describe the biocompatibility of a single material in relation to a single cell type or tissue. So, ultimately, only an extensive number of tests, including analytical characterization of the material and in vivo testing, can fulfill all the requirements of the ISO definition of biocompatibility (ISO 10993). Few other definitions which are relevant are listed below.

Biodegradable: Materials break down under the action of naturally occurring microorganisms (e.g., bacteria, fungi, or algae) into low-weight and nontoxic products, but with no specific timeframe.

Compostable: Materials undergo degradation by biological processes during composting to yield carbon dioxide, water, inorganic compounds, and biomass, at a rate consistent with other known compostable materials (e.g., cellulose), and leave no visible, distinguishable, or toxic residue.

Dissolvable/Bioresorbable: Materials dissolve via hydrolysis or are absorbed in the body or in the environment.

In the chapter the terms "degradable" and "transient" are used to indicate nonspecific (bio)degradation processes but rather general decomposition with a consequent loss of functionalities (electrical and mechanical) and physical disappearance or disintegration.

28.1.2 Polymeric Substrates and Encapsulations

Polymers are the class of materials which have been studied in more details and which have been employed in a large variety of applications. The worldwide consumption of biodegradable polymers (BPs) was of about 1 million tons in 2016, and it is expected to grow up to 2.5 million tons in 2021 [14]. Target markets for BPs include packaging materials (trash bags, wrappings, loose-fill foam, food containers, film wrapping, laminated paper), disposable nonwovens (engineered fabrics) and hygiene products (diaper back sheets, cotton swabs), consumer goods (fast-food tableware, containers, egg cartons, razor handles, toys), and agricultural tools (mulch films, planters) [15]. Here, the focus is on the polymers which are more commonly used and which can be deposited in thin film to serve as substrate and encapsulation of electronic devices.

Biodegradable Natural Plastics. Starch, cellulose, and silk-based films have been used as coatings and substrates in recent studies on transient electronics. Starch is an inexpensive, annually renewable material derived from corn and other crops. Starch-based BPs can be produced by blending or mixing them with synthetic polymers. By varying the synthetic blend component and its miscibility with starch, the morphology and hence the properties can be regulated easily and efficiently. Thermoplastic starch can also be mixed with cellulose to produce rigid and mechanically stable film. Innovia Films [16], for example, provides a family of cellulose-based films (NatureFlex) which are highly transparent, highly permeable to moisture, and compostable-certified in both industrial and home composting environments. "Green" electronics using disintegrable organic semiconductors fabricated on cellulose substrates are shown in Fig. 28.1a–c. BASF produces EcoFlex® [17] which is blended from corn starch, potato, and polylactic acid. It is one of the few biodegradable plastics, which complies with the European (U Directive 2002/72/EC) and American food legislation for food contact (FCN 907). Bauer's group used EcoFlex® as substrate for the fabrication of organic transistor, while Salvatore et al. used it as substrate and encapsulation of fully biodegradable and highly flexible temperature sensors [18]. Silk is another appealing biopolymer as a temporary, soluble supporting substrate. It is optically transparent, mechanically robust, and flexible in thin-film form. Silk is biocompatible, bioresorbable, and water soluble with programmable rates of dissolution. Moreover, recent work demonstrates the ability of silk films to serve as a platform for transistors and various classes of photonic devices [13, 19]. Thin film silicon-based CMOS circuits fabricated from a foundry process transferred on silk substrates appear in Fig. 28.1d. A resorbable and implantable electronic device with silk substrate and encapsulation for in vivo infection abatement has been also reported [20]. In addition, polymers directly extracted from fruits also have the potential to be used in biodegradable electronics. A resistive switching (RS) memory based on biocompatible pectin extracted from natural orange peel exhibits

excellent RS characteristics [21]. Meanwhile, such device can dissolve in DI water within 10 min due to the good solubility introduced by the ionization of the carboxyl groups in pectin.

Biodegradable Plastics from Polyesters and Citric Acid. As early as 1973, it was shown that the polyester poly(ε-caprolactone), PLGA, degrades when disposed in bioactive environments such as soil [22]. Polyglycolic acid (PGA), polylactic acid (PLA), and their copolymers are some of the most frequently used biodegradable and bioresorbable polymer materials, in part because their properties can be tuned by changing the polymer composition within the basic PLA/PGA theme. PGA is a highly crystalline polymer and it has a high strength and modulus (7 GPa) which has promoted investigation to their use in bone internal fixation devices and sutures. PLA is often the polymer of choice for cast/extruded biomedical devices because it breaks down into L(+)-lactic acid units, which is the naturally occurring stereoisomer and is therefore excreted with minimal toxicity. Extensive research has been performed in developing a full range of PLGA polymers [23]. When the crystalline PGA is co-polymerized with PLA, the degree of crystallinity is reduced, and as a result this leads to increases in rates of hydration and hydrolysis. It can therefore be concluded that the degradation time of the copolymer is related to the ratio of monomers used in synthesis, and it ranges from 2–3 weeks to 3–4 months. Bao's group recently used PLGA (85:15) as substrate for the fabrication of organic transistors [24]. Another biodegradable polymer which is particularly important is poly(1,8-octanediol-co-citric acid), POC [9]. Rogers' group reported foundry-based microelectronics fabricated on PLGA substrates whose dissolution process is shown in Fig. 28.1e. It has shown potential to be used in tissue engineering, thanks to its nontoxic monomers, a relatively simply synthesis, an easy processing, and inherent surface affinity for various cells. Elasticity and biodegradability can be tailored by controlling the number of crosslinks. Young's modulus ranges from 1 to 16 MPa which are values comparable to those of elastin from bovine ligament. POC has been recently used as substrate for stretchable electrodes [25]. Electrospun poly(caprolactone)-poly(glycerol sebacate) (PGS-PCL) can also be utilized as substrates for engineering biodegradable electronics, in which PGS is another biodegradable elastomer widely used in cardiac tissue engineering [26].

Water-Soluble Polymers. The largest volumes of water-soluble polymers are prepared from acrylic acid, maleic anhydride, methacrylic acid, and various combinations of these monomers. With the exception of their oligomers, these polymers are not biodegradable. Conventional water-soluble polymers therefore persist in oceans, lakes, and other water depositories. To date, poly (vinyl alcohol) (PVA) is the only polymer with exclusively carbon atoms in the main chain that is regarded as biodegradable. PVA has been recently used in electronics as sacrificial layer for membrane release [27], as dielectric in organic devices [24], and as substrate for fully dissolvable IGZO transistors [28].

In all, these aforementioned polymers demonstrate desirable biocompatibility and biodegradability that can be tunable in wide timeframes. Degradation rates are closely associated with monomer structure, molecular weight, crystallinity, material processing, crosslinking, etc. [29]. Most of the biodegradable plastics based on polyesters and citric acid (PLGA, PGS, etc.) have a relatively faster degradation rate, e.g., PLGA (50:50) lost 20% of mass after 10 days in PBS [30], and PGS completely degraded in the subdermal region of SD rats within 60 days [31]; while degradation of PCL [32] and POC [9] can take more than 2 years. As for naturally derived polymers, silk can have degradation time over orders of magnitude (a few hours to a year) [13, 33], and the degradation time of BASF EcoFlex® is 11 weeks or more [17].

28.1.3 Metallic Conductors

Generally, metals serve as electrode contacts and interlayer connections for electronics due to the advantage of high conductivity and stable properties. Magnesium (Mg) is a representative biodegradable metallic material, with the combination of ease in processing, rapid rates of hydrolysis, and biocompatibility [13]. Alternative metals which share similar characteristics, such as zinc (Zn), iron (Fe), tungsten (W), and molybdenum (Mo), are also potential choices. An accurate study of the chemical dissolution of dissolvable metals has been conducted by Yin et al. [37]. The dissolution rate of different metal thin films in various solutions, which is defined as electrical dissolution rates (EDRs), was investigated by making patterned serpentine metal traces and monitoring the trend of resistance over time in DI water and salt solution under different conditions, as shown in Fig. 28.2. The dissolution rates of magnesium, tungsten, iron, molybdenum, and zinc metal thin films have been studied in deionized (DI) water and Hanks' solution at different pH and temperatures (Fig. 28.2a–f). The change in microstructure of these metals after soaking in DI water has also been investigated using transmission electron microscopy (TEM) (Fig. 28.2a–d). In general, the degradation rates in salt solution are higher than those in DI water, and changes in electrical conductions occur before the ones in the structural morphology. However, Mo demonstrates slower dissolution rates in salt solution than those in DI water. The rates also depend on how the materials have been deposited. Tungsten dissolves at a rate six times faster if deposited by sputtering rather than chemical vapor

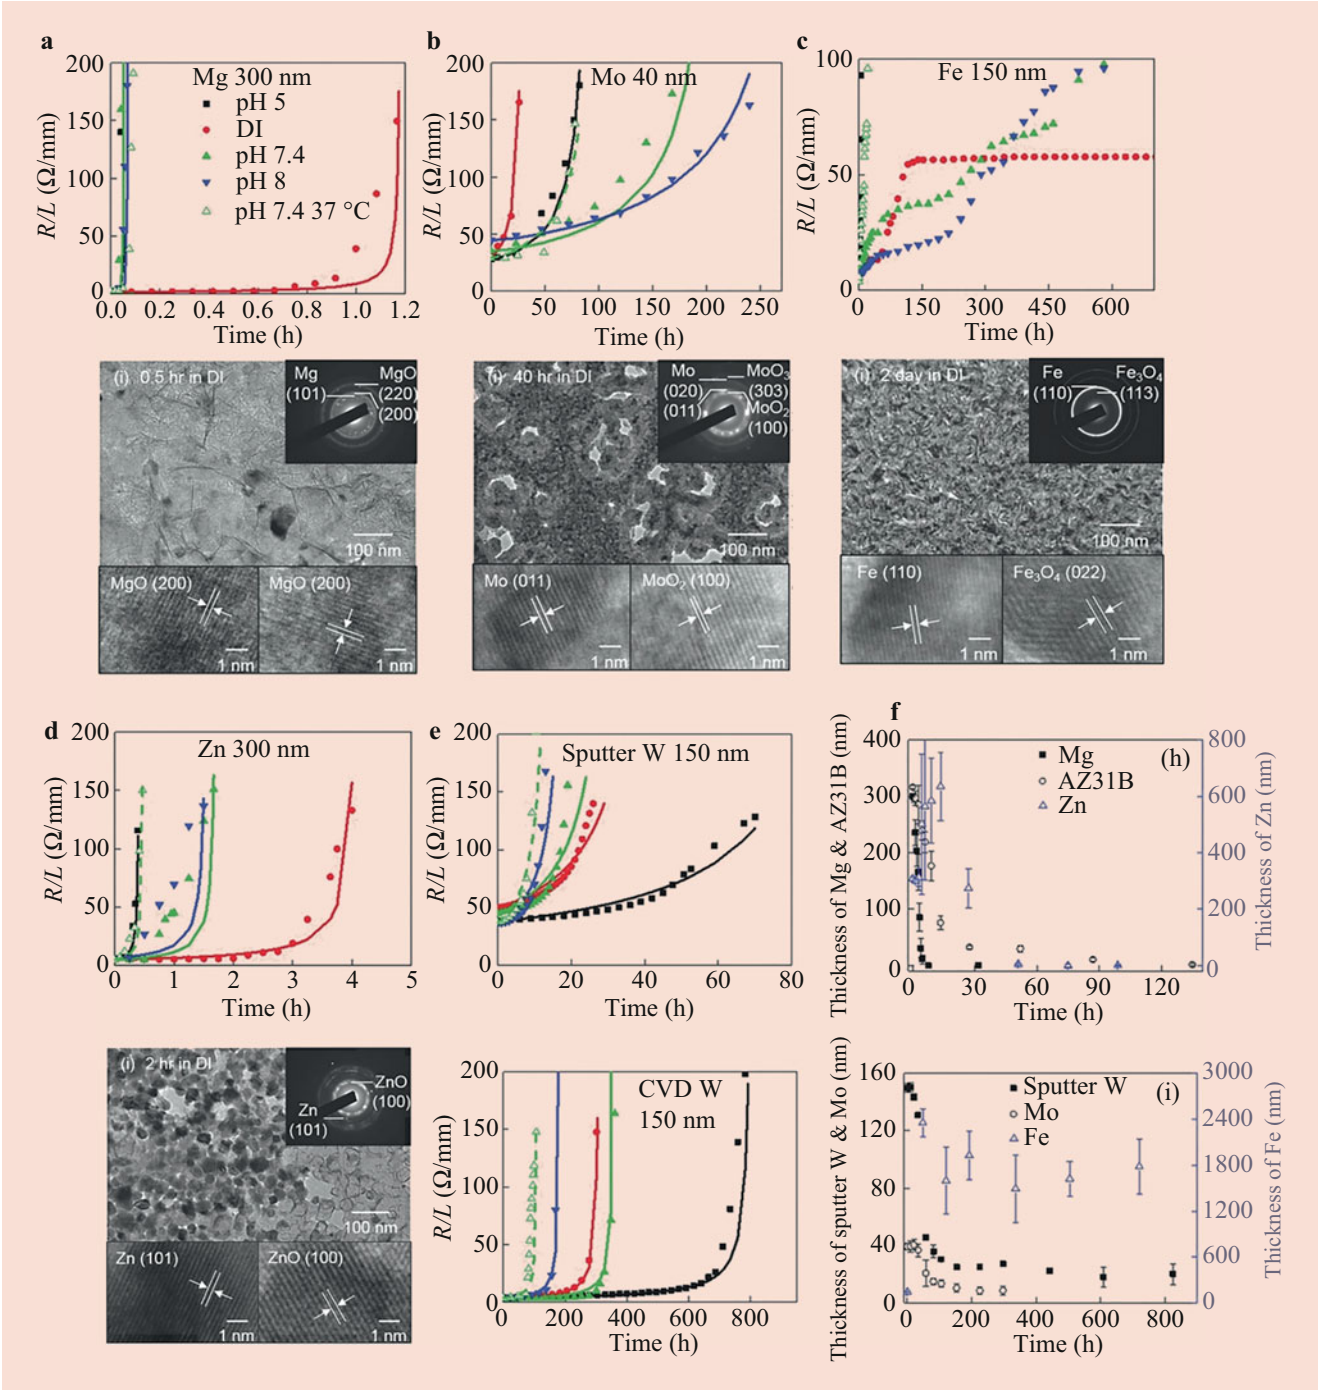

Fig. 28.2 Metals. The trend of resistance change over time during the dissolution process in Hanks' solution (pH 5, 7.4, and 8 at RT and pH 7.4 at 37 °C) and DI water at 37 °C, and TEM bright field images of the metals after dissolution: (**a**) Mg; (**b**) Mo; (**c**) Fe; (**d**) Zn. deposition (CVD). TEM characterizations of metal thin films after dissolution in DI water show oxide formations on exposed surfaces as dissolution products. These residual oxides have much slower dissolution rates compared to those of the metals. So far, magnesium has shown excellent performance for contacting n-type silicon and oxide-based transistors [13, 38]. Table 28.1 summarizes the dissolution rates of the metals in various aqueous solutions and conditions.

Table 28.1 Metals. Dissolution rates of degradable metals in various solutions and conditions

Metals	T (°C)	Aqueous solution	pH	Dissolution rate ($\mu m\ h^{-1}$)
Mg [37, 39]	RT	DI water	–	0.3 ± 0.1
		HBBS	5, 7.4, 8	4.8 ± 2.2
		0.05 m NaCl	–	0.05–3[a]
	37	Simulated body fluid (SBF)	7.4	0.05–0.5[a]
AZ31B [40]	RT	DI water	–	0.08 ± 0.02
		HBBS	5, 7.4, 8	2.6 ± 2.1
		0.05 m NaCl	–	≈0.3[a]
		0.6 m NaCl		≈0.1[a]
	37	SBF	7.4	0.02–0.1[a]
W (S) [37, 40]	RT	DI water	–	$(4 \pm 1) \times 10^{-3}$
		HBBS	5	$(1.4 \pm 0.4) \times 10^{-3}$
			7.4–8	$(8 \pm 2) \times 10^{-3}$
		SBF	7.4	0.02–0.06[a]
	37	HBBS	7.4	≈0.02
W (C) [37, 41]	RT	DI water	–	$(7 \pm 2) \times 10^{-4}$
		HBBS	5	$\approx 2 \times 10^{-4}$
			7.4–8	$(7 \pm 2) \times 10^{-4}$
	37	HBBS	7.4	$\approx 2 \times 10^{-3}$
Zn [37, 42]	RT	DI water		0.07 ± 0.02
		HBBS		0.3 ± 0.2
		In vivo	–	$\approx 5 \times 10^{-3}$[a]
		Sea water		$\approx (2–8) \times 10^{-3}$[a]
Mo [37, 43]	RT	DI water	–	$(1 \pm 0.1) \times 10^{-3}$
		HBBS	5	$(6 \pm 2) \times 10^{-4}$
			7.4–8	$(2 \pm 0.3) \times 10^{-4}$
		Buffer solution	7	1×10^{-3}[a]
				Thin film: 2×10^{-4}[a]
	37	HBBS	7.4	$(7 \pm 4) \times 10^{-4}$
Fe [37, 40]	RT	DI water	–	$<1 \times 10^{-3}$
		HBBS	5	$\approx 9 \times 10^{-3}$
			7.4–8	$\approx 2 \times 10^{-4}$
	37	HBBS	7.4	$\approx 7 \times 10^{-3}$
		SBF		≈0.02[a]

All the dissolution rates are electrical dissolution rates (EDR) unless specified

[a] Stands for corrosion rates derived from mass loss, W (S) stands for sputter deposited W, W (C) stands for CVD W, HBBS stands for Hanks' balanced salt solution, SBF stands for simulated body fluid

28.1.4 Semiconductors

This class of materials is of great importance for the realization of high-performance electronic devices. Here the focus is mostly on inorganic materials. Table 28.2 summarizes the dissolution of the most widely studied degradable semiconductors in various aqueous solutions and conditions.

Si and III-V Semiconductors Hydrolysis of Si and SiO_2 is particularly important [13, 44–47]. Literature studies, involving basic aqueous solutions, suggest that silicon can form neutral ortho-silicic acid $Si(OH)_4$ either through an initial oxidation step to SiO_2 or through a direct equilibrium $Si + 4H_2O \rightarrow Si(OH)_4 + 2H_2$. In both cases, the silicic acid leaves the silicon surface by diffusion into the surrounding solution. The details depend not only on the crystalline form and morphology of the silicon and its doping level but also on the temperature and composition of the solution. Mechanisms for hydrolysis of silicon oxide are $SiO_2 + 2H_2O \rightarrow Si(OH)_4$. Because OH- initiates this reaction, the pH strongly influences the dissolution rates. Studies on the dissolution of alloys of silicon and germanium (SiGe) and monocrystalline Germanium have been also carried out [48].

ZnO and a-IGZO Oxide semiconductors such as zinc oxide (ZnO) and amorphous indium gallium zinc oxide (a-IGZO) are particularly attractive because they can be deposited on large scale at low temperature and exhibit properties (electric mobility, environmental stability) that
